* Based on scrubber efficiency input.

The calculation further assumes that the heat loss to the surroundings is 5%. This is conservative but useful for the purpose. As a result, the heat available to raise the temperature of the 2420 lb-moles/hr of gases is 34.968 MMBtu/hr for a sensible heat content of 14,450 Btu/lb. It is now possible to compute the temperature of the flue gas by solving Eqs. (13.10) or (13.12) for temperature. The form of these equations requires that their solution for temperature involve an iteration, readily accomplished with a computer. If a computer is not available, the calculation can be time consuming; however, one can use the enthalpy of gases given in Table 13.3 to estimate the temperature for the calculated enthalpy. Table 13.3 indicates that the gas temperature is, therefore, approximately 1850°F, well within the level of error of the calculation to 1872°F calculated by iteration. This is an unusually good agreement between the two methods of calculations. The typical difference is usually in the range ±150°F.

The heat loss through the walls of the combustion chamber is rarely known. It can, however, be estimated during shakedown or during the trial burn by comparing the measured temperature of the flue gas to that calculated by a mass and energy balance. The heat loss from the incinerator as a whole will not vary from this value by more than a few percent. If necessary, even this small variation can be taken into account by assuming that the rate of heat loss is proportional to the difference between combustion chamber or duct temperatures and the ambient temperature. The temperature of the gases in the combustion chamber or duct is usually constant, the ambient temperature will not, normally, vary by more than about 100°F between the seasons.

Assume that these results were obtained during the summer, when the temperature was 100°F. The heat loss was 1.84 MMBtu/hr. The combustion chamber temperature was 1872°F, so the temperature difference was 1772°F. On a cold winter day when the ambient temperature would be, for example, 0°F, the temperature difference would be 1872°F. The heat loss in the winter could then be estimated to be:

$$1.84\ \text{MMBtu/hr} \times \left(1872/1772\right) = 1.94\ \text{MMBtu/hr}$$

Since, in this case, the heat loss was assumed to be only 5% of the incinerator's thermal duty, the difference is only 6% of the heat loss, the impact of temperature variation on the incinerator's thermal duty is only a negligible 0.3%.

Obviously, factors such as heavy winds or rain or snow hitting the incinerator surface can increase the heat loss, but usually a small correction for the measured heat loss will adequately take such considerations into account. Localized cooling can have an impact on the incinerator's operation. For example, unusually cold weather or a large amount of precipitation can cool a portion of ductwork or refractory to the point where ash can solidify at that point, causing a blockage. Similarly, cold weather can result in the condensation of acid gases onto the walls of an air pollution, or a control device corroding the materials of construction. However, these localized pockets of cooling will rarely impact the mean temperature of the combustion chamber to a degree where the destruction efficiency of the system is jeopardized.

The above calculations are carried out to a large number of significant figures only for illustrative purposes. Doing so makes it easier for the reader to duplicate and follow the calculations. The number of significant figures shown should in no way be construed as a reflection on the accuracy of the calculations, which are good estimates, but not substitutes for actual test data. In addition, these calculations do not consider the trace constituents such as CO and the POHCs, which must be considered as part of the overall incinerator evaluation. Because their concentrations in the exit of most incinerators and other combustors is low compared to the gases shown here, they can be ignored for the purpose of the overall mass and energy balance.

13.4 Incineration and Combustion Systems

The following three categories of devices are used to incinerate hazardous wastes: (1) incinerators, (2) boilers, and (3) industrial furnaces. The three categories are differentiated only by their primary function, not by the fundamental concepts associated with waste combustion. Incinerators are specifically designed to burn waste materials, including hazardous wastes. Boilers and industrial process furnaces (BIFs) are not specifically designed and built to burn wastes. Boilers are intended to generate steam, and industrial furnaces are intended to produce a product such as cement or lime. A BIF, which is used to burn wastes, must provide the high temperature combustion environment needed to destroy organic materials. Burning wastes in BIFs destroys the waste and utilizes its heating value to replace fossil fuel. Incinerators are broken down into two further categories by the type of waste they burn: (1) nonhazardous waste (termed here "refuse incinerators") and (2) hazardous waste. Each type is subject to different regulations. Both types are increasingly required to meet the same low emission limits. The main design difference between them relates to the fact that hazardous waste incinerators must achieve high levels of destruction for toxic contaminants, while refuse incinerators must handle large quantities of highly inhomogeneous solids.

Nonhazardous Waste Incinerators

While nonhazardous wastes can be incinerated in a wide variety of different types of furnaces, the vast majority of municipal refuse and nonhazardous commercial and industrial wastes are incinerated in mass-burn waste-to-energy plants similar to the one shown in Fig. 13.2. The term mass burn refers to the fact that the waste is not pretreated prior to being fed to the incinerator, although large objects such as large appliances (white goods) or construction debris (most especially gypsum board) will usually be removed.

Incinerator systems incorporate the following components: (1) waste receiving, (2) waste storage and segregation, (3) waste burning, (4) ash discharge, (5) heat recovery, (6) acid gas control, (7) particulate control, and (8) fan and stack.

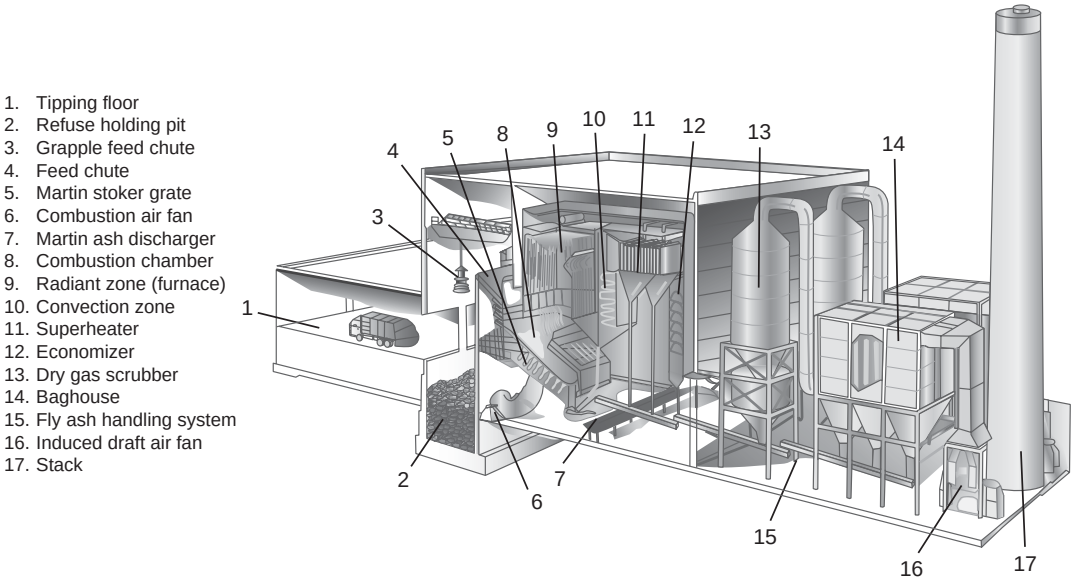

FIGURE 13.2 Waste to energy facility. (Reproduced courtesy of COVANTA Energy.)

Wastes are received on the tipping floor, where vehicles arrive and dump their loads of refuse into the holding pit. During this process, an operator will typically identify objects and materials that are unsuitable for incineration, such as large objects, major appliances (white goods), or noncombustible construction debris, most especially gypsum board and other gypsum products. The waste feed-crane operator typically segregates these wastes from the waste that will be incinerated. Large objects can result in jamming of the waste feed and transport mechanism and, if they are combustible, they will, if possible be broken up prior to incineration.

White goods, typically appliances and fixtures, have very few combustible components and are typically segregated in the receiving area. Refrigerators and air conditioners are a particular concern because they may contain chlorofluorocarbons (CFCs), which can produce highly corrosive hydrogen fluoride during combustion. CFC incineration is also not legal in most nonhazardous waste incinerators. Gypsum is kept out of the combustion chamber, because it will release sulfur dioxide (S~) in excess of the environmentally acceptable limits for the combustor when heated to combustion temperatures.

The waste from the refuse holding pit is fed by a crane into a chute leading to a grate. The grate may be a moving screen, a set of reciprocating, or fixed grates. The important factor is to move the burning mass through the combustion chamber and to discharge the ash into a suitable receiver. The grate must allow a sufficient solids residence time for the combustibles in the waste to burn down completely. Typical solids residence times range from 30 min to several hours for municipal refuse. Shorter solids residence times occur for highly flammable, light, materials, longer residence times for heavy materials such as flammable furniture. Waste consisting of paper and other light materials could have an even shorter solids residence time. The ash remaining after incineration passes fall into a collection and discharge system. The ash may drop into a water-filled tank or trough, where it is cooled and then the slurry discharged or moved onto a dry conveyor where it is air cooled prior to discharge. The steam and hot gases from either type of ash handling system are typically drawn back into the furnace.

The combustion chamber can be refractory lined or it may (as shown in Fig. 13.2) be lined with steam tubes similar to those in a boiler. Steam-tube lined combustion chambers are often termed "water-wall furnaces." The gases then pass through a series of heat exchangers similar in concept to the heat recovery parts of any steam boiler. The gases are thus cooled, and energy is converted to useful steam. Some incinerator designs will include a quench, where (not shown) the gases are further cooled with water sprays. The cooled gases enter the air pollution control system.

The air pollution control system on a refuse incinerator is designed to control acid gas and particulate. Typical acid gas control devices are dry or wet scrubbers. Typical particulate removal devices are fabric filter baghouses or electrostatic precipitators. Venturi scrubbers have been used for particulate and acid gas removal; however, the high pressure drop inherent in the design coupled with the high gas flows of large refuse incinerators tend to result in higher energy usage than with the fabric filter or electrostatic precipitator.

The principal emissions of concern from a refuse incinerator are particulate, mercury, and other toxic metals, chlorodibenzodioxins and chlorodibenzofurans (dioxins and furans), and acid gases. The particulate forms by the entrainment of ash and other inert material and by the vaporization of salts or metal compounds in the hot flame zones followed by their condensation in the cooler zones of the system. Mercury has a significant vapor pressure at even the low temperatures encountered in the incineration system. It can pass through the system as a vapor. Fortunately, it is usually present in only minute quantities in refuse and does not require special removal techniques. In most cases, chlorodibenzodioxins and chlorodibenzofurans can form in the combustion chamber from the combustion of chlorinated materials. The most common chlorinated material in refuse is polyvinyl chloride (vinyl plastic). There is increasing evidence (Bruce, 1990) that chlorodibenzodioxins and chlorodibenzofurans can form by the recombination of other compounds in the air pollution control system. Temperatures in the range of 230 to 400°C (450 to 750°F) (EPA, 1992) appear to favor the formation of these compounds. At this point, the information is preliminary, but if verified, it would tend to encourage the use of fabric filters [which operate at temperatures below 230°C (450°F)].

Hazardous Waste Incinerators

There are many types of hazardous waste incinerators in use today. The following are examples of six types:

1. Liquid injection
2. Rotary kiln
3. Fluidized bed
4. Fixed and moving hearth
5. Infrared furnace
6. Plasma arc furnace

The liquid injection, rotary kiln, and hearth systems are traditional designs that have been in use for many years. Fluidized and circulating bed, and infrared combustors represent newer generation designs for treatment of a variety of solid wastes, often with claims of higher efficiency at lower operating costs for specific applications. Infrared and plasma arc furnaces are highly experimental at this time and are not discussed further herein. Numerous tests performed in support of regulatory development and for RCRA permitting (EPA, 1986a) have shown that, when properly designed and operated, hazardous waste incinerators can meet virtually any remission and destruction standards required.

Many incinerator designs are available as modular and transportable systems designed to treat contaminated materials and wastes directly at the site of contamination. Portable incinerators refer to those units with major units (i.e., kiln, SCC, APCE, etc.) mounted on trailers for which assembly on-site consists largely of bolting the modules together and connecting utilities. The capacity of portable incinerators is limited by restrictions on the size of over-the-road loads. Transportable incinerators are built in prefabricated pieces that are assembled on-site to form the major units. Assembly of a transportable incinerator typically requires a foundation and significant on-site construction that can require several months. The operating units can be as large as desired and, hence, have a waste treatment capacity approaching that of fixed-site systems.

Liquid Injection Incinerators

Liquid injection incinerators are currently the most common types used. As the name implies, these units are designed to incinerate liquid or pumpable slurry and sludge wastes, usually in a single, refractory-lined cylindrical combustion chamber positioned in a horizontal or vertical arrangement. Often,

process vent gases are incinerated in liquid injection incinerators as well. The secondary combustion chamber of a multiple chamber incinerator is similar in design to a liquid injection incinerator. Most liquid injection incinerators consist of only a primary combustion chamber; however, for some cases, it may prove necessary to stage the combustion in multiple chambers.

Typical liquid injection incinerator combustion chamber mean gas residence time and temperature ranges are 0.5 to 2+ sec and 700 to 1200°C (1300 to 2200°F). The combustion chambers vary in dimensions with length-to-diameter ratios in the range of 2 or 3 to 1 and a diameter less than 12 ft. Liquid injection feed rates are as high as 6000 L/h (1500 gal/h) of organic liquid and 16,000 L/h (4000 gal/h) of aqueous liquid.

The primary advantages of liquid incinerators are their ability to process a wide range of gases and pumpable liquid wastes and to operate with a minimum of moving parts. Because the wastes are injected through atomizing nozzles, the physical properties of the waste are important to the safe and efficient operation of these units. The primary waste properties that must be considered when evaluating a liquid injection incinerator (or any combustor burning liquid wastes) are the viscosity and solids content. Viscosity is important because the liquids must be atomized into fine droplets for adequate vaporization or pyrolysis. The viscosity should be, typically, less than 10,000 Saybolt seconds (SSU). High solids content can lead to nozzle erosion, plugging, and caking, which can result in poor atomization of the wastes and less efficient combustion. Wastes are often blended and pretreated to meet burner and nozzle specifications.

Liquid injection incinerators can be positioned horizontally or vertically. Horizontally fired incinerators are the simplest design in that the waste feed systems, the air inlets, the combustion gas exhaust, and the air pollution control systems are at ground level and are readily accessible. Piping and ductwork runs tend to be shorter than in other designs as well. Such incinerators, however, have relatively large footprints. In addition, any ash in the waste will collect in the combustion chamber so that, unless the waste has a very low ash content, the furnaces have to be shut down for manual ash removal on a regular basis.

Vertical liquid injection incinerators may be downfire or upfire, depending primarily on the type of wastes being incinerated. Upfire incinerators require relatively little space, but they require that the hot flue gas be brought down to the APCD in refractory-lined ducts. Like the horizontally fired units, they also tend to accumulate ash in the combustion chamber. Their principal use is for burning clean solvents with a low ash content under conditions that may not require the use of air pollution control devices. Upfire incinerators are relatively less common for hazardous waste applications, and when used, they are limited to small installations, less than about 1000 lb/hr waste feed.

Downfire incinerators have the burner(s) at the top of the combustion chamber. Figure 13.3 illustrates a forced draft, downfired liquid injection incinerator. In this particular system, the combustion gases move downward and impinge on a wet quench located at the bottom of the chamber — called a wet-bottom. In other variations on the design, in the combustion chamber, the wastes, fuel, and air are introduced into the combustion chamber tangentially, causing a swirling "vortex" gas flow pattern, shown in Fig. 13.4. The vortex pattern increases the velocity of the gas and tends to increase the mixing of the gases with air. The swirling or "vortex" flow is imparted by the shape of the air inlets at the bottom of the combustor and by the arrangement of the air tuyeres in a cyclonic combustor, which are aimed to inject the combustion air with a tangential component to its flow.

The combination of vortex flow and wet bottom is useful when wastes contain significant quantities of inorganic materials with melting points that lie in the combustor's temperature range. The melting inorganic materials form a slag that can stick to the refractory, building up on it and eventually reducing the combustor's cross-sectional area. Some slags can corrode or otherwise damage the refractory. Cyclonic flow combined with a wet bottom tends to sweep the slag and ash from the walls into the wet-bottom, thereby reducing buildup.

The organic compound destruction achieved by a liquid injection incinerator is largely determined by how well the particular design (1) atomizes the waste materials, (2) converts the organic constituents to a vapor by vaporization or pyrolysis, (3) maintains a stable flame, and (4) provides adequate mixing

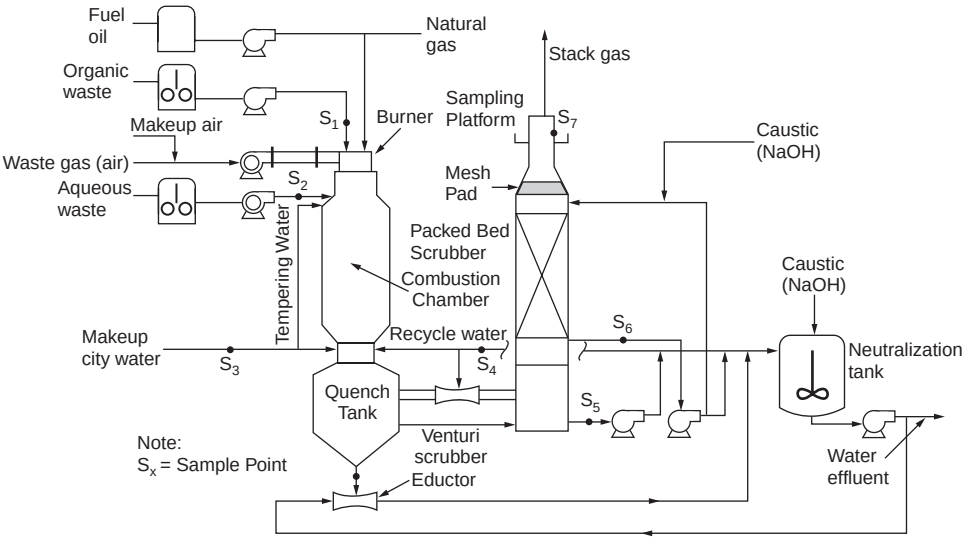

FIGURE 13.3 Typical downfired liquid incinerator arrangement.

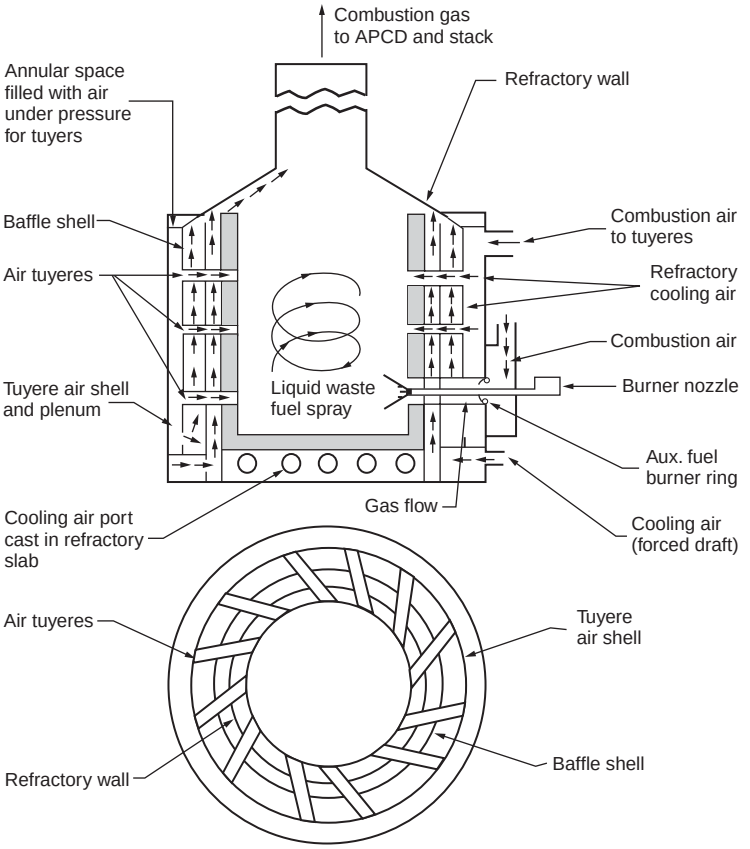

FIGURE 13.4 Tangentially fired vortex combustor (Bonner, 1981).

of the combustion gases with oxygen at temperatures sufficiently high to destroy the organics. Some of the factors that need to be considered are as follows:

1. Particle size distribution of the droplets produced by the nozzle
2. Droplet impaction on walls or other surfaces
3. Presence of cool zones in the organics' destruction zone
4. Presence of stagnant zones, where poor mixing of organics and oxygen (localized pyrolyzing conditions) may occur

The first two factors relate to the precombustion zone and the combustion zone of the incinerator. If the waste droplets do not completely evaporate prior to exiting the flame zone, then there is a risk that a fraction of the waste may be evaporated and incompletely destroyed. Improper evaporation can occur because the droplet size is too large, the heating value of the waste drops, or because the nozzle is spraying a fraction of the liquid onto a cool surface, preventing its ignition. The atomizing nozzle must be selected to match the properties of the fluids involved and must be properly mounted so that no spray hits any surfaces. In addition, it is necessary to continuously test the viscosity and heating value and (for some types of nozzles) vapor pressure of the waste stream to assure that it remains within the nozzle's design specifications.

Rotary Kiln Incinerators

The rotary kiln incinerator is the single most common design for the large-scale combustion of solid hazardous waste. The typical system consists of a solid waste feed system, a pumpable waste feed system, an auxiliary fuel combustor, a kiln, a transition section, an ash drop and dump system, a secondary combustion chamber with auxiliary fuel, pumpable waste feed systems, and an air pollution control system. Most rotary kiln incinerators are the first stage of a two- (or more) chamber incinerator. The secondary combustion chamber (sometimes called an afterburner) destroys the remainder of the volatilized combustible matter released from the heating of the solid wastes. Exceptions exist — most industrial furnace kilns that have been tested with hazardous waste appear to perform well without a secondary combustion chamber, as do a few hazardous waste incinerator kilns. For the most part, rotary kiln hazardous waste incinerators require the secondary combustion chamber to complete the destruction of the organic constituents released from the solids. The secondary combustion chamber is essentially identical to a liquid injection incinerator, which was discussed previously.

A rotary kiln is a cylindrical shell mounted on a slight incline from a horizontal plane. It is usually refractory-lined, although, if the temperature is low enough, it may simply be a metal shell. Its design is an adaptation of industrial process kilns used in the manufacture of lime, cement, and aggregate materials. The rotary kiln is used extensively for the incineration of bulk and containerized solids, sludges, liquids, and gases. Most rotary kiln incinerators consist of two combustion chambers. The first chamber is the kiln. The second chamber is similar to a liquid injection incinerator. It often burns pumpable hazardous wastes along with the off-gases from the kiln.

Figure 13.5 is a schematic of a rotary kiln incinerator system that illustrates how the two combustion chambers treat wastes. The kiln consists of a firing end (shown on the left) containing a solids feed system and a series of nozzles and lances to feed the wastes and supplementary fuels if needed.

Solid materials, either containerized or bulk, are fed to the kiln by many methods. Four common methods of feeding are gravity feed, conveyors, augur, and shredder. With gravity feed, a chute is built into the front of the kiln (front is defined as the point at which the wastes are fed), and the wastes are simply dumped through the chute and into the kiln. In larger kilns, the chute may be left open during operation. Combustion air is pulled through the chute by the induced draft system. Alternatively, the chute may be fitted with a door, a ram feeder, or another device that reduces air infiltration but allows solids to be fed into the kiln.

A somewhat more automated method of feeding the solids to the kiln is to use a conveyor, which transports the waste to a chute (gravity feeder) or directly into the kiln. In the latter case, the conveyor must be made of a material capable of withstanding the kiln temperatures. Screw augers are also used to transport bulk wastes into the kiln; however, their use is limited to wastes that will not jam the auger

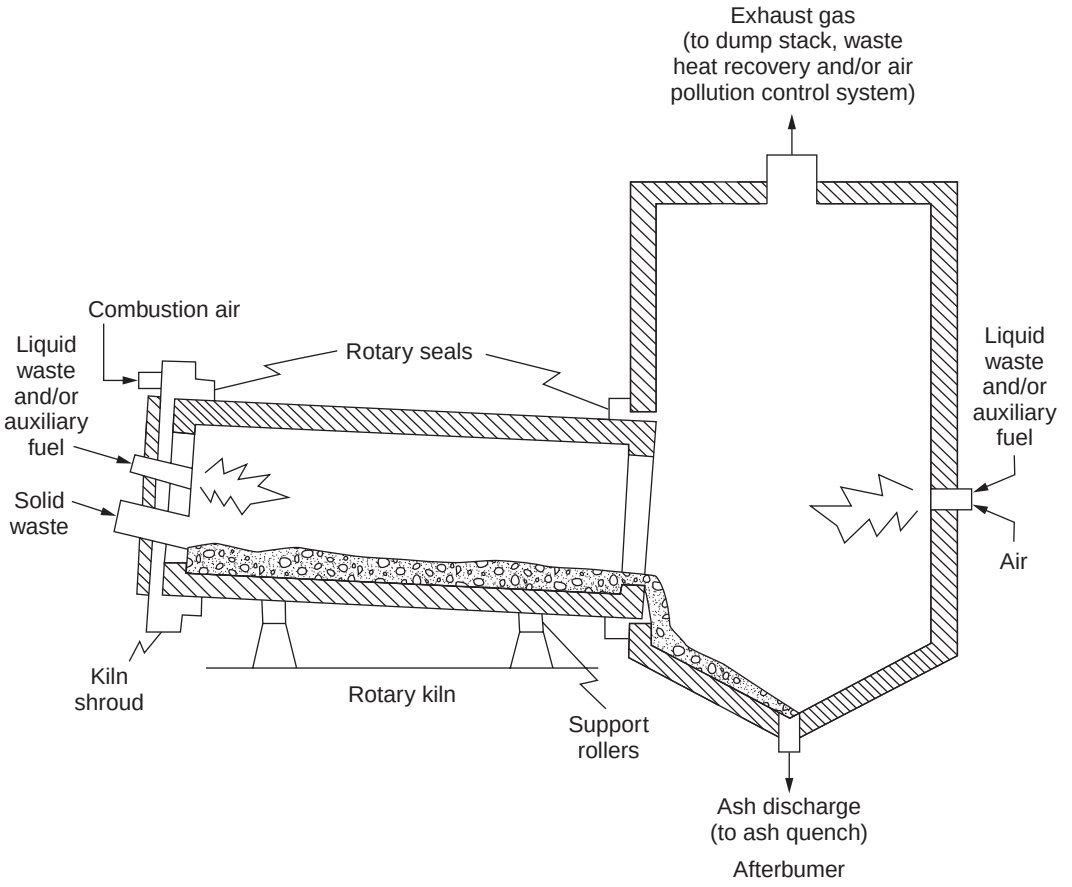

FIGURE 13.5 Rotary kiln incinerator schematic. (Reproduced courtesy of LVW Associates, Inc.)

and that can be moved by such a device. They can successfully be used for feeding powdered materials in many cases.

A blender-feeder is a common method for feeding highly inhomogeneous wastes into an incinerator. It combines a hammer mill with a solid feed system. These devices can be large and powerful enough to shred steel drums of waste material. Their advantage is that the blended and shredded wastes burn more smoothly and with a lower probability of flaring up and causing puffing or explosions in the combustion chamber.

Pumpable wastes can be fed to a kiln in two ways. Those wastes that can be atomized (usually with viscosity of under about 740 SSU) are fed through atomizing nozzles. Atomization is highly desirable for autogenous waste or auxiliary fuel. The considerations for the nozzle are similar to those for a nozzle in a liquid injection incinerator. Those pumpable wastes that cannot be atomized are typically fed to the kiln through a lance, a pipe discharging directly into the kiln with a minimum of bends or constrictions. Steam, air, or nitrogen is sometimes injected with the waste into the lance to facilitate the waste's flow and to provide limited atomization.

As the kiln rotates, it mixes the solid wastes with combustion air and moves the wastes toward the discharge end. The constant rotation also promotes exposure of waste surface to the radiant heat from the flames and hot refractory to enhance heat transfer efficiency and release combustible organics into the gas. As the solids and liquids burn, they produce combustion gases, which are swept down the kiln into a secondary combustion chamber or (for a single-chamber system) the air pollution control equipment.

Operation of a rotary kiln incinerator involves several concerns. The first concern is the seals at the front and rear ends. As can be seen in Fig. 13.5, the rotating kiln must slide past the fixed wall at the front, where the waste feed and burner nozzles are, and at the rear by the ash drop and combustion gas exhaust. There is no practical way to seal a rotary kiln to withstand positive pressure at the points where the rotating equipment meets the stationary components. As a result, a rotary kiln is operated under negative pressure. The system is designed to draw air at a specified maximum rate through the seals and other openings. If the seals become worn or damaged, the air infiltration can become excessive, and the incinerator will have trouble maintaining temperature at an acceptable gas flow rate. A properly operating incinerator must include routine inspections and a regular maintenance program of the seals.

A second potential problem that is of particular concern with rotary kiln incinerators is that of "puffing." Normally, the gases leaving the kiln are "pulled" into the secondary combustion chamber by the pressure differential between the two. If there is a sudden increase in the gas production rate in the kiln (due to sudden explosion, combustion, or volatilization of a chunk of waste, for example) or a draft decrease in the secondary combustion chamber (due, for example, to a problem with the fan), the gas flow rate may exceed the capacity of the downstream equipment, and an over-pressure could result. Flue gas from the kiln, potentially containing unburned POHCs and PICs, could thus be released as a "puff" from the rotating juncture between the kiln and the secondary combustion chamber. Normally, the seals can contain the gas from a specified level of overpressure. When the level is exceeded or the seals are damaged or worn, however, puffing could occur.

This problem is of special concern in incinerators burning munitions or other explosive wastes. In these cases, puffing could occur when a shell or piece of explosive detonates suddenly. These incinerators are designed to withstand explosions, but puffing can frequently occur then. The burning of drummed wastes can also lead to puffing. In this case, if the contents of a drum burn rapidly, the effect could be similar (although usually not as severe) to an explosion, as discussed above. The resultant overpressure could produce puffing. When puffing may occur, incinerators are equipped with an "emergency vent stack," water column, or other emergency relief vents.

The length-to-diameter ratios of rotary kilns can range from 2 to 10. Outside shell diameters are generally limited to less than 15 ft to allow shipping of the cylinder sections. Rotational speeds of the kiln are usually measured as a linear velocity at the shell. Typical values are on the order of 0.2 to 1 in./sec. Temperatures for burning vary between 800 to 1600°C (1500 to 3000°F). Bulk gas residence times in the kiln are generally maintained at 2 sec or higher.

The solids retention time in a rotary kiln is a function of the length-to-diameter ratio of the kiln, the slope of the kiln, and its rotational velocity. The functional relationship between these variables is given by the following rough approximation (Bonner, 1981):

$$t_{solids} = 0.19\ (L/D)/SN \tag{13.13}$$

where t_{solids} is the retention time (in min), L is the length of the kiln (in ft), D is the diameter of the kiln (in ft), S is the slope of the kiln (in ft/ft), and N is the revolutions per minute (rpm). Typical ranges of these parameters are L/D: 2–10, S: 0.03–0.09 ft/ft, and rotational speed 1 to 5 ft/min (which can be converted to rpm by dividing by the kiln circumference measured in ft). The retention time requirements for burnout of any particular solid waste should be determined experimentally or extrapolated from operating experience with similar wastes. In a movable grate furnace, the retention time is given by the ratio of the length of the grate, L, and its speed, S.

Air/solids mixing in the kiln is primarily a function of the kiln's rotational velocity, assuming a relatively constant gas flow rate. As rotational velocity is increased, the solids are carried higher along the kiln wall and showered down through the air/combustion gas mixture. Because solids retention time is also affected by rotational velocity, there is a tradeoff between retention time and air/solids mixing. Mixing is improved to a point by increased rotational velocity, but the solids retention time is also reduced. Mixing is also improved by increasing the excess air rate, but this reduces the operating temperature. Thus, there is a tradeoff between gas and solids retention time and mixing.

The longer the solid waste is kept in the kiln, the cleaner the bottom ash becomes. The additional cost of prolonging the solid waste retention time in the kiln is small compared to the total cost of incineration. The solid waste retention time is typically changed by varying the kiln rotational speed. Slowing the rotation increases the solids' residence time.

Rotary kiln incinerators can be operated in two modes, slagging and nonslagging. If the kiln is operated in the nonslagging mode, the ash temperature is kept below its fusion point. In the slagging mode, the ash temperature is allowed to rise above its fusion temperature, and the ash forms a liquid (or more accurately semiliquid) mass in the kiln. The type of kiln refractory (or other wall material) and the type of ash removal equipment used will be influenced by whether the kiln is a slagging or nonslagging type. Many types of molten ash, called slags, are corrosive and will dissolve improperly chosen refractory.

Fluidized Bed Incinerators

The fluidized bed incinerator consists of a bed of sand, limestone, or other mineral type of material and the combustion residue in a refractory chamber. The bed is fluidized by blowing air, and if additional gas is needed, recirculated combustion gases into the bottom through a set of tuyeres. The flowing gas agitates the bed material and turns it into an expanded turbulent mass that has properties similar to a fluid, hence the name. Bed depth typically varies between 1.5 and 10 ft, and gas velocities are typically in the range of 2.5 to 8.0 ft/s. It is generally desirable to maintain the depth of the bed as small as possible, consistent with complete combustion and excess air levels, to minimize the pressure drop and power consumption. Figure 13.6 is a schematic of a fluidized bed incinerator. Trenholm, Gorman, and Jungclaus (1984) gives performance data for a fluidized bed incinerator burning industrial wastes.

The combustion chamber of a fluidized bed is lined with brick or castable refractory. It has two distinguishable zones: a fluidized bed zone composed of inert granular bed material that is fluidized by directing air upward through the bed and a freeboard area extending from the top of the bed to the exit of the combustor. Wastes and fuel, if needed, are fed directly into the fluidized bed or into the windbox beneath the bed, where it ignites. Auxiliary fuel nozzles, which are used for startup or supplemental heat, are located in the windbox (hot-windbox) or in the freeboard cold windbox. The combustion of the

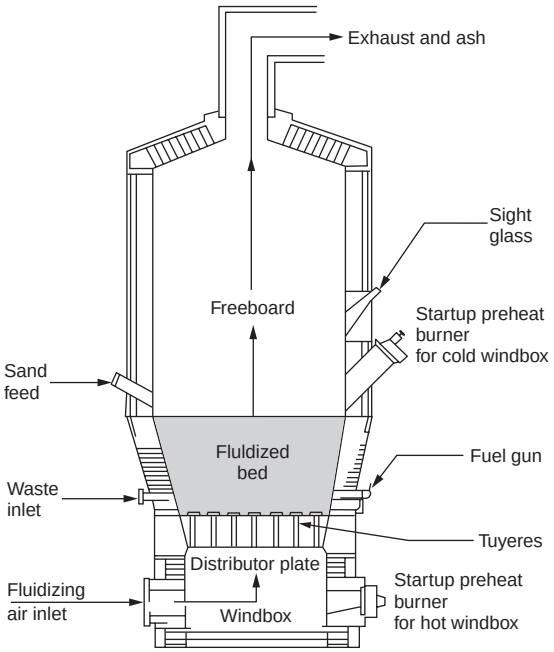

FIGURE 13.6 Fluidized bed incinerator schematic (Battelle Columbus Laboratories, 1972).

wastes and fuel heats the bed material to temperatures high enough that it, rather than the flame, acts as the combustion source.

The freeboard serves two major functions. First, its larger cross-sectional area slows the fluidizing gas velocity and keeps the larger bed particles from escaping. Second, it acts as a secondary combustion chamber for the off-gases from the bed. Higher heating value liquid wastes or auxiliary fuels can be burned in the freeboard area in a manner analogous to the secondary combustion chamber of a two-chamber incinerator.

The fluidized bed combustor is especially appropriate for burning tars and other sticky materials. In fact, it has been used for many years in the petroleum industry to burn still bottoms and other high-molecular weight residues. The tars coat the bed particles and increase the particles' sizes and weights. The enlarged particles tend to remain in the bed until the waste is burned off. The residence time for wastes in the fluidized bed can be as much as 12 to 14 sec. The rapid mixing of the bed also provides good agitation, exposing new surfaces to the hot combustion gases.

The fluidized bed has a high thermal mass that helps even out fluctuations in the combustion of highly heterogeneous wastes. As discussed for rotary kilns, heterogeneous wastes can burn unevenly. When a highly flammable clump of waste ignites, it can release a puff of gas that overloads the downstream combustion gas handling system. This can result in puffing, a potentially dangerous condition. The thermal mass of the fluidized bed reduces such uneven burning, making this type of incinerator a likely candidate for such wastes.

While sand is the commonly used bed material for fluidized bed incinerators, other materials that participate in the chemical reaction can be used as well. For example, lime or limestone is sometimes used in fluidized bed boilers that burn high-sulfur coal. The bed material absorbs the sulfur oxides formed in the combustion. A similar method is used to absorb the acid gases formed during incineration.

Fluidized bed combustors operate at relatively low bed temperatures, 425 to 800°C (800 to 1500°F), and freeboard temperatures up to about 1000°C (1800°F) (EPA, 1971). At startup, the bed is preheated by a burner located above and impinging down onto it. Because of its high thermal mass and excellent ability to transfer heat from the bed to the incoming waste, a fluidized bed incinerator is capable of burning materials using a low heating value. Normal incinerators require that the mean heating value of the combined wastes and fuels be a minimum of about 3300 to 4400 kcal/kg (6000–8000 Btu/lb). Any one waste stream could have a lower heating value, but the total of all of them should be above this minimum. A fluidized bed incinerator requires a minimum gross heating value of 2500 kcal/kg (4500 Btu/lb) and as little as 550 kcal/kg (1000 Btu/lb) if no water is present.

The rapid motion of the fluidized bed can cause attrition of the bed particles and of the refractory. This creates particulate that will be carried over into the flue gas. As a result, fluidized bed incinerators often place a greater load on the APCD than similarly sized conventional incinerators. Attrition requires that the operators keep tight control of the gas flow. The flow must be great enough to fluidize the bed, but it should not be much greater than required for this purpose. Note that particulate formed by attrition, while fine enough to be carried out in the flue gas, is rarely sufficiently fine to cause difficulty with most types of air pollution control devices. The large quantity of particulate matter captured can overload the flyash handling system.

The fluidized bed combustor offers several advantages, including the ability to incinerate a wide variety of wastes. It operates at relatively low and uniform temperatures, thereby tending to have lower NO_x emissions than standard combustors. It also achieves a higher combustion efficiency because of the high mixing and large surface area for reaction. The large mass of the bed makes it tolerant of wide variations in waste heating values. Finally, proper use of additives such as limestone or lime give this type of incinerator the potential to neutralize acids in the bed.

The fluidized bed combustor has limitations in its applicability. First, it is mechanically complex. Second, it cannot typically burn wastes with ash that forms particulate much larger than the bed material. Large ash particles will fall to the bottom of the bed and will eventually cause defluidization. Defluidization is a phenomenon whereby the bed settles down and is not blown about by the combustion gas.

Third, the ash formed must have a fusion temperature (melting point) greater than the bed temperature. If the ash should melt, it would agglomerate the bed and also cause defluidization.

The composition of the ash that a waste material will produce must thus be carefully controlled to keep the particle size small and prevent the fusion temperature of the bed material from dropping below the bed temperature. The fusion temperature of the bed material places an upper limit on the combustion chamber temperature. For purposes of illustration, the fusion temperature of sand, for example, is 900°C (1650°F). Another disadvantage is poor combustion efficiency under low loads.

Multiple Hearth Incinerators

The multiple hearth incinerator was originally developed for ore roasting and drying of wet materials. It is typically used today to incinerate sewage sludges and liquid combustible wastes, but it is rarely used for solid wastes. Its design is most appropriate for wastes containing large amounts of water and requiring long solids residence times. It is illustrated in Fig. 13.7. The furnace is a refractory-lined vertical steel shell containing a series of flat hearths. Each hearth has a hole in the middle. A rotating shaft with rabble arms attached at each hearth runs the length of the cylindrical shell. The incinerator is also equipped with an air blower, burners, an ash removal system, and a waste feeding system. Liquid wastes and auxiliary fuel can be injected at points in the furnace to assist the combustion of the solids or simply to destroy the liquid. Multiple hearth furnaces that burn hazardous waste are usually equipped with a secondary combustion chamber (afterburner).

Solid waste is fed to the incinerator in a continuous stream, usually from an auger, onto the top hearth, where it is plowed by the rotating rabble arms. They also slowly move the waste across the hearth and into a hole leading to the lower hearth, where another rabble arm plows the waste. The waste thus falls from hearth to hearth until it is discharged from the bottom. The bottom-most hearth is usually the only one supplied with overfire air; the other hearths are fed just underfire air. The gases in the multiple hearth incinerator flow upward, countercurrent to the waste. The hot gases from the lower hearths dry the waste fed to the upper hearths and eventually ignite the dried solids.

Because a multiple hearth incinerator operates in a countercurrent mode, it has the same difficulties in dealing with volatile hazardous organic as a countercurrent kiln. The initial drying zone typically

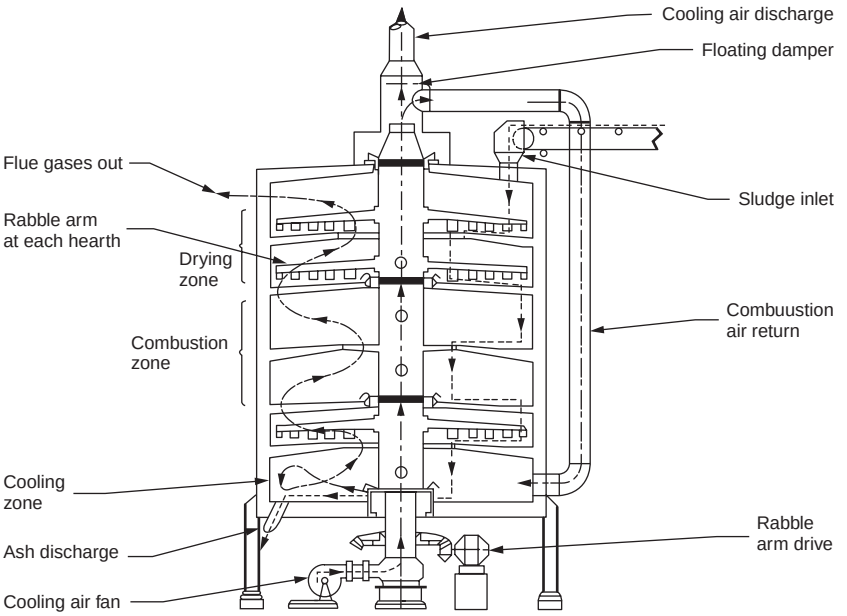

FIGURE 13.7 Typical multiple hearth incinerator (EPA, 1980).

operates at moderate temperatures; any volatile materials in the solid will evaporate and leave the combustor without being exposed to a flame. It is, therefore, necessary to duct the off-gases to a secondary combustion chamber in order to ensure efficient incineration of the volatilized organics.

The incineration process in a multiple hearth furnace occurs in three stages. In the uppermost sets of hearths, the incoming wastes are dried at moderate temperatures. In this zone, volatile organics can also be released into the gas stream. Incineration of combustible matter takes place in the middle sets of hearths. The final set of hearths serves to cool the waste prior to discharge. Discharge of the solids is usually by means of a second auger.

Multiple hearth incinerators are rarely used for hazardous waste destruction. Their principle application is for the combustion of sewage sludge. The wet, homogeneous nature of this waste is well suited to the multiple hearth design. Little test data are available on their efficiency of destruction of organics. One set of published information on tests of four multiple hearth incinerators conducted by the U.S. EPA (Bostian et al., 1988; Bostian and Crumpler, 1989), indicates the presence of trace amounts of common organic POHCs in the emissions, even when they were not detected in the sewage sludge. The reason for this is not given, but the measured levels were very low. The incinerators were equipped with "afterburners" or secondary combustion chambers, and inlet/outlet tests were conducted at one of the four sites. Destruction efficiencies of 90 to 99+% were observed.

The metal emissions tests conducted as part of the same program showed that small amounts of a variety of metals (from the sewage sludge) were released from these incinerators. The size of the metal particulate was not given, but based on the poor removal efficiency of the scrubber at one of the sites (less than 90% and as low as 50% for beryllium), one can probably assume that the particulate was very fine.

Commercial multiple hearth incinerators come in several sizes ranging from 6 to 25 ft in diameter and from 12 to 75 ft in height. Upper zone temperatures, depending on the heat content of the wastes and supplementary fuel firing, range from 350 to 550°C (650 to 1000°F); midzone temperatures range from 800 to 1000°C (1500 to 1800°F); and lower zone temperatures range from 300 to 550°C (600 to 1000°F).

Controlled Air Incinerators

Figure 13.8 is a schematic of such a unit. The design offers advantages of lower fuel requirements and lower particulate formation than similarly sized fixed hearth incinerators. However, they are technically more complex and require that the equipment and operation be designed and maintained to prevent random air infiltration. Their use, at present, is generally limited to the burning of hospital and pathological wastes.

Controlled air systems are batch units. Waste is continually fed to them, through an air lock or ram feeder, and the ash accumulates. Periodically, the system is shut down and cooled, and the ash is removed. Combustion air to the primary chamber is tightly controlled to maintain an oxygen level close to or even slightly at substoichiometric conditions. This results in pyrolysis of the waste. The combustion gases from the primary chamber go into the secondary chamber, where they mix with additional air to complete the combustion process. Such staged combustion results in very low gas flows in the primary chamber and minimization of particulate releases from the solids.

Boilers and Industrial Furnaces

Many boilers and high-temperature industrial process furnaces (BIFs) operate at conditions suitable for the destruction of selected types of hazardous wastes, and their use for the purpose is common. The practice achieves two things. First, it destroys the waste. Second, the heating value of the waste replaces fossil fuel with an economic benefit. The practice must, however, be approached with caution.

First, wastes, including hazardous wastes, by their nature, have a highly variable composition. Boilers and industrial furnaces, on the other hand, are primarily operated to produce energy or a product and are relatively intolerant of impurities or "off-specification" raw materials. Furthermore, the systems may not be capable of withstanding some of the products of combustion of certain types of wastes. For example, HC1 from the combustion of chlorinated wastes may damage refractory. Finally, many boilers or high-temperature industrial processes are not equipped with scrubbers or other air pollution control

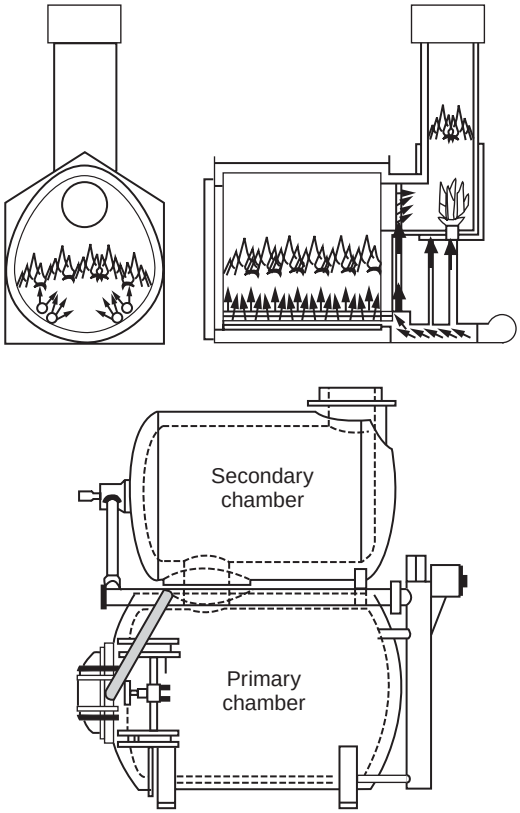

FIGURE 13.8 Two controlled air incinerator configurations (EPA, 1980).

devices. Even when the processes include an APCD, the ash or combustion products from the waste may damage the components and reduce their operating efficiency. Clearly, any program of co-firing wastes into such a combustion device must include a high level of waste selectivity and quality control. This fact must be considered when evaluating the feasibility of using any one of these processes to burn a waste.

A second factor that must be considered is the temperature/time/oxygen regime to which a given BIF exposes the waste. Many furnaces have high flame temperatures, but the mean gas temperature in the combustion chamber may be low. For example, most fire-tube boilers have the flame virtually surrounded by the tube walls. The flame may be hot enough to achieve organic destruction, but the walls cool the combustion gases quickly, so that the postflame zone may not provide the extended residence time at elevated temperature needed to destroy those organics that escape destruction in the flame zone.

A third factor that must be considered before burning hazardous waste in a process furnace is the point at which the waste is introduced. Take, for example, the introduction of wastes at a point other than the flame zone of a cement kiln. Because cement kilns are countercurrent kilns (where the solids flow in the opposite direction to the combustion gases), the problem is of special concern in co-countercurrent kilns such as cement kilns. The waste may be vaporized and swept out of the combustion chamber before it has sufficient time to be destroyed.

The U.S. hazardous waste regulations (40 CFR §260.10) define boiler as an enclosed device using controlled flame combustion and having three major characteristics. First, the combustion chamber and energy recovery section must be of integral design. That means that a boiler must have heat transfer surfaces in the combustion chamber rather than as an added-on feature in the duct. A combustion chamber that has a heat exchanger or economizer mounted on the flue gas outlet and no tubes or other steam-generating surfaces in its walls is not a boiler. Second, the boiler must recover at least 60% of the thermal energy of the fuel. Finally, at least 75% of the recovered energy must be utilized to perform some

function. The function can be internal (for example, to preheat air or pump liquids) or external (for example, to make electricity). The following processes are listed by the definition:

1. Cement kilns
2. Lime kilns
3. Aggregate kilns (e.g., lightweight aggregate or asphalt plant aggregate drying kilns)
4. Phosphate kilns
5. Coke ovens
6. Blast furnaces
7. Smelting, melting, and refining furnaces
8. Titanium dioxide chloride process oxidation reactors
9. Ethane reforming furnaces
10. Pulping liquor recovery furnaces
11. Waste sulfuric acid furnaces and halogen acid furnaces

The "Technical Implementation Document for EPA's BIF Regulations" (EPA, 1992) as well as the EPA regulations for BIFS give the legal description of the specific types of furnaces that are regulated. There are other furnace types that are not listed in the regulations that have operating temperatures and other conditions which may be adequate for the destruction of hazardous waste and which appear to meet the criteria of the regulations. They are not regulated at present, but they may be subject to hazardous waste combustion regulation if used for the purpose. Examples are as follows:

- Glass melt furnaces
- Carbon black furnaces
- Activated carbon retort kilns

The most common industrial furnaces used for waste disposal are cement kilns, lime kilns, lightweight aggregate plants, blast furnaces, and spent acid recovery furnaces. The main factor that differentiates a boiler or industrial furnace from an incinerator is the purpose of its use. An incinerator is built and operated mainly for the purpose of destroying waste materials. While heat may be recovered from this operation, that is ancillary to the system's main function, which is waste destruction. A boiler or industrial furnace, on the other hand, is operated for the purpose of making a physical product or producing energy. Waste materials may be utilized in doing this, but that is an ancillary purpose to the operation.

Both the boiler and industrial furnace equipment categories can achieve the high organic compound destructions of incinerators. Emissions test data on three boilers have shown a largely unimpaired performance under a wide operating window that extends well beyond normal operating practices for the units (Wool, Castaldini, and Lips, 1989). However, other data have shown that "cofiring," if not properly done, can result in increased emissions (EPA, 1987). In 1991, the U.S. EPA expanded the hazardous waste incinerator regulations (40 CFR § 260) to include boilers and industrial furnaces, (FR Vol. 56, No. 35, P7134, and subsequent amendments). These "BIF Regulations" require incinerators and BIFs to meet the same performance standards with operating requirements adjusted for the unique characteristics of the individual types of furnaces.

In order to fire hazardous wastes in existing boilers and industrial furnaces, it may be necessary to add equipment and modify the system. Examples of such modifications are as follows:

- Install waste storage, blending, pretreatment, and handling facilities.
- Set up sampling and analytical facilities to characterize the wastes and to assure that the waste composition is acceptable.
- Add burners, guns, nozzles, or other types of equipment to feed the wastes to the furnace.
- Upgrade combustion controls to handle the wastes.
- Add monitors for waste feed rate, oxygen, CO, etc., which are required for a facility burning hazardous waste.
- Upgrade or modify the air pollution control equipment to meet the BIF emission requirements.

Waste storage and handling equipment will generally have to be added to a boiler or industrial furnace that is being modified to burn hazardous waste. The facilities may consist of little more than a tank truck, which is hooked directly to the waste feed system; however, in most cases, permanent tankage will be preferable. Provisions for blending the wastes to maintain a consistent composition must usually be made. Waste blending is usually needed for incinerators and is often more important for boilers and furnaces, because boilers will typically have tighter waste specifications. In all cases, the facilities must meet the same requirements for spill prevention containment and control as would any waste handling facility.

A testing program to verify that the wastes received satisfy the specifications for combustion in the boiler or furnace must be included in the waste management program. The legal requirements for such a "waste analysis plan" are beyond the scope of this type of technical handbook. See the Technical Implementation Document for the BIF Rules (EPA, 1992) and related guidance for legal requirements. Operationally, it is important for a boiler or industrial furnace to keep tight control on the wastes fed to the furnace. Undesirable waste properties or components could result in damage to the system or to the production of off-specification products. As a minimum, the testing program should include properties such as the following:

- **Heating value** — Large amounts of low heating value materials could have a deleterious impact on flame stability and furnace performance and could cause a drop in temperature.
- **Viscosity, density, vapor pressure** — This information is needed to assure that the wastes can be atomized satisfactorily by the nozzles and burners. Poor waste atomization was the probable cause of unsatisfactory performance in a number of tests conducted on boilers and industrial furnaces burning hazardous wastes, discussed below.
- **Halogen, sulfur, and nitrogen content** — These values should be within bounds to keep acid gas emissions within acceptable limits, to minimize corrosion, and to maintain product quality.
- **Ash and metals** — These values need to be controlled to prevent the formation of fumes and to keep the release of particulate and, specifically, toxic metals to the environment within acceptable limits. Ash constituents with a low fusion temperature can cause an unacceptable rate of deposition on system components, especially boiler tubes.

Clearly the decision to burn hazardous waste in a boiler or industrial furnace, means modifications to the equipment and to the operating procedures must be made, to provide for a means of getting the wastes into the combustion device. Process changes that will usually be required in order to legally burn hazardous waste are as follows:

- **Addition of waste feed nozzles and guns —** It is generally not recommended that wastes be fed through the same firing guns as the primary fuel, as the wastes will have chemical and physical properties significantly different from those of the fuel.
- **Addition of automatic waste feed cutoffs —** These are legally required for any combustor burning hazardous waste.
- **Addition or upgrading of combustion control equipment —** Combustion of hazardous waste requires tight control of operating parameters. For example, a wide temperature excursion may be acceptable for normal operation of a boiler, but it is unacceptable when hazardous waste is burned. Existing controllers may not be able to maintain the tighter bounds on the control parameters legally required when burning hazardous wastes.
- **Addition of continuous monitors —** These are required for combustion gas, CO, CO_2, O_2, and HC1, and possibly, particulate, mercury, and others as they are developed. Other required monitors are for temperatures of the flue gases, indicators of combustion gas flow, and indicators of proper operation of the waste nozzles and of the air pollution control equipment. The waste flame must be equipped with a cutoff that stops the hazardous waste flow in case any operating parameter goes outside its permit limits.

The existing indicators for the primary fuel feeds must be wired into the waste feed system so that the primary fuel and the waste fuel are shut off in case of primary flame failure. The control system should incorporate a means of maintaining the primary flame if the problem lies with the waste combustion system only. In this way, residual hazardous waste in the combustion chamber will be destroyed, and operation of the system will continue.

The final general area of consideration that will be discussed here is the impact of the waste feed on the air pollution control device. Very few boilers and industrial furnaces are presently equipped with acid gas control devices so the impact will be restricted to particulate. Tests on boilers and cement kilns have shown that burning wastes containing halogens in cement kilns or (for any type of combustor) containing metals or salts can increase the amount of fine particulate that is formed. In addition to having very small diameters, the particulate can have a lower resistivity than that produced when only primary fuel is used. These changes can impact the performance of the air pollution control device. The impact is especially of concern for an electrostatic precipitator or ionizing wet scrubber because their performance is especially susceptible to size and resistivity, although the finer particulate could reduce the collection efficiency of any type of device. The impact on all air pollution control equipment should, therefore, be considered when evaluating the feasibility of burning hazardous waste in a boiler or process furnace.

13.5 Air Pollution Control and Gas Conditioning Equipment for Incinerators

Incineration is one of the most difficult applications of air pollution control systems. The gas must be cooled and multiple pollutants must be controlled with very high efficiencies. Hydrogen chloride, hydrogen fluoride, and sulfuric acid vapors can be highly corrosive if handled improperly. Particulate matter generated in the incinerators is primarily in the submicron range. Pollutants having special toxicity problems, such as metal compounds and dioxin/furan compounds, generally enter the systems at very low concentrations and must be reduced to concentrations that challenge the limits of analytical techniques. The air pollution control system typically can consist of a heat recovery boiler, a quench, a particulate removal device, and an acid gas removal device. The devices are often mounted in series. For example, the off-gas treatment system for a typical high-performance rotary kiln incinerator in hazardous waste duty can include (1) a boiler to partially cool the combustion gas and recover steam; (2) a dry scrubber, also called a spray dryer, to remove some acid gas and reduce downstream caustic requirements; (3) a quench to further cool the gases; (4) a reheater to prevent condensation in the fabric filter; (4) a fabric filter; (5) a packed column for further acid gas removal; (6) a HydroSonics scrubber that includes a steam ejector to provide the motive force for the flue gases and to act as a backup air pollution control device in case of failure of an upstream component; and (7) a stack. As can be seen, the air pollution control system represents a major fraction of the total system cost.

Quench

The first step in the air pollution control system is the gas cooling, which is usually accomplished by means of a water quench sometimes preceded by a boiler. The boiler is a noncontact heat exchanger, which utilizes the heat from the combustion gases to make steam. The quench is a portion of the duct, or a separate chamber, in which water is sprayed into the duct to cool it by evaporative cooling. The quench increases the water vapor content of the gas stream substantially and drops the gas temperature by adiabatic evaporation. Typically, the gas stream exiting the quench reaches the adiabatic saturation temperature, and further cooling by evaporation is impossible. Any additional cooling must occur due to sensible heat transfer to the exiting liquid stream.

The solids content of the quench liquor is important. Submicron particles can be formed by droplet evaporation if aqueous stream containing dissolved solids is injected into the hot portions of the evaporative cooler. Suspended solids in the aqueous stream will also be released to the gas stream on evaporation of the water; however, this particulate will tend to be larger and, hence, more easily removed

by the particulate control system. Particulate noncompliance conditions can be created if the potential particulate formation in the quench is not considered.

Because of the critical nature of the quench system, a backup, emergency quench system is desirable. The emergency quench consists of a separate set of nozzles and water feed lines from an independent source. The water supply for the emergency quench should be active even during a complete power failure. A fire supply or gravity water feed from an elevated supply tank are possible sources. The system's response time must be short because catastrophic damage can occur to the system within seconds of quench failure. The required short response time necessitates automatic activation of the emergency quench system.

Heat Recovery Systems

Many incinerator designs incorporate some form of heat recovery systems. Municipal waste incinerators (waste-to-energy systems) recover heat through steam tubes in the combustion chamber walls — these are termed water-wall incinerators. Such water-wall units are not commonly used for the combustion of hazardous wastes because the relatively cold walls can reduce the incinerator's combustion zone temperature and, hence, the level of organic compound destruction achieved. A notable exception to this is the use of large industrial or utility boilers for waste destruction. In this case, the amount of waste burned is small compared to the amount of fuel used. In addition, the large size of the furnace minimizes the effect of the cold walls.

In general, however, incinerators burning hazardous wastes do not utilize water-wall designs. They do, however, often include a boiler, which is mounted in the exhaust gas immediately after the final combustion chamber. The boiler serves two functions. First, it recovers heat from the flue gas in the form of usable steam. Second, it cools the flue gas without increasing its volume and mass by injecting steam as a quench.

Heat recovery is an important aspect of the boiler. The combustion gas, with its high temperature and volume, lends itself to the production of usable steam to drive steam ejectors, to provide steam for atomization in the nozzles, to drive turbine pumps, or for numerous other applications. The steam coming directly from a hazardous waste incinerator is generally not at a high enough pressure to drive turbines for electrical generation. If cogeneration is desirable, then the low-pressure steam is fed to a second furnace to boost its temperature. In most cases, however, an incinerator does not produce enough steam to warrant the expense of an electricity cogeneration system.

The second purpose for the heat recovery system, gas cooling, makes it a significant component in the incinerator design. The temperature of the combustion gas leaving the secondary combustion chamber is typically on the order of 1000°C (2000°F). It must be cooled to below about 70°C (160°F) prior to entering the air pollution control system. A quench cools the gas by evaporating water, which then increases the mass of the combustion gas stream. A boiler cools the combustion gas by indirect heat transfer without increasing its mass. If the boiler can cool the combustion gas from 1100 to 250°C (2000 to 500°F), it will reduce the amount of water that the downstream quench will produce by approximately 75%. The quench, the air pollution control system, the fan or ejector, and the stack can thus be proportionately smaller.

A number of factors must be considered prior to including a boiler in an incineration system. First, a boiler is designed to cool the gas stream, and hence, it must be placed downstream from all combustion chambers that destroy hazardous constituents. If it is placed in the combustion chamber, it will cool the gases and change the temperature-residence time regime to which the combustion gases are exposed, potentially causing a lesser destruction of organics. Second, in some cases, the ash particles present in the secondary combustion chamber exhaust gas may be at least partially melted. Sodium chloride, a common component of wastes, melts at flame temperatures. The molten particles can solidify on the cool walls of the boiler tubes, fouling them and even restricting gas flow. The boiler may thus be impractical for incinerators burning wastes with high salt content or those with ash that has a fusion temperature (melting point) below that found in the combustion chamber.

Another factor is the presence of corrosive gases in the gas stream. The boiler must be operated to assure that it has no spots below the combustion gas stream's dewpoint. Acid gases (such as SO_2, HC1,

or HF) in the combustion gas will dissolve in the condensed aqueous liquid, corroding the tubes. HCl is especially corrosive to metals, including most forms of stainless steel. HF is also corrosive to metals, but it attacks silica-based refractory. SO_2 is relatively insoluble in water and is relatively noncorrosive; however, it lowers the dewpoint of water substantially, and its presence requires that the boiler be operated at a higher temperature to prevent condensation. To minimize the risk of condensation, boilers are typically sized so that the temperature of the exit gas is above 450°F. Furthermore, because of the particularly corrosive nature of HF on refractory materials, the presence of more than trace amounts of fluorides may prevent the use of boilers.

A final consideration in the use of heat recovery boilers is chlorodibenzodioxins and chlorodibenzofurans formation. These contaminants have been found to form at temperatures in the 200 to 370°C (400 to 700°F) range, which is the same operating range creating the risk of these hazardous materials forming in the boiler and on the boiler surfaces.

Acid gas control devices are of two types, wet and dry. The wet devices include packed bed scrubbers, Venturi and Venturi-like scrubbers, "wet" electrostatic precipitators, and proprietary wet scrubbers. Dry particulate removal devices include fabric filters, electrostatic precipitators, and high-efficiency particulate absolute (HEPA) filters. HEPA filters are used for particulate control, where a high level of particulate removal is required, such as in radioactive waste incinerators. They are similar in operation to fabric filters, although the nature of the fabric is such that a high level of particulate control is achieved. Wet devices remove acid gases as well as particulate, and the two functions are often combined in one device.

Dry scrubbing is a technique whereby lime or another lime-based sorbent is injected into the hot zone of the incinerator. The sorbent removes a fraction of the acid gas in suspension and is collected on the particulate removal device, usually a fabric filter. Dry scrubbers are usually used in conjunction with another form of acid gas removal device.

Electrostatic Precipitators

Electrostatic precipitators (ESPs) can be used for two entirely different types of service. "Wet" precipitators can be used as the principal particulate control device within a wet scrubbing system including a gas cooler and an acid gas absorber. While basic operating principles of the wet and conventional ESP are similar, the two different styles are subject to quite different operating problems. They both use the principle of electrostatic attraction. The incoming particulate is ionized and then collected on charged plates. In a dry precipitator, the plates are periodically rapped or shaken, and the accumulated dust is collected in hoppers at the bottom. In a wet precipitator, a continuous stream of recirculated liquor drains over the plates and removes the accumulated particulate matter. A wet ESP can be used to control acid gas as well as particulate. Wet ESPs operate at relatively low gas temperatures, and the precipitators are limited to one or two electrical fields in series.

Figure 13.9 is a drawing of a conventional dry electrostatic precipitator. In electrostatic precipitators, particles are electrically charged during passage through a strong, nonuniform electrical field. The field is generated by a transformer-rectifier set that supplies pulsed D.C. power to a set of small diameter electrodes suspended between grounded collection plates. Corona discharges on these electrodes generate electron flow, which in turn, leads to the formation of negative ions as the electrons travel on the electrical field lines toward the grounded plates. The negative ions also continue on the field lines toward the plates. Within the corona itself, positive ions form, and these travel back to the high-voltage electrodes.

An ESP's performance depends on the ability of the particulate matter to receive and maintain a charge, the velocity of the particulate migration to the collection plates, the ability of the particulate to adhere to the plates after they are captured, and the ability of the system to minimize re-entrainment of the particulate during the cleaning or rapping cycle.

The ability of the particulate to maintain a charge and to adhere to the collection plates is a function of the resistivity of the particulate and of the flue gas. The resistivity is a measure of the ability of electrical charges on the particles to pass through the dust layer to the grounded collection plates. Dust layer

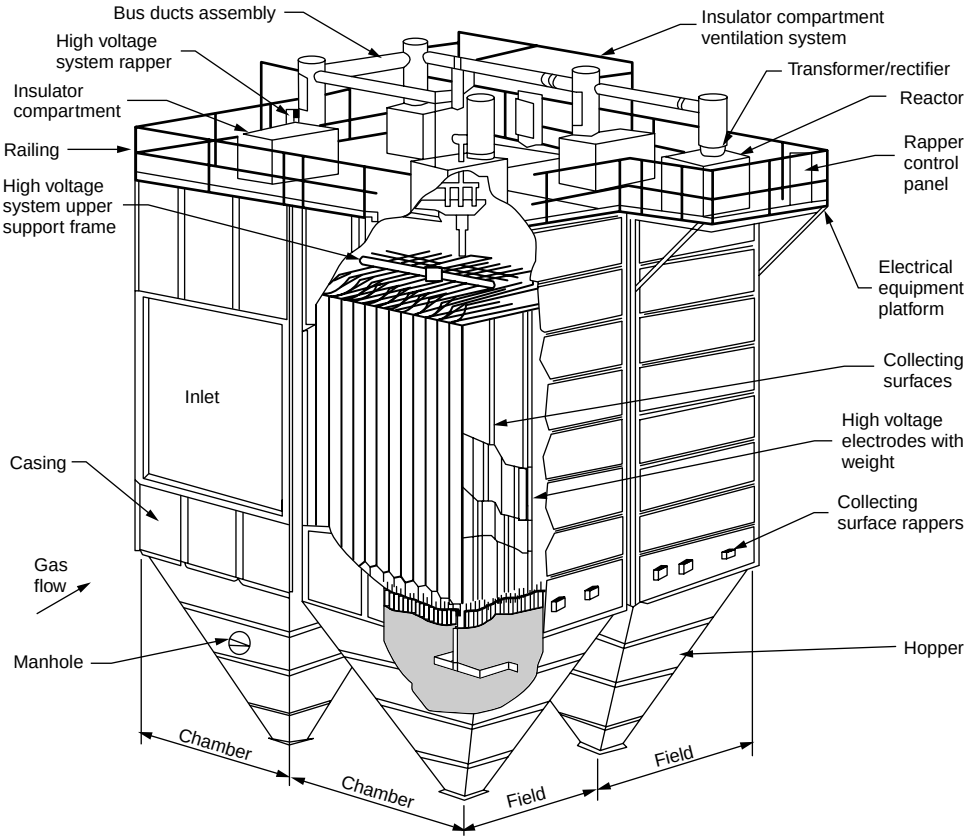

FIGURE 13.9 Conventional dry electrostatic precipitator (Western Precipitation, undated).

resistivity is expressed in units of ohm-centimeters, and the values can range from 1×10^8 to more than 1×10^{13}. The effective migration velocity increases nonlinearly as the resistivity decreases.

Dust layer resistivity at any given site in a precipitator is the net effect caused by two different paths of charge conduction. When there are conductive compounds adsorbed on the surfaces of the particles, the electrons can pass along the particle surfaces within the dust layer to reach the grounded collection plates. The most common conductive materials on the surfaces of particles include sulfuric acid and water vapor. When there are conductive materials in the particles, there can be an electrical path directly through the bulk material. The most common conductive compounds within the precipitated particles include carbonaceous materials, sodium compounds, and potassium compounds. The overall particle size distribution affects the resistivity simply because, in both types of conductivity, the electrical current must pass through a number of separate particles in the dust layer prior to reaching the grounded surface. Smaller particles form a dust layer with less voids and greater particle-to-particle contact.

Dust layer resistivity is not a constant value throughout a precipitator at any given time, and the "average" resistivity can vary substantially over time at a given incinerator. This temporal and spatial variability is due to the extreme sensitivity of resistivity values to the gas temperature, the presence of vapors such as sulfuric acid mist, and the dust chemical composition. The rate of electrical charge conduction through the dust layer on the collection plates determines the electrostatic voltage drop across the layer, and this can affect the ability of the dust to adhere to the plates and the ability of the plates to attract additional dust. When conductivity by either path is high, the dust layer voltage drop is low. Some of the weakly held particulate matter can be re-entrained due to rapping with excessive force. Also,

localized high gas velocity zones through the precipitator can scour off some of the dust layer. In applications where the dust shows a high resistivity, the precipitator will have to be larger. It is sometimes possible to modify resistivity by injecting small amounts of sulfuric acid into the gas stream entering the ESP as a conditioning agent.

One of the first steps in precipitator design is to determine the necessary collection plate area for the efficiency desired. The efficiency should increase as the specific collection area is increased. However, the cost and mechanical complexity of the precipitator also increase with the specific collection area. Also, the vulnerability to malfunctions can increase as the size increases. The optimum size that provides for high-efficiency performance without excessive costs and reliability problems must be determined. Equipment sizing must take into account the numerous nonideal factors, which are difficult to express mathematically but, nevertheless, have important effects on performance. This has generally been done by the determination of "effective" migration velocities that include theoretical parameters plus the effects due to nonuniform particle size distribution, nonuniform gas flow distribution, nonuniform gas temperature distribution, and rapping re-entrainment. During the design stage, the anticipated dust layer resistivity range should be carefully evaluated. For existing units, the resistivity variability can be measured by a variety of instruments, such as the cyclonic probe and the point-to-plane probes. For new units, the resistivity range in similar incinerators handling similar wastes should be reviewed.

High-efficiency precipitators have more than one electrical field. Two or more fields are normally provided in the direction of the gas flow. For large incinerators, the gas flow can be split into two or more chambers, each of which has several fields in series. The sectionalization of the precipitators improves precipitator performance and reliability. For this reason, sectionalization should be considered in the preparation of precipitator specifications. As in the case of precipitator sizing, there is an optimum balance between the number of independent fields and the cost. One of the underlying reasons for sectionalization is the significant particle concentration gradiant and dust layer thickness gradients between the inlet and outlet of the precipitator. At the inlet of the precipitator, the dust layer accumulates rapidly, because 60 to 80% of the mass is collected rapidly. This makes this field more prone to electrical sparking due to the nonuniformities in the dust layer electrical fields. Also, the fine particles initially charged in the inlet field but not collected create a space charge in the interelectrode zone. This space charge inhibits current flow from the discharge electrodes and collection plates. By sectionalizing the precipitator, the inherent electrical disturbances in the inlet field do not affect the downstream fields. Another reason for sectionalization is the differences in electrical sparking, which are normally moderate-to-frequent in the inlet fields and low-to-negligible in the outlet fields. The number of fields in series and the number of chambers in parallel are generally determined empirically, based on the performance of previous commercial units. In the case of hazardous waste incinerators, there are some practical limits to the number of fields used, simply because the gas flow rates are relatively small.

Because of the high voltage, sparks will occur in a precipitator. The sparking rate needs to be maintained at a specified level, and the ESP includes automatic voltage controllers to quench the electrical sparks. These are electronic devices that reduce the applied voltage to zero for milliseconds and then increase it in several steps to a level close to the one at which sparking occurred. When sparking rates increase in a field, the net effect is to lower the peak voltages and to lower the applied time of the electrical power.

Rapping Techniques

For dry-type electrostatic precipitators, there are two major approaches to rapping: (1) external roof-mounted rappers and (2) internal rotating hammer rappers. The external rappers are connected to groups of collection plates or an individual high-voltage frame by means of rapper shafts, insulators, and shaft seals. The advantage of these roof-mounted rappers is that there is access to the rapper during operation, and the intensities can be adjusted for variations in dust layer resistivity. The disadvantage is that the large number of rapper shaft components can attenuate rapping energy and become bound to the hot or cold decks.

The internal rotating hammer rappers have individual rappers for each collection plate. Due to the greater rapping forces possible, these can be used for moderately high resistivity dusts. The disadvantages

of these rappers are the inability to adjust the frequency and intensity in various portions of the precipitator and the inaccessibility for maintenance. Also, the internal rotating hammer rappers can be vulnerable to maintenance problems, such as shearing of the hammer bolts, distortion of the hammer anvils, bowing of the support shafts, and failure of the linkages.

The type of rapping system chosen should be based on the anticipated resistivity range, the frequency of routine incinerator outages, and the cost of the equipment. For both styles of rappers, the high-voltage frame rapper shafts must include high-voltage insulators to prevent transmission of high D.C. voltages to external, accessible equipment. These insulators must be kept clean and dry. Purge air blowers with electrical resistance heaters are used for this purpose.

Hoppers and Solids Discharge Equipment

For dry-type electrostatic precipitators used in dry scrubbing systems, proper design of the hopper and solids discharge equipment is especially important. These units handle high mass loadings, and some of the reaction products are hygroscopic and prone to bridging. Hopper heaters and thermal insulation are important to avoid the hopper overflow conditions that could cause an undervoltage trip of a field and that could possibly cause serious collection plate-to-discharge electrode alignment problems.

Gas Distribution

One of the most important steps in ensuring adequate gas distribution is to allow sufficient space for gradual inlet and outlet transition sections. Units with very sharp duct turns before and after the transition are also prone to gas distribution problems.

Proper gas distribution is achieved by the use of one or more perforated gas distribution screens at the inlet and outlet of the precipitator. These are generally hung from the top and cleaned by means of externally mounted rappers. Location of the gas distribution screens (and ductwork turning vanes) is usually based on either $1/16^{th}$ scale flow models or gas distribution computer models.

Fabric Filters

The fabric filter consists of a series of filter bags made of fabric and hung from a frame in a "baghouse." The gas to be treated enters the baghouse and passes through the fabric of the bags that filter out particulate. The cleaned gas exits the baghouse to subsequent cleaning or discharge. The parameters that influence baghouse construction are (1) type of filter bag material; (2) gas-to-cloth ratio, also called facial velocity; (3) direction of gas flow through the bags; and (4) type of bag cleaning employed.

Particulate collection on a fabric filter occurs primarily by the combined action of impaction and interception within the dust cake supported on the fabric. Without a well-developed dust cake, the filtration efficiencies would be very low. Particulate capture efficiency in a typical baghouse is normally very high. Penetration of particles through a fabric filter is due not to inefficient impaction/interception, but rather to dust seepage through the dust cake and fabric, gas flow through gaps or tears in the fabric, gas flow through gaps between the bags and the tubesheet, and gas flow through gaps in tubesheet welds. The emissions are minimized by operating the unit at proper air-to-cloth ratios and by ensuring that the bags have not deteriorated due to chemical attack, high temperature damage, flex/abrasion, or other mechanical damage. The efficiency of fabric filters is not highly sensitive to the inlet particle size distribution. The particle size distribution of the material penetrating the baghouse is similar to the inlet gas stream particulate due to the emission mechanisms.

The typical baghouse is arranged in compartments with dampers that permit isolation of each compartment from the rest with poppet or butterfly dampers. In case of failure of one or more bags in one compartment, the compartment can be isolated, and the system can keep operating until the bags are replaced or repaired. For some systems, the individual compartments are closed prior to rapping or shaking in order to minimize the release of particulate during the cleaning cycle.

The two basic styles of fabric filters used on incinerators are pulse-jet units and reverse air units. Reverse air units are identified by bags that are suspended under tension from tube sheets directly above the hopper. The particulate-laden gas stream enters the interior of the bags through the tube sheet and

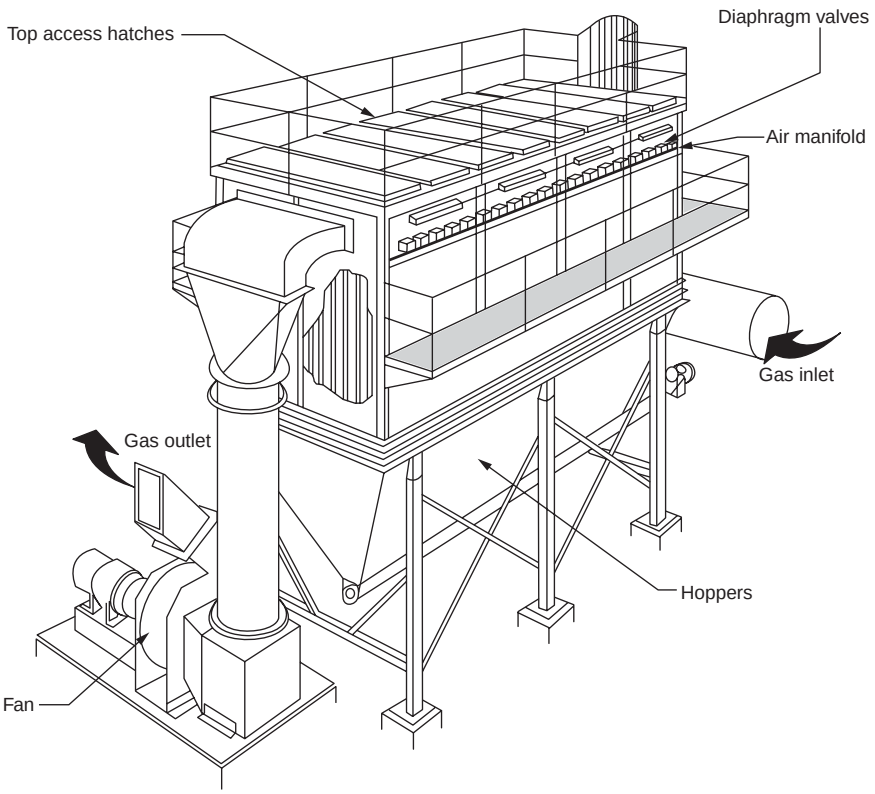

FIGURE 13.10 Isometric sketch of a top access type pulse-jet unit (Richards and Quarles, 1986).

collects as a dust on the inside of the bags. The bags are cleaned by passing blowing filtered gas from the exhaust through the bags in a reverse direction to normal gas flow. The reverse flow dislodges the dust cake into the hopper. In order to accomodate the reverse flow of air necessary for cleaning, reverse air baghouses have multiple compartments. For cleaning, each compartment is isolated from the flow gas stream with dampers.

Pulse-jet baghouses are the most common because these are well suited for the relatively small gas flow rates in hazardous waste incinerators. In pulse-jet units, the fabric is supported on a cage that is suspended from a tube sheet near the top of the collector. The particulate-laden gas stream enters through a duct on the side of the baghouse or in the upper portions of the hoppers. The dust cake accumulates on the exterior surfaces of the bags. The bags are cleaned by the combined action of a compressed air pulse and the reverse airflow induced by this pulse. A set of solenoid valve controlled diaphragm valves are used to supply compressed air cleaning flow to each row of bags. Some units have multiple compartments to allow for bag cleaning off-line or to allow for maintenance of a portion of the unit during incinerator operation.

The following discussion of fabric filters emphasizes pulse-jet-type units. Two sketches of pulse-jet baghouses are shown in Figs. 13.10 and 13.11. The first of these is an isometric sketch that illustrates the locations of the clean side access hatches on the top and the filtered gas exit duct. The second sketch is a side elevation showing the bag support and the bag cleaning apparatus.

The air-to-cloth ratio is the total fabric area divided by the total gas flow rate in ACFM (wet basis). It is defined in Eq. (13.14). The units should be specified along with the air-to-cloth ratio dimensions of length/time, because the value of x in English units is quite different from a value of x in metric units.

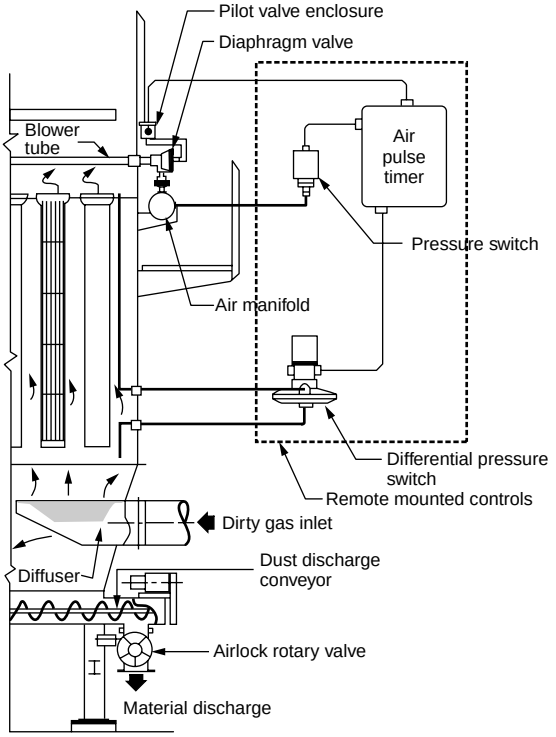

FIGURE 13.11 Side elevation cutaway of pulse-jet unit (Richards and Quarles, 1986).

$$A/C\ (\text{gross}) = G/F \tag{13.14}$$

where A/C (gross) is the gross air-to-cloth ratio in ft/min, G is the total gas flow rate in ACFM (wet basis), and F is the total fabric filter area in square feet.

The gross air-to-cloth ratio is selected based on prior experience with similar sources and dusts. For pulse jet baghouses on incinerators, typical values are less than 4.0 ft/min. Specific values are based on a number of site-specific factors including but not limited to the following:

- Average and maximum particulate mass loadings (should be decreased with increasing particulate loading)
- Typical particle size distributions
- Allowable maximum static pressure drops
- The need for off-line cleaning
- The need for on-line maintenance and inspection
- Purchased equipment costs

Pulse-Jet Bag Cleaning Equipment

Pulse-jet bags are cleaned with an intermittant pulse of compressed air delivered to the top, center of the bags. The cleaning apparatus includes a source of compressed air, a compressed air manifold, a set of diaphragm valves, a set of solenoid valves, and compressed air delivery tubes. Cleaning is done on a row-by-row basis. On-line cleaning means that the gas stream is continuing to flow through the compartments as the rows of bags are cleaned one by one. During off-line cleaning, a compartment is isolated, while the rows are cleaned one by one. Off-line cleaning minimizes dust cake discharge problems because the falling solids from the outside of the bags are not being opposed by an upward flowing unfiltered gas stream.

TABLE 13.8 Fabric Capabilities

Material	Temperature Limits		Chemical Resistance		Flex/Abrasion Resistance
	Long-Term	Short-Term	HCl and H_2SO_4	HF	
Acrylic copolymer	225	250	Good	—	Fair
Modacrylic	275	300	Good	—	Fair
Polyester	250	275	Fair	Fair	Good
Polyphenylene sulfide	375	400	Good	—	Good
Nylon arimid	400	425	Poor	Poor	Good
Fluorocarbon	450	500	Good	Good	Good

Sources: Richards, J. and Segall, R. 1985. *Inspection Techniques for Evaluation of Air Pollution Control Equipment,* Vol. II. EPA Report 340/1-85-022b; PEI, 1986. PEI Associates, Inc. *Operation and Maintenance Manual for Fabric Filters.* U.S. EPA Report EPA-625/1-86-020.

As a general rule, the minimum baghouse gas temperature should be 50°F above the acid dewpoint to take into account the gas temperature spatial variability in the baghouse and the short-term fluctuations in the average gas temperature. Sufficient thermal insulation should be provided so that the gas temperature drop across the baghouse does not exceed 25 to 40°F (depending on the inlet gas temperature). Also, air infiltration should be minimized by selecting proper hatch gaskets and latches, proper solids discharge valves, and proper shell welding practices.

Fabrics and Support Cages

The selection of fabric materials must be based on the expected gas stream temperatures and acid gas concentrations. A summary of the general capabilities of commonly used fabrics is shown in Table 13.8. The long-term temperature limits presented in Table 13.8 are slightly below the general temperature limits often stated for the various types of materials. The reduced long-term temperature values increase the service life of the bags. The short-term maximum temperature limits specified in Table 13.8 are slightly higher than general temperature values. However, these values should not be exceeded for more than 15 min. Severe gas temperature spikes will lead to premature bag failure, even if the long-term temperatures are maintained in the proper range.

It should be noted that for many units, there is only a narrow optimum gas temperature range. There can be only 100 to 150°F difference between the long-term upper gas temperature limit and the acid dewpoint related lower gas temperature limits. Proper process control and conscientious maintenance are necessary to maintain the narrow gas temperature range throughout the baghouse.

In addition to the temperature and acid sensitivities, the abrasion and flex resistance of the material should be considered. Materials that are vulnerable to flex and abrasion problems should be used only on cages that provide the maximum support. Finally, the cages should not have exposed sharp edges that could cut the fabric.

Hoppers and Solids Discharge Equipment

The proper design of the hopper and solids discharge equipment is important in ensuring long-term reliable operation. Hopper heaters and thermal insulation are important to prevent the hygroscopic, acidic ash from cooling. This can result in bridging of solids and in hopper overflows. Due to the gas entry ducts in the upper portions of the hoppers, dust re-entrainment blasting of the pulse-jet bags occurs as the hopper solids levels increase.

Fabric Filter System Instruments

Table 13.9 summarizes the categories of instruments often used on pulse-jet fabric filters. The gas temperature monitors are especially important since they provide indications of incinerator upset and baghouse air infiltration. The pulse-jet fabric filter static pressure drop gauges should be mounted in

TABLE 13.9 Pulse Jet Fabric Filter System Instruments

Vessel	Parameter Measured	Process/Equipment Controlled	Portable Instrument Port or Sampling Tap
Stack	Opacity	—	—
Fan	Fan motor current	—	—
	Fan vibration	—	—
Pulse jet	Fabric filter		
	Inlet gas temperature	Emergency bypass	Yes
	Outlet gas temperature	—	Yes
	Compressed air pressure (each separate header)	—	—
	Static pressure drop, overall bag house	Cleaning system	Yes
	Static pressure drop, each compartment	—	Yes

accessible locations because they are prone to pluggage of one or both of the lines. Finally, compressed air gauges are necessary on each separate header to identify units with leak problems.

High-Efficiency Particulate Absolute Filters

These high-efficiency collectors are conceptually similar to fabric filters. They are used for the control of relatively small gas volume incinerators firing low-level radioactive wastes. The filter elements are composed of thick fiberglass matts with radiation-resistant binders. The filters are constructed in small 2-ft square panels approximately 1 ft deep. The filter is placed within each of the panels in order to increase the filtering area. A prefilter is often used to reduce the frequency of replacement of the expensive HEPA filters. This usually consists of a set of low-efficiency panel filters. The average approach velocities range between 300 to 500 m (1000 to 1500 ft/min). Particles are collected by the combined action of impaction and Brownian diffusion on the surfaces of the filter mat. Unlike fabric filters, the accumulated material (or dust cake) is not the main filtering element in HEPA filters. The particulate removal efficiencies are rated at least 99.97% efficient for DOP droplets with a mean size of 0.3 microns.

The initial static pressure drop across a set of new HEPA filter panels is between 1 and 1.5 inches W.G. The units are replaced whenever the pressure drop reaches a preset maximum limit of approximately 2.5 in. High-pressure drops are not desirable, because this increases the risks of leakage through the seals around the panels and the risks of particle seepage through the filter elements.

Gas Atomized (Venturi) Scrubbers

A large number of quite different devices fall into the general category of "gas atomized scrubbers." These include but are not limited to adjustable throat Venturi, rod decks, and collision scrubbers. The common element of all of these devices is the utilization of a high-velocity gas stream to atomize a relatively slow moving injected liquid stream. One commercial type of adjustable throat Venturi is shown in Fig. 13.12. This includes a wedge, which moves up and down within the diverging section of the throat in order to vary the cross-sectional area. The wedge is moved by means of a hydraulic actuator below the elbow of the Venturi diverging section. The particular scrubber shown in Fig. 13.12 has a cyclonic demister for collection of the liquor droplets formed in the Venturi throat.

A second type of "Venturi" scrubber is the rod deck. The deck consists of one or more horizontal rows of rods across the throat of the scrubber. Liquor is introduced by means of downward oriented nozzles above the rod decks. Some models include the provision for movement of one of the decks in order to vary the cross-sectional area and the operating static pressure drop.

A schematic of a collision scrubber is shown in Fig. 13.13. The gas stream is split into two equal streams that are directed against each other. Impaction occurs due to the significant differences in relative velocities of the water droplets and the particles in the colliding streams. This particular unit has a chevron-like demister for collection of the water droplets.

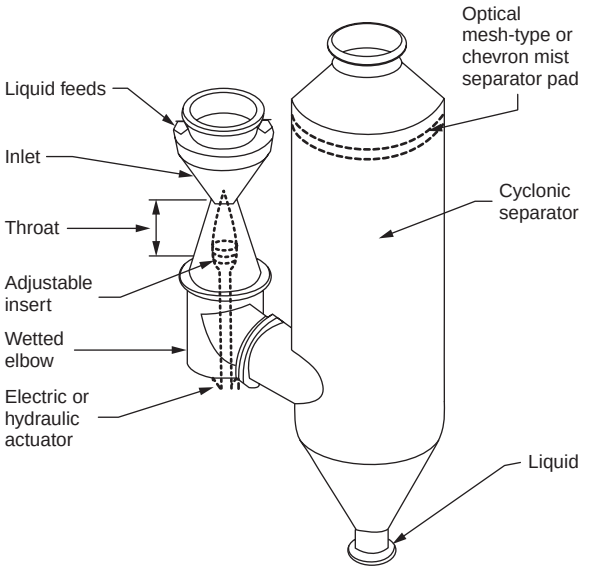

FIGURE 13.12 Adjustable throat Venturi scrubber (Brady, 1982).

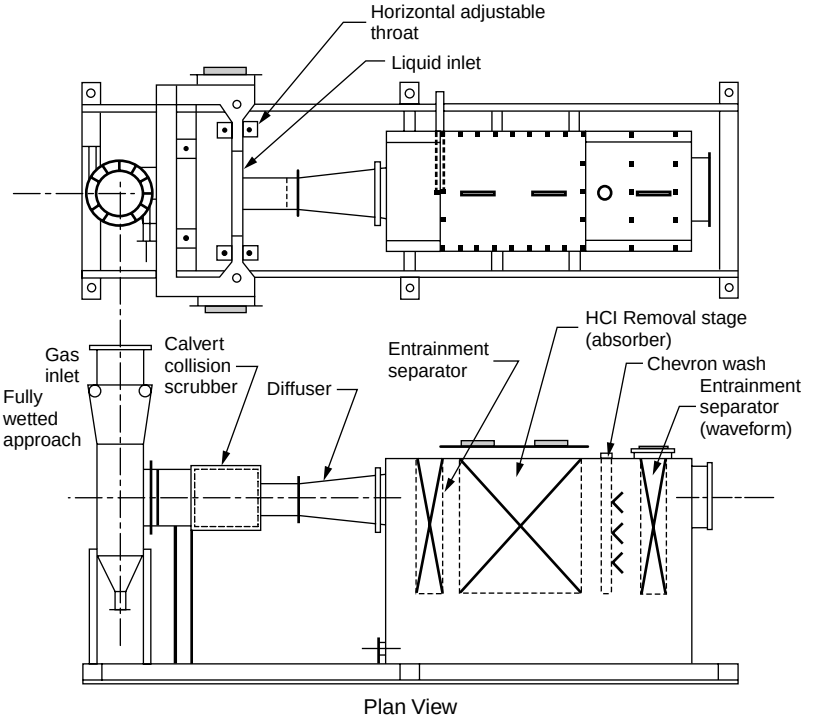

FIGURE 13.13 Collision scrubber (Schifftner, 1989).

All of the fundamental mechanisms employed in gas-atomized scrubbers are particle size dependent. The two most commonly used mechanisms are impaction and Brownian diffusion. Impaction is an effective means of capture for particles larger than 0.5 μm, and Brownian diffusion is the primary capture

mechanism for the particles in the less than 0.1 μm range. In the 0.1 to 0.5 μm range, both collection mechanisms can be active, but they are not especially effective.

The rate of Brownian diffusion is inversely proportional to the particle size diameter. As particle size decreases, Brownian diffusion increases. It also increases as the gas temperature increases due to the increased kinetic energy of the gas molecules striking the small particles. Due to the combined action of impaction and Brownian diffusion, penetration of particulate matter in gas atomized scrubbers is low in the >1 micron range and in the <0.10 micron range. However, there is a peak in the penetration curve (penetration = 1 -%collection efficiency/100%) at approximately 0.2 to 0.5 μm. Gas atomized scrubbers and other air pollution control devices using impaction and Brownian diffusion are least effective in the submicron particle size range.

Scrubbing systems that can achieve high particulate removal efficiencies in the submicron particle size range utilize a flux force/condensation mechanism to aid capture. Flux force/condensation conditions are initiated by removing the sensible heat from the gas stream downstream of the quench, so that a portion of the gas stream water vapor condenses on the particles to be removed. The two primary physical mechanisms active in flux force/condensation are diffusiophoresis and heterogeneous condensation (Calvert et al., 1973; Calvert and Jhaveri, 1974). Diffusiophoresis is the net force due to nonequal molecular collisions around the surface of a particle. The conditions that favor diffusiophoresis occur when the particle is near another particle or its surface is undergoing condensation. The mass flux of water vapor toward the condensation surface creates the nonequal moleculer forces on the second particle. Diffusiophoresis is important only for submicron particles affected by molecular collisions.

The static pressure drop through a Venturi scrubber can be estimated by means of the pilot-scale tests or by one of the published theoretical equations. The Calvert et al. pressure drop calculation (Yung et al., 1977) is presented in the following equation.

$$\gamma_p = 0.005\,(L/G)\,V^2 \tag{13.15}$$

where γ_P is the static pressure drop, in W.C.; V is the gas velocity in ft/sec; and (L/G) is the liquid-to-gas ratio, in consistent units (i.e., liters per minute of liquid to liters per minute of gas). This equation indicates that the pressure drop is a strong function of the gas velocity through the throat used to accelerate and atomize the liquid. The pressure drop is directly proportional to the liquid-to-gas ratio. It does not take into account the relatively small dry frictional energy losses of the gas stream passing through the restricted throat.

The static pressure drops for most gas atomized scrubbers on hazardous waste incinerators is in the range of 25 to 60 inches W.C. However, some units operate at pressure drops as high as 100 inches W.C. (Anderson, 1984). The liquid-to-gas ratios for most commercial gas atomized scrubbers is in the range of 4 to 15 gal/1000 ACFM. At liquor rates less than 4 gal/1000, efficiency drops rapidly due to an insufficient number of liquor droplet "targets" in the throat. This can be a problem in relatively arid areas, where makeup water is limited, necessitating a high purge rate. The scrubber system efficiency decreases at high liquor flow rates due to a change in the droplet size distribution formed in the scrubber. A liquid-to-gas ratio of 10 gal/1000 ACFM is generally considered optimal.

Due to the complexity of most wet scrubber systems, numerous instruments are necessary to monitor performance. Table 13.10 summarizes the categories of instruments usually necessary and the types of units used.

Hydrosonics™ Scrubber

This is a group of ejector-type scrubbers. Most of the units used for high-efficiency particulate collection use a fan as a source of motive power. However, one of the designs using a supersonic steam (or compressed air nozzle) can be used without a fan. The scrubbers consist of a cyclonic pretreatment chamber, one or more converging section "nozzles" for flue gas, a ring of liquor spray nozzles around the flue gas converging sections, a gas-liquor mixing section, a long contact throat, and a mist eliminator.

TABLE 13.10 Gas-Atomized Scrubber System Instruments

Vessel	Parameter Measured	Process/Equipment Controlled	Portable Instrument Port or Sampling Tap

	Fan vibration	Fan trip	—

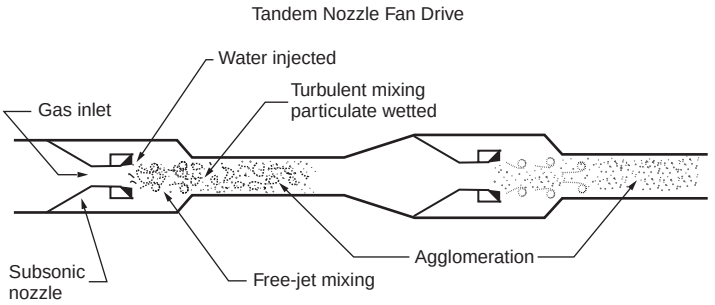

FIGURE 13.14 Tandem nozzle Hydro-Sonics scrubber (Holland and Means, 1988). (Reproduced courtesy of HydroSonics Corporation.)

The units rely on a combination of particle condensation growth and particle impaction. Accordingly, the relationships presented earlier between pressure drop and scrubber performance also apply to this category of scrubbers.

Two of the most common types of HydroSonics™ systems used are shown in Figs. 13.14 and 13.15. The unit in Fig. 13.14 is a Tandem Nozzle design, and the unit in Fig. 13.15 is the SuperSub™ unit having the steam or compressed air ejector nozzle. For both types of units, the gas stream from the incinerator initially enters a cyclonic chamber, where the temperature is reduced to approximately the adiabatic saturation temperature. This chamber also serves as a cyclonic precleaner for the removal of large particles emitted from the incinerator.

For the unit shown in Fig. 13.15, a compressed air nozzle operating at supersonic velocities is used for the initial atomization of scrubber liquor and for the generation of suction. The flue gas and atomized liquor then pass through a subsonic nozzle. A ring of spray nozzles around the subsonic nozzle injects an additional cocurrent stream of liquor. The flue gas is then accelerated in a long throat, where particle growth by condensation and particle capture by impaction occur. Water droplets are collected in a low-pressure drop cyclonic collector or in a horizontally oriented chevron demister vessel.

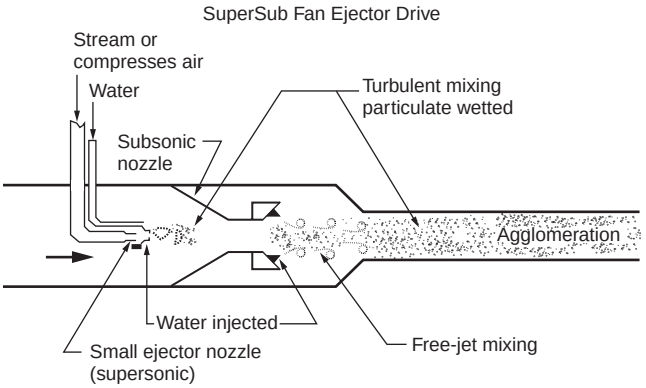

FIGURE 13.15 SuperSub Hydro-Sonics scrubber (John Zink Co., 1988a). (Reproduced courtesy of HydroSonics Corporation.)

The compressed air requirements for the supersonic ejector unit are 0.04 to 0.05 pounds per pound of flue gas (John Zink Co., 1988a). For a flue gas stream of 50,000 ACFM saturated at 180°F, this is equivalent to approximately 125 to 160 lb/min or 1600 to 2100 SCFM. Compressor horsepower requirements based on the manufacturer's data are 0.06 to 0.07 Hp/lb of flue gas per minute (John Zink Co., 1988b). For the 50,000 ACFM example, the horsepower required is approximately 185 to 220. The compressor must be equipped with a means of removing condensed oil so that this material is not volatilized and recondensed as non-wet-table particles. If low-pressure steam is available from a waste heat boiler or other source, it can be used instead of compressed air in the nozzle. The steam requirements are typically on the order of 0.03 pounds per pound of flue gas (John Zink Co., 1988b).

The fan horsepower requirements are a function of the static pressure drop across entire system. The common range is 10 to 35 in. of water. The fan horsepower requirements range between 2.1 HP/1000 ACFM for a 10-in. pressure drop to 7.3 HP/1000 ACFM for a 35-in. pressure drop (John Zink Co., 1988b).

The instrumentation requirements for a HydroSonics™ scrubber are similar as those for a Venturi scrubber.

Ionizing Wet Scrubbers

The ionizing wet scrubber (IWS) utilizes electrostatic charges for capture of particulate matter. The initial part of the control device is an ionizer section that functions like an electrostatic precipitator. Instead of grounded precipitator collection plates within the nonuniform electric field, the ionizer scrubber uses a packed bed scrubber downstream of the electric field for particle capture. The operating principles of an ionizing wet scrubber are similar to those of a conventional electrostatic precipitator with two major exceptions. Due to the removal of collected particulate matter on wetted packing, resistivity is not a major factor. Also, the migration velocities of the charged particles are lower because the applied electric field does not extend into the packed bed. However, this is offset by the much shorter migration velocities to the collection surfaces.

The power source for an IWS consists of a standard transformer-rectifier set (T-R set) identical to the type used on electrostatic precipitators. A separate T-R set is used for each ionizer/packed bed module in series. For incinerators, the number of modules in series can range from one to four, depending on the particle size distribution, the mass emission regulatory limits, and the presence of an upstream adjustable throat Venturi section. The overall power requirements of the units range between 0.2 and 0.4 kVA per 1000 ACFM (Ceilcote Co., 1975).

The ionizer is a set of small diameter negatively charged wires centered between grounded metallic plates. Alignment is maintained at 3 in. ± 0.25 in. to ensure maximum operating voltages. The actual operating voltage normally varies between secondary voltages of 20 and 25 kV and secondary amperages

of 25 to 100 mÅ (Ceilcote Co., undated). The operating voltages are controlled by an automatic voltage controller that utilizes spark rate as the monitored variable. The spark rate is a function of the particle size distribution, the particulate matter loading, and the ionizer electrode alignment. The spark rate is usually maintained between 50 and 100 sparks per minute (Ceilcote Co., 1975).

Until the secondary voltage reaches the onset point, there is insufficient voltage to initiate a sustained corona on the negatively charged discharge electrodes. Once this voltage is exceeded, the secondary current rises rapidly as the voltage is increased. Generally, the maximum currents and voltages are a function of the spark rate set by the operator, with 50 to 100 sparks per minute being the manufacturer's recommendation for most facilities. However, the controller also has maximum primary current, secondary current, and primary voltage limits to protect the T-R set. There are also undervoltage limits with a short time delay to protect against short circuits due to broken wires or failure of an insulator.

The size of the ionizing wet scrubber is based primarily on the actual gas flow rate. The cross-sectional area of the ionizer is based on the desired superficial velocity necessary to achieve adequate particle charging. The packed bed size is based primarily on the acid gas removal requirements, not the charged particle removal requirements. The turndown capability of the IWS system is good. As long as particle size distribution and loadings remain relatively constant, the performances for gas removal and particulate removal should improve as the gas flow rate is decreased.

The ionizer is cleaned using a programmable controller. During washing, the ionzier is shut down for approximately 3 min to prevent electrical sparking related damage to the small diameter discharge wires and to the T-R set. Generally, cleaning is done on a 4 to 8 h schedule. However, this depends strongly on the particulate loading.

Acid gas removal is accomplished within a packed bed immediately downstream of the ionizer. This is usually a 4 ft irrigated bed of 2-in. diameter Tellerette™ packing. A set of sprays is used to maintain recirculation liquor flow across the packing. An internal sump is used as part of the recirculation loop. The pH of the liquor is maintained between 6 and 8 by means of alkaline addition. The liquor recirculation rates within an IWS stage are approximately 10 gal per 1000 ACFM. This includes the deluge water used on a routine basis to clean the electrodes. Make-up water requirements are generally in the range of 2 gal per 1000 ACFM per stage.

Packed Bed and Tray Tower Scrubbers

Hydrogen chloride, hydrogen fluoride, and sulfur dioxide are the main pollutants collected in packed bed and tray tower scrubbers. These are relatively soluble gases that can be collected with high efficiencies in a variety of units. The most common type of packed bed scrubber is the vertical tower with randomly stacked packing. The counterflow arrangement inherent in the vertical tower design has a performance advantage in that the driving forces for absorption are maximized by this flow arrangement. The gas stream encounters progressively cleaner liquor as it approaches the scrubber outlet at the top of the vessel. Another advantage of this approach is that it requires little plant area. The main disadvantage is the length of the ductwork from the outlet at the top to the inlet of ground-mounted fans. The tray tower scrubbers share the advantages and limitations of the vertical packed bed scrubbers.

Another common scrubber style is the horizontal crossflow packed bed. The configuration of this unit is compatible with rod deck and ionizing particulate wet scrubbers. Demisters installed in the exhaust ends of the horizontal vessels are also slightly more efficient than demisters in vertical towers because the collected liquor drains without being opposed by the gas stream. The main disadvantage is the possible absorption performance problems caused by the driving force gradiant across the packed bed. Removal efficiency can be high for gas passing across the top of the bed and somewhat lower for gas passing through the bottom. This is due to the reduction in pH levels as the liquor flows downward through the bed.

Gas and vapor collection in air pollution control devices is achieved by absorption or adsorption. Absorption is the dissolving of a soluble component into droplets or sheets of liquid. Adsorption is the physical bonding of molecules to the surface of dry particles entrained in the gas stream or contained

within a bed. Some of the newer air pollution control systems use absorption and adsorption in separate control devices arranged in series.

Absorption is the transfer of a gas or vapor phase compound into a liquid phase. In the gas of hazardous waste incinerators, the gas or vapor phase compounds primarily include hydrogen chloride, hydrogen fluoride, and sulfur dioxide. The liquid streams that receive these contaminants generally consist of recirculated liquids containing sufficient alkali to maintain the design pH for the system. Numerous chemical engineering texts and handbooks give the design procedures for absorbers. See, for example, Perry's *Chemical Engineering Handbook*, McGraw Hill, a book that is updated at regular intervals. The key operating conditions for an absorber are the types of packing material, and the liquid-to-gas ratio, for the system, and the height and diameter of the absorber. Table 13.11 lists some common types of packing material.

The pressure drop through the packed tower can be estimated using manufacturer supplied data relating the pressure drop per foot of packing as a function of the type of packing, how it is placed in the column (random packed or stacked in a pattern), and the liquid loading rate in terms of gallons per square foot per minute. Typical static pressure drops per foot of packing are generally in the range of 0.1 to 1.5 in. of water (Schifftner and Hesketh, 1983).

Dry Scrubbing Systems

There are two basic styles of dry scrubbing systems in use for hazardous incinerators: spray atomizer systems and dry injection systems. The spray atomizer systems generally include two fluid nozzles and rotary atomizers. Spray atomizer systems utilize an evaporating alkali slurry for absorption and adsorption of acid gases. The systems generally consist of a large atomizer vessel followed by a fabric filter or an electrostatic precipitator. Dry injection systems use a finely divided alkali solid for adsorption of the acid gases. The dry injection systems require more alkali reagent due to the lower collection efficiency inherently involved. However, dry injection systems are less expensive and easier to operate. Spray atomizer and dry injection scrubbing systems use recycle loops to increase the utilization of the alkali materials.

A number of physical processes combine in the removal of acid gases in dry scrubbing systems. Those systems using atomized liquid droplets initially have gas-phase controlled absorption into the drops as they are beginning to evaporate. The factors that influence mass transfer rates are similar to those for absorption. These include the diffusivity of the acid gas molecule in air, the gas temperature, the liquor

spray rate, the droplet size distribution, and the flue gas distribution around each of the nozzles or rotary atomizers used in the reaction vessel.

As droplet evaporation continues, the accumulating reaction products lower the droplet water vapor pressure and reduce the evaporation rate. Mass transfer of pollutants into the droplets begins to be controlled by the diffusion of water molecules through the precipitating matrix of reaction products and the undissolved reagent. Eventually, mass transfer of acid gases and volatile metals to the dried alkali particles is limited by the vapor pressures and diffusion rates of the pollutants within the drying particles. The important operating variables during this phase include the gas temperature, the size distribution of the adsorbent particles, the quantity of adsorbent available, and the residence time. These factors also limit the mass transfer rates of systems using only dry alkali particles.

Dry scrubber system vessels are designed by the equipment suppliers. The information necessary to select the most appropriate and economical unit for a specific incinerator should be based on visits to operating dry scrubbing systems, on available performance data for existing systems, and on information supplied by the suppliers. In a typical spray dryer dry scrubber, the incinerator flue gas initially enters a cyclonic chamber for removal of the large particles. The cyclone outlet gas is then treated in an upflow quench reactor for removal of HCl and other acid gases.

The reagent is usually calcium hydroxide slurry at 5 to 15% by weight atomized with compressed air (Dhargalkar and Goldbach, 1988). The atomizer vessel outlet gas temperature is carefully controlled to ensure that it does not approach the saturation temperature so closely that the solids are difficult to handle. The acid gas neutralization reactions in the quench reactor are shown below. The efficiency of acid gas removal is primarily a function of the stoichiometric ratio of alkali (such as calcium hydroxide) to the combined quantities of acid gas. Typical operating stoichiometric ratios are in the range of 2.5 to 3.5 moles of alkali per mole of acid gas.

The size of the atomizing vessel is based on the evaporating rates of the slurry droplets at the prevailing gas stream temperatures. Generally, the residence time is between 6 and 8 sec. Nozzle operating pressures and spray angles are selected by the manufacturer to achieve the necessary initial droplet size populations for proper evaporation. An atomizer vessel can have one or more spray nozzles.

Calcium hydroxide is the most common alkali used because it is relatively inexpensive and easy to handle. Calcium oxide (quick lime) is less expensive. However, a lime slaker is necessary in order to prepare the atomizer feed slurry. Improper operation of the lime slaker can result in reduced effectiveness of the absorption step. Other possible alkali materials include soda ash and sodium bicarbonate.

To increase acid gas removal efficiency, an alkali dry injection system can be installed downstream of the atomizer vessel. The manufacturer of this type of system uses a mixture of waste alkali materials termed "TESISORB" for dry adsorption. It is also claimed that this material improves the dust cake properties in the downstream fabric filter used for particulate and adsorbent collection (Dhargalkar, 1988).

Compliance Test for Hazardous Waste Incinerators

This section summarizes how to design a trial burn for an incinerator or BIF. The discussion focuses on setting the operating procedures for the unit. Guidance documents on the various aspects of trial burn design are available from the U.S. EPA (specifically, EPA, 1983, 1986a, 1986b, 1989a, 1989b, 1992, 1999, 2000b, 2001). An especially important reference is "Test Methods for Evaluating Solid Waste," SW-846 (EPA, updated), which is a multivolume description of the sampling and analytical methods. SW-846 is continuously expanded and updated to reflect the latest EPA procedures and is incorporated into the RCRA regulations by reference.

Limits on operating conditions for incinerators can be set as an absolute or a rolling average limit. The absolute limit is based on the mean measured value of the control parameter during the trial burn. It is easy to determine and to monitor, but as discussed below, it is conservative to the point where it may not be usable for many combustors. If the absolute limit is unacceptable, then an hourly rolling average (HRA) can be used as an alternative.

The HRA is the average of the instantaneous measurements taken over the past hour of operation. Every minute, the average is computed by dropping the –60 min measurement (counting the present at time zero) and adding the most recent measurement to the calculation.

The BIF regulations require that a maximum temperature also be set to limit the formation of metal fumes. The regulations specify that this maximum be set as the mean of the maximum HRA from each of the three runs of the trial burn or compliance test. To illustrate, consider a compliance test consisting of three runs. The maximum value of the HRA (note that this is not the same as the maximum temperature observed) during each run was 1900, 2100, and 2030°F. The limit on the maximum HRA temperature would thus be the mean of these three values or 2010°F. The trial burn or the compliance test serves the following two main purposes:

1. Demonstrate that the combustor can meet all applicable regulations.
2. Establish the conditions under which the combustor can meet the applicable regulations.

Assuming, of course, that the combustor is capable of meeting the applicable regulations, the trial burn should use measurement methods that are adequate to demonstrate the requirements. Methods have been developed for the vast majority of measurements required by the trial burn. If these methods and the associated QA/QC procedures are adhered to, then the trial burn will be capable of demonstrating compliance or noncompliance. Achievement of the second purpose requires that the combustor be operated during the test at the worst-case conditions that will be encountered during normal operation. If the combustor satisfies the regulatory, health, and safety demands under these worst-case conditions, it will satisfy them under less severe operation.

Worst-case conditions for the combustor are defined by a series of limits (absolute or rolling, maxima or minima) on the parameters summarized in Table 13.12. Most of the parameters listed in Table 13.12 are reasonably independent of one another. Changes in one will not affect other parameters to a significant extent, so they can be set as extremes, but as combustion calculations show, the following parameters are highly interdependent:

1. Primary and secondary chamber (PCC, SCC) temperatures
2. Flue gas velocity
3. Waste feed rates
4. Waste composition
5. Oxygen or excess air

Their values must be set by a series of iterative combustion calculations to find the waste compositions, waste feed rates, and airflows that result in the desired temperature and flue gas flow rates. A great deal of combustion calculation can result if they are not set in an orderly process.

The first step in establishing the conditions for the trial burn is to specify the temperatures of each of the combustion chambers. In a multichamber system, the temperature of the secondary combustion chamber is usually more critical, and that should be set first. Maximum temperatures are set from equipment limits and metals emission considerations. Minimum temperatures are set on the basis of operating experience or the experience of the vendor, which identify the minimum temperature at which a given design successfully destroyed organic constituents.

The next operating condition that should be set is the maximum gas flow rates. The goal here is to come as close as practical to the capacity of the fans, ducts, and air pollution control equipment. The maximum gas flow rate that is desired during actual operation, which may be lower than the theoretical maximum based on equipment capacity, should be the goal. The permit will place an upper limit on this value, and maximizing it will thus give the operators as much flexibility as possible.

Waste feed rates for the trial burn should also be considered as a relatively inflexible condition. The permit will set an upper limit on the feed rate of each waste category to each combustion chamber. A common mistake in many permit applications is to overly categorize the waste. Normally, the following waste categorization should prove adequate:

TABLE 13.12 Control Parameters for Incinerators

Group	Parameter
	Group A
Continuously monitored parameters are interlocked with the automatic waste feed cutoff. Interruption of waste feed is automatic when specified limits are exceeded. The parameters are applicable to all facilities.	1. Minimum temperature measured at each combustion chamber exit 2. Maximum CO emissions measured at the stack or other appropriate location 3. Maximum flue gas flow rate or velocity measured at the stack or other appropriate location 4. Maximum pressure in PCC and SCC 5. Maximum feed rate of *each* waste type to *each* combustion chamber 6. The following as applicable to the facility: • Minimum differential pressure across particulate venturi scrubber • Minimum liquid-to-gas ratio and pH to wet scrubber • Minimum caustic feed to dry scrubber • Minimum kVA settings to ESP (wetdry) and kV for ionized wet scrubber (IWS) • Minimum pressure differential across bag house • Minimum liquid flowrate to IWS
	Group B
Parameters do *not* require continuous monitoring and are thus *not* interlocked with the waste feed cutoff systems. Operating records are nevertheless required to ensure that trial burn worst-case conditions are not exceeded.	7. POHC incinerability limits 8. Maximum total halides and ash feed rate to the incinerator system 9. Maximum size of batches or containerized waste 10. Minimum particulate scrubber blowdown or total solids content of the scrubber liquid
	Group C
Limits on these parameters are set independently of trial burn test conditions. Instead, limits are based on equipment manufacturers' design and operating specifications and are thus considered good operating practices. Selected parameters do *not* require continuous monitoring and are *not* interlocked with the waste feed cutoff.	11. Minimum/maximum nozzle pressure to scrubber 12. Maximum total heat input capacity for each chamber 13. Liquid injections chamber burner settings: • Maximum viscosity of pumped waste • Maximum burner turndown • Minimum atomization fluid pressure • Minimum waste heating value (only applicable when a given waste provides 100% heat input to a given combustion chamber) 14. APCE inlet gas temperature

Items 5 and 9 are closely related; therefore these are discussed under group A parameters.
Item 14 can be a group B or C parameter. See text.
Source: Environmental Protection Agency, 1989b. *Handbook, Guidance on Setting Permit Conditions and Reporting Trial Burn Results,* Volume II of the Hazardous Waste Incineration Guidance Series. EPA/625/6-89/019. Center for Environmental Research Information, Cincinnati, OH.

1. High heating value (or Btu) liquid waste (greater than 5000 Btu/lb)
2. Low heating value liquid wastes (less than 5000 Btu/lb)
3. Solid wastes

The values are maximized by varying the composition of each waste stream. Typically, one does this by setting the type and amount of POHCs required, then adding ash (as a soil or as a flyash, for example). Heating values are increased by then adding fuel oil. They are decreased by replacing a portion of the fuel oil with an oxygenated fuel such as methanol or by adding water. Combustion calculations are useful for finding the waste compositions and quantities that give the required temperatures, halogen inputs, and gas flow rates.

It is necessary that the operating conditions during the trial burn include the desired maximum or minimum values for the Group A and B control parameters. For example, the "Handbook, Guidance for Setting Permit Conditions and Reporting Trial Burn Results" (EPA, 1989b) specifies that the permit

condition on PCC and SCC exit gas temperatures be set at the mean temperature measured during the trial burn. Assume that the mean during a trial burn was 1800 ± 100°F. If the permit condition were determined by the first, simpler condition, the absolute minimum operating temperature specified by the permit condition would be 1800°F. If one desired that the incinerator be allowed to burn hazardous waste at a mean temperature of 1800°F with a variation of ±l00°F, it would be necessary to conduct the trial burn at a lower mean temperature, 1700°F. Then during operation, the normal 100°F temperature fluctuation would not result in frequent waste feed cut-off. Similarly, the trial burn would have to be conducted at somewhat lower excess air (oxygen concentration), higher gas flow rate, higher waste feed rates, etc., than the minimum or maximum (as the case may be) during operation.

POHC Selection — Incinerability Ranking

Because of the wide range of organic compounds present in most wastes, it is impossible to test for each one. The approach taken is to select the most difficult to destroy compounds (POHCs) that will occur in the waste and demonstrate during the trial burn that they can be properly destroyed under the worst-case operating conditions of the system. The POHCs are chosen on the basis of the types of organic hazardous (usually those listed in Appendix VIII) compounds that will be in the waste and incinerability ranking or rankings that are most suited for this application.

The POHC selection process begins with examination of the waste stream that will be burned during operation and identification of those Appendix VIII organics that occur in significant quantities. There is no specific guidance available at present to specify what constitutes a significant quantity. The decision must be made on a case-by-case basis, evaluating anticipated concentrations or Appendix VIII organics, their potential impact on health or the environment, or the public concern they generate. Those Appendix VIII organics so identified are then grouped into categories such as aliphatics, aromatics, chlorinated aliphatics, etc., and the POHCs selected from the most refractory (as established by an appropriate incinerability ranking) compound from each category. This procedure establishes the POHCs as representing the worst-case conditions of organic hazardous compounds in the waste feed.

A point in POHC selection is summarized by the glib statement "Do not choose a POHC that is a PIC." Certain compounds such as chloroform, carbon tetrachloride, and methane can be normal products of combustion. Their formation appears to be dominated by a quasi-equilibrium so that their presence cannot be reduced without radically changing the incinerator. The reader is referred to Dellinger et al. (1988) for information that could be used to identify which compounds could be PICs and to the U.S. EPA (1986b) for further guidance on the limits of measurement methods to assist in determining the amount of POHC that should be fed to an incinerator. If a given compound forms in the incinerator, its presence in the stack would decrease its apparent DRE. As a result, such compounds have been avoided in the past when possible. If, due to sampling and analysis, compound availability, or other constraints, a POHC must be selected that is also a PIC, the compound should be spiked up to levels high enough to override the "PIC effect" on DRE.

The amount of each POHC that must be fed to the incinerator during a trial burn is determined by the sensitivity of the measurement method that will be used. The quantity should be sufficient so the measurement method used can show 99.99% DRE (or 99.9999% DRE for PCB or dioxin listed wastes). The amount fed must be greater than 104 (106 for PCB and dioxin listed wastes) times the method's detection limit to assure that the test shows greater than 99.99% DRE (99.9999% DRE for PCB or dioxin listed wastes).

For example, if the sampling and analytical method used to measure the emissions of a given POHC has a detection limit of 10 g emitted from the stack, then one must feed a minimum of 10×10^4 g or 100 kg of that POHC for each run of the trial burn to establish a DRE of 99.99% or 10×10^6 mg (1000 kg) to establish a 99.9999% DRE. The sampling train only removes a small fraction of the total gas emitted, so the determination must be based on the minimum sensitivity of the contained sampling and analytical methods for measuring the incinerator's total emissions, not just on the sensitivity of the analytical methods.

Incinerability ranking is a concept that was developed to identify those organic compounds that are the most difficult to destroy. The incinerability ranking allows the incinerator operator the flexibility to burn other wastes that are less difficult to destroy than those tested. Without this ability, incinerator operation might be limited to only those specific compounds that were burned during the trial burn. The RCRA regulations [40 CFR §170.62(b)(4)] require that the following occur:

> Director will specify as trial Principal Organic Hazardous Constituents (POHCs)…based on his estimate of the difficulty of incineration of the constituents identified in the waste analysis, their concentration or mass in the waste feed, and for wastes listed in Part 261, Subpart D (listed wastes) the hazardous waste organic constituent or constituents identified in Appendix VII of that part as the basis for listing.

A number of incinerability rankings have been proposed (Dellinger et al., 1986), and any of them may be appropriate for a given application. Each ranking strives to correlate a measurable property of the compound to its "incinerability" – how readily it is destroyed in an incinerator. Each ranking is based on a different property, such as the compound's heat of combustion or how readily it is destroyed under substoichiometric oxygen conditions. The difficulty in using such a ranking lies in the fact that while each ranking method can be tied to a specific destruction mechanism, any properly operating incinerator subjects the waste to a combination of destruction mechanisms. As a result, each ranking system lists specific compounds in somewhat different order. There is no single recommended ranking system at present, but virtually all incinerator and BIF tests are conducted on the basis of the heat of combustion ranking (EPA, 1983) and the thermal stability ranking (EPA, 1992). The recommended procedure in the selection process is as follows:

1. Examine the wastes that will be incinerated during the actual operation, and identify those compounds that are likely to be present in significant amounts.
2. Classify the compounds that will be burned into broad categories such as aliphatics, aromatics, chlorinated aliphatics, and chlorinated aromatics.
3. Select the POHCs by choosing at least one representative compound from each category. The compound should be the most difficult to destroy of those present within the category by the above two incinerability ranking schemes.

In October 2001, the EPA published new guidance on the design of the trial burn, including POHC selection. This guidance incorporates a number of changes in the design of the incinerator performance tests. The full guidance, entitled "Risk Burn Guidance for Hazardous Waste Combustion Facilities" is available from the EPA's Office of Solid and Hazardous Waste, and it can be downloaded from the website, *http://www.epa.gov/epaoswer/hazwaste/combust.htm*.

Defining Terms

ΔP — Pressure difference, pressure drop, pressure change over a piece of equipment
μg/dL — Micrograms per deciliter
μM — Micron, 10^{-6} meters
ACFM — Actual cubic feet per minute
AMU — Atomic mass units, units for atomic or molecular weight of elements or compounds (1 AMU = the weight of one hydrogen nucleus); Avogadro's Number, 6.023×10^{23} AMU = 1 gram.
APCD — Air pollution control device
APCE — Air pollution control equipment
APCS — Air pollution control system
AWFCO — Automatic waste feed cutoff
AWFCS — Automatic waste feed cutoff system
AWMA — Air and Waste Management Association

Bagasse — Waste cellulosic material remaining after a plant has been processed. For example, the solids remaining after the juice has been extracted from sugar cane. Bagasse is sometimes used for fuel in boilers at the plants that process materials such as sugar cane.

BIF — Boiler and industrial furnace

BOD — Biological oxygen demand

Btu — British thermal unit. The amount of energy required to raise the temperature of one pound mass of water one Fahrenheit degree.

CAA — Clean Air Act

CAAA — Clean Air Act Amendments

Carcinogen — A material likely to cause an increased incidence of cancer in the exposed population.

CEM(s) — Continuous emission monitor(s)

CEMS — Continuous emission monitor system

CERCLA — Comprehensive Environmental Restoration, Compensation and Liability Act of 1980

CFM — Cubic feet per minute

CFR — Code of *Federal Register*

CFS — Cubic feet per second

CMS — Cubic meters per second

CNAEL — Committee for the National Accreditation of Environmental Laboratories

CO — Carbon monoxide

CoC — Certification of Compliance

COD — Chemical oxygen demand

COPCs — Compounds of potential concern. Chemical compounds and elements that may may have a significant impact on the risk associated with a facility and, hence, are measured during testing to collect risk assessment emission data.

C_p — Heat capacity (Btu/lb-°F or calories/g-°C) at constant pressure

C_p — Pitot coefficient

CPT(s) — Comprehensive performance test(s)

CSAP — Comprehensive sampling and analysis plan

CSF — Carcinogenic slope factor

Cv — Heat capacity (Btu/lb-°F or calories/g-°C) at constant volume

CWA — Clean Water Act

D/F — Dioxins/furans, actually chlorodibenzodioxins/chlorodibenzofurans

DE — Destruction efficiency, a measure of the percentage of a given component that is destroyed by the combustion process. This term is often confused with the DRE (see below), but it is very different. It represents the fraction of the organics entering a cumbustor which are destroyed. The DRE represents the fraction of the organics entering an incinerator which are emitted. The following equation defines the DE: $DE = (W_{in} - W_{out\ combustion\ chamber}/W_{in}) \times 100$ (percent), where *W* is the weight or mass of the POHC being measured.

DRE — Destruction and removal efficiency of the combustor, defined in 40 CFR 264.34(a)(1). This value does not include the POHC remaining in the ash and captured by the APCE as part of the W_{out} APCE term. The following equation defines the DRE: $DRE = (W_{in} - W_{out\ APCE}/W_{in}) \times 100$ (percent), where *W* is the weight or mass of the POHC being measured.

dscf — Dry standard cubic foot. Gas volume corrected to standard conditions (see **scf**), and excluding water vapor.

dscfm — Dry standard cubic feet per minute (see **scf**)

dscm — Dry standard cubic meter (see **dscf**)

EA or %EA — Excess air or percent excess air. The quantity of air above the stoichiometric quantity needed for combustion. The value is equivalent to that for excess oxygen or percent excess oxygen for combustion devices using only air as a source of combustion oxygen, no oxygen enrichment. See also **Stoichiometric Oxygen**.

EPA — U.S. Environmental Protection Agency

Equivalence — Equivalent to the excess air ratio. An equivalence ratio of 1 is ratio

ESP — Electrostatic Precipitator

ESV, EVS — Emergency safety vent, emergency vent stack, also known as a "dump stack."

FACA — Federal Advisory Committee Act

FBI — Fluidized bed incinerator

Feedrate — The rate of feed (lb/hr, kg/hr, ton/hr) of a waste or fuel stream to a combustion device.

FF — Fabric filter

Forced Air — A means of supplying air to a combustion chamber or APCD draft by placing the fan (or other air mover) upstream (in front) of the device so that the fan forces the air through the device. A forced draft system operates at a pressure above atmospheric. See also **ID**.

FRP — Fiber reinforced plastic. A composite material of construction consisting of strands of fiber embedded in a polymer matrix. The most commonly used is fiberglass, although other fibers such as graphite or steel can be used. The polymeric material is selected to provide strength and corrosion resistance. The fiber provides tensile strength to the composite and the polymer provides compression strength and resistance to chemical attack.

Fuel — Any combustible material fed to a combustor. The term can refer to supplemental fuel (oil, natural gas, LP-gas, or a nonhazardous waste) or to a combustible hazardous waste stream.

g — Gram or grams

g-mole — Gram mole, the number of atoms or molecules of a substance that equals its atomic or molecular weight in grams. For example, 1 gram mole of benzene, molecular weight 78, is equivalent to 78 grams of benzene. This term is also equal to, approximately, 6.023×10^{23} atoms or molecules of the substance. A quantity of the substance of this size is referred to as a g-mole.

GPO — Government Printing Office

gr/dscf — Grains per dry standard cubic foot (1 grain = 1/7000 lb)

GSA — General Services Administration

H, Qsens — Enthalpy or sensible heat of a stream. It is the heat contained by a material which manifests itself as a temperature. It is defined as $H = c_p\, dT$.

HAF — Halogen acid furnace

HAP(s) — Hazardous air pollutant(s)

H_c — Heat of combustion

HC — Hydrocarbons

HCl — Hydrogen chloride. Hydrochloric acid emissions regulated under RCRA 40 CFR §264.343(b) to 99% removal efficiency, 1.8 kg/h (4 lb/h) maximum emission rate, or a risk-based level.

H_f — Heat of formation

Hg — Mercury

HHV — Higher heating value. The heat of combustion of a fuel or waste which includes the latent heat of condensation of the water formed in the process. While this value is the one measured by calorimetric means, the LHV is more appropriate for combustor determinations. See LHV. HHV = LHV + $?_{hw}$, where $?H_w$ = latent heat of vaporization of the water produced by the combustion process.

H_L — Latent heat. The heat or energy that is released by a phase change such as evaporation, boiling, or freezing. For example, the latent heat of evaporation of water is approximately 950 Btu/lb, which is the energy required to convert one pound of liquid water to one pound of vapor or steam.

HON — Hazardous Organic NESHAP

hr or h — hour(s)

HSWA — Hazardous and Solid Waste Amendments of 1986. The law that reauthorized RCRA with a number of changes and expansions.

HW — Hazardous waste

HWC — Hazardous waste combustor

HWI — Hazardous waste incinerator

ID — Induced draft. A means of supplying air to a combustion chamber or APCD by placing the fan (or other air mover) downstream (after) the device so that the fan pulls the air through the device. An induced draft system operates at a pressure below atmospheric. See also Forced Draft.

Impinger — A device used in sampling trains for collecting gaseous and (at times) particulate components from stack gases. Impingers are produced in two sizes.

Incinerator — A closed furnace or similar device specifically intended to burn waste material.

IR — Infrared light

IWS — Ionizing wet scrubber. An air pollution control device that combines the performance of a scrubber for HCl control and an ESP for particulate control.

kV — Kilovolts, 103 Volts

kVA — Kilovolt-amperes (product of voltage and current). A measure of the power usage of an electrical device. It is one of the parameters that is used to describe the operating performance of an ESP or IWS. kVA is dimensionally analogous to kW, although they actually measure somewhat different parameters.

kW — Kilowatts, 103 watts. A measure of the power input into an electical device such as a motor. For DC systems, the power input in kW is equivalent to the kVA. For AC systems, the power input is equivalent to kVA times the phase angle shift due to inductance in the circuit.

lb(s) — Pound(s), avoirdupois (avdp.)

lb-mole — Pound mole, the number of atoms or molecules of a substance that equals its atomic or molecular weight in grams. For example, 1 pound-mole of benzene, molecular weight 78, is equivalent to 78 pounds of benzene. This term is also equal to, approximately, 2.732×10^{25} atoms or molecules of the substance. A quantity of the substance of this size is referred to as a lb-mole.

LD-50 — Lethal dose-50, The concentration of a contaminant in air or the quantity as a mg of contaminant per kg of body weight of a solid or liquid which results in the mortality of 50% of a population of test animals. The LD-50 often also specifies the type of animal, i.e., mouse, rat, etc. This is a common indicator of the acute toxicity of materials.

L/G — Liquid-to-gas ratio. This is a ratio commonly used in the design and operation of wet scrubbers.

LHV — Lower heating value. The heat of combustion of a fuel or waste that does not take into account the latent heat of water. The LHV is usually the more appropriate value to use for most incinerator calculations.

LI — Liquid (injection) incinerator

LVM — Low volatility metals

LWA — Lightweight aggregate

LWAK — Lightweight aggregate kiln

M — Minute of time (60 seconds)

M — Meter of length

MACT — Maximum achievable control technology

mg/kg — Milligrams per kilogram

mg/m^3 — Milligrams per cubic meter

MHI — Multiple hearth incinerator

MM — Million (10^6) as in MMBtu = 106 Btu

MM5 — EPA Modified Method 5. A commonly used name for SW-846 Method 0010 that measures organic compunds with boiling points that are greater than 100°C (212°F). It is sometimes referred to as "semi-VOST."

MSDS — Material Safety Data Sheet

Mutagen — Material that triggers mutations (changes in DNA composition) which manifest themselves in various ways in an exposed population, for example, an increased level of birth defects.

MWC — Municipal waste combustor

NAAQS — National Ambient Air Quality Standard

NESHAP — National Emission Standards for Hazardous Air Pollutants (HAPs)

Ng/dscm — Nanogram per dry standard cubic meter

NO_2 — Nitrogen dioxide

NPDES — National pollutant discharge elimination system. The permitting and regulatory program under the Clean Water Act that restricts discharges to waterways.

O_3 — Ozone

Orsat — A type of apparatus used to measure the concentration of carbon dioxide, oxygen, and carbon monoxide in a gas. It operates on the principle of sequential absorption of the target gases in a solution.

Overfire — Air fed to a furnace above the flame.

Oxidizing conditions — Combustion in the presence of a stoichiometric quantity, or more, conditions. See also **Reducing Conditions.**

P&ID — Piping and Instrumentation Diagram, also "P&I Diagram" (plural form — "P&IDs").

PAH — Polynuclear aromatic hydrocarbons, synonymous with POMs, POHs. A polycyclic compound similar in structure to naphthalene or anthracene but containing varying numbers of interlocking benzene rings. PAHs are considered to be carcinogenic. Proper combustion results in only minute (ppb) quantities in the flue gas.

PCB(s) — Polychlorinated biphenyl(s)

PCDD(s) — Polychlorinated dibenzo-*p*-dioxin(s)

PCDF(s) — Polychlorinated dibenzofuran(s)

PDF — Portable document format

PIC — Products of incomplete combustion, also sometimes known as "Hazardous Products of Combustion." Those organic materials are formed during the combustion process, either as equilibrium products that escaped combustion or as breakdown or recombinant organic compouds that do not exist in the original waste. Legally, PIC refers to RCRA Appendix VIII organic compounds not present in the feed that result from combustion of waste.

PM — Particulate matter. This term refers to solid or liquid material entrained in a gas stream.

PM10 or PM-10 — Particulate matter of less than 10μM in diameter

PM2.5 or PM-2.5 — Particulate matter of less than 2.5μM in diameter. This size particulate may be regulated because fine particulate (of small diameter) will have a greater impact on health than larger particulate.

POH — Polynuclear organic hydrocarbon, synonymous with **PAH** and **POM**

POHC — Principal organic hazardous constituent. These are the organic constituents measured during a trial burn. They are selected to be representative of all of the organic hazardous constituents in the waste and typically include those constituents that are more difficult to destroy. POHC normally refers to RCRA Appendix VIII organic compounds present in the feed as either a component of the waste or added for the tests selected for evaluation of DRE during the trial burn.

POM — Polycyclic organic material, synonymous with **PAH** and **POH**

ppb, ppbv — Parts per billion, 10^{-9}. The definition is completely analogous to ppm and ppmv.

ppm — Parts per million, 10^{-6}. A measure of concentration on the basis of mg of analyte per kg of sample. Synonyms are mg/kg and μg/g. The term ppm is sometimes used to indicate mg of analyte per liter of sample; however, this definition is incorrect unless the sample is reasonably pure water or another material with a density of 1 g/ml.

ppmv — Parts per million by volume, 10^{-6}. A measure of concentration on the basis of volume such as l/l or ml/1000 l. This unit of measurement is normally used to specify concentrations of gaseous contaminants in air.

ppt, pptv — Parts per trillion, 10^{-12}. The definition is completely analogous to **ppm** and **ppmv**.

Primary air — Air mixed with the fuel prior to the point of ignition, usually at a high velocity to improve turbulence in the combustion chamber. It may be aimed at the flame or simply into the post-flame combustion zone to increase turbulence and add oxygen, through the nozzle, or as underfire air through a burning solid bed. See also **Secondary Air**.

QA — Quality assurance

QA/QC — Quality assurance/quality control. QC is the system of activities to provide a quality product or a measurement of satisfactory quality. QA is the system of activities to provide assurance that the quality control system is performing adequately (from *QA Handbook for Air Pollution Measurements*, Vol. 1, Principles, EPA-600/9–76–005, March, 1976).

QC — Quality control

RCRA — Resource Conservation and Recovery Act of 1976 and Amendments, see **HSWA**

Reducing conditions — Combustion in the absence of at least a stoichiometric quantity of oxygen. See also **Oxidizing Conditions**.

Risk — The incremental probability of a person incurring cancer from a carcinogen or being adversely impacted by a noncarcinogenic material. The risk to the MEI from exposure to a particular carcinogen is calculated by multiplying the predicted maximum annual average ground-level concentration of the substance by its unit risk.

Sampling train — A series of equipment including filters, absorbers, impingers and adsorbers and gas moving and measuring devices that are used to collect samples of gases from a stack or other ducts.

SARA — Superfund Amendments and Reauthorization Act

scf — Standard cubic foot. Gas volume corrected to standard temperature and pressure, usually 20°C, or 70°F and 1 atmosphere

scfm — Standard cubic feet per minute. Gas flow rate corrected to standard temperature and pressure (see **scf**)

scm — Standard cubic meter. Gas volume corrected to standard temperature and pressure (see **scf**)

Secondary air — Air mixed with the fuel after ignition as in the combustion chamber, see also **primary air**

Sludge — Fine particles of solid suspended in a liquid which form a slow-flowing multiphase material that is relatively stable (see also **Slurry**).

Slurry — Particles of solid or immiscible liquid suspended in liquid (see also **Sludge**). A slurry normally consists of larger particles than a sludge, and it will tend to form a pasty material that will settle with time.

SO_2, SO_3, SO_x — Sulfur dioxide, sulfur trioxide, sulfur oxides (mixture of SO_2 and SO_3)

SOCMI — Synthetic Organic Chemical Manufacturing Industry

Soot — Carbonaceous material formed during pyrolysis or combustion in the absence of sufficient oxygen. Soot is considered to be the high molecular weight portion of the PAHs. Formation of visible soot is usually an indication of improper combustion conditions, although soot may form in the primary combustion process if it is destroyed in a secondary combustor or captured by the APCE.

Stoichiometric oxygen — The amount of oxygen required to exactly react with a fuel or waste for the combustion reaction. If the source of oxygen is air, then the term commonly used is stoichiometric air. When no external source of oxygen is used other than air (no oxygen enrichment), the two values are equivalent.

STP — Standard temperature and pressure, 70°F (530 R) and 1 atmosphere (29.92" Hg) for English Units, 20°C (293 K) 760 mmHg, 101.3 kPa for metric and SI units, respectively. Other standard conditions are often used for presentation of data in the literature. While the pressure of 1 atmosphere is virtually universal, temperatures used may be 68°F (20°C) and 0°C. The reader is cautioned to check the standard conditions for any thermodynamic data obtained from the literature. The standard temperatures used in this manual for English and metric units (70°F

and 68°C, respectively) are slightly different; these were chosen as the most common conditions (in the author's experience) encountered in practice, and the slight differences between them are negligible in the context of incineration.

THC — Total hydrocarbons. Total organic compound releases from a source such as an incinerator. This can be continuously monitored during operation by a hydrocarbon analyzer.

Theoretical oxygen or air — Synonymous with stoichiometric oxygen or stoichiometric air

TSCA — Toxic Substance Control Act

TSD — Treatment, storage, and disposal

TSDF — Treatment, storage, and disposal facility. A facility regulated under RCRA that is used to treat, store, or dispose of hazardous wastes.

TSLoO_2 — Thermal stability at low or deficient oxygen conditions. A method for estimating how readily a compound will be destroyed in the absence of oxygen compared to other compounds. This ranking is being evaluated by EPA as a method of selecting POHCs for a trial burn. It is sometimes referred to as the University of Dayton Research Institute (or UDRI) incinerability ranking system.

Turndown — Fraction of design capacity at which a system is operating. For example, a combustor operating at 30 MM Btu/h at 70% turndown will be operating at $30 \times 0.70 = 21$ MM Btu/h.

Underfire air — Air fed under a bed of burning solids in a boiler or furnace. See also, **overfire** air.

v — Velocity or gas velocity, ft/sec, m/sec

V — Volume, ft^3 or m^3, specific volume. ft^3/lb, ft^3/lb-mole, m^3/g, m^3/g-mole. This is the inverse of the density of a material.

VMT — Vehicle-miles-of-travel

VOC — Volatile organic compound

WESP — Wet electrostatic precipitation

14.1 Introduction

The proper management of solid waste is now, more than ever, a matter of national and international concern. As a nation, we are generating more solid waste than ever before. At the same time, we are finding that there are limitations to traditional solid waste management practices. As the generation of solid waste continues to increase, the capacity to handle it is decreasing. Many landfills and incinerators have closed, and new disposal facilities are often difficult to cite.

Even though municipal solid waste (MSW) constitutes only a portion of the solid waste streams, the rate of its generation is staggering. The U.S. Environmental Protection Agency's (EPA) most recent data show that in 1988, 180 million tons, or 4.0 pounds per person per day of MSW, were generated in the U.S. [EPA, 1990a]. By the year 2000, generation of MSW is projected by the EPA to reach 216 million tons, or 4.4 pounds per person per day. Based on current trends and information, EPA anticipates that 20 to 28% of MSW will be recovered annually by 1995. Exceeding this projected range will require fundamental changes in government programs, technology, and corporate and consumer behavior. According to EPA data [EPA, 1990a], recovery of MSW materials for recycling and composting was 13% in 1988, combustion was 14% of total generation, and the remaining 73% of the MSW stream was taken to landfills.

In response to the growing national concern about the solid waste disposal crisis, EPA developed an "agenda for action" and a national strategy for addressing the MSW management problems [EPA, 1989a]. The cornerstone of the strategy is "integrated waste management," where source reduction (i.e., reduction of the quantity and toxicity of materials and products entering the solid waste stream) followed by recycling are the first steps of an effective solid waste management system, and are complemented by environmentally sound combustion and landfilling.

14.2 Solid Waste

Regulatory Framework

Solid waste is regulated under Subtitle D of the Resource Conservation and Recovery Act (RCRA) and the corresponding federal regulations found in 40 Code of Federal Regulation (CFR) Parts 257 and 258.

Subtitle D solid waste is not subject to the hazardous waste regulations under Subtitle C of RCRA. Solid waste is defined in 40 CFR 257 as "any garbage, refuse, sludge from waste treatment plant, water supply treatment plant, or air pollution control facility and other discarded material, including solid, liquid, semisolid, or contained gaseous material resulting from industrial, commercial, mining, and agricultural operations, and from community activities."

Household hazardous wastes and hazardous small quantity generator (SQG) wastes from businesses and industry generating less than 100 kilograms of hazardous waste per month are exempt from RCRA's Subtitle C regulations for hazardous waste and thus are regulated as solid waste under RCRA's Subtitle D. In accordance with the RCRA definition of solid waste, the following categories of Subtitle D solid waste has been identified by EPA:

- Municipal solid waste
- Household hazardous waste
- Municipal sludge
- Municipal waste combustion ash
- Industrial nonhazardous process waste
- Small quantity generator hazardous waste
- Agricultural waste
- Oil and gas waste
- Mining waste

Subtitle D of RCRA establishes a framework of federal, state, and local government cooperation in controlling the management of nonhazardous solid waste. The federal role in this arrangement is to establish the overall regulatory direction, by providing minimum nationwide standards for protecting human health and the environment from the disposal practices of solid waste. The actual planning, direct implementation, and enforcement of solid waste programs under Subtitle D, however, remain largely state and local functions.

Solid Waste Characteristics

To analyze the characteristics of solid waste, EPA has conducted numerous studies to determine the weight, volume, characteristics, and management methods of wastes, regulated under Subtitle D of RCRA [EPA, 1990a; EPA, 1990b; EPA, 1989a; EPA, 1988a; EPA, 1986]. These studies revealed that based on data collected up to 1988, more than 11 billion tons of solid waste are generated each year, including 7.6 billion tons of industrial nonhazardous waste, which includes about 56 million tons of electric utility waste and 240 million tons of solid wastes generated by three industrial categories: iron and steel, inorganic chemicals, and plastics and resins. The studies also recorded 2 to 3 billion tons of oil and gas waste (including both drilling and produced wastes), more than 1.4 billion tons of mining waste, and nearly 180 million tons of municipal solid waste.

The Subtitle D solid waste regulations in 40 CFR Parts 257 and 258 focus on municipal solid waste, including household hazardous waste and small quantity generator hazardous waste, as well as industrial nonhazardous process wastes and municipal sludge. Several Subtitle D wastes, in particular oil and gas wastes, utility wastes, and mining wastes, are being considered separately for rule making by EPA. In addition, EPA has been closely evaluating, in a separate effort, the characteristics and management practices for municipal waste combustion ash.

Municipal Solid Waste

EPA's definition of municipal solid waste states that MSW comes from residential, commercial, institutional, and industrial sources and includes durable goods, nondurable goods, containers and packaging, food waste, yard wastes, and miscellaneous inorganic wastes [EPA, 1990a; EPA, 1989a]. Examples of wastes from these categories include appliances, newspapers, clothing, food scraps, boxes, disposable diapers, disposable tableware, office and classroom paper, wood pallets, and cafeteria wastes.

TABLE 14.1 Materials Generated in Municipal Solid Waste (MSW) by Weight, 1988

Material	Weight Generated (in Million Tons)	Percent of Total MSW
Paper and paperboard	71.8	40.0
Glass	12.5	7.0
Metals		
Ferrous	11.6	6.5
Aluminum	2.5	1.4
Other nonferrous	1.1	0.6
Plastics	14.4	8.0
Rubber and leather	4.6	2.5
Textiles	3.9	2.2
Wood	6.5	3.6
Food wastes	13.2	7.4
Yard wastes	31.6	17.6
Other	5.8	3.1
Total MSW	179.5	100

TABLE 14.2 Products Generated in Municipal Solid Waste (MSW) by Weight, 1988

Product	Weight Generated (in Million Tons)	Percent of Total MSW
Containers/packaging (boxes, bottles, can, bags, etc., made of glass, steel, aluminum, paper, and plastic)	56.8	31.6
Nondurable goods (newspapers, office paper, disposable tableware, diapers, books/printed material, clothing)	50.4	28.1
Yard wastes (grass, leaves, etc.)	31.6	17.6
Durable goods (appliances, furniture, tires, batteries, electronics)	24.9	13.9
Food wastes	13.2	7.4
Other (stones, concrete, dirt, demolition, etc.)	2.7	1.4
Total MSW	179.5	100

Generation of MSW in 1988, the latest year for which information is available, totaled approximately 180 million tons [EPA, 1990a]. The EPA 1990 MSW characterization report provides detailed information on the generation of MSW and other projections for its future production [EPA, 1990a]. Table 14.1 provides a breakdown by weight of the materials generated in MSW in 1988. Paper and paperboard products were the largest component of MSW by weight (40%) and yard wastes were the second largest component (about 18%).

The various materials in MSW make up the many individual products that enter the MSW stream. The products generated in MSW by weight, grouped into major product categories, are shown in Table 14.2 for 1988. Containers and packaging, including all types of packaging materials, were the largest product category generated in MSW by weight (about 32%). Nondurable goods, such as newspapers, disposable diapers, and disposable tableware, were the second largest category by weight (28%).

Although solid waste is usually characterized by weight, information about volume is important for such issues as determining landfill capacity uptake. Volume estimates of MSW, however, are far more difficult to make than weight estimates. Wide ranges for the volume occupied by solid waste are reported in the literature [Salvato, 1972; Bond et al., 1973]. Loose refuse can weigh from 100 to 240 lb/yd^3, while refuse compacted in a landfill can weigh 700 to 1250 lb/yd^3, depending on the compaction applied. EPA has attempted to estimate the volume of materials as they would typically be found in a landfill, after a significant amount of compaction [EPA, 1990a]. These estimates were largely based on empirical data that were used to estimate density factors (pounds per cubic yard) with corroboration from actual landfill studies. Table 14.3 compares 1988 volume and weight figures for discarded materials in MSW as estimated

TABLE 14.3 Weight and Volume of Materials Discarded in Municipal Solid Wastes (MSW), 1988

Material	Solid Waste Weight Generated (in Million Tons)	Solid Waste Weight Recovered by Recycling/ Composting (in Million Tons)	Solid Waste Weight Discarded (in Million Tons)	Solid Waste Weight (% of Total Discarded MSW)	Solid Waste Volume-Compacted in Landfill (% of Total Discarded MSW)
Paper and paperboard	71.8	18.4	53.4	34.2	34.1
Glass	12.5	1.5	11.0	7.1	2.0
Ferrous metals	11.6	0.7	10.9	7.0	9.8
Aluminum	2.5	0.8	1.7	1.1	2.3
Plastics	14.4	0.2	14.2	9.2	19.9
Rubber and leather	4.6	0.1	4.5	2.9	6.4
Textiles	3.9	0.0	3.9	2.5	5.3
Wood	6.5	0.0	6.5	4.2	4.1
Food wastes	13.2	0.0	13.2	8.5	3.3
Yard wastes	31.6	0.5	31.1	19.9	10.3
Miscellaneous	6.9	1.4	5.5	3.6	2.5
Total	179.5	23.6	155.9	100.0	100.0

by EPA. Discarded materials constitute the MSW remaining after recovery for recycling and composting has taken place. The paper and paperboard category ranked first in both volume and weight, at about 34% of the discarded MSW for the 1988 data. Plastics ranked second in volume at 20%, while yard waste ranked second in weight at 20%. Four materials constitute significantly larger proportions by volume of the discarded MSW than by weight: plastics, rubber and leather, textiles, and aluminum. By contrast, three materials constitute significantly smaller proportions by volume than by weight: yard wastes, food, and glass. The remaining four materials, namely paper and paperboard, ferrous metals, wood, and miscellaneous wastes, make up almost the same portion of the discarded MSW, either by weight or volume.

Trends in Municipal Solid Waste Generation

Generation of municipal solid waste grew steadily between 1960 and 1988, from 88 million to almost 180 million tons per year. The per capita generation of MSW for the same period saw an increase from 2.7 to 4.0 pounds per person per day. By 2000, projected per capita MSW generation is 4.4 pounds per person per day, for a total of 216 million tons per year. The projection for MSW generation in the year 2010 is over 250 million tons, or approximately 4.9 pounds per person per day [EPA, 1990a], marking an increase of more than 21% over the 1988 MSW generation. Figure 14.1 shows the generation, in millions of tons, of materials in MSW between 1960 and 1988, with projections to 2010. Paper and plastics have shown the most remarkable increase over the years and a continued increase in their generation is projected to the year 2010. Food and yard wastes as well as glass and metal, on the other hand, have had only a nominal increase over the period 1960 to 1988, and no marked increased is projected for the generation of these wastes.

Some further insight into projected generation of materials in MSW can be gained from Table 14.4, which presents detailed projected per capita generation of MSW by material category. Paper and plastics are projected to grow substantially in per capita generation. Other materials are projected to decline in per capita generation or to increase only slightly.

14.3 Landfills

A landfill is an area of land or an excavation in which wastes are placed for permanent disposal. While alternative waste disposal methods, such as incineration, along with the advent of recycling, composting, and pollution prevention, are scaling back the numbers of active landfills, the engineering, construction, and operation of landfills are now more complex than ever. Driven by public pressure and subsequent regulatory requirements, landfill design and operation now have to conform to strict federal standards.

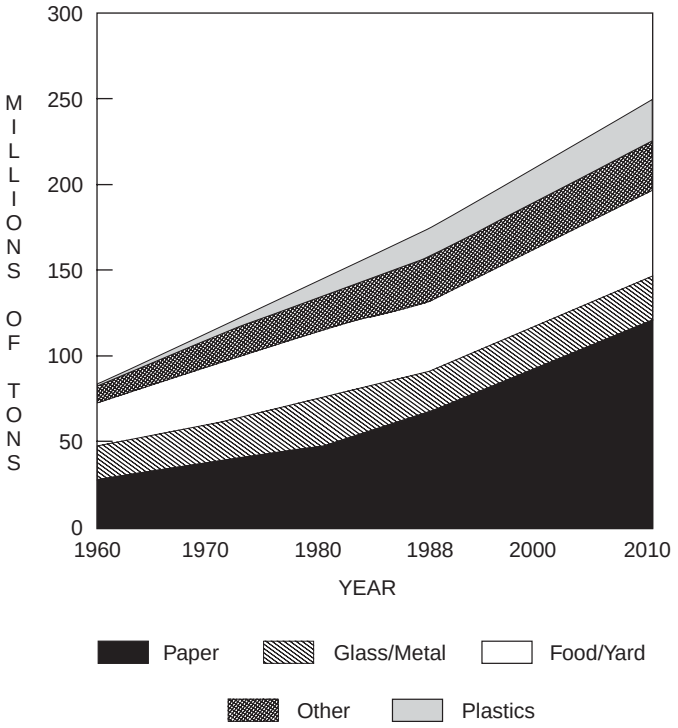

FIGURE 14.1 U.S. municipal solid waste generation, 1960–2010.

TABLE 14.4 Projected Per Capita Generation of Municipal Solid Waste (MSW), by Material, 1988 to 2010 (in Pounds per Person per Day)

Material	1988	1995	2000	2010
Paper and paperboard	1.60	1.80	1.96	2.35
Glass	0.28	0.23	0.21	0.18
Metals	0.34	0.34	0.35	0.34

Miscellaneous	0.06	0.06	0.06	0.06
Inorganic wastes				
Total MSW generated	4.00	4.21	4.41	4.86

Source: U.S. EPA, OSWER, 1990a. *Characterization of Municipal Solid Waste in the United States: 1990 Update.* p. 61, EPA/530-SW-90-042.

The EPA had mandated double liners, environmental controls for groundwater protection, and other design standards for hazardous waste landfills since 1984, under the Subtitle C requirements of RCRA. Since 1993, the nation's 6000 municipal solid waste landfills have been required to comply with similar strict standards under new federal regulations issued in accordance with Subtitle D requirements of RCRA.

Under the authority of Subtitle D of RCRA, EPA first promulgated the Criteria for Classification of Solid Waste Disposal Facilities and Practices (40 CFR Part 257) in 1979 [EPA, 1979]. Those Subtitle D criteria established minimum national performance standards necessary to ensure that "no reasonable probability of adverse effects on health or the environment" will result from solid waste disposal facilities. A facility that meets the criteria is classified in 40 CFR 257 as a "sanitary landfill." A facility that fails to satisfy any of the criteria is considered an "open dump." The criteria under 40 CFR 257 include general environmental performance standards addressing eight major topics: flood plains, endangered species, surface water, groundwater, land application, disease, air, and safety.

In 1984, Congress made significant modifications to Subtitle D of RCRA through the Hazardous and Solid Waste Amendments (HSWA). To fulfill its responsibilities under HSWA, EPA conducted a comprehensive study of solid waste characteristics, waste disposal practices, and environmental and public health impacts resulting from solid waste disposal. The results of this study were submitted to Congress in 1988 [EPA, 1988a]. The 1984 HSWA provisions, furthermore, required EPA to revise the criteria, then in existence, for solid waste disposal facilities that may receive household hazardous waste or hazardous waste from small quantity generators as part of the municipal solid waste stream disposed of at those facilities. As a result of these requirements, EPA promulgated the Criteria for Municipal Solid Waste Landfills, a broad new solid waste regulation [EPA, 1991a] in 1991. The new rule, which took effect in 1993, imposes minimum national criteria for **municipal solid waste landfills (MSWLFs)** in the areas of location, operation, design, groundwater monitoring and corrective action, closure and postclosure, and financial assurance. Under the new rule, states may incorporate the new federal requirements into state solid waste permitting programs and, with EPA approval, assume primary responsibility for implementing and enforcing them. "Approved" states have flexibility in applying EPA criteria, so that state-specific environmental conditions can be accommodated. In states that fail to gain approval, MSWLFs are subject to the federal criteria as specified in 40 CFR 258, with no allowance to alter the criteria for special environmental considerations.

Minimum Federal Regulatory Criteria for Municipal Solid Waste Landfills

The Subtitle D Federal criteria for MSWLFs [EPA, 1991a] apply to all existing and new MSWLFs, as well as to lateral expansions, with few exceptions for some small landfills, under certain conditions. A summary of the Subtitle D minimum criteria imposed on MSWLFs [EPA, 1991a] is presented below.

Location Restrictions

There are six restricted areas. Sites located near airports, floodplains, unstable areas, wetlands, seismic impact zones, and fault areas are unsuitable for operating MSWLFs, unless the MSWLF can meet the specific criteria stated under the rule for each location.

Operating Criteria

Ten new operating criteria for MSWLFs have been mandated, to address procedures for excluding the receipt of regulated quantities of hazardous wastes; daily cover material requirements; disease vector control; explosive gases control; air criteria; public access requirements; run-on/run-off control systems; control of discharges to surface waters; liquid disposal restrictions; and recordkeeping requirements.

Design Criteria

The design criteria of the solid waste disposal rule [EPA, 1991a] have as their goal the protection of groundwater and apply to new MSWLFs and lateral expansions. The design requirements to not apply to MSWLF units in existence as of October 9, 1993. The rule provides owners of MSWLFs with two design options. These two design options are depicted in Fig. 14.2, as presented in the federal regulation (40 CFR Part 258).

The first option is a **composite liner** system, whose minimum requirements are specified in the rule (40 CFR Part 258), and is believed to ensure a protective uniform design standard for MSWLFs in all locations [EPA, 1988b]. It consists of a flexible membrane liner, a two-foot, compacted soil component,

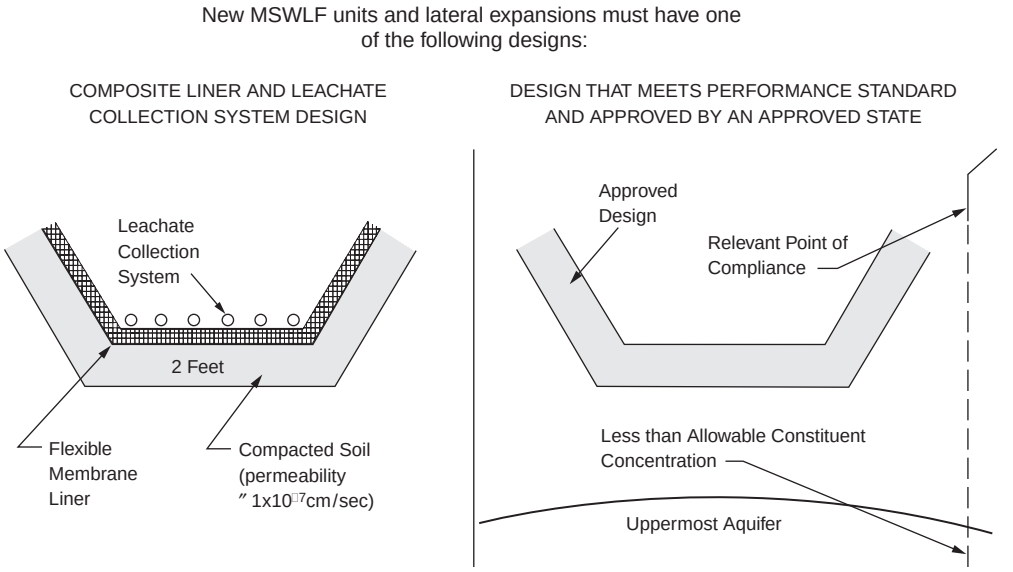

FIGURE 14.2 Municipal solid waste landfill design criteria mandated by federal regulations.

and a **leachate** collection and removal system that is designed to maintain less than a 30-cm depth of leachate over the liner.

The second option, which is available in states with an EPA-approved solid waste program, allows owners of MSWLFs to consider site-specific conditions in developing a design. This design must be approved by the state environmental agency and must meet the performance standard set in the federal regulations (40 CFR Part 258). Under the regulatory performance standard, the design of an MSWLF must ensure that the **maximum contaminant level (MCL)** values will not be exceeded in the groundwater of the **uppermost aquifer** at the **relevant point of compliance** at the landfill. Factors a state will consider when evaluating a site-specific landfill design include, at a minimum, the following: hydrogeologic characteristics of the site and surrounding land; climatic factors of the area; volume and physical and chemical characteristics of the leachate; and public health effects.

Groundwater Monitoring and Corrective Action

Extensive groundwater monitoring systems and a detection groundwater monitoring program are standard requirements for MSWLFs under the federal solid waste regulations (40 CFR Part 258). The groundwater monitoring system must consist of wells able to provide information on the quality of unaffected, background groundwater as well as of groundwater at the MSWLF's relevant point of compliance. If any of the detection monitoring parameters are found at a statistically significant level over background concentrations, the landfill owner is required to proceed to more intensive groundwater monitoring requirements and, subsequently, to investigate studies to define the extent of the groundwater contamination. If contamination has migrated off-site, the owner of the landfill has to develop and implement a corrective action plan. The remedy selected by the MSWLF owner has to be approved by the state prior to its implementation. The regulations provide explicit procedures for sampling wells and methods for the statistical analysis, and provide detailed analytical requirements for the groundwater under the various possible monitoring phases.

Closure and Postclosure Requirements

A final cover system designed to minimize infiltration and erosion is required under federal regulations (40 CFR Part 258). The infiltration layer must be a minimum of 18 inches of soil with permeability less than or equal to the permeability of the bottom liner system or natural subsoils, or no greater than 1×10^{-5} cm/s, whichever is less. The erosion layer must be a minimum of six inches of soil, able to sustain

native plant growth. Written closure and postclosure plans, with provisions for maintenance of final cover, groundwater and methane gas monitoring, and leachate management are required by the regulations. Closure must commence within 30 days of last receipt of waste at the MSWLF, and postclosure activities must continue for a period of 30 years.

Financial Assurance

Under the federal solid waste regulations (40 CFR Part 258) the owner of a MSWLF is required to demonstrate financial responsibility for the cost of the landfills closure, postclosure care, and corrective action for known releases in an amount equal to the cost of a third part conducting these activities. The financial assurance requirements must be met by the owner before a construction permit is approved for the landfill by the regulatory agency. The cost estimates must be updated annually for inflation and operational changes.

Environmental Effects of Municipal Landfills

Old municipal landfills typically did not conform to today's location restrictions. In addition, several had poor operational records and minimal environmental controls. As a result of ever tightening regulations, many old landfills were literally abandoned by their owners. Today, abandoned municipal landfills compose approximately 20% of the sites on the Superfund Program's National Priorities List (NPL). Landfill sites on the NPL contain a combination of principally municipal and to a lesser extent co-disposal and hazardous waste landfills and range in size from one acre to over 600 acres. Superfund municipal landfills are primarily composed of municipal solid waste, therefore, they typically pose a low-level environmental threat rather than a principal threat [EPA, 1991b].

Potential concerns stemming from old, unprotected municipal landfills include leachate generation and possible groundwater contamination; soil contamination; landfill contents; landfill gas; and contamination of surface waters, sediments, and adjacent wetlands. Because these sites share similar characteristics, they lend themselves to remediation by similar technologies. The EPA, after considerable study of these landfills due to their high presence in the Superfund NPL, has developed methods and tools to streamline their investigation and selection of remedy process through a simplified Remedial Investigation/Feasibility Study (RI/FS) approach [EPA, 1991b].

Evaluation and selection of appropriate remedial action alternatives for Superfund municipal landfill sites is a function of a number of factors, including:

- Sources and pathways of potential risks to human health and the environment
- Potential Applicable or Relevant and Appropriate Requirements (ARARs) for the landfill as the landfill's cleanup standards under the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), commonly known as Superfund; significant ARARs might include RCRA and/or state closure requirements, and federal or state requirements pertaining to landfill gas emissions
- Waste characteristics
- Site characteristics (including surrounding area)
- Regional surface water (including wetlands) and groundwater characteristics and potential uses

Remedial Alternatives for Superfund Municipal Landfills

In general, the remedial actions implemented at most Superfund municipal landfill sites include:

- Containment of landfill contents (i.e., landfill cap)
- Remediation of hot spots
- Control and treatment of leachate
- Control and treatment of landfill gas

Other areas that may require remediation include groundwater, surface waters, sediments, and adjacent wetlands. A summary of the issues associated with the main remedial actions commonly applied to Superfund municipal landfills is presented below.

Landfill Contents

Characterization of a landfill's contents is generally not necessary because containment of the landfill contents by a cap, which is often the most practical remedial alternative, does not require such information. Certain data, however, are necessary to evaluate capping alternatives and should be collected in the field. For instance, certain landfill properties such as the fill thickness, lateral extent, and age will influence landfill settlement and gas generation rates, which will thereby have an influence on the cover type at a site.

The main purpose of a cap is to prevent vertical infiltration of surface water. Lateral migration of water or gases into and out of the landfill can be prevented by a perimeter trench-type barrier. The type of cap would likely be either a native soil cover, single-barrier cap, or composite-barrier cap. The appropriate type of cap to be considered will be based on remedial objectives for the site. For example, a soil cover may be sufficient if the primary objective is to prevent direct contact and minimize erosion. A single barrier or composite cap may be necessary where infiltration is also a significant concern. Similarly, the type of trench will be dependent on the nature of the contaminant to be contained. Impermeable trenches, such as slurry walls, may be constructed to contain liquids while permeable trenches may be used to collect gases.

Hot Spots

More extensive characterization activities and development of remedial alternatives (such as thermal treatment or stabilization) may be appropriate for known or suspected hot spots within a landfill. Hot spots consist of highly toxic and/or highly mobile material and present a potential principal threat to human health or the environment. Hot spots should be characterized if documentation or physical evidence exists to indicate the presence and approximate location of the hot spots. Hot spots may be delineated using geophysical techniques or soil gas surveys and typically are confirmed by excavating test pits or drilling exploratory borings. Excavation or treatment of hot spots is generally practicable where the waste type or mixture of wastes is in a discrete, accessible location of a landfill. A hot spot should be large enough that its remediation would significantly reduce the risk posed by the overall site, but small enough that it is reasonable to consider removal or treatment. Consolidation of hot spot materials under a landfill cap is a potential alternative in cases when treatment is not practical or necessary.

Leachate

Characterization of a site's geology and hydrogeology will affect decisions on capping options as well as on extraction and treatment systems for leachate and possibly groundwater. Although leachate quality is different in each municipal landfill, generally the variables affecting it are the age of the landfill, climate variables such as annual rainfall and ambient temperature, final cover, and factors such as permeability, depth, composition, and compaction of the waste in the landfill. New landfills typically have leachates high in biodegradable organics. As a landfill ages, its contents degrade and produce more complex organics, not so readily amenable to biodegradation, and inorganics.

Characteristics of leachate produced, as well as differences in the quality of leachate generated, by municipal, codisposal, and hazardous waste landfills have been documented [EPA, 1988c]. In general, the collected data show that although the same chemicals are routinely detected at both municipal and hazardous waste landfills, considerably higher concentrations of many chemicals are found at the leachate of hazardous waste facilities. In particulate, chemicals such as 1,1,1-trichloroethane, trichloroethene, vinyl chloride, chloroform, pesticides, and PCBs occur with greater frequency and at higher concentrations in leachates at hazardous waste landfills than at municipal facilities. Typical chemical constituents in leachate from municipal landfills are shown in Tables 14.5 and 14.6 [EPA, 1988c].

Leachate generation is of special concern when investigating municipal landfill sites. The principal factors contributing to the leachate quantity are precipitation and recharge from groundwater and surface

TABLE 14.5 Municipal Landfill Leachate Data — Indicator Parameters and Inorganic Compounds

	Municipal Landfills Leachate Concentration Reported (ppm)	
Indicator Parameters	Minimum	Maximum
Alkalinity	470	57,850

water. In many landfills, leachate is perched within the landfill contents, above the water table. Placing a limited number of leachate wells in the landfill could be an efficient way to gather information regarding the depth, thickness, and types of wastes present; the moisture content and degree of decomposition of the waste; leachate composition and head levels; and the elevation of the underlying natural soil layer. Leachate wells, in addition, provide good access for landfill gas sampling. It is important to note, however, that without extreme precautions, placing wells into the landfill contents may create health and safety risks. Such installation, furthermore, may create conduits through which leachate can migrate to lower geologic strata, thus contaminating previously nonimpacted groundwater.

Extraction and treatment of leachate may be required to control off-site migration of wastes. Collection and treatment may be necessary indefinitely because of continued contaminant loadings from the landfill. Biological processes are one possible step in the treatment of leachate, given its usually high organic

matter manifested as biochemical oxygen demand (BOD). Chemical and physical processes are also applicable, as well as combinations of the three. A cost-effective alternative to on-site leachate treatment, if available, is the discharge of the leachate into the municipal sewer system and the eventual treatment of the leachate by the city's wastewater treatment plant.

Landfill Gas

Several gases typically are generated by decomposition of organic materials in a landfill. The composition, quantity, and generation rates of the gases depend on such factors as refuse quantity and composition, placement characteristics, landfill depth, refuse moisture content, and amount of oxygen present. The principal gases generated (by volume) are carbon dioxide, methane, trace thiols, and, occasionally, hydrogen sulfide. Volatile organic compounds may also be present in landfill gases, particularly at codisposal facilities. Data generated during the landfill gas characterization should include, in addition to the landfill gas characteristics, the role of on-site and off-site surface emissions, and the geologic and hydrogeologic conditions of the site. Constructing an active landfill gas collection and treatment system should be considered where (1) existing or planned homes or buildings may be adversely affected through either explosion or inhalation hazards, (2) final use of the site includes allowing public access, (3) the landfill produces excessive odors, or (4) it is necessary to comply with ARARs. Most landfills will require at least a passive gas collection system (that is, venting) to prevent buildup of pressure below the cap and to prevent damage to the vegetative cover.

FIGURE 14.3 Geosynthetic fabric liner installation conforms to composite liner federal requirements for MSWLFs at the expansion site of Caldwell Sanitary Landfill. (*Source:* Caldwell Sanitary Landfill. With permission.)

Landfills — Present Status

Several landfills across the country have already incorporated the federal criteria for MSWLF into their expansion process. A typical landfill expansion under the new federal criteria as shown in Fig. 14.3 where the newly installed geosynthetic fabric liner, part of a composite liner system for the expansion of the existing MSWLF, is adjoining the active site of the landfill.

Even though the open dumps of the past have given way to high-tech landfill facilities where advanced engineering principles are applied to ensure environmentally safe and aesthetically pleasing conditions, public opposition to citing new landfills has not diminished. As a result, lateral and vertical expansions of existing MSWLF units are today the predominant means of generating new landfill space.

Defining Terms

Composite liner — A liner system for municipal solid waste landfills which, according to 40 CFR 258, consists of two components with the following specifications: The upper component is a minimum 30 mil flexible membrane liner (FML), and the lower component is at least a two-foot layer of compacted soil with a hydraulic conductivity of no more than 1×10^{-7} cm/sec. FML components consisting of high density polyethylene (HDPE) shall be at least 60 mil thick.

Leachate — A liquid that has passed through or emerged from solid waste in a landfill and contains soluble, suspended, or miscible materials removed from such waste.

Maximum contaminant levels (MCLs) — Enforceable, allowable concentrations of contaminants in public drinking water supplies, protective of human health, under the federal Safe Drinking Water Act.

Municipal solid waste landfill (MSWLF) — A discrete area of land that receives household waste, and that is not a land application unit, surface impoundment, injection well, or waste pile, as those terms are defined in 40 CFR 257. An MSWLF may also receive other types of RCRA Subtitle D wastes, such as commercial solid waste, nonhazardous sludge, and industrial solid waste. Such a landfill may be publicly or privately owned and may be a new MSWLF, an existing MSWLF, or a lateral expansion.

Relevant point of compliance — Under the federal solid waste regulations, this is the point where an MSWLF's impact on groundwater is evaluated. This point, which is specified by a state with an EPA approved solid waste program, cannot be more than 150 meters from the waste management unit boundary and has to be located on land owned by the MSWLF owner.

Uppermost aquifer — The geologic formation nearest the ground surface that is an aquifer, including lower aquifers interconnected with this aquifer within an MSWLF's property boundary.

CIVIL ENGINEERS ARE IN THE MIDST of a construction revolution. Heavy structures are being located in areas formerly considered unsuitable from the standpoint of the supporting power of the underlying soils. Earth structures are contemplated that are of unprecedented height and size; soil systems must be offered to contain contaminants for time scales for which past experience is either inadequate or absent. Designs must be offered to defy the ravages of floods and earthquakes that so frequently visit major population centers.

All structures eventually transmit their loads into the ground. In some cases this may be accomplished only after circuitous transfers involving many component parts of a building; in other cases, such as highway pavements, contact is generally direct. Load transfer may be between soil and soil or, as in retaining walls, from soil through masonry to soil. Of fundamental importance is the response that can be expected due to the imposed loadings. It is within this framework that *geotechnical engineering* is defined as *that phase of civil engineering that deals with the state of rest or motion of soil bodies under the action of force systems*.

Soil bodies, in their general form, are composed of complex conglomerations of discrete particles, in compact arrays of varying shapes and orientations. These may range in magnitude from the microscopic elements of clay to the macroscopic boulders of a rock fill. At first glance, the task of establishing a predictive capability for a material so complicated appears to be overwhelming.

Although man's use of soil as a construction material extends back to the beginning of time, only within very recent years has the subject met with semiempirical treatment. In large measure, this change began in 1925 when Dr. Karl Terzaghi published his book *Erdbaumechanik*. Terzaghi demonstrated that soils, unlike other engineering materials, possess a mechanical behavior highly dependent on their prior history of loading and degree of saturation and that only a portion of the boundary energy is effective in producing changes within the soil body. Terzaghi's concepts transferred foundation design from a collection of rules of thumb to an engineering discipline. The contents of the present section offer, in a concise manner, many of the products of this and subsequent developments.

Had the section on geotechnical engineering in this handbook been written a mere decade or two ago, the table of contents would have been vastly different. Although some of the newer subjects might have been cited, it is unlikely that their relative importance would have precipitated individual chapters such as contained in the present section, namely: Chapter 16, "Accounting for Variability (Reliability)"; Chapter 24, "Geosynthetics"; Chapter 25, "Geotechnical Earthquake Engineering"; Chapter 26, "Geo-Environment"; Chapter 27, "*In Situ* Subsurface Characterization"; and Chapter 28, "*In Situ* Testing and Field Instrumentation." These make up approximately half the chapters in the present section on geotechnical engineering in the *Handbook*. Necessity *does* give birth to invention.

15.1 Soil Classification

There are two soil classification systems in common use for engineering purposes. The **Unified Soil Classification System** [ASTM D 2487-93] is used for virtually all geotechnical engineering work except highway and road construction, where the **AASHTO classification system** [AASHTO M 145-87] is used. Both systems use the results of **grain-size analysis** and determinations of **Atterberg limits** to determine a soil's classification. Soil components may be described as **gravel, sand, silt,** or **clay.** A soil comprising one or more of these components is given a descriptive name and a designation consisting of letters or letters and numbers which depend on the relative proportions of the components and the **plasticity** characteristics of the soil.

Grain-Size Characteristics of Soils

Large-grained materials such as **cobbles** and **boulders** are sometimes considered to be soil. The differentiation of cobbles and boulders depends somewhat on local practice, but boulders are generally taken to be particles larger than 200 to 300 mm or 9 to 12 in. The Unified Soil Classification System suggests that boulders be defined as particles that will not pass a 12-in. (300 mm) opening. Cobbles are smaller than boulders and range down to particles that are retained on a 3-inch (75 mm) sieve. Gravels and sands are classified as **coarse-grained** soils; silts and clays are **fine-grained** soils. For engineering purposes, gravel is defined as soil that passes a 3-inch (75 mm) sieve and is *retained* by a No. 4 sieve (4.75 mm or 0.187 in.) or No. 10 sieve (2.00 mm or 0.078 in.), depending on the classification system. Sand is defined as soil particles smaller than gravel but retained on a No. 200 sieve (0.075 mm or about 0.003 in.). Soils passing the No. 200 sieve may be silt or clay. Although grain-size criteria were used in some older classification systems to differentiate silt from clay, the two systems described herein make this differentiation based on plasticity rather than grain size.

TABLE 15.1 Opening Sizes of Commonly Used Sieves

Inches	Millimeters
1.5	37.5
1	25
0.75	19
0.5	12.5
Sieve No.	**Millimeters**
4	4.75
10	2.00
20	0.850
40	0.425
70	0.212
100	0.150
200	0.075

The grain-size characteristics of soils that are predominantly coarse grained are evaluated by a **sieve analysis.** A **nest of sieves** is prepared by stacking sieves one above the other with the largest opening at the top followed by sieves of successively smaller openings and a catch pan at the bottom. Opening sizes of commonly used sieves are shown in Table 15.1. A sample of dry soil is poured onto the top sieve, the nest is covered, and it is then shaken by hand or mechanical shaker until each particle has dropped to a sieve with openings too small to pass, and the particle is *retained.* The cumulative weight of all material larger than each sieve size is determined and divided by the total sample weight to obtain the *percent retained* for that sieve size, and this value is subtracted from 100% to obtain the *percent passing* that sieve size. Results are displayed by plotting the percent passing (on a linear scale) against the sieve opening size (on a log scale) and connecting the plotted points with a smooth curve referred to as a **grain-size distribution curve.** A sample of some grain-size distribution curves is presented in Fig. 15.1.

The notation D_{xx} refers to the size D, in mm, for which xx percent of the sample by weight passes a sieve with an opening equal to D. The $\boldsymbol{D_{10}}$ **size,** sometimes called the **effective grain size,** is the grain diameter for which 10% of the sample (by weight) is finer. It is determined from the grain-size distribution curve at the point where the curve crosses a horizontal line through the 10% passing value on the y axis. Other D sizes are found in a similar manner. The D_{50} size, called the **median grain size,** is the grain diameter for which half the sample (by weight) is smaller and half is larger.

Two parameters are used to describe the general shape of the grain-size distribution curve. The **coefficient of uniformity,** C_u, is:

$$C_u = \frac{D_{60}}{D_{10}} \tag{15.1}$$

The **coefficient of curvature,** C_c, is:

$$C_c = \frac{D_{30}^2}{D_{60} \times D_{10}} \tag{15.2}$$

Atterberg Limits and Plasticity

Atterberg limits, named after the Swedish soil scientist A. Atterberg, are water content values at which notable changes in soil behavior occur. The **liquid limit**, denoted LL or w_L, marks the transition between liquid and plastic behavior. At water contents above the liquid limit the soil behaves as a viscous liquid; below the liquid limit the soil behaves as a plastic solid. The liquid limit is determined in the laboratory by partly filling a standard brass cup with wet soil and cutting a groove of a standard dimension in the

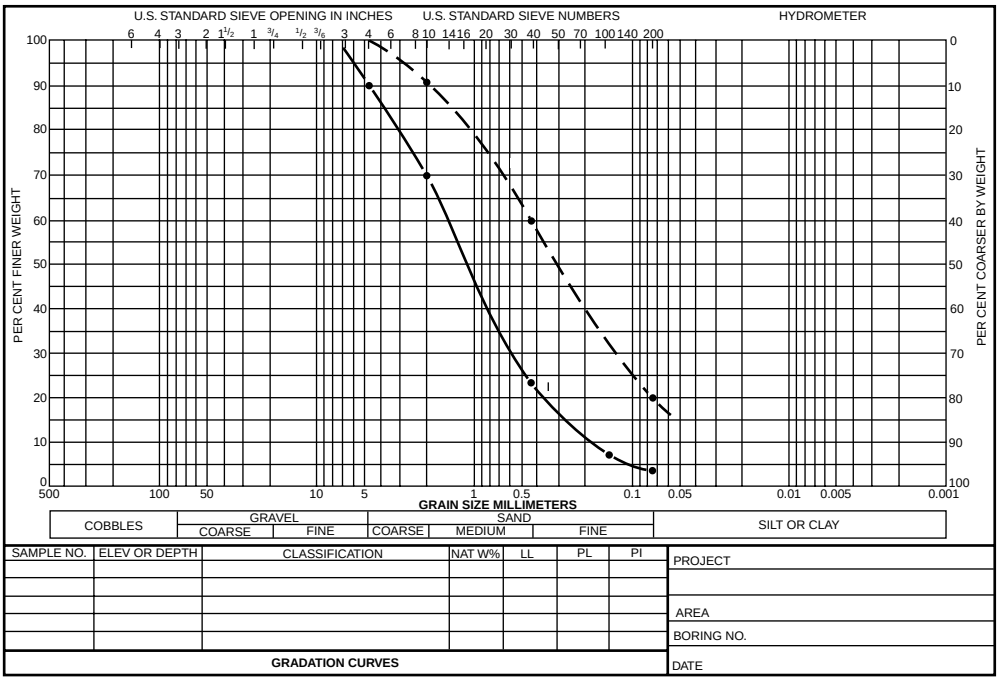

FIGURE 15.1 Typical grain size distribution curves. (From U.S. Army, 1970.)

soil. The liquid limit is taken as the water content at which the groove closes a specified amount when the cup is lifted and dropped 1 cm exactly 25 times. The details of the test are given in AASHTO T 89 and ASTM D 4318-93. The **plastic limit**, denoted PL or w_p, is the transition between plastic and brittle behavior. It is determined in the laboratory as the water content at which a 1/8-inch diameter thread of soil begins to crumble when rolled under the palm of the hand. Details of the liquid limit and plastic limit tests are provided by AASHTO T 90 and ASTM D 4318-93. The **shrinkage limit**, denoted SL or w_S, is the water content below which the soil no longer reduces in volume when the water content is reduced. Although Atterberg limits are water contents and are properly decimals or percentages, they are usually expressed as an integer percentage without a percent sign. Thus, a liquid limit of 40% is usually reported as LL = 40.

The **plasticity index**, denoted PI or I_P, is the difference of the liquid limit and the plastic limit:

$$\text{PI} = \text{LL} - \text{PL} \tag{15.3}$$

The **liquidity index**, denoted LI or I_L, is a measure of the natural water content (w) relative to the plastic limit and the liquid limit:

$$\text{LI} = I_L = \frac{w - \text{PL}}{\text{LL} - \text{PL}} \tag{15.4}$$

The Unified Soil Classification System (USCS)

The Unified Soil Classification System is based on the airfield classification system developed by A. Casagrande during World War II. With some modification it was jointly adopted by several U.S. government agencies in 1952. Additional refinements were made and it is currently standardized as ASTM D 2487-93. It is used in the U.S. and much of the world for geotechnical work other than roads and highways.

In the unified system soils are designated by a two-letter symbol: the first identifies the primary component of the soil, and the second describes its grain size or plasticity characteristics. For example, a poorly graded sand is designated SP and a low plasticity clay is CL. Five first-letter symbols are used:

G for gravel
S for sand
M for silt
C for clay
O for organic soil

Clean sands and gravels (having less than 5% passing the No. 200 sieve) are given a second letter P if poorly graded or W if well graded. Sands and gravels with more than 12% by weight passing the No. 200 sieve are given a second letter M if the fines are silty or C if fines are clayey. Sands and gravels having between 5 and 12% are given dual classifications such as SP-SM. Silts, clays, and organic soils are given the second letter H or L to designate high or low plasticity. The specific rules for classification are summarized as follows and described in detail in ASTM D 2487.

Organic soils are distinguished by a dark-brown to black color, an organic odor, and visible fibrous matter.

For soils that are not notably organic the first step in classification is to consider the percentage passing the No. 200 sieve. If less than 50% of the soil passes the No. 200 sieve, the soil is *coarse grained,* and the first letter will be G or S; if more than 50% passes the No. 200 sieve, the soil is *fine grained* and the first letter will be M or C.

For coarse-grained soils, the proportions of sand and gravel in the **coarse fraction** (not the total sample) determine the first letter of the classification symbol. The coarse fraction is that portion of the total sample retained on a No. 200 sieve. If more than half of the coarse fraction is gravel (retained on the No. 4 sieve), the soil is *gravel* and the first letter symbol is G. If more than half of the coarse fraction is sand, the soil is *sand* and the first letter symbol is S.

For sands and gravels the second letter of the classification is based on gradation for clean sands and gravels and plasticity of the fines for sands and gravels with fines. For clean sands (less than 5% passing the No. 200 sieve), the classification is well-graded sand (SW) if $C_u \geq 6$ *and* $1 \leq C_c \leq 3$. *Both* of these criteria must be met for the soil to be SW, otherwise the classification is poorly graded sand (SP). Clean gravels (less than 5% passing the No. 200 sieve) are classified as well-graded gravel (GW) if $C_u \geq 4$ *and* $1 \leq C_c \leq 3$. If both criteria are not met, the soil is poorly graded gravel (GP).

For sands and gravels where more than 12% of the total sample passes the No. 200 sieve, the soil is a clayey sand (SC), clayey gravel (GC), silty sand (SM), or silty gravel (GM). The second letter is assigned based on whether the fines classify as clay (C) or silt (M) as described for fine-grained soils below.

For sands and gravels having between 5 and 12% of the total sample passing the No. 200 sieve, both the gradation and plasticity characteristics must be evaluated and the soil is given a dual classification such as SP-SM, SP-SC, GW-GC, etc. The first symbol is always based on gradation, whereas the second is always based on plasticity.

For fine-grained soils and organic soils, classification in the unified system is based on Atterberg limits determined by the fraction passing the No. 40 sieve. The liquid limit and plasticity index are determined and plotted on the plasticity chart (Fig. 15.2). The vertical line at LL = 50 separates high-plasticity soils from low-plasticity soils. The *A-line* separates clay from silt. The equation of the A-line is PI = 0.73(LL – 20). The U-line is not used in classification but is an upper boundary of expected results for natural soils. Values plotting above the U-line should be checked for errors.

Inorganic soils with liquid limits below 50 that plot above the A-line and have PI values greater than 7 are **lean clays** and are designated CL; those with liquid limits above 50 that plot above the A-line are **fat clays** and are designated CH. Inorganic soils with liquid limits below 50 that plot below the A-line are silt and are designated ML; those with liquid limits above 50 that plot below the A-line are elastic silts and are designated MH. The plasticity chart has a shaded area; soils that plot in this area (above the A-line with PI values between 4 and 7) are silty clay and are given the dual symbol CL-ML. If the soil

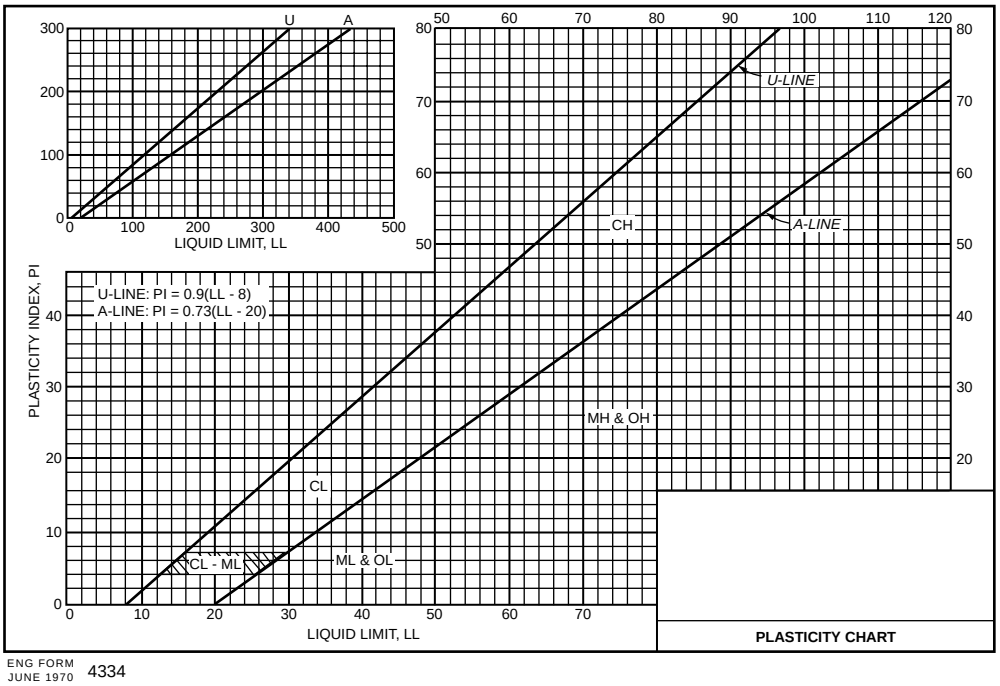

FIGURE 15.2 Plasticity chart for Unified Soil Classification System. (From U.S. Army, 1970.)

under consideration is the fines component of a dually classified sand or gravel, the soil is classified as SM-SC or GM-GC.

Soils with sufficient organic contents to influence properties that have liquid limits below 50 are classified as OL; those with liquid limits above 50 are classified as OH. Soils that are *predominantly* organic, with visible vegetable tissue, are termed **peat** and given the designation Pt.

The AASHTO Classification System

The AASHTO system classifies soils into seven primary groups, named A-1 through A-7, based on their relative expected quality for road embankments, subgrades, subbases, and bases. Some of the groups are in turn divided into subgroups, such as A-1-a and A-1-b. Furthermore, a *group index* may be calculated to quantify a soil's expected performance within a group.

To determine a soil's classification in the AASHTO system, one first determines the relative proportions of gravel, coarse sand, fine sand, and silt-clay. In the AASHTO system gravel is material smaller than 75 mm (3 in.) but retained on a No. 10 sieve; coarse sand is material passing a No. 10 sieve but retained on a No. 40 sieve; and fine sand is material passing a No. 40 sieve but retained on a No. 200 sieve. Material passing the No. 200 sieve is *silt-clay* and is classified based on Atterberg limits. It should be noted that the division between gravel and sand is made at a smaller size (No. 10 sieve) in the AASHTO system than in the unified system (No. 4 sieve). Secondly, if any fines are present, Atterberg limits are determined and the plasticity index is calculated.

A soil is a **granular material** if less than 35% of the soil by weight passes the No. 200 sieve. Granular materials are classified into groups A-1 through A-3. Soils having more than 35% passing the No. 200 sieve are silt-clay and fall in groups A-4 through A-7.

Having the proportions of the components and the plasticity data, one enters one of the two alternative AASHTO classification tables (Tables 15.2 and 15.3) and checks from left to right until a classification is found for which the soil meets the criteria. It should be noted that, in this scheme, group A-3 is checked before A-2. The AASHTO plasticity criteria are also illustrated in Fig. 15.3.

TABLE 15.2 Classification of Soils and Soil-Aggregate Mixtures by the AASHTO System

General Classification	Granular Materials (35% or Less Passing 0.075 mm)			Silt-Clay Materials (More than 35% Passing 0.075 mm)			
Group Classification	A-1	A-3[a]	A-2	A-4	A-5	A-6	A-7
Sieve analysis, percent passing:							
2.00 mm (No. 10)	—	—	—	—	—	—	—
0.425 mm (No. 40)	50 max.	51 min.	—	—	—	—	—
0.075 mm (No. 200)	25 max.	10 max.	35 max.	36 min.	36 min.	36 min.	36 min.
Characteristics of fraction passing 0.425 mm (No. 40)							
Liquid limit	—	—		40 max.	41 min.	40 max.	41 min.
Plasticity index	6 max.	N.P.	*b*	10 max.	10 max.	11 min.	11 min.
General rating as subgrade	Excellent to good			Fair to poor			

[a] The placing of A-3 before A-2 is necessary in the "left to right elimination process" and does not indicate superiority of A-3 over A-2.

[b] See Table 15.3 for values.

From *Standard Specification for Transportation Materials and Methods of Sampling and Testing.* Copyright 1990 by the American Association of State Highway and Transportation Officials, Washington, D.C. Used by permission.

Soils classified as A-1 are typically well-graded mixtures of gravel, coarse sand, and fine sand. Soils in subgroup A-1-a contain more gravel whereas those in A-1-b contain more sand. Soils in group A-3 are typically fine sands that may contain small amounts of nonplastic silt. Group A-2 contains a wide variety of "borderline" granular materials that do not meet the criteria for groups A-1 or A-3.

Soils in group A-4 are silty soils, whereas those in group A-5 are high-plasticity elastic silt. Soils in group A-6 are typically lean clays, and those in group A-7 are typically highly plastic clays.

Within groups containing fines, one may calculate a *group index* to further evaluate relative quality and supporting value of a material as subgrade. The group index is calculated according to the following empirical formula:

$$\text{Group index} = (F - 35)[0.2 + 0.005(\text{LL} - 40)] + 0.01(F - 15)(\text{PI} - 10) \qquad (15.5)$$

In this equation F is the percentage of fines (passing the No. 200 sieve) expressed as a whole number. When calculating the group index for A-2-6 and A-2-7, only the PI term is used. The group index is rounded to the nearest whole number and, if negative, it is taken as zero. The expected performance is inversely related to group index. A value of zero indicates a good subgrade material and a value above 20 indicates a very poor material.

Example 15.1

Classify the soil shown by the solid curve in Fig. 15.1. Assume the soil is nonplastic. The following data are obtained:

Percent passing No. 4 sieve:	90%
Percent passing No. 10 sieve:	70%
Percent passing No. 40 sieve:	23%
Percent passing No. 200 sieve:	4%
D_{60} size:	1.50 mm
D_{30} size:	0.61 mm
D_{10} size:	0.18 mm

To classify the soil in the Unified Soil Classification System, the percent passing the No. 200 sieve is first checked. As only 4% passes the No. 200 sieve, the soil is coarse grained. The coarse fraction makes up 96% of the soil, with 10% being gravel (larger than the No. 4 sieve) and 86% being sand (the difference between the Nos. 4 and 200 sieves). As there is more sand than gravel, the soil is a sand and the first letter is S.

TABLE 15.3 Classification of Soils and Soil-Aggregate Mixtures

General Classification	Granular Materials (35% or Less Passing 0.075 mm)							Silt-Clay Materials (More than 35% Passing 0.075 mm)			
	A-1			A-2							A-7
Group Classification	A-1-a	A-1-b	A-3	A-2-4	A-2-5	A-2-6	A-2-7	A-4	A-5	A-6	A-7-5, A-7-6
Sieve analysis, percent passing:											
2.00 mm (No. 10)	50 max.	—	—	—	—	—	—	—	—	—	—
0.425 mm (No. 40)	30 max.	50 max.	51 min.	—	—	—	—	—	—	—	—
0.075 mm (No. 200)	15 max.	25 max.	10 max.	35 max.	35 max.	35 max.	35 max.	36 min.	36 min.	36 min.	36 min.
Characteristics of fraction passing 0.425 mm (No. 40)											
Liquid limit	—		—	40 max.	41 min.	40 max.	41 min.	40 max.	41 min.	40 max.	41 min.
Plasticity index	6 max.		N.P.	10 max.	10 max.	11 min.	11 min.	10 max.	10 max.	11 min.	11 min.[a]
Usual types of significant constituent materials	Stone fragments, gravel, and sand		Fine sand	Silty or clayey gravel and sand				Silty soils		Clayey soils	
General rating as subgrade	Excellent to good							Fair to poor			

[a] Plasticity index of A-7-5 subgroup is equal to or less than LL minus 30. Plasticity index of A-7-6 subgroup is greater than LL minus 30.

From *Standard Specification for Transportation Materials and Methods of Sampling and Testing.* Copyright 1990 by the American Association of State Highway and Transportation Officials, Washington, D.C. Used by permission.

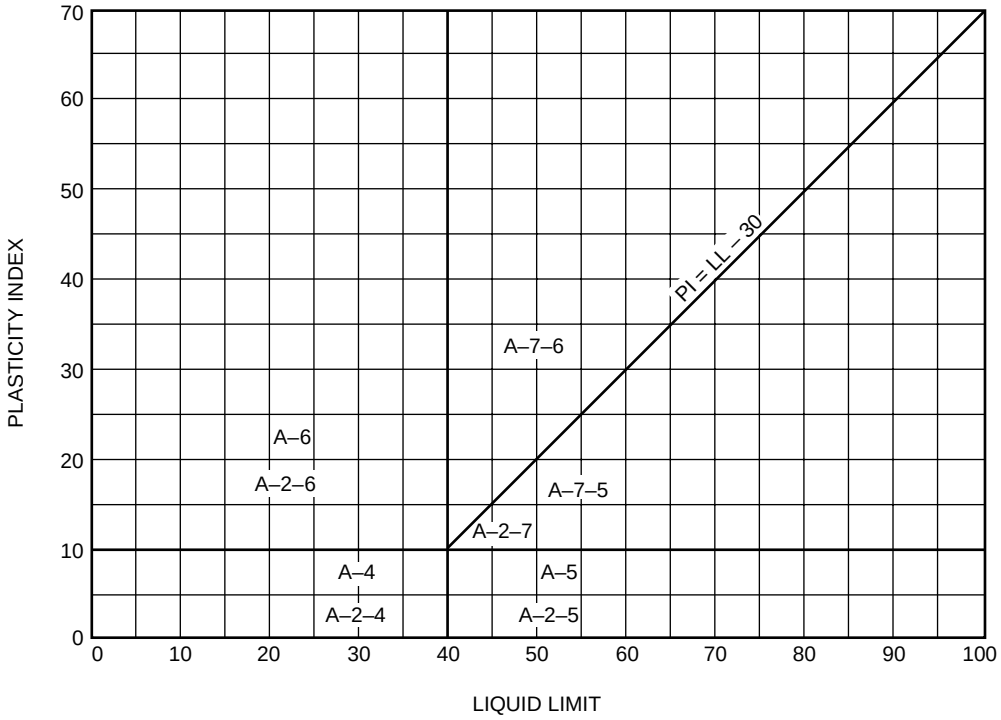

FIGURE 15.3 Plasticity chart for AASHTO Classification System. (From *Standard Specification for Transportation Materials and Methods of Sampling and Testing.* Copyright 1990 by the American Association of State Highway and Transportation Officials, Washington, D.C. Used by permission.)

As less than 5% passes the No. 200 sieve, the sand is clean (SP or SW). The coefficient of uniformity is (1.5)/(0.18) = 8.33. The coefficient of curvature is $0.61^2/(1.5)(0.18) = 1.38$. As the coefficient of uniformity is greater than 6.0 and the coefficient of curvature is between 1 and 3, the soil meets both of the criteria for SW and is so classified.

In the AASHTO system the soil is 30% gravel, 47% coarse sand, 19% fine sand, and 4% silt-clay. Proceeding from left to right on the classification chart, the soil cannot be classified as A-1-a because the soil has 70% passing the No. 10 and that classification permits a maximum of 50%. The soil meets the classification criteria for A-1-b and is so classified.

Example 15.2

Classify the soil represented by the dashed curve in Fig. 15.1. The liquid limit and plastic limit are found to be 30 and 20, respectively. The following data are obtained:

Percent passing No. 4 sieve:	100%
Percent passing No. 10 sieve:	91%
Percent passing No. 40 sieve:	60%
Percent passing No. 200 sieve:	20%
D_{60} size:	0.41 mm
D_{30} size:	0.12 mm
D_{10} size:	<0.074 mm
Liquid limit:	30
Plastic limit:	20

First the soil is classified by the Unified Soil Classification System. As only 20% of the soil is smaller than a No. 200 sieve, the soil is coarse grained. All of the coarse fraction is smaller than the No. 4 sieve, so the soil is sand (first letter S).

As the percentage passing the No. 200 sieve is greater than 12%, the gradation characteristics are not considered, and the Atterberg limits are examined to determine whether the sand is a clayey sand or silty sand. The plasticity index is calculated as 30 – 20 = 10, and the coordinates LL = 30, PI = 10 are entered on the plasticity chart. As this plots in the CL region, the fines are clay and the soil is a clayey sand SC.

Next the soil is classified according to the AASHTO system. Following the classification table from left to right, group A-1 is eliminated due to too much material passing the No. 40 sieve, and group A-3 is eliminated due to too much material passing the No. 200 sieve. The soil passes the criteria for A-2-4 and is so classified. The group index is calculated as:

$$\text{Group index} = (F - 35)[0.2 + 0.005(\text{LL} - 40)] + 0.01(F - 15)(\text{PI} - 10)$$

where $F = 20$, the percent passing the No. 200 sieve. Thus:

$$\begin{aligned}\text{Group index} &= (20 - 35)[0.2 + 0.005(30 - 40)] + 0.01(20 - 15)(10 - 10)\\ &= (15)[0.2 + (-0.05)] + 0\\ &= 15(0.15)\\ &= 2.25\end{aligned}$$

This is rounded to the nearest whole number, 2, and the soil classification is reported as A-2-4(2).

Example 15.3

A fine-grained soil has the following properties:

Percent passing No. 200 sieve:	65%
Liquid limit:	60
Plastic limit:	28

First the soil is classified according to the unified system. As more than 50% of the sample passes the No. 200 sieve, the soil is fine grained and the plasticity chart is used. The plasticity index is 60 – 28 = 32. The coordinates (60, 32) plot in the CH region, so the soil is a high-plasticity clay (CH).

To classify the soil in the AASHTO system, one notes that more than 35% passes the No. 200 sieve, so the soil is silt-clay. Entering the coordinates (60, 32) on the AASHTO plasticity chart, the classification is A-7-6. The group index is calculated as follows:

$$\begin{aligned}\text{Group index} &= (F - 35)[0.2 + 0.005(\text{LL} - 40)] + 0.01(F - 15)(\text{PI} - 10)\\ &= (65 - 35)[0.2 + 0.005(60 - 40)] + 0.01(65 - 15)(32 - 10)\\ &= 30[0.2 + 0.1] + 0.01(50)(22)\\ &= 9.0 + 11.0\\ &= 20\end{aligned}$$

The complete classification is A-7-6(20), which indicates a poor quality soil for highway construction.

15.2 Weight, Mass, and Volume Relationships

In an engineering context, soil comprises three components: solid particles, water, and air. Many problems in soil mechanics and construction quality control involve making calculations and communicating information regarding the relative proportions of these components and the volumes they occupy,

individually or in combination. Given some known values of mass, weight, volume, or density (or relationships among them), it is often necessary to calculate other values. This section defines the terms commonly used in geotechnical engineering to describe such relationships and provides worked examples of typical calculations.

The Phase Diagram

In a typical volume of soil the three components are arranged in a complex mixture. To visualize the relationships among the components when performing weight-volume or mass-volume calculations, drawing a phase diagram is recommended. Much like checking equilibrium with a free body diagram in statics, completing and balancing a phase diagram with numerical values of all quantities permits cross-checking the solution. Figure 15.4 shows an element of soil and the corresponding phase diagram. All solid particles in the element are taken as an equivalent single mass at the bottom of the diagram. Above the solids is the water—also represented as a single equivalent mass—and above that, the air. On the sides of the diagram are variable names; numerical values are entered here during calculations. On the left side are the total volume V, the volume of solids V_s, the volume of water V_w, and the volume of air V_a. The combined volume of water and air is the volume of voids V_v. On the right side are shown the total weight W, the weight of solids W_s, and the weight of water W_w. The weight of air is negligible. For problems involving masses, mass values are shown on the right instead of weights and given the equivalent designations M, M_s, and M_w.

Volume Relationships

Volume relationships include the void ratio, the porosity, and the degree of saturation. The **void ratio,** denoted e, is the ratio of the volume of voids to the volume of solids:

$$e = \frac{V_v}{V_s} \tag{15.6}$$

The **porosity**, denoted n, is the ratio of the volume of voids to the total volume:

$$n = \frac{V_v}{V} \tag{15.7}$$

The void ratio and porosity are related as follows:

$$n = \frac{e}{1 + e} \tag{15.8}$$

$$e = \frac{n}{1 - n} \tag{15.9}$$

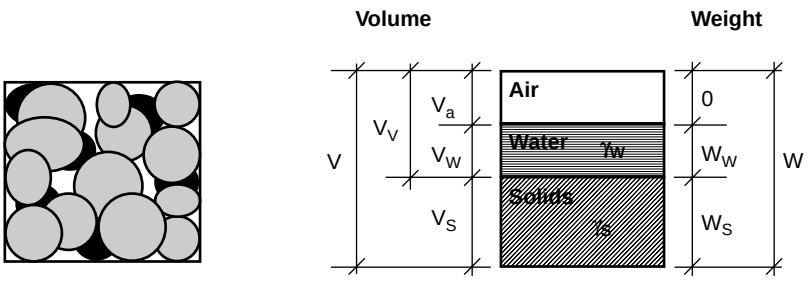

FIGURE 15.4 Soil element and phase diagram.

The **degree of saturation**, denoted S, is the ratio of the volume of water to the volume of voids. It is commonly expressed as a percentage:

$$S = \frac{V_w}{V_v} \times 100\% \tag{15.10}$$

If all the soil voids are filled with water and no undissolved air is present, the soil is said to be **saturated**.

Weight and Mass Relationships

The **water content** (or moisture content), denoted w, is the only relationship involving weights or masses. It is the ratio of the weight of water to the weight of solids or, equivalently, the ratio of the mass of water to the mass of solids:

$$w = \frac{W_w}{W_s} = \frac{M_w}{M_s} \tag{15.11}$$

Unit Weight

The ratio of the weight of a material to its volume is its **unit weight**, sometimes termed *specific weight* or *weight density*. The unit weight of water, γ_w, is 9.81 kN/m^3 in the SI system and 62.4 lb/ft^3 in the English system. The unit weight of solids, γ_s, varies with the mineralogy of the soil particles but is commonly in the range of 26.0 to 27.0 kN/m^3 or 165 to 172 lb/ft^3. The **total unit weight** of a soil (the solids-water-air system), denoted γ, is the ratio of the total weight to the total volume occupied:

$$\gamma = \frac{W}{V} = \frac{W_s + W_w}{V_s + V_w + V_a} \tag{15.12}$$

The **saturated unit weight**, denoted γ_{sat}, is the total unit weight that would be obtained if the air voids were filled with an equal volume of water ($S = 100\%$ and $V_w = V$). The **dry unit weight**, denoted γ_d, is often termed the **dry density** and has particular importance in field control of soil compaction. It is the ratio of the weight of solids to the total volume:

$$\gamma_d = \frac{W_s}{V} = \frac{W_s}{V_s + V_w + V_a} \tag{15.13}$$

Note that the dry unit weight matches the weight of a single component—the solids—with the *entire* volume of solids, water, and air. It does not represent the unit weight of any component or consistent set of components, but rather provides a measure of how much solid material by weight is in the total volume of a container, such as an earthmover or a compaction mold. The **buoyant unit weight** or **effective unit weight**, γ', is equal to the saturated unit weight minus the unit weight of water, γ_w:

$$\gamma' = \gamma_{sat} - \gamma_w \tag{15.14}$$

The buoyant unit weight is sometimes used to directly calculate vertical effective stresses below the water table instead of calculating total stresses and subtracting pore pressures.

Density

The term **density** is used herein to denote the mass-to-volume ratio of a material. However, some references, particularly older ones, use the term to describe unit weight. Density is denoted by ρ. Because $m = W/g$, the unit weight terms defined above can be converted to mass densities as follows:

$$\rho = \frac{\gamma}{g} = \frac{M}{V} \tag{15.15}$$

$$\rho_{sat} = \frac{\gamma_{sat}}{g} = \frac{M_{sat}}{V} \tag{15.16}$$

$$\rho_d = \frac{\gamma_d}{g} = \frac{M_s}{V} \tag{15.17}$$

$$\rho' = \rho_{sat} - \rho_w \tag{15.18}$$

In the SI system mass densities are commonly expressed in Mg/m^3, kg/m^3, or g/ml. The mass density of water can therefore be expressed $\rho_w = 1000\ kg/m^3 = 1\ Mg/m^3 = 1$ g/ml. The mass density of soil solids typically ranges from 2640 to 2750 kg/m^3. Where mass or mass density values (g, kg, or kg/m^3) are given or measured, they must be multiplied by $g(9.81\ m/s^2)$ to obtain weights or unit weights before performing stress calculations. In the English system mass density values are virtually never used in geotechnical engineering and all work is performed in terms of unit weights (lb/ft^3).

Specific Gravity

To facilitate working problems across different sets of units, it is convenient to express the unit weight and density of solids as a ratio to the unit weight and density of water. This ratio is termed the **specific gravity** and denoted G_s. For most soil minerals G_s is commonly in the range 2.64 to 2.75. Note that:

$$\gamma_s = G_s\gamma_w \tag{15.19}$$

and

$$\rho_s = G_s\rho_w \tag{15.20}$$

Conversion of Unit Weight and Density

A soil sample has a total unit weight of 125 lb/ft^3. It is desired to find its total unit weight in kN/m^3 and its density in kg/m^3. Although the problem can be worked using a chain of conversion factors, a simpler approach is to consider that the unit weight and density of the soil sample have a constant ratio to the unit weight and density of water. Placing the unit weight or density of water in any system of units in both the numerator and denominator of a fraction forms an equality. (It is assumed that the problem is on the planet Earth and a *mass* of 1000 kg *weighs* 9.81 kN!) Thus,

$$\gamma = (125\ lb/ft^3)\left(\frac{9.81\ kN/m^3}{62.4\ lb/ft^3}\right) = 19.7\ kN/m^3$$

$$\rho = (125\ lb/ft^3)\left(\frac{1000\ kg/m^3}{62.4\ lb/ft^3}\right) = 2003\ kg/m^3$$

Weight–Volume Problems Involving Defined Quantities

Weight-volume problems may be divided into two categories: those where there is a defined quantity of soil, and those where the quantity of soil is not defined and it is only desired to make conversions among relationships. The solution to problems of the first category is discussed first; discussion of the second category follows. Problems of the first category can be solved in four steps:

1. A blank phase diagram is sketched and known weights, volumes, and unit weights are entered on the diagram.
2. Known volumes are multiplied by their respective unit weights to obtain weights. Known weights are divided by unit weights to obtain volumes. Where values of some relationships are given,

additional weight and volume values are calculated using the definitions of Eqs. (15.6), (15.7), (15.10), and (15.11). To numerically balance the phase diagram it is recommended that all calculations be carried to at least four significant digits.

3. Multiplication and division horizontally across the diagram and addition and subtraction vertically along the sides is continued until all weights, volumes, and unit weights are determined and found to numerically balance.
4. All desired values and relationships can now be calculated from the completed and checked diagram.

Example 15.4 (English Units)

Assume that a **compaction mold** having a volume of 1/30 ft^3 was filled with moist soil. The total weight of the soil in the mold was found to be 4.10 lb. The soil was oven dried and its weight after drying was 3.53 lb. The specific gravity of solids was known to be 2.70. Water content, void ratio, porosity, degree of saturation, total unit weight, and dry unit weight must be determined. A phase diagram is shown in Fig. 15.5, with the known quantities in bold. The weight and volume of water are calculated as

$$W_w = W - W_s = 4.10 - 3.53 = 0.57 \text{ lb}$$
$$V_w = W_w / \gamma_w = 0.57/62.4 = 0.00913 \text{ ft}^3$$

The volume of solids is

$$V_s = W_s / G_s \gamma_w = 3.53/[(2.70)(62.4)] = 0.02095 \text{ ft}^3$$

The volume of air is

$$V_a = V - V_w - V_s = 0.03333 - 0.00913 - 0.02095 = 0.00325 \text{ ft}^3$$

The volume of voids is

$$V_v = V_w + V_a = 0.00913 + 0.00325 = 0.01238 \text{ ft}^3$$

With all quantities now known, all relationships can be determined.

$$w = W_w / W_s = 0.57/3.53 = 0.161 = 16.1\%$$
$$e = V_v / V_s = 0.01238/0.02095 = 0.590$$
$$n = V_v / V = 0.01238/(1/30) = 0.371$$
$$S = (V_w / V_s)\ 100\% = (0.00913/0.01238)\ 100\% = 73.7\%$$
$$\gamma = W/V = 4.10/(1/30) = 123.0 \text{ lb/ft}^3$$
$$\gamma_d = W_s / V = 3.53/(1/30) = 105.9 \text{ lb/ft}^3$$

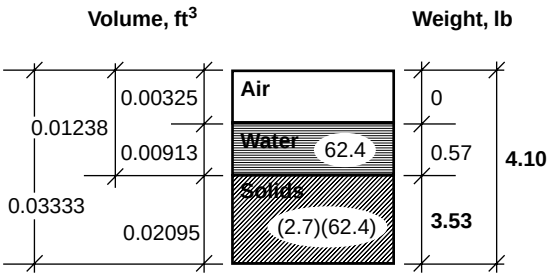

FIGURE 15.5 Phase diagram for Example 15.4.

If the same soil now becomes saturated by the addition of water at constant total volume, the saturated water content and saturated unit weight can be calculated as follows. The new volume of water is the entire void volume, 0.01238 ft^3. Multiplying this value by 62.4 lb/ft^3, the new weight of water is 0.77 lb. The water content at saturation is then

$$w = W_w / W_s = 0.77/3.53 = 0.218 = 21.8\%$$

The total weight is then

$$W = W_s + W_w = 3.53 + 0.77 = 4.30 \text{ lb}$$

The total and dry unit weights are then

$$\gamma = W/V = 4.30/(1/30) = 129.0 \text{ lb/ft}^3$$
$$\gamma_d = W_s/V = 3.53/(1/30) = 105.9 \text{ lb/ft}^3$$

Note that the dry unit weight does not change if water is added without changing total volume.

Example 15.5 (SI units)

A soil sample has a volume of 2.5 liters (2.5×10^{-3} m^3) and a total mass of 4.85 kg. A water content test indicates the water content is 28%. Assuming that the specific gravity of solids is 2.72, it is desired to determine the total density, total unit weight, dry density, dry unit weight, void ratio, porosity, and degree of saturation.

A phase diagram is shown in Fig. 15.6, with known values shown in bold.

$$M = M_s + M_w = 4.85 \text{ kg}$$

From the definition of the water content,

$$M_s + 0.28 M_s = 4.85 \text{ kg}$$
$$1.28 M_s = 4.85 \text{ kg}$$
$$M_s = 3.789 \text{ kg}$$
$$M_w = M - M_s = 1.061 \text{ kg}$$

With the mass side of the diagram complete, the masses are divided by density values to obtain volumes:

$$V_s = M_s/\rho_s = 3.789 \text{ kg}/(2720 \text{ kg/m}^3) = 0.00139 \text{ m}^3$$
$$V_w = M_w/\rho_w = 1.061 \text{ kg}/(1000 \text{ kg/m}^3) = 0.00106 \text{ m}^3$$

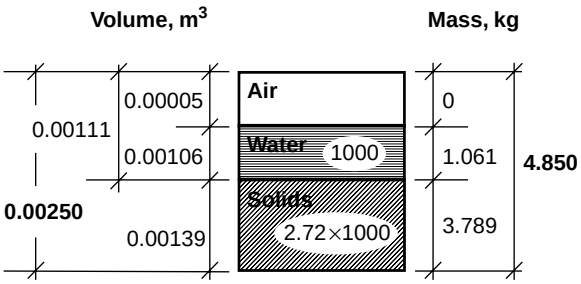

FIGURE 15.6 Phase diagram for Example 15.5.

Then

$$V_a = V - V_s - V_w = 0.00250 - 0.00319 - 0.00106 = 0.00005 \text{ m}^3$$

The total density is

$$\rho = M/V = 4.850 \text{ kg}/0.00250 \text{ m}^3 = 1940 \text{ kg}/\text{m}^3$$

The total unit weight is

$$\gamma = \rho g = (1940 \text{ kg}/\text{m}^3)(9.81 \text{ m}/\text{s}^2) = 19{,}031 \text{ N}/\text{m}^3 = 19.03 \text{ kN}/\text{m}^3$$

The dry density is

$$\rho_d = M/V = 3.789 \text{ kg}/0.00250 \text{ m}^3 = 1515 \text{ kg}/\text{m}^3$$

The dry unit weight is

$$\gamma_d = \rho_d g = (1515 \text{ kg}/\text{m}^3)(9.81 \text{ m}/\text{s}^2) = 14{,}862 \text{ N}/\text{m}^3 = 14.86 \text{ kN}/\text{m}^3$$

The void ratio is

$$e = V_v/V_s = 0.00111/0.00139 = 0.799$$

The porosity is

$$n = V_v/V = 0.00139/0.00250 = 0.556$$

The degree of saturation is

$$S = V_w/V_v = 0.00106/0.00111 = 0.955 = 95.5\%$$

Weight–Volume Problems Involving Only Relationships

If only relationships (e.g., void ratio or unit weight) are given, the quantity of soil is indefinite and only other relationships can be calculated. Nevertheless, it is convenient to solve such problems using a phase diagram and assuming one fixed weight or volume value. That quantity of solids, water, or soil is "brought to the paper" and used to calculate corresponding quantities of components. Although any one quantity can be assumed to have any value, the following assumptions simplify calculations:

- If a water content is known, assume $W_s = 1.0$ or 100.0 (lb or kN); then $W_w = w$ or $100w$.
- If a void ratio is known, assume the volume of solids $V_s = 1.0$ ft^3 or 1.0 m^3; then $V_v = e$.
- If a dry unit weight is known, assume the total volume $V = 1.0$ ft^3 or 1.0 m^3; then $W_s = \gamma_d$.
- If a total unit weight is known, assume the total volume $V = 1.0$ ft^3 or 1.0 m^3; then $W = \gamma$.

Example 15.6

Assume that a soil has a water content of 30%, a void ratio of 0.850, and a specific gravity of 2.75. It is desired to find the degree of saturation, porosity, total unit weight, and dry unit weight. Any single fixed quantity of soil or water may be assumed in order to start the calculations; it is assumed that the volume of solids $V_s = 1.000$ m^3. A phase diagram for the problem is shown in Fig. 15.7. The calculations then proceed as follows:

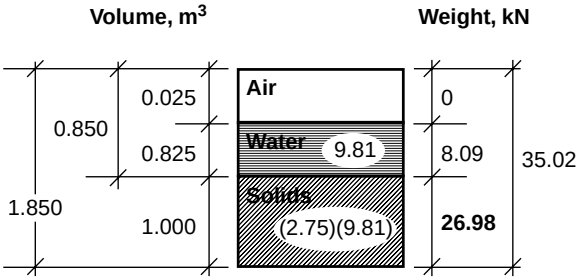

FIGURE 15.7 Phase diagram for Example 15.6.

$$V_v = eV_s = (0.850)(1.000) = 0.850 \text{ m}^3$$
$$V = V_s + V_v = 1.000 + 0.850 = 1.850 \text{ m}^3$$
$$W_s = V_s G_s \gamma_w = (1.000)(2.75)(9.81) = 26.98 \text{ kN}$$
$$W_w = wW_s = (0.30)(26.98) = 8.09 \text{ kN}$$
$$W = W_s + W_w = 26.98 + 8.09 = 35.02 \text{ kN}$$
$$V_w = W_w/\gamma_w = 8.09/9.81 = 0.825 \text{ m}^3$$
$$V_a = V_v - V_w = 0.850 - 0.825 = 0.025$$

At this point the weights and volumes of all components are known for the assumed 1.000 m³ of solids and all desired relationships can be calculated as follows:

$$S = (V_w/V_v)100\% = (0.825/0.850)100\% = 97.1\%$$
$$n = V_v/V = 0.850/1.850 = 0.459$$
$$\gamma = 35.02/1.850 = 18.93 \text{ kN/m}^3$$
$$\gamma_d = 26.98/1.850 = 14.58 \text{ kN/m}^3$$

These relationships derive from the given relationships regardless of the quantity of soil considered.

Equations among Relationships

Solving weight-volume problems using a phase diagram provides a visual display of whether sufficient information is available to complete the problem, whether additional assumptions must be introduced, or whether the problem is overconstrained by an unwarranted assumption. For example, without completing a phase diagram, it may not be immediately apparent from the information given whether a soil is saturated. Nevertheless, a few additional equations are sometimes very useful for converting from one relationship to another.

Four distinct relationships combine to form the equation

$$Se = wG_s \tag{15.21}$$

For saturated soils $S = 100\%$, and this can be written

$$e = wG_s \tag{15.22}$$

The total unit weight can be obtained using the following:

$$\gamma = \frac{(G_s + Se)\gamma_w}{1 + e} = \frac{(1 + w)\gamma_w}{w/S + 1/G_s} \tag{15.23}$$

The dry unit weight can be obtained using the following:

$$\gamma_d = \frac{G_s \gamma_w}{1 + e} = \frac{G_s \gamma_w}{1 + (wG_s/S)} \tag{15.24}$$

Example 15.6 can be reworked using the equations as follows:

$$Se = wG_s$$

$$S = wG_s/e = (0.30)(2.75)/0.850 = 0.971 = 97.1\%$$

$$n = \frac{e}{1 + e} = \frac{0.850}{1 + 0.850} = 0.459$$

$$\gamma = \frac{(1 + w)\gamma_w}{w/S + 1/G_s} = \frac{(1.30)(9.81)}{(0.30/0.971) + (1/2.75)} = 18.96 \text{ kN/m}^3$$

$$\gamma_d = \frac{G_s \gamma_w}{1 + e} = \frac{(2.75)(9.81)}{1.85} = 14.58 \text{ kN/m}^3$$

The discrepancy in the fourth decimal place for the unit weight γ is due to rounding and the use of only three significant figures in the input values.

Defining Terms

Section 15.1

AASHTO classification system — A classification system developed by the American Association of State Highway and Transportation Officials that rates soils relative to their suitability for road embankments, subgrades, subbases, and basis.

Atterberg limits — Water contents at which soil changes engineering behavior; the most important ones in classification are the liquid limit and plastic limit.

Boulders — Rock particles larger than 9 to 12 inches or 200 to 300 mm.

Clay — Fine-grained soil that exhibits plasticity.

Coarse grained — Soils that are retained on a No. 200 sieve.

Coarse fraction — In the Unified Soil Classification System, that portion of a soil sample retained on a No. 200 sieve.

Cobbles — Rock particles smaller than a boulder but larger than 3 inches (75 mm).

Coefficient of curvature — A mathematical parameter, $D_{30}^2/(D_{60}D_{10})$, used as a measure of the smoothness of a gradation curve.

Coefficient of uniformity — A mathematical parameter, D_{60}/D_{10}, used as a measure of the slope of a gradation curve.

D_{10} size — The grain size, in mm, for which 10% by weight of a soil sample is finer.

Effective grain size — Another name for the D_{10} size.

Fat clay — Highly plastic clay; clay with a liquid limit greater than 50.

Fine fraction — In the unified soil classification system, that portion of a soil sample passing a No. 200 sieve.

Fine grained — Soil passing a No. 200 sieve.

Grain-size analysis — The determination of the relative proportions of soil particles of each size in a soil sample, performed by passing the sample over a nest of sieves.

Grain-size distribution curve — A plot of percent finer or coarser versus soil-grain size. Grain size is plotted on a logarithmic scale.

Granular material — In the AASHTO classification system, soil with less than 35% passing the No. 200 sieve.

Gravel — Soil or rock particles smaller than 3 inches but retained on a No. 4 sieve (Unified Soil Classification System) or on a No. 10 sieve (AASHTO system).

Lean clay — Clay with low plasticity; clay with a liquid limit less than 50.

Liquid limit — The water content above which soil behavior changes from a plastic solid to a viscous liquid.

Median grain size — The grain size for which one-half of a soil sample, by weight, is larger and half is smaller.

Nest of sieves — A stack of sieves of different sizes, having the largest opening on the top and progressing downward to successively smaller openings.

Peat — A highly organic soil, dark brown to black in color, with noticeable organic odor and visible vegetable matter.

Plastic limit — The water content above which the soil behavior changes from a brittle solid to a plastic solid.

Plasticity — The ability of a soil, when mixed with water, to deform at constant volume.

Plasticity index — The difference between the liquid and plastic limit.

Sand — Soil particles retained on the No. 200 sieve that pass the No. 4 sieve (Unified Soil Classification System) or the No. 10 sieve (AASHTO system).

Shrinkage limit — The water content at which further reduction in water content does not cause a further reduction in volume.

Sieve analysis — A grain-size analysis using a nest of sieves.

Silt — Fine-grained soil having a low plasticity index or not exhibiting plasticity.

Unified Soil Classification System — A descriptive classification system based on Casagrande's airfield system and now standardized by ASTM D 2487-93.

Section 15.2

Buoyant unit weight — The apparent unit weight of a submerged soil, obtained as the total unit weight minus the weight of water.

Compaction mold — A metal mold, typically 1/30 ft^3, used to determine the density of compacted soil.

Degree of saturation — The ratio of the volume of water to the volume of void space in a sample of soil.

Density — The mass per unit volume of a soil or one of its components.

Dry density — The ratio of the mass of solids to the total volume of a soil sample.

Dry unit weight — The ratio of the weight of solids to the total volume of a soil sample.

Effective unit weight — Another term for buoyant unit weight.

Porosity — The ratio of the volume of void spaces to the total volume of a soil sample.

Saturated — The condition in which all of the void spaces in a soil are filled with water and the volume of air is zero.

Saturated unit weight — The unit weight obtained if a soil sample is saturated by adding water at constant total volume.

Specific gravity — The ratio of the density of a material to the density of water; usually refers to the specific gravity of soil solids.

Total unit weight — The total combined weight of solids and water in a unit volume of soil.

Unit weight — The ratio of the weight of a material to its volume.

Void ratio — The ratio of the volume of void space in a soil sample to the volume of solid particles.

Water content — The ratio of the weight of water to the weight of solids of a soil sample.

Further Information

The development and underlying philosophy of the Unified Soil Classification System was summarized by Casagrande [1948]. The complete and official rules for classifying soil according to the Unified Soil Classification System are given in ASTM Designation D 2487-92. The complete and official rules for classifying soil according to the AASHTO classification system is given in AASHTO Standard M 145-87. The procedures for performing index tests related to soil classification are specified in the other AASHTO and ASTM standards listed in the references.

A more detailed presentation of soil relationships and classification is given in most introductory geotechnical engineering textbooks. Two notable examples are *An Introduction to Geotechnical Engineering* by Holtz and Kovacs and *Principles of Geotechnical Engineering* by B. M. Das.

16.1 Introduction

The trend in civil engineering today, more than ever before, is toward providing economical designs at specified levels of safety. Often these objectives necessitate a prediction of the performance of a system for which there exists little or no previous experience. Current design procedures, which are generally learned only after many trial-and-error iterations, lacking precedence, often fall short of expectations in new or alien situations. In addition, there is an increasing awareness that the raw data, on which problem solutions are based, themselves exhibit significant variability. It is the aim of this presentation to demonstrate how concepts of probability analysis may be used to supplement the geotechnical engineer's judgment in such matters.

16.2 Probabilistic Preliminaries

Fundamentals

Within the context of engineering usage there are two primary definitions of the concept of probability: *relative frequency* and *subjective* interpretation. Historically, the measure first offered for the probability of an outcome was its relative frequency. If an outcome A can occur T times in N equally likely trials, the probability of the outcome A is

$$P[A] = \frac{T}{N} \tag{16.1a}$$

Implied in Eq. (16.1a) is that the probability of an outcome A equals the number of outcomes favorable to A (within the meaning of the experiment) divided by the total number of possible outcomes, or

$$P[A] = \frac{\text{Favorable outcomes}}{\text{Total possible outcomes}} \tag{16.1b}$$

Example 16.1

Find the probability of drawing a red card from an ordinary well-shuffled deck of 52 cards.

Solution. Of the 52 equally likely outcomes, there are 26 favorable (red card) outcomes. Hence,

$$P[\text{drawing red card}] = \frac{26}{52} = \frac{1}{2}$$

Understood in the example is that if one were to repeat the process a large number of times, a red card would appear in one-half of the trials. This is an example of the relative frequency interpretation. Now, what meaning could be associated with the statement, "The probability of the failure of a proposed structure is 1% ($P[\text{failure}] = 0.01$)"? The concept of repeated trials is meaningless: the structure will be built only once, and it will either fail or be successful during its design lifetime. It cannot do both. Here we have an example of the subjective interpretation of probability. It is a measure of information as to the likelihood of the occurrence of an outcome.

Subjective probability is generally more useful than the relative frequency concept in engineering applications. However, the basic rules governing both are identical. As an example, we note that both concepts specify the probability of an outcome to range from zero to one, inclusive. The lower limit indicates there is no likelihood of occurrence; the upper limit corresponds to a certain outcome.

$$\langle \textbf{Axiom I} \rangle \qquad 0 \le P[A] \le 1 \tag{16.2a}$$

The certainty of an outcome C is a probability of unity:

$$\langle \textbf{Axiom II} \rangle \qquad P[C] = 1 \tag{16.2b}$$

Equations (16.2a) and (16.2b) provide two of the three axioms of the theory of probability. The third axiom requires the concept of *mutually exclusive* outcomes. Outcomes are mutually exclusive if they cannot occur simultaneously. The third axiom states the probability of the occurrence of the sum of a number of mutually exclusive outcomes $A(1), A(2), \ldots, A(N)$ is the sum of their individual probabilities (addition rules), or

$$\langle \textbf{Axiom III} \rangle \qquad P[A(1) + A(2) + \cdots + A(N)] = P[A(1)] + P[A(2)] + \cdots + P[A(N)] \tag{16.2c}$$

As a very important application of these axioms consider the proposed design of a structure. After construction, only one of two outcomes can be obtained in the absolute structural sense: either it is successful or it fails. These are mutually exclusive outcomes. They are also exhaustive in that, within the sense of the example, no other outcomes are possible. Hence, the second axiom, Eq. (16.2b), requires

$$P[\text{success} + \text{failure}] = 1$$

Since they are mutually exclusive, the third axiom specifies that

$$P[\text{success}] + P[\text{failure}] = 1$$

The **probability** of the success of a structure is called its **reliability**, R. Symbolizing the probability of failure as $p(f)$, we have the important expression

$$R + p(f) = 1 \tag{16.3}$$

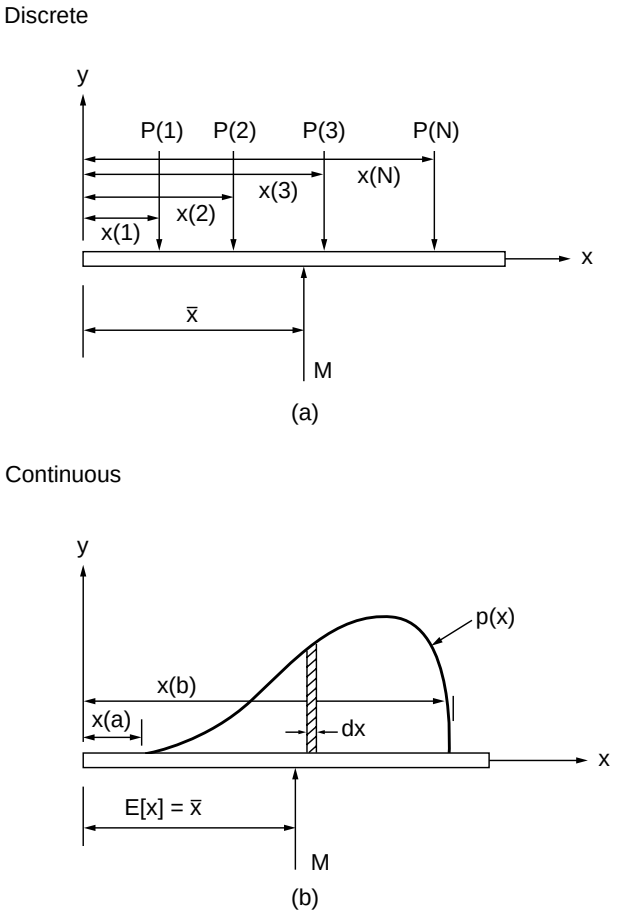

FIGURE 16.1 Equilibrant for discrete and continuous distributions.

Moments

Consider a system of *discrete* parallel (vertical) forces, $P(1)$, $P(2)$, …, $P(N)$, acting on a rigid beam at the respective distances $x(1), x(2), \ldots, x(N)$, as in Fig. 16.1(a). From statics we have that the magnitude of the *equilibrant, M*, is

$$M = \sum_{i=1}^{N} P(i) \tag{16.4a}$$

and its point of application, $\bar{x}$, is

$$\bar{x} = \frac{\sum_{i=1}^{N} x(i)P(i)}{\sum_{i=1}^{N} P(i)} \tag{16.4b}$$

For a continuously distributed parallel force system [Fig. 16.1(b)] over a finite distance, say from $x(a)$ to $x(b)$, the corresponding expressions are

$$M = \int_{x(a)}^{x(b)} p(x)dx \tag{16.5a}$$

and

$$\bar{x} = \frac{\int_{x(a)}^{x(b)} xp(x)dx}{M} \tag{16.5b}$$

Suppose now that the discrete forces $P(i)$ in Fig. 16.1(a) represent the frequencies of the occurrence of the N outcomes $x(1)$, $x(2)$, …, $x(N)$. As the distribution is exhaustive, from axiom II, Eq. (16.2b), the magnitude of the equilibrant must be unity, $M = 1$. Hence, Eq. (16.4b) becomes

$$\langle \text{Discrete} \rangle \quad E[x] = \bar{x} = \sum_{i=1}^{N} x(i)P(i) \tag{16.6a}$$

Similarly, for the continuous distribution [Fig. 16.1(b)], as all probabilities $p(x)\,dx$ must lie between $x(a)$ and $x(b)$, in Eq. (16.5a) $M = 1$. Hence, Eq. (16.5b) becomes

$$\langle \text{Continuous} \rangle \quad E[x] = \bar{x} = \int_{x(a)}^{x(b)} xp(x)dx \tag{16.6b}$$

The symbol $E[x]$ in Eqs. (16.6) is called the **expected value** or the **expectation** or simply the *mean* of the variable x. As is true of the equilibrant, it is a measure of the central tendency, the *center of gravity* in statics.

Example 16.2

What is the expected value of the number of dots that will appear if a fair die is tossed?

Solution. Here each of the possible outcomes 1, 2, 3, 4, 5, and 6 has the equal probability of $P(i) = 1/6$ of appearing. Hence, from Eq. (16.6a),

$$E[\text{toss of a fair die}] = \frac{1}{6}[1 + 2 + 3 + 4 + 5 + 6] = 3.5$$

We note in the above example that the expected value of 3.5 is an impossible outcome. There is no face on the die that will show 3.5 dots; however, it is still the best measure of the central tendency.

Example 16.3

Find the expected value of a continuous probability distribution wherein all values are equally likely to occur (called a *uniform distribution,* Fig. 16.2) between $y(a) = 0$ and $y(b) = 1/2$.

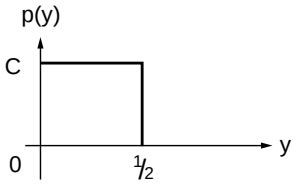

FIGURE 16.2 Uniform distribution.

Solution. From Eq. (16.5a), as $M = 1$ and $p(y) = C$ is a constant, we have

$$1 = C\int_0^{1/2} dy, \qquad C = 2$$

From Eq. (16.6b), $E[y] = 2\int_0^{1/2} y\,dy = 1/4$, as expected.

As the variables x and y in the above examples are determined by the outcomes of random experiments, they are said to be **random variables**. In classical probability theory, random variables are generally represented by capital letters, such as X and Y. The individual values are customarily denoted by their corresponding lowercase letters, x and y; however, no such distinction will be made here.

The expected value (mean) provides the locus of the central tendency of the distribution of a random variable. To characterize other attributes of the distribution, recourse is had to higher moments. Again, returning to statics, a measure of the dispersion of the distribution of the force system about the centroidal axis, at $x = E[x]$ in Fig. 16.1(b), is given by the *moment of inertia* (the *second central moment*),

$$I(y) = \int_{x(a)}^{x(b)} (x-\bar{x})^2 p(x)dx \tag{16.7}$$

The equivalent measure of the scatter (variability) of the distribution of a random variable is called its **variance**, denoted in this text as $v[x]$ and defined as

$$\langle \text{Discrete} \rangle \quad v[x] = \sum_{\text{all } x(i)} [x(i)-\bar{x}]^2 p(i) \tag{16.8a}$$

$$\langle \text{Continuous} \rangle \quad v[x] = \int_{x(a)}^{x(b)} (x-\bar{x})^2 p(x)dx \tag{16.8b}$$

In terms of the expectation these can be written as

$$v[x] = E[(x-\bar{x})^2] \tag{16.9}$$

which, after expansion, leads to a form more amenable to computations:

$$v[x] = E[x^2] - (E[x])^2 \tag{16.10}$$

This expression is the equivalent of the parallel-axis theorem for the moment of inertia.

Example 16.4

Find the expected value and the variance of the *exponential distribution,* $p(x) = a \exp(-ax)$; $x > 0$, a is a constant.

Solution. We first show that $p(x)$ is a valid probability distribution:

$$\int_0^\infty p(x)dx = a\int_0^\infty e^{-ax}dx = 1, \quad \text{Q.E.D.}$$

The expected value is

$$E[x] = a\int_0^\infty xe^{-ax}dx = \frac{1}{a}$$

Continuing,

$$E[x^2] = a\int_0^\infty x^2e^{-ax}dx = \frac{2}{a^2}$$

whence, using Eq. (16.10),

$$v[x] = \frac{2}{a^2} - \left(\frac{1}{a}\right)^2 = \frac{1}{a^2}$$

It is seen that the variance has the units of the square of those of the random variable. A more meaningful measure of dispersion of a random variable (x) is the positive square root of its variance (compare with radius of gyration of mechanics) called the **standard deviation**, $\sigma[x]$,

$$\sigma[x] = \sqrt{v[x]} \tag{16.11}$$

From the results of the previous example, it is seen that the standard deviation of the exponential distribution is $\sigma[x] = 1/a$.

An extremely useful relative measure of the scatter of a random variable (x) is its *coefficient of variation* $V(x)$, usually expressed as a percentage:

$$V(x) = \frac{\sigma[x]}{E[x]} \times 100(\%) \tag{16.12}$$

For the exponential distribution we found, $\sigma[x] = 1/a$ and $E[x] = 1/a$, hence V (exponential distribution) = 100%. In Table 16.1 representative values of the coefficients of variation of some parameters common to civil engineering design are given. Original sources should be consulted for details.

The coefficient of variation expresses a measure of the reliability of the central tendency. For example, a mean value of a parameter of 10 with a coefficient of variation of 10% would indicate a standard deviation of 1, whereas a similar mean with a coefficient of variation of 20% would demonstrate a standard deviation of 2. The coefficient of variation has been found to be a fairly stable measure of variability for homogeneous conditions. Additional insight into the standard deviation and the coefficient of variation as measures of uncertainty is provided by Chebyshev's inequality [for the derivation see Lipschutz, 1965].

The spread of a random variable is often spoken of as its *range*, the difference between the largest and smallest outcomes of interest. Another useful measure is the range between the mean plus-and-minus h standard deviations, $\bar{x} + h\sigma[x]$, called the *h-sigma bounds* (see Fig. 16.3). If x is a random variable with mean value $\bar{x}$ and standard deviation σ, then Chebyshev's inequality states

$$P(\bar{x} - h\sigma) \le x \le (\bar{x} + h\sigma) \ge \frac{1}{h^2} \tag{16.13}$$

In words, it asserts that for any probability distribution (with finite mean and standard deviation) the probability that random values of the variate will lie within h-sigma bounds is at least $[1 - (1/h^2)]$. Some numerical values are given in Table 16.2. It is seen that quantitative probabilistic statements can be made without complete knowledge of the probability distribution function; only its expected value and coefficient of variation (or standard deviation) are required. In this regard, the values for the coefficients of variation given in Table 16.1 may be used in the absence of more definitive information.

Example 16.5

The expected value for the ϕ-strength parameter of a sand is 30°. What is the probability that a random sample of this sand will have a ϕ-value between 20° and 40°?

Solution. From Table 16.1, $V(\phi) = 12\%$; hence, $\sigma[\phi]$ is estimated to be $(0.12)(30) = 3.6°$ and $h = (\phi - \bar{\phi})/\sigma = 10°/3.6° = 2.8$. Hence, $P[20° \le \phi \le 40°] \ge 0.87$. That is, the probability is at least 0.87 that the ϕ-strength parameter will be between 20° and 40°.

If the unknown probability distribution function is symmetrical with respect to its expected value and the expected value is also its maximum value (said to be *unimodal*), it can be shown [Freeman, 1963] that

$$P[(\bar{x} - h\sigma) \le x \le (\bar{x} + h\sigma)] \le 1 - \frac{4}{9h^2} \tag{16.14}$$

This is sometimes called *Gauss's inequality.* Some numerical values are given in Table 16.2.

Example 16.6

Repeat the previous example if it is assumed that the distribution of the ϕ-value is symmetrical with its maximum at the mean value ($\bar{\phi} = 30°$).

Solution. For this case, Gauss's inequality asserts

TABLE 16.2 Probabilities for Range of Expected Values ± h-Sigma Units

h	Chebyshev's Inequality	Gauss's Inequality	Exact Exponential Distribution	Exact Normal Distribution	Exact Uniform Distribution
½	0	0	0.78	0.38	0.29
1	0	0.56	0.86	0.68	0.58
2	0.75	0.89	0.95	0.96	1.00
3	0.89	0.95	0.982	0.9973	1.00
4	0.94	0.97	0.993	0.999934	1.00

$$P[20° \le \phi \le 40°] \ge 1 - \frac{4}{9(2.8)^2} \ge 0.94$$

Recognizing symmetry we can also claim $P[\phi \le 20°] = P[\phi \ge 40°] = 0.03$.

Example 16.7

Find the general expression for the probabilities associated with h-sigma bounds for the exponential distribution, $h \ge 1$.

Solution. From Example 16.4, we have (with $E[x] = 1/a$, $\sigma[x] = 1/a$)

$$P[(\bar{x} - h\sigma) \le x \le (x + h\sigma)] = \int_0^{(h+1)/a} ae^{-ax}dx = 1 - e^{-(h+1)}$$

Some numerical values are given in Table 16.2. The normal distribution noted in this table will be developed subsequently.

The results in Table 16.2 indicate that lacking information concerning a probability distribution beyond its first two moments, from a practical engineering point of view, it may be taken to range within 3-sigma bounds. That is, in Fig. 16.1(b), $x(a) \approx \bar{x} - 3\sigma[x]$ and $x(b) \approx \bar{x} + 3\,\sigma[x]$.

For a symmetrical distribution all moments of odd order about the mean (central moments) must be zero. Consequently, any odd-ordered moment may be used as a measure of the degree of *skewness*, or *asymmetry*, of a probability distribution. The third central moment $E[(x - \bar{x})^3]$ provides a measure of the peakedness (called *kurtosis*) of a distribution.

As the units of the third central moment are the cube of the units of the variable, to provide an absolute measure of skewness, Pearson [1894, 1895] proposed that its value be divided by the standard deviation cubed to yield the dimensionless *coefficient of skewness*,

$$\beta(1) = \frac{E[(x - \bar{x})^3]}{(\sigma[x])^3} \tag{16.15}$$

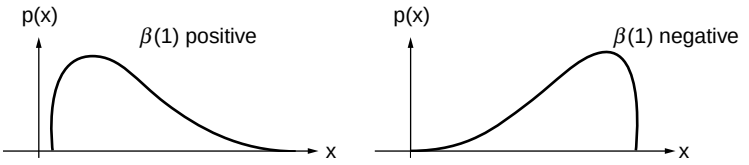

FIGURE 16.4 Coefficient of skewness.

If $\beta(1)$ is positive, the long tail of the distribution is on the right side of the mean; if it is negative, the long tail is on the left side (see Fig. 16.4). Pearson also proposed the dimensionless *coefficient of kurtosis* as a measure of peakedness:

$$\beta(2) = \frac{E[(x-\bar{x})^4]}{(\sigma[x])^4} \tag{16.16}$$

In Fig. 16.5 are shown the regions occupied by a number of probability distribution types, as delineated by their coefficients of skewness and kurtosis. Examples of the various types are shown schematically.

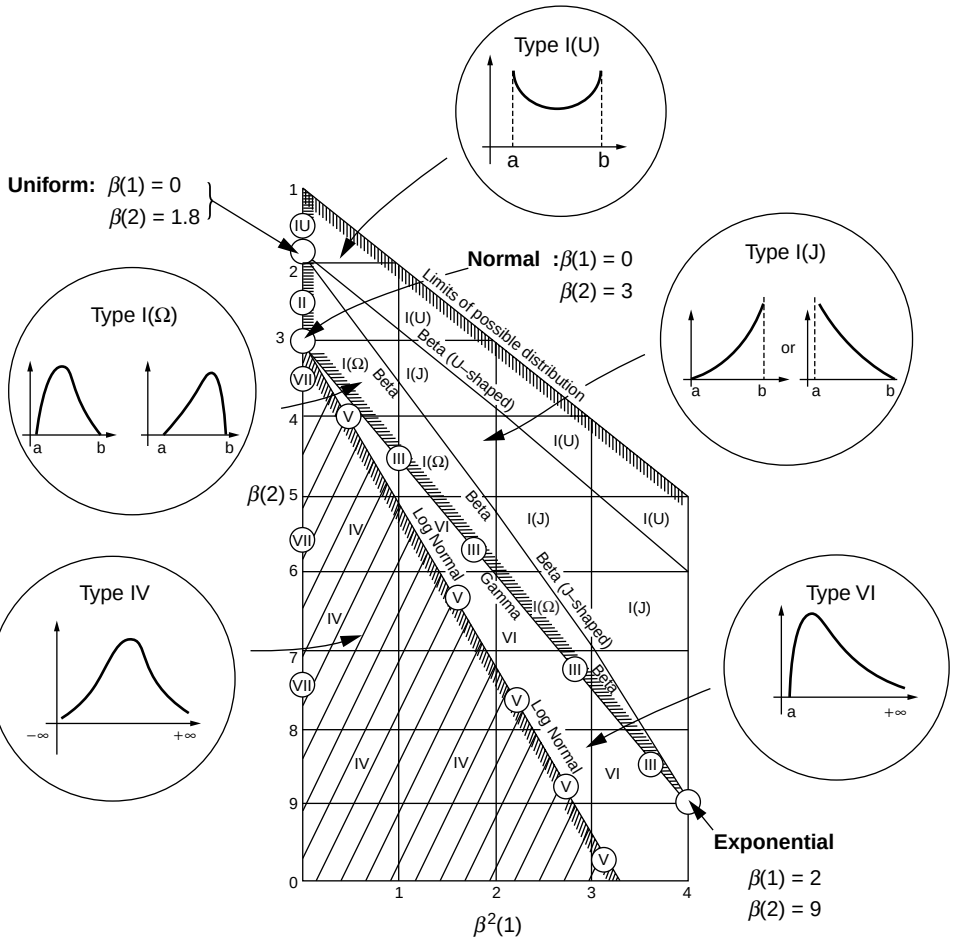

FIGURE 16.5 Space of probability distributions. (After Pearson, E. S. and Hartley, H. O. 1972. *Biometrika Tables for Statisticians,* Vol. II. Cambridge University Press, London.)

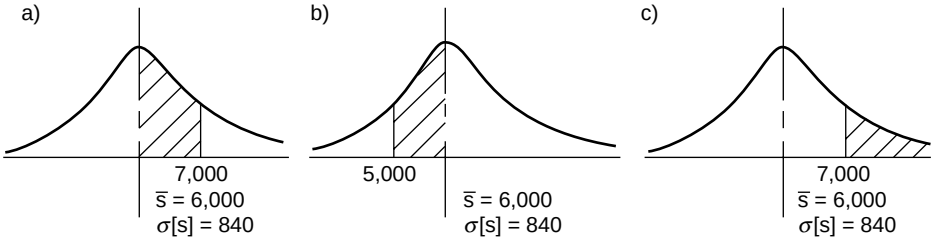

FIGURE 16.6

16.3 Probability Distributions

We note in Fig. 16.5 that the type IV distribution and the symmetrical type VII are unbounded (infinite) below and above. From the point of view of civil engineering applications this represents an extremely unlikely distribution. For example, all parameters or properties (see Table 16.1) are positive numbers (including zero).

The type V (the lognormal distribution), type III (the gamma), and type VI distributions are unbounded above. Hence, their use would be confined to those variables with an extremely large range of possible values. Some examples are the coefficient of permeability, the state of stress at various points in a body, the distribution of annual rainfall, and traffic variations.

The normal (Gaussian) distribution $[\beta(1) = 0, \beta(2) = 3]$, even though it occupies only a single point in the universe of possible distributions, is the most frequently used of probability models. Some associated properties were given in Table 16.2. The normal distribution is the well-known symmetrical bell-shaped curve (see Fig. 16.6). Some tabular values are given in Table 16.3. The table is entered by forming the standardized variable z for the normal variate x as

$$z = \left| \frac{x - \bar{x}}{\sigma[x]} \right| \tag{16.17}$$

Tabular values yield the probabilities associated with the shaded areas shown in the figure: area $= \psi(z)$.

Example 16.8

Assuming the strength s of concrete to be a normal variate with an expected value of $\bar{s} = 6000$ psi and a coefficient of variation of 14%, find (a) $P[6000 \le s \le 7000]$, (b) $P[5000 \le s \le 6000]$, and (c) $P[s \ge 7000]$.

Solution. The standard deviation is $\sigma[s] = (0.14)(6000) = 840$ psi. Hence (see Fig. 16.6),

- $z = |(7000 - 6000)/840| = 1.19$, $\psi(1.19) = 0.383$.
- By symmetry, $P[5000 \le s \le 6000] = 0.383$.
- $P[s \ge 7000] = 0.500 - 0.383 = 0.117$.

As might be expected from its name, the lognormal distribution (type V) is related to the normal distribution. If x is a normal variate and $x = \ln y$ or $y = \exp(x)$ then y is said to have a lognormal distribution. It is seen that the distribution has a minimum value of zero and is unbounded above. The probabilities associated with lognormal variates can be obtained very easily from those of mathematically corresponding normal variates (see Table 16.3). If $E(y)$ and $V(y)$ are the expected value and coefficient of variation of a lognormal variate, the corresponding normal variate x will have the expected value and standard deviation [Benjamin and Cornell, 1970]:

$$(\sigma[x])^2 = \ln\{1 + [V(y)]^2\} \tag{16.18a}$$

$$E[x] = \ln E(y) - (\sigma[x])^2/2 \tag{16.18b}$$

Example 16.9

A live load of 20 kips is assumed to act on a footing. If the loading is assumed to be lognormally distributed, estimate the probability that a loading of 40 kips will be exceeded.

Solution. From Table 16.1 we have that the coefficient of variation for a live load, L, can be estimated as 25%; hence, from Eqs. (16.18) we have for the corresponding normal variate, x,

$$\sigma[x] = \sqrt{\ln[1 + (0.25)^2]} = 0.25 \tag{16.19a}$$

and

$$E[x] = \ln 20 - (0.25)^2/2 = 2.96 \tag{16.19b}$$

As $x = \ln L$, the value of the normal variate x equivalent to 40 K is $\ln 40 = 3.69$. We seek the equivalent normal probability $P[3.69 \le x]$. The standardized normal variate is $z = (3.69 - 2.96)/0.25 = 2.92$. Hence, using Table 16.3,

$$P[40 \le L] = 0.50 - \psi(2.92) = 0.500 - 0.498 = 0.002 \tag{16.20}$$

As was noted with respect to Fig. 16.5 many and diverse distributions (as well as the normal, lognormal, uniform, and exponential) can be obtained from the very versatile beta distribution. The beta distribution is treated in great detail by Harr [1977, 1987]. The latter reference also contains FORTRAN programs for beta probability distributions. Additional discussion is given below following Example 16.11.

16.4 Point Estimate Method — One Random Variable

Various probabilistic methods have been developed that yield measures of the distribution of functions of random variables [Harr, 1987]. The simple and very versatile procedure called the *point estimate method* (PEM) is advocated by this writer and will be developed in some detail. This method, first presented by Rosenblueth [1975] and later extended by him in 1981, has since seen considerable use and expansion by this writer and his coauthors (see references). The methodology is presented in considerable detail in Harr [1987].

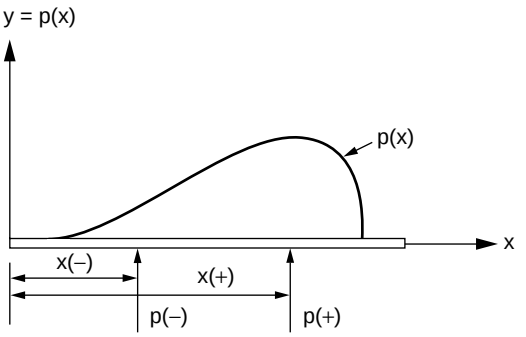

FIGURE 16.7 Point estimate approximations.

Consider $y = p(x)$ to be the probability distribution of the random variable x. With analogy to Fig. 16.1, we replace the load on the beam by two reactions, $p(-)$ and $p(+)$, acting at $x(-)$ and $x(+)$, as shown in Fig. 16.7.

Pleading symmetry, probabilistic arguments produce for a random variable x:

$$p(+) = p(-) = \tfrac{1}{2} \tag{16.21a}$$

$$x(+) = \bar{x} + \sigma[x] \tag{16.21b}$$

$$x(-) = \bar{x} - \sigma[x] \tag{16.21c}$$

With the distribution $p(x)$ approximated by the point estimates $p(-)$ and $p(+)$, the moments of $y = p(x)$ are

$$E[y] = \bar{y} = p(-)y(-) + p(+)y(+) \tag{16.22a}$$

$$E[y^2] = p(-)y^2(-) + p(+)y^2(+) \tag{16.22b}$$

where $y(-)$ and $y(+)$ are the values of the function $p(x)$ at $x(-)$ and $x(+)$, respectively. These reduce to the simpler expressions

$$\bar{y} = \frac{y(+) + y(-)}{2} \tag{16.23a}$$

$$\sigma[y] = \left| \frac{y(+) - y(-)}{2} \right| \tag{16.23b}$$

Example 16.10

Estimate the expected value and the coefficient of variation for the well-known coefficient of active earth pressure $K_A = \tan^2(45 - \phi/2)$, if $\bar{\phi} = 30$.

Solution. With the standard deviation of the ϕ-parameter not given, we again return to Table 16.1, $V(\phi) = 12\%$, and $\sigma[\phi] = 3.6^\circ$. Hence, $\phi(+) = 33.6^\circ$, $\phi(-) = 26.4^\circ$. Hence, $K_A(+) = 0.29$, $K_A(-) = 0.38$, and Eqs. (16.23) produce $\bar{K}_A = 0.34$, $\sigma[K_A] = 0.05$; hence, $V(K_A) = 13\%$.

16.5 Regression and Correlation

Thus far, only one-dimensional (*univariate*) random variables have been considered. More generally, concern is directed toward *multivariate formulations,* wherein there are two or more random variables. As an example, consider the *flexure formula*

$$s = Mc/I$$

where s is the stress at the extreme fiber at a distance c from the neutral axis acted on by a bending moment M for a beam in which I is the moment of inertia of the section. If the parameters M, c, and I are random variables (possess uncertainty), what can be said about the unit stress s? Needless to say, granted the probability distribution function of the stress, statements could be made with respect to the reliability of the beam relative to, say, a maximum allowable stress $\hat{s}$; for example,

$$\text{Reliability} = P[s \leq \hat{s}]$$

We first study the functional relationship between random variables called ***regression*** *analysis*. It is regression analysis that provides the grist of being able to predict the value of one variable from that of another or of others. The measure of the degree of correspondence within the developed relationship belongs to *correlation analysis.*

Let us suppose we have N pairs of data $[x(1), y(1)]$, …, $[x(N), y(N)]$ for which we postulate the linear relationship

$$y = Mx + B \tag{16.24}$$

where M and B are constants. Of the procedures available to estimate these constants (including best fit by eye), the most often used is the *method of least squares*. This method is predicated on minimizing the sum of the squares of the distances between the data points and the corresponding points on a straight line. That is, M and B are chosen so that

$$\Sigma(y - Mx - B)^2 = \text{Minimum}$$

This requirement is met by the expressions

$$M = \frac{N\Sigma xy - \Sigma x\,\Sigma y}{N\Sigma x^2 - (\Sigma x)^2} \tag{16.25a}$$

$$B = \frac{\Sigma x^2 \Sigma y - \Sigma x \Sigma xy}{N\Sigma x^2 - (\Sigma x)^2} \tag{16.25b}$$

It should be emphasized that a straight line fit was assumed. The reasonableness of this assumption is provided by the **correlation coefficient** ρ, defined as

$$\rho = \frac{\mathrm{cov}\,[x, y]}{\sigma[x]\sigma[y]} \tag{16.26}$$

where $\sigma[x]$ and $\sigma[y]$ are the respective standard deviations and $\mathrm{cov}[x, y]$ is their *covariance*. The covariance is defined as

$$\mathrm{cov}\,[x, y] = \frac{1}{N}\sum_{i=1}^{N}[x(i) - \bar{x}][y(i) - \bar{y}] \tag{16.27}$$

With analogy to statics the covariance corresponds to the product of inertia.

In concept, the correlation coefficient is a measure of the tendency for two variables to vary together. This measure may be zero, negative, or positive; wherein the variables are said to be *uncorrelated, negatively correlated,* or *positively correlated*. The variance is a special case of the covariance as

$$\mathrm{cov}\,[x, x] = v[x] \tag{16.28}$$

Application of their definitions produces [Ditlevsen, 1981] the following identities (a, b, and c are constants):

$$E[a + bx + cy] = a + bE[x] + cE[y] \tag{16.29a}$$

$$v[a + bx + cy] = b^2 v[x] + c^2 v[y] + 2bc\ \mathrm{cov}[x, y] \tag{16.29b}$$

$$\mathrm{cov}\,[x, y] \le \sigma[x]\sigma[y] \tag{16.29c}$$

$$v[a + bx + cy] = b^2 v[x] + c^2 v[y] + 2bc\sigma[x]\sigma[y]\rho \tag{16.29d}$$

Equation (16.29c) demonstrates that the correlation coefficient, Eq. (16.26), must satisfy the condition

$$-1 \le \rho \le +1 \tag{16.30}$$

If there is perfect correlation between variables in the same direction, $\rho = +1$. If there is perfect correlation in opposite directions (one variable increases as the other decreases), $\rho = -1$. If some scatter exists, $-1 < \rho < +1$, with $\rho = 0$ if there is no correlation. Some examples are shown in Fig. 16.8.

16.6 Point Estimate Method — Several Random Variables

Rosenblueth [1975] generalized the methodology for any number of correlated variables. For example, for a function of three random variables — say, $y = y[x(1), x(2), x(3)]$ — where $\rho(i, j)$ is the correlation coefficient between variables $x(i)$ and $x(j)$,

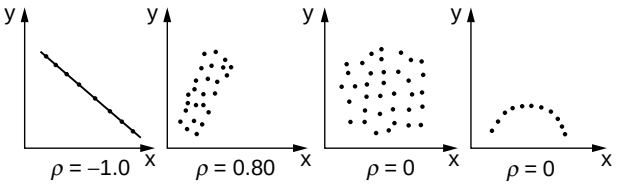

FIGURE 16.8 Example of scatter and correlation coefficients.

$$E[y^N] = p(+++)y^N(+++) + p(++-)y^N(++-) + \cdots + p(---)y^N(---) \tag{16.31a}$$

where

$$y(\pm\pm\pm) = y[\bar{x}(1) \pm \sigma[x1], \bar{x}(2) \pm \sigma[x2], \bar{x}(3) \pm \sigma[x3]] \tag{16.31b}$$

$$p(+++) = p(---) = \frac{1}{2^3}[1 + \rho(1,2) + \rho(2,3) + \rho(3,1)]$$

$$p(++-) = p(--+) = \frac{1}{2^3}[1 + \rho(1,2) - \rho(2,3) - \rho(3,1)]$$

$$p(+-+) = p(-+-) = \frac{1}{2^3}[1 - \rho(1,2) - \rho(2,3) + \rho(3,1)]$$

$$p(+--) = p(-++) = \frac{1}{2^3}[1 - \rho(1,2) + \rho(2,3) - \rho(3,1)] \tag{16.31c}$$

where $\sigma[xi]$ is the standard deviation of $x(i)$. The sign of $\rho(i, j)$ is determined by the multiplication rule of i and j; that is, if the sign of $i = (-)$, and of $j = (+)$, then $(i)(j) = (-)(+) = (-)$.

Equation (16.31a) has $2^3 = 8$ terms, all permutations of the three + s and – s. In general for M variables there are 2^M terms and $M(M-1)/2$ correlation coefficients, the number of combinations of M objects taken two at a time. The coefficient on the right-hand side of Eqs. (16.31c), in general, is $(1/2)^M$.

Example 16.11

The recommendation of the American Concrete Institute [Galambos et al., 1982] for the design of reinforced concrete structures is (in simplified form)

$$R \geq 1.6D + 1.9L$$

where R is the strength of the element, D is the dead load, and L is the lifetime live load. (a) If $\bar{D} = 10$, $\bar{L} = 8$, $V(D) = 10\%$, $V(L) = 25\%$, and $\rho(D, L) = 0.75$, find the expected value and standard deviation of R for the case $R = 1.6D + 1.9L$. (b) If the results in part (a) generate a normal variate and the maximum strength of the element R is estimated to be 40, estimate the implied probability of failure.

Solution. The solution is developed in Fig. 16.9.

Generalizations of the PEM to more than three random variables are given by Harr [1987]. The PEM procedure yields the first two moments of the dependent random functions under consideration. Functional distributions must then be obtained and statements must be made concerning the probabilities of events. Inherent in the assumption of the form of a particular distribution is the imposition of the limits or range of its applicability. For example, for the normal it is required that the variable range from $-\infty$ to $+\infty$; the range of the lognormal and the exponential is 0 to $+\infty$. Such assignments may not be critical if knowledge of distributions is desired in the vicinity of their expected values and their coefficients

a) $R = 1.6D + 1.9L$

Variable, x	$\bar{x}$	$\sigma[x]$	x(+)	x(–)
D	10	1	11	9
L	8	2	10	6

$\rho(D,L) = +0.75$

	R(ij)	$R(ij)^2$
R(++):	36.6	1340
R(+–):	29.0	841
R(–+):	33.4	1116
R(––):	25.8	666

$p(++) = \frac{1}{4}(1+\rho) = 0.44$

$p(+-) = \frac{1}{4}(1-\rho) = 0.06$

$p(-+) = \frac{1}{4}(1-\rho) = 0.06$

$p(--) = \frac{1}{4}(1+\rho) = 0.44$

$E[R] = \bar{R} = \Sigma R(ij)p(ij)$
$= 0.44(36.6+25.8) + 0.06(29.0+33.4)$
$= \underline{31.20}$

$E[R^2] = \Sigma R(ij)^2 p(ij)$
$= 0.44(1340+666) + 0.06(841+1116)$
$= \underline{1000.06}$

$v[R] = E[R^2] - (E[R])^2 = 1000.06 - (31.20)^2 = \underline{26.62}$
$\sigma[R] = 5.16; \quad V(R) = 16.5\%$

From Eq. (15.29a), the exact solution for $E[R] = 1.6\,\bar{D} + 1.9\bar{L} = \underline{31.20}$
Eq. (15.29d), the exact solution for $v[R] = (1.6)^2 v[D] + (1.9)^2 v[L]$
$+ 2(1.6)(1.9)(1)(2)(0.75) = \underline{26.12}$

Of course, for this example the exact solution is easier to obtain.
This is not generally the case.

b) $P_f = P[R \geq 40] = \frac{1}{2} - \psi\left[\frac{40-31.20}{5.16}\right] = \frac{1}{2} - \psi[1.71] = \underline{0.044}$ (Table 3)

The exact solution is $\underline{0.043}$

FIGURE 16.9 Solution to Example 16.11.

of variation are not excessive (say, less than 25%). On the other hand, estimates of reliability (and of the probability of failure) are vested in the tails of distributions. It is in such characterizations that the beta distribution is of great value. If the limits are known, zero is often an option, and probabilistic statements can readily be obtained. In the event that limits are not defined, the specification of a range of the mean plus or minus three standard deviations would generally place the generated beta distribution well within the accuracy required by most geotechnical engineering applications (see Table 16.2).

16.7 Reliability Analysis

Capacity–Demand

The adequacy of a proposed design in geotechnical engineering is generally determined by comparing the estimated resistance of the system to that of the imposed loading. The resistance is the **capacity** C (or strength) and the loading is the induced **demand** D imposed on the structure. In the present writing, because of its greater generality, we shall use a *capacity– demand* concept. Some common examples are the bearing capacity of a soil and the column loads, allowable and computed maximum stresses, traffic

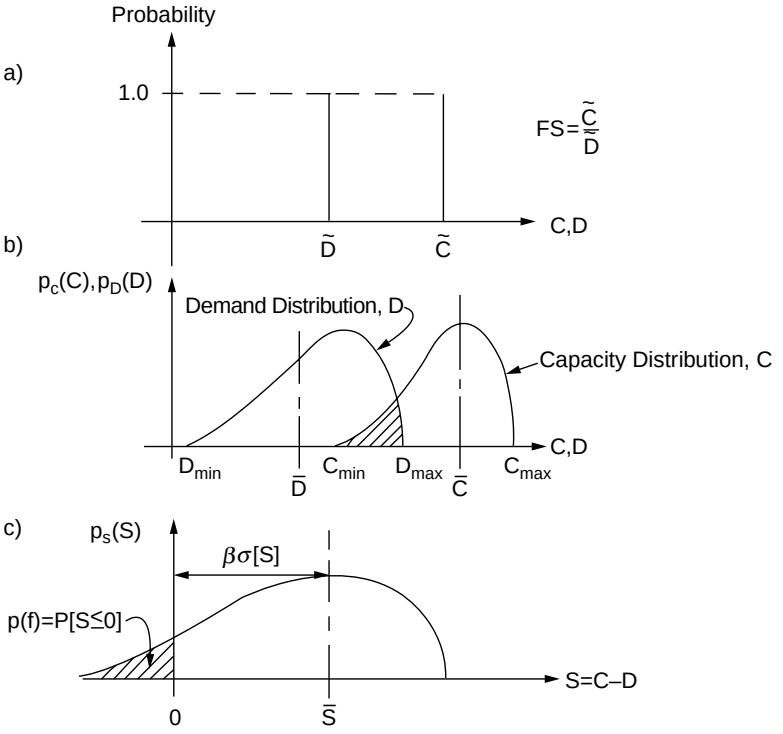

FIGURE 16.10 (a) Conventional factor of safety, (b) capacity–demand model, (c) safety margin.

capacity and anticipated traffic flow on a highway, culvert sizes and the quantity of water to be accommodated, and structural capacity and earthquake loads.

Conventionally, the designer forms the well-known factor of safety as the ratio of the single-valued nominal values of capacity $\bar{C}$ and demand $\bar{D}$ [Ellingwood et al., 1980], depicted in Fig. 16.10(a),

$$FS = \frac{\bar{C}}{\bar{D}} \tag{16.32}$$

For example, if the allowable load is 400 tons per square foot and the maximum calculated load is 250 tons per square foot, the conventional factor of safety would be 1.6. The design is considered satisfactory if the calculated factor of safety is greater than a prescribed minimum value learned from experience with such designs. Thus, in concept, in the above example, if a factor of safety of 1.6 was considered intolerable, the system would be redesigned to decrease the maximum induced load.

In general, the demand function will be the resultant of the many uncertain components of the system under consideration (vehicle loadings, wind loadings, earthquake accelerations, location of the water table, temperatures, quantities of flow, runoff, and stress history, to name only a few). Similarly, the capacity function will depend on the variability of material parameters, testing errors, construction procedures and inspection supervision, ambient conditions, and so on.

A schematic representation of the capacity and demand functions as probability distributions is shown in Fig. 16.10(b). If the maximum demand (D_{max}) exceeds the minimum capacity (C_{min}), the distributions overlap (shown shaded), and there is a nonzero probability of failure.

The difference between the capacity and demand functions is called the safety margin (S); that is,

$$S = C - D \tag{16.33}$$

Obviously, the safety margin is itself a random variable, as shown in Fig. 16.10(c). Failure is associated with that portion of its probability distribution wherein it becomes negative (shown shaded); that is, that portion wherein $S = C - D \leq 0$. As the shaded area is the probability of failure $p(f)$, we have

$$p(f) = P[(C - D) \leq 0] = P[S \leq 0] \tag{16.34}$$

Reliability Index

The number of standard deviations that the mean value of the safety margin is beyond $S = 0$, Fig. 16.10(c), is called the *reliability index*, β; that is,

$$\beta = \frac{\bar{S}}{\sigma[S]} \tag{16.35a}$$

The reliability index is seen (compare also with h-sigma bounds in Table 16.2) to be the reciprocal of the coefficient of variation of the safety margin, or

$$\beta = \frac{1}{V(S)} \tag{16.35b}$$

Example 16.12

Obtain a general expression for the reliability index in terms of the first two moments of the capacity and the demand functions.

Solution. From Eq. (16.29a) we have $E[S] = E[C] - E[D] = \bar{C} - \bar{D}$. Equation (16.29c) produces $\sigma^2[S] = \sigma^2[C] + \sigma^2[D] - 2\rho\sigma[C]\sigma[D]$. Hence,

$$\beta = \frac{\bar{C} - \bar{D}}{\sqrt{\sigma^2[C] + \sigma^2[D] - 2\rho\sigma[C]\sigma[D]}} \tag{16.36}$$

It is seen that β is a maximum for a perfect positive correlation and a minimum for a perfect negative correlation.

It can be shown that the sum of difference of two normal variates is also a normal variate [Haugen, 1968]. Hence, if it is assumed that the capacity and demand functions are normal variates, it follows directly from Example 16.12 that

$$p(f) = \frac{1}{2} - \psi[\beta] \tag{16.37}$$

where $\psi[\beta]$ is standard normal probability as given in Table 16.3.

16.8 Recommended Procedure

We list at this point some desirable attributes of a reliability-based design procedure:

1. It should account for the pertinent capacity and demand factors, their components, and their interactions.
2. It should produce outputs that can be related to the expected performance during the design life of the system under consideration.
3. It should employ as input into formulations quantities, parameters, or material characterizations that can be ascertained within the present state of the art.

4. It should not disregard indices currently considered to be pertinent, such as factor of safety or reliability index. It should serve to supplement this knowledge and reduce uncertainty.
5. Ideally, mathematical computations should be reduced to a minimum.

All of the above can be accommodated by an extension of the point estimate method. The recommended procedure is as follows, where applicable:

1. Using PEM, or an equally valid probabilistic formulation, obtain the expected values and standard deviations of the capacity and demand functions: $E[C]$, $E[D]$, $\sigma[C]$, $\sigma[D]$.
2. Calculate the expected value and standard deviation of the safety margin, $E[S]$, $\sigma[S]$.
3. Fit a beta distribution (and normal distribution, as a check) to the safety margin, using appropriate upper and lower bounds. If unknown, take them as $E[S] \pm 3\sigma[S]$; see Table 16.2.
4. Obtain the probability of failure, $p(f) = P[S \leq 0]$, the reliability, central factor of safety, and reliability index, as appropriate.

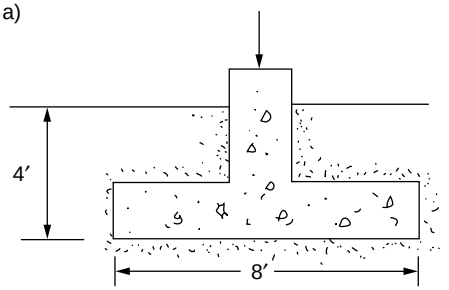
Example 16.13

The ultimate bearing capacity Q per unit length of a long footing of width B founded at a depth D below the ground surface, Fig. 16.11(a), is

$$Q = \frac{\gamma B^2}{2} N_\gamma + \gamma D B N_q + c B N_c$$

where γ is the unit weight of the soil, c is the c-parameter of strength (sometimes called the *cohesion*). The dimensionless factors N_γ, N_q, and N_c, called *bearing capacity factors,* are functions of the friction angle ϕ as given by the tabulated values in Fig. 16.11(b).

a)



b)

Bearing capacity factors

ϕ	N_γ	N_q	N_c
0	0.00	1.00	5.14
5	0.45	1.57	6.49
10	1.22	2.47	8.34
15	2.65	3.94	10.98
20	5.39	6.40	14.83
25	10.88	10.66	20.72
30	22.40	18.40	30.14
35	48.83	33.30	46.12
40	109.41	64.20	75.31
42.5	170.25	91.90	99.20
45	271.75	133.87	134.87
50	762.86	319.06	266.88

FIGURE 16.11 Example 16.13.

(a) A very long footing 8 ft wide is founded at a depth of 4 ft in a soil with the parameters

Parameter, x	Expected Value	Standard Deviation	$x(+)$	$x(-)$
g	110 lb/ft^3	0	110	110
f	35°	5°	40	30
c	200 lb/ft^2	80 lb/ft^2	280	120

The correlation coefficient $\rho(\phi, c) = -0.50$. Estimate the expected value and standard deviation of the bearing capacity.

(b) If a central factor of safety (CFS) of 4 is required and it is assumed that $V(D) = 50\%$, estimate the probability of failure.

Solution. (a) Forming the required values, as the bearing capacity factors are functions of ϕ only. From Fig. 16.11(b),

$$N_\gamma(+) = 109.41 \qquad N_\gamma(-) = 22.40$$
$$N_q(+) = 64.20 \qquad N_q(-) = 18.40$$
$$N_c(+) = 75.31 \qquad N_c(-) = 30.14$$

Forming the respective values, $Q(\phi, c)$ in tons,

$Q(i, j)$	$Q^2(i, j)$
$Q(++)$: 389.9	152,020
$Q(+-)$: 341.7	116,758
$Q(-+)$: 105.6	11,144
$Q(--)$: 86.3	7,444

and

$$p(++) = p(--) = \tfrac{1}{4}(1+\rho) = \tfrac{1}{8}$$

$$p(+-) = p(-+) = \tfrac{1}{4}(1-\rho) = \tfrac{3}{8}$$

and

$$E[Q] = \bar{Q} = \Sigma Q(ij)p(ij) = 227.3 \text{ tons/ft}$$
$$E[Q]^2 = \Sigma Q^2(ij)p(ij) = 67{,}896$$
$$v[Q] = E[Q]^2 - (E[Q])^2 = 16{,}231$$

and

$$\sigma[Q] = 127.40 \text{ tons}, \qquad V(Q) = 56\%$$

(b) For a CFS = 4, $\bar{D} = 56.8$. As $V(D) = 50\%$, $\sigma[D] = 28.4$. Forming the characteristics of the safety margin, with $\rho(Q, D) = +3/4$, we have $E[S] = \bar{C} - \bar{D} = 170.50$, $\sigma[S] = 143.72$, $S_{\min} = -152.75$, $S_{\max} = 493.75$, $\beta = 170.50/107.75 = 1.58$.

If S is taken at a beta variate	$p(f) = 0.059$
If S is taken to be normal	$p(f) = 0.057$

Defining Terms

Capacity — The ability to resist an induced demand; resistance or strength of entity.
Correlation coefficient — Measure of the compliance between two variables.
Demand — Applied loading or energy.
Expected value, expectation — Weighted measure of central tendency of a distribution.
Probability — Quantitative measure of a state of knowledge.
Random variable — An entity whose measure cannot be predicted with certainty.
Regression — Means of obtaining a functional relationship among variables.
Reliability — Probability of an entity (or system) performing its required function adequately for a specified period of time under stated conditions.
Standard deviation — Square root of variance.
Variance — Measure of scatter of variable.

17.1 Introduction

The shear strength of soil is generally characterized by the Mohr–Coulomb failure criterion. This criterion states that there is a linear relationship between the shear strength on the failure plane at failure (τ_{ff}) and the normal stress on the failure plane at failure (σ_{ff}) as given in the following equation:

$$\tau_{ff} = \sigma_{ff} \tan\phi + c \tag{17.1}$$

where ϕ is the friction angle and c is the intrinsic cohesion. The strength parameters (ϕ, c) are used directly in many stability calculations, including bearing capacity of shallow footings, slope stability, and stability of retaining walls. The line defined by Eq. (17.1) is called the **failure envelope.** A **Mohr's circle** tangent to a point on the failure envelope (σ_{ff}, τ_{ff}) intersects the x-axis at the **major** and **minor principal stresses** at failure (σ_{1f}, σ_{3f}) as shown in Fig. 17.1. For many soils, the failure envelope is actually slightly concave down rather than a straight line. However, for most situations Eq. (17.1) can be used with a reasonable degree of accuracy provided the strength parameters are determined over the range of stresses that will be encountered in the field problem. For a comprehensive review of Mohr's circles and the Mohr–Coulomb failure criterion, see Lambe and Whitman [1969] and Holtz and Kovacs [1981].

17.2 Strength Parameters Based on Effective Stresses and Total Stresses

The shear strength of soils is governed by **effective stress** ($\boldsymbol{\sigma'}$), which is given by

$$\sigma' = \sigma - u \tag{17.2}$$

where σ is the **total stress** and u is the pore water pressure. Equation (17.1) written in terms of effective stresses is

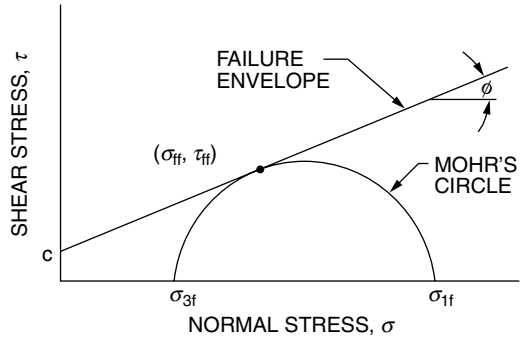

FIGURE 17.1 Mohr–Coulomb failure criteria.

$$\tau_{ff} = (\sigma_{ff} - u)\tan\phi' + c' = \sigma'_{ff}\tan\phi' + c' \tag{17.3}$$

where σ'_{ff} is the effective normal stress on the failure plane at failure, and ϕ' and c' are the friction angle and cohesion based on effective stresses. Use of Eq. (17.3) requires knowledge of the pore pressure, but this can be difficult to predict for fine-grained soils. In this case, it is often convenient to assess stability of a structure based on total applied stresses and strength parameters based on total stresses. Determination of strength parameters based on effective and total stresses is discussed further in the following sections.

17.3 Laboratory Tests for Shear Strength

The choice of appropriate shear strength tests for a particular project depends on the soil type, whether the parameters will be used in a total or effective stress analysis, and the relative importance of the structure. Laboratory tests are discussed in this chapter and field tests were discussed in Chapter 15. Common laboratory tests include direct shear, triaxial, direct simple shear, unconfined compression, and laboratory vane. The applicability, advantages, disadvantages, and sources of additional information for each test are summarized in Table 17.1.

Of the available tests, the triaxial test is often used for important projects because of the advantages listed in Table 17.1. The types of triaxial tests are classified according to their drainage conditions during the consolidation and shearing phases of the tests. In a consolidated-drained (CD) test the sample is fully drained during both the consolidation and shear phases of the test. This test can be used to determine the strength parameters based on effective stresses for both coarse- and fine-grained soils. However, the requirement that the sample be sheared slowly enough to allow for complete drainage makes this test impractical for fine-grained soils. In a consolidated-undrained (CU) test the sample is drained during consolidation but is sheared with no drainage. This test can be used for fine-grained soils to determine strength parameters based on total stresses or, if pore pressures are measured during shear, strength parameters based on effective stresses. For the latter use, a CU test is preferred over a CD test because a CU test can be sheared much more quickly than a CD test. In an unconsolidated-undrained (UU) test the sample is undrained during both the consolidation and shear phases. The test can be used to determine the undrained shear strength of fine-grained soils. Further discussion of triaxial tests is given in Holtz and Kovacs [1981] and Head [1982, 1986].

17.4 Shear Strength of Granular Soils

Granular soil is a frictional material. The friction angle (ϕ') is affected by the grain size distribution and dry density. In general, ϕ' increases as the dry density increases and as the soil becomes more well graded, as illustrated in Figs. 17.2 and 17.3. Other typical values of ϕ' for granular soils are given in Holtz and

TABLE 17.1 Summary of Common Shear Strength Tests

Test Type	Applicability	Advantages	Disadvantages	Additional Information
Direct shear	a. Effective strength parameters for coarse-grained and fine-grained soils	a. Simple and inexpensive b. Thin sample allows for rapid drainage of fine-grained soils	a. Only for drained conditions b. Failure plane forced to occur at joint in box c. Nonuniform distribution of stress and strain d. No stress-strain data	a. ASTM D3080* b. U.S. Army, 1970 c. Saada and Townsend, 1981 d. Head, 1982
Triaxial	a. Effective and total strength parameters for coarse-grained and fine-grained soils b. Compared to direct shear tests, triaxial tests are preferred for fine-grained soils	a. Easy to control drainage b. Useful stress-strain data c. Can consolidate sample hydrostatically or to *in situ* K_o state of stress d. Can simulate various loading conditions	a. Apparatus more complicated than other types of tests b. Drained tests on fine-grained soils must be sheared very slowly	a. ASTM D2850* b. U.S. Army, 1970 c. Donaghe et al., 1988 d. Head, 1982 e. Head, 1986
Direct simple shear	a. Most common application is undrained shear strength of fine-grained soils	a. K_o consolidation b. Gives reasonable values of undrained shear strength for design use	a. Nonuniform distribution of stress and strain	a. Bjerrum and Landva, 1966 b. Saada and Townsend, 1981
Unconfined	a. Undrained shear strength of 100% saturated samples of homogenous, unfissured clay b. Not suitable as the only basis for design on critical projects	a. Very rapid and inexpensive	a. Not applicable to soils with fissures, silt seams, varves, other defects, or less than 100% saturation b. Sample disturbance not systematially accounted for	a. ASTM D2166* b. U.S. Army, 1970 c. Head, 1982
Lab vane	Same as for unconfined test	Same as for unconfined test	Same as for unconfined test	Head, 1982

* Designation for American Society of Testing and Materials test procedure.

Kovacs [1981] and Carter and Bentley [1991]. The friction angle also increases as the angularity of the soil grains increases and as the surface roughness of the particles increases. Wet sands tend to have a ϕ' that is 1° or 2° lower than for dry sands [Holtz and Kovacs, 1981]. The **intermediate principal stress** ($\boldsymbol{\sigma_2}$) also affects ϕ'. In triaxial tests σ_2 is equal to either the major principal stress or minor principal stress (σ_1 or σ_3, respectively); however, most field problems occur under **plane strain conditions** where $\sigma_3 \leq \sigma_2 \leq \sigma_1$. It has been found that ϕ' for plane strain conditions (ϕ'_{ps}) is higher than for triaxial conditions (ϕ'_{tx}) [Ladd et al., 1977]. Lade and Lee [1976] recommend the following equation for estimation of ϕ'_{ps}:

$$\phi'_{ps} = 1.5\ \phi'_{tx} - 17° \qquad (\phi'_{tx} > 34°) \tag{17.4a}$$

$$\phi'_{ps} = \phi'_{tx} \qquad (\phi'_{tx} \leq 34°) \tag{17.4b}$$

In practice ϕ' for granular soils is determined using correlations with results from SPT, CPT, and other *in situ* tests, as discussed in Chapter 15, or laboratory tests on samples compacted to the same density as the *in situ* soil. Appropriate laboratory tests are drained direct shear and CD triaxial tests. CU triaxial tests with pore pressure measurements are sometimes used for granular soils with appreciable fines. The method used to prepare the remolded sample and the direction of shearing relative to the direction of deposition has been found to affect ϕ' by up to 2.5° [Oda, 1977; Mahmood and Mitchell, 1974; Ladd

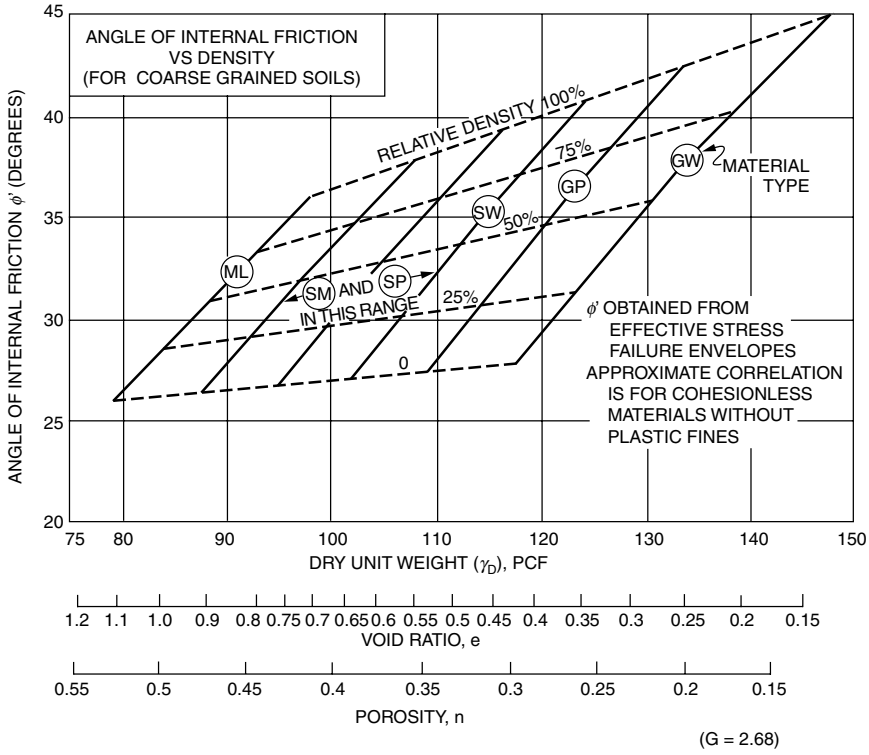

FIGURE 17.2 Correlation of friction angle of granular soils with soil classification and relative density. (*Source:* U.S. Navy. 1986. *Soil Mechanics,* Design Manual 7.1, p. 7.1-149. Naval Facilities Engineering Command, Alexandria, VA.)

et al., 1977]. The c' of granular soils is zero except for lightly cemented soils which can have an appreciable c' [Clough et al., 1981; Head, 1982].

17.5 Shear Strength of Cohesive Soils

The friction angle of cohesive soil based on effective stresses generally decreases as the plasticity increases. This is shown for normally consolidated clays in Fig. 17.4. The c' of normally consolidated, noncemented clays with a preconsolidation stress (defined in Chapter 19) of less than 10,000 to 20,000 psf (500 to 1000 kPa) is generally less than 100 to 200 psf (5 to 10 kPa) [Ladd, 1971]. Overconsolidated clays generally have a lower ϕ' and a higher c' than normally consolidated clays. Compacted clays at low stresses also have a much higher c' [Holtz and Kovacs, 1981].

The shear strength of cohesive soils based on effective stresses is generally determined using a CU triaxial test with pore pressure measurements. To obtain accurate pore pressure measurements it is necessary to fully saturate the sample using the techniques described in U.S. Army [1970], Black and Lee [1973], and Holtz and Kovacs [1981]. This test can be run much more quickly than a CD triaxial test and it has been shown that the ϕ' from both tests are similar [Bjerrum and Simons, 1960].

For clays and some sedimentary rocks that are deformed slowly to large strains under drained conditions, it may be necessary to use the **residual friction angle** ϕ'_r, which can be significantly lower than ϕ'. The ϕ'_r for the clay minerals kaolinite, illite, and montmorillonite range from 4° to 12° [Mitchell, 1993]. ϕ'_r generally decreases as the clay fraction (percent of particle sizes smaller than 0.002 mm) increases [Mitchell, 1993]. Test procedures for ϕ'_r are discussed in Saada and Townsend [1981].

The shear strength of cohesive soils based on total stresses is described in terms of the undrained shear strength (c_u). If the soil is saturated, the undrained friction angle ϕ_u is always zero. For partly saturated

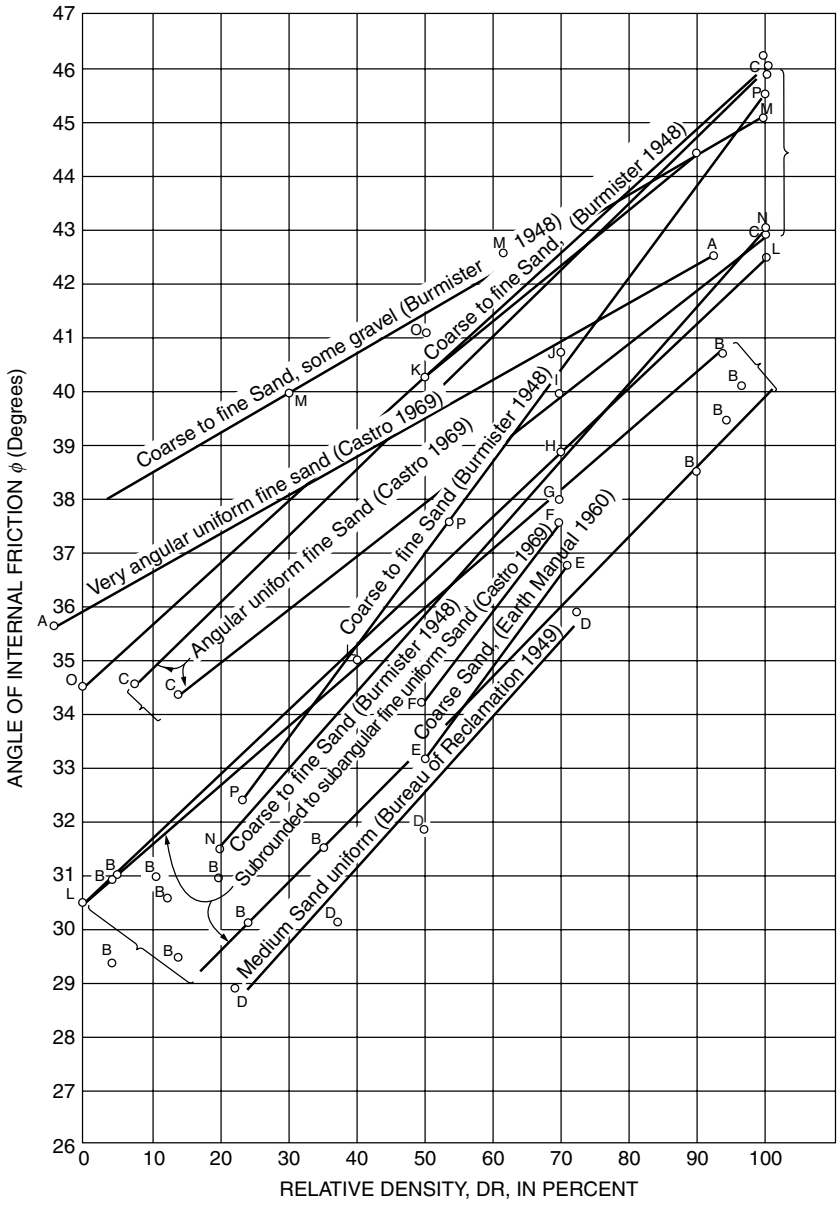

FIGURE 17.3 Friction angle versus relative density for cohesionless soils. (*Source:* Hilf, J. W. 1991. Compacted fill. In *Foundation Engineering Handbook,* ed. H. -Y. Fang, p. 268. Van Nostrand Reinhold, New York. With permission.)

soils, such as compacted soils, it is possible to have $\phi_u > 0$. Normally consolidated and lightly overconsolidated clays generally exhibit the stress strain behavior shown in Fig. 17.5. Overconsolidated and cemented clays generally reach a peak at small strains and then lose strength with further straining, which is also shown in Fig. 17.5. Similar behavior occurs for sensitive clays, that is, clays that lose strength when they are remolded.

The undrained shear strength of clay is a function of its stress history. This is often expressed in dimensionless form as the ratio of c_u / σ'_{vc} where σ'_{vc} is the effective vertical consolidation stress. This ratio is empirically related to the overconsolidation ratio (OCR) by [Ladd, 1991]:

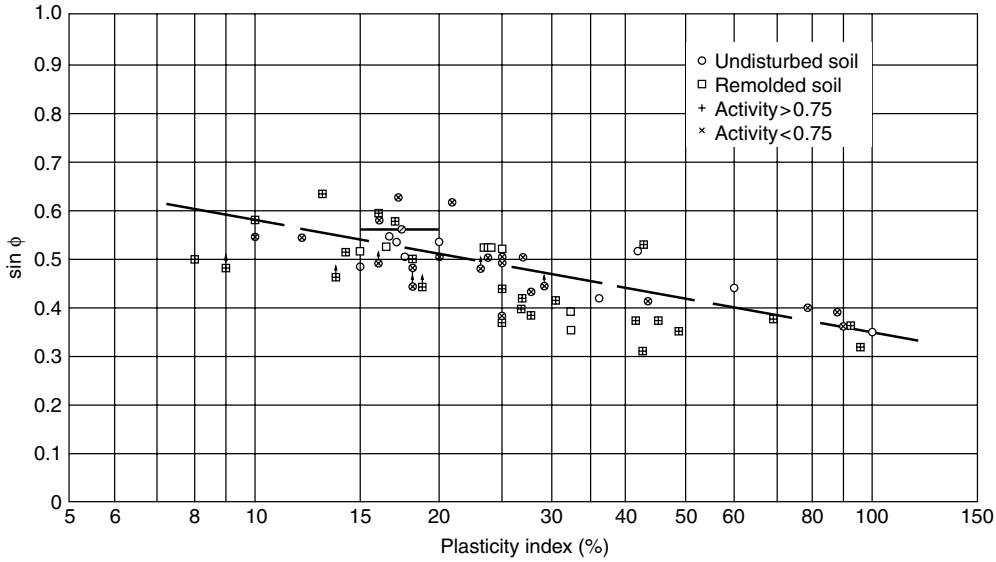

FIGURE 17.4 Friction angle of fine grained soil based on effective stresses versus plasticity index [Kenney, 1959]. (*Source:* Lambe, T. C., and Whitman, R. V. 1969. *Soil Mechanics*, p. 307. John Wiley & Sons, Inc. New York. Copyright © 1969.)

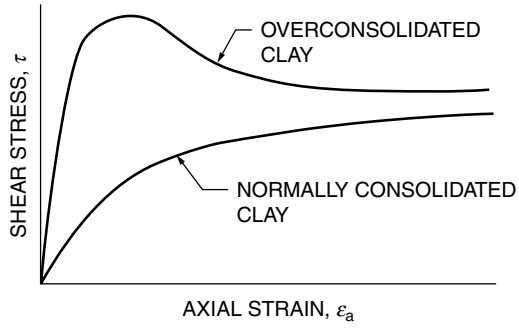

FIGURE 17.5 Stress-strain behavior of normally consolidated and heavily overconsolidated clay.

$$c_u / \sigma'_{vc} = S(\text{OCR})^m \tag{17.5}$$

where

S = 0.22 ± 0.03 for sedimentary clay plotting above A-line on plasticity chart
S = 0.25 ± 0.05 for silts and organic clays plotting below A-line
OCR = overconsolidation ratio = σ'_p/σ'_{vc} (see Chapter 19)
σ'_p = preconsolidation pressure (see Chapter 19)
m = $0.88(1 - C_s/C_c)$
C_s = swelling index from consolidation test (see Chapter 19)
C_c = compression index from consolidation test (see Chapter 19)

Alternately, the undrained shear strength can be expressed as the ratio of c_u/σ'_p. This is shown for the results from K_0 consolidated triaxial compression (TC), triaxial extension (TE), and direct simple shear (DSS) tests in Fig. 17.6. In a TC test the vertical stress is increased to failure while in a TE test the vertical stress is decreased to failure. It is seen that TC tests give higher strengths than TE tests while DSS tests

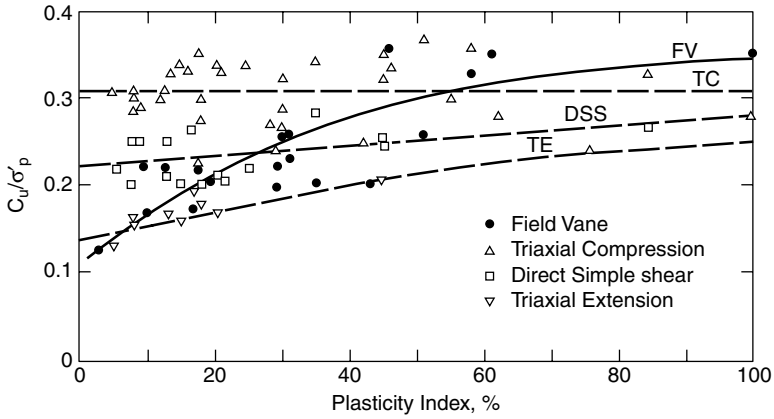

FIGURE 17.6 Undrained shear strength from K_o consolidated CU triaxial compression, triaxial extension, and direct simple shear tests as well as field vane tests. (*Source:* Mesri, G. 1989. FIGURE 17.7 Relevance of laboratory shear tests to shear strength in the field. (*Source:* Bjerrum, L. 1972. Embankments on soft ground. In *Performance of Earth and Earth-Supported Structures,* Vol. II, p. 16. ASCE, New York. With permission of ASCE.)

give results that are intermediate between the two. Results from field vane (FV) tests are also shown in Fig. 17.6. The applicability of undrained shear strengths from TC, TE, and DSS tests to a typical stability problem is shown in Fig. 17.7. Thus, Mesri [1989] concluded that an average of the results from these three tests would be reasonable for use in design. When this is applied to the data in Fig. 17.6, the following relationship results:

$$c_u = 0.22\sigma'_p \tag{17.6}$$

Mesri [1975] found an identical relationship using results from the FV test and a similar relationship was obtained by Larsson [1980] from a back analysis of 15 embankment failures. It is significant that Eq. (17.6) is independent of the plasticity index of the soil and that the same relationship was obtained using results from laboratory and field tests. This tends to confirm Bjerrum's [1973] conclusion that the "field vane test is the best possible approach for determining the strength for undrained strength stability analysis" [Mesri, 1989, p. 164]. Furthermore, Eq. (17.6) provides a valuable technique for estimating the undrained shear strength of soft clays using σ'_p profiles from consolidation test results.

In practice, the undrained shear strength is often determined *in situ* using field vane tests. For routine projects, c_u may be determined from the results of unconfined or lab vane tests; however, the resulting

strength will generally be less than the *in situ* value because of sample disturbance. Undrained direct simple shear tests also can give reasonable estimates of c_u [Ladd, 1981]. For important projects, CU triaxial tests are often performed on undisturbed samples. For highly structured clays with high sensitivities and water contents in excess of the liquid limit and for cemented clays, the sample should first be recompressed to its *in situ* K_0 state of stress to minimize the effects of sample disturbance [Bjerrum, 1973; Jamiolkowski et al., 1985]. For unstructured, uncemented clays, the SHANSEP technique can be used to develop the relationship between c_u/σ'_{vc} and OCR [Ladd and Foote, 1974; Ladd et al., 1977; Jamiolkowski et al., 1985]. For both cases it is necessary to perform both TC and TE tests as Fig 17.6 shows that TC results greatly overestimate the shear strength on a failure surface while the average of TC and TE results yields a more realistic shear strength for use in design. UU triaxial tests do not give meaningful stress-strain data and often give scattered c_u results because of the inability of this test to account for varying degrees of sample disturbance [Jamiolkowski et al., 1985] making the use of this test undesirable for important projects.

17.6 Elastic Modulus of Granular Soils

The **elastic modulus** (E_s) of granular soils based on effective stresses is a function of grain size, gradation, mineral composition of the soil grains, grain shape, soil type, relative density, soil particle arrangement, stress level, and prestress [Lambe and Whitman, 1969; Ladd et al., 1977; Lambrechts and Leonards, 1978]. A granular soil is prestressed if, at some point in its history, it has experienced a stress level that is greater than is currently acting on the soil. This is analogous to overconsolidation of a fine-grained soil, which is discussed in Chapter 19. Of the several factors controlling E_s, the ones having the largest influence are prestress, which can increase E_s by more than a factor of six, and extreme differences in relative density, which can make a fivefold difference in E_s [Lambrechts and Leonards, 1978]. The effect of stress level on modulus is often represented by [Janbu, 1963]

$$E_i = Kp_a\left(\frac{\sigma_3}{p_a}\right)^2 \tag{17.7}$$

where E_i is the initial slope of a stress–strain curve, σ_3 is the minor principal stress, K is a dimensionless modulus number that varies from 300 to 2000, n is an exponent number typically between 0.3 and 0.6, and p_a is atmospheric pressure in the same units as σ_3 and E_i [Mitchell, 1993]. Typical values of K and n are given in Wong and Duncan [1974].

Measuring E_s is very difficult since it is nearly impossible to measure the prestress of an *in situ* deposit of granular soil or to obtain undisturbed samples for laboratory testing. While CD triaxial tests can be used to measure E_s [Head, 1986], they are restricted to reconstituted samples that cannot duplicate the *in situ* prestress. For these reasons, E_s is often estimated using *in situ* tests (Chapter 15). Typical values of E_s and Poisson's ratio (μ) for normally consolidated granular soils are given in Table 17.2.

TABLE 17.2 Typical Values of Elastic Modulus and Poisson's Ratio for Granular Soils

	Elastic Modulus, E_s		
Type of Soil	MPa	lb/in.^{2}	Poisson's ratio, μ
Loose sand	10–24	1,500–3,500	0.20–0.40
Medium dense sand	17–28	2,500–4,000	0.25–0.40
Dense sand	35–55	5,000–8,000	0.30–0.45
Silty sand	10–17	1,500–2,500	0.20–0.40
Sand and gravel	69–170	10,000–25,000	0.15–0.35

17.7 Undrained Elastic Modulus of Cohesive Soils

The undrained elastic modulus (E_u) of cohesive soils is a function primarily of soil plasticity and overconsolidation (defined in Chapter 19). It can be determined from the slope of a stress-strain curve obtained from an undrained triaxial test [Holtz and Kovacs, 1981]. However, E_u is very sensitive to sample disturbance, which results in values measured in laboratory tests that are too low [Lambe and Whitman, 1969; Jamiolkowski et al., 1985]. Alternatively, E_u can be measured using *in situ* tests (Chapter 15) or a crude estimate of E_u can be made from the undrained shear strength using the empirical relations shown in Table 17.3. However, there is significant variability in the ratio E_s/c_u, which has been reported to vary from 40 to more than 3000 [Holtz and Kovacs, 1981].

Defining Terms

Effective stress (σ') — Intergranular stress that exists between soil particles.
Elastic modulus (E_s) — Ratio of the change in stress divided by the corresponding change in strain for an axially loaded sample. Also called Young's modulus.
Failure envelope — A line tangent to a series of Mohr's circles at failure.
Intermediate principal stress (σ_2) — In a set of three principal stresses acting at a point in a soil mass, the intermediate principal stress is the one that is less than or equal to the major principal stress but greater than or equal to the minor principal stress.
Major principal stress (σ_1) — The largest of a set of three principal stresses acting at a point in a soil mass.
Minor principal stress (σ_3) — The smallest of a set of three principal stresses acting at a point in a soil mass.
Mohr's circle — A graphical representation of the state of stress at a point in a soil mass.
Plane strain conditions — A loading condition where the normal strain on one plane is zero as would occur for a long retaining wall or embankment.
Principal planes — A set of three orthogonal (mutually perpendicular) planes that exist at any point in a soil mass on which the shear stresses are zero.
Principal stresses — The normal stresses acting on a set of three principal planes.
Residual friction angle (ϕ'_r) — For clays and some sedimentary rocks it is the friction angle that is reached after very large strains.
Total stress (σ) — The sum of the effective stress and the pore water pressure.

18.1 Introduction

Figure 18.1 shows the pore space available for flow in two highly idealized soil models: *regular cubic* and *rhombohedral*. It is seen that even for these special cases, the pore space is not regular, but consists of cavernous cells interconnected by narrower channels. Pore spaces in real soils can range in size from molecular interstices to cathedral-like caverns. They can be spherical (as in concrete) or flat (as in clays), or display irregular patterns which defy description. Add to this the fact that pores may be *isolated* (inaccessible) or *interconnected* (accessible from both ends) or may be *dead-ended* (accessible through one end only).

In spite of the apparent irregularities and complexities of the available pores, there is hardly an industrial or scientific endeavor that does not concern itself with the passage of matter, solid, liquid, or gaseous, into, out of, or through porous media. Contributions to the literature can be found among such diverse fields (to name only a few) as soil mechanics, groundwater hydrology, petroleum, chemical, and metallurgical engineering, water purification, materials of construction (ceramics, concrete, timber, paper), chemical industry (absorbents, varieties of contact catalysts, and filters), pharmaceutical industry, traffic flow, and agriculture.

The flow of groundwater is taken to be governed by *Darcy's law,* which states that the velocity of the flow is proportional to the **hydraulic gradient**. A similar statement in an electrical system is *Ohm's law* and in a thermal system, *Fourier's law*. The grandfather of all such relations is *Newton's laws of motion*. Table 18.1 presents some other points of similarity.

18.2 Some Fundamentals

The literature is replete with derivations and analytical excursions of the basic equations of steady state groundwater flow [e.g., Polubarinova-Kochina, 1962; Harr, 1962; Cedergren, 1967; Bear, 1972; Domenico and Schwartz, 1990]. A summary and brief discussion of these will be presented below for the sake of completeness.

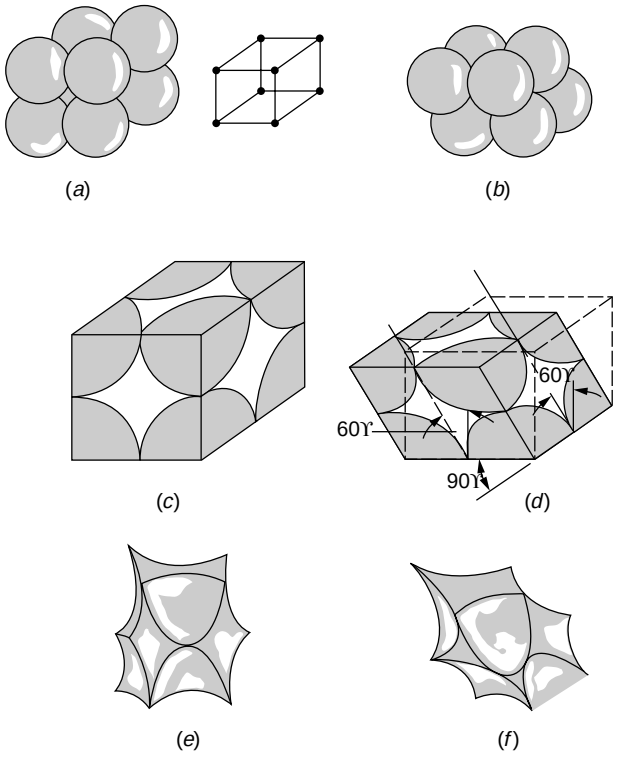

FIGURE 18.1 Idealized void space.

TABLE 18.1 Some Similarities of Flow Models

Form of Energy	Name of Law	Quantity	Storage	Resistance
Electrical	Ohm's law	Current (voltage)	Capacitor	Resistor
Mechanical	Newton's law	Force (velocity)	Mass	Damper
Thermal	Fourier's law	Heat flow (temperature)	Heat capacity	Heat resistance
Fluid	Darcy's law	Flow rate (pressure)	Liquid storage	Permeability

Bernoulli's Equation

Underlying the analytical approach to groundwater flow is the representation of the actual physical system by a tractable mathematical model. In spite of their inherent shortcomings, many such analytical models have demonstrated considerable success in simulating the action of their prototypes.

As is well known from fluid mechanics, for steady flow of nonviscous incompressible fluids, Bernoulli's equation [Lamb, 1945]

$$\frac{p}{\gamma_w} + z + \frac{\bar{v}^2}{2g} = \text{constant} = h \tag{18.1}$$

where p = pressure, lb/ft^2
γ_w = unit weight of fluid, lb/ft^3
$\bar{v}$ = seepage velocity, ft/sec
g = gravitational constant, 32.2 ft/s^2
h = total head, ft

demonstrates that the sum of the *pressure head,* p/γ_w, *elevation head,* z, and *velocity head,* $\bar{v}^2/2g$ at any point within the region of flow is a constant. To account for the loss of energy due to the viscous resistance within the individual pores, Bernoulli's equation is taken as

$$\frac{p_A}{\gamma_w} + z_A + \frac{\bar{v}_A^2}{2g} = \frac{p_B}{\gamma_w} + z_B + \frac{\bar{v}_B^2}{2g} + \Delta h \tag{18.2}$$

where Δh represents the total head loss (energy loss per unit weight of fluid) of the fluid over the distance Δs. The ratio

$$i = -\lim_{\Delta s \to 0} \frac{\Delta h}{\Delta s} = -\frac{dh}{ds} \tag{18.3}$$

is called the *hydraulic gradient* and represents the space rate of energy dissipation per unit weight of fluid (a pure number).

In most problems of interest the velocity heads (the kinetic energy) are so small they can be neglected. For example, a velocity of 1 ft/s, which is large compared to typical seepage velocities through soils, produces a velocity head of only 0.015 ft. Hence, Eq. (18.2) can be simplified to

$$\frac{p_A}{\gamma_w} + z_A = \frac{p_B}{\gamma_w} + z_B + \Delta h$$

and the total head at any point in the flow domain is simply

$$h = \frac{p}{\gamma_w} + z \tag{18.4}$$

Darcy's Law

Prior to 1856, the formidable nature of the flow through porous media defied rational analysis. In that year, Henry Darcy published a simple relation based on his experiments on the flow of water in vertical sand filters in "Les fontaines publiques de la ville de Dijon," namely,

$$v = ki = -k\frac{dh}{ds} \tag{18.5}$$

Equation (18.5), commonly called *Darcy's law,* demonstrates a linear dependency between the hydraulic gradient and the *discharge velocity* v. The discharge velocity, $v = n\bar{v}$, is the product of the porosity n and the seepage velocity, $\bar{v}$. The coefficient of proportionality k is called by many names depending on its use; among these are the **coefficient of permeability**, *hydraulic conductivity,* and *permeability constant.* As shown in Eq. (18.5), k has the dimensions of a velocity. It should be carefully noted that Eq. (18.5) states that flow is a consequence of differences in total head and not of pressure gradients. This is demonstrated in Fig. 18.2, where the flow is directed from A to B, even though the pressure at point B is *greater* than that at point A.

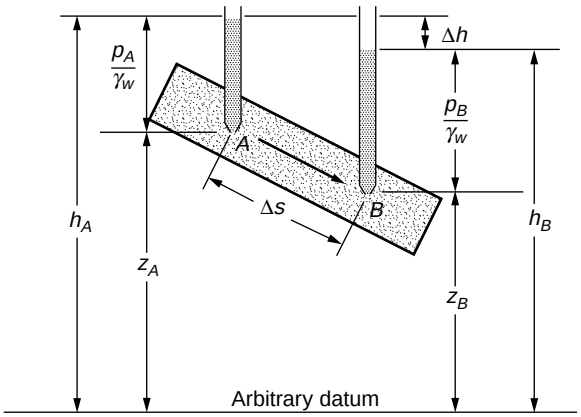

FIGURE 18.2 Heads in Bernoulli's equation.

TABLE 18.2 Some Typical Values of Coefficient of Permeability

Soil Type	Coefficient of Permeability k, cm/s
Clean gravel	1.0 and greater
Clean sand (coarse)	1.0–0.01
Sand (mixtures)	0.01–0.005
Fine sand	0.05–0.001
Silty sand	0.002–0.0001
Silt	0.0005–0.00001
Clay	0.000001 and smaller

Defining Q as the total volume of flow per unit time through a cross-sectional area A, Darcy's law takes the form

$$Q = Av = Aki = -Ak\frac{dh}{ds} \tag{18.6}$$

Darcy's law offers the single parameter k to account for both the characteristics of the medium and the fluid. It has been found that k is a function of γ_f, the unit weight of the fluid, μ, the coefficient of viscosity, and n, the porosity, as given by

$$k = C\frac{\gamma_f n}{\mu} \tag{18.7}$$

where C (dimensionally an area) typifies the structural characteristics of the medium independent of the fluid properties. The principal advantage of Eq. (18.7) lies in its use when dealing with more than one fluid or with temperature variations. When employing a single relatively incompressible fluid subjected to small changes in temperature, such as in groundwater- and seepage-related problems, it is more convenient to use k as a single parameter. Some typical values for k are given in Table 18.2.

Although Darcy's law was obtained initially from considerations of one-dimensional macroscopic flow, its practical utility lies in its generalization into two or three spatial dimensions. Accounting for the directional dependence of the coefficient of permeability, Darcy's law can be generalized to

$$v_s = -k_s\frac{\partial h}{\partial s} \tag{18.8}$$

where k_s is the coefficient of permeability in the s direction, and v_s and $\partial h/\partial s$ are the components of the velocity and the hydraulic gradient, respectively, in that direction.

Reynolds Number

There remains now the question of the determination of the extent to which Darcy's law is valid in actual flow systems through soils. Such a criterion is furnished by the Reynolds number R (a pure number relating inertial to viscous force), defined as

$$R = \frac{vd\rho}{\mu} \tag{18.9}$$

where v = discharge velocity, cm/s
d = average of diameter of particles, cm
ρ = density of fluid, g(mass)/cm^3
μ = coefficient of viscosity, g-s/cm^2

The critical value of the Reynolds number at which the flow in aggregations of particles changes from laminar to turbulent flow has been found by various investigators [see Muskat, 1937] to range between 1 and 12. However, it will generally suffice to accept the validity of Darcy's law when the Reynolds number is taken as equal to or less than unity, or

$$\frac{vd\rho}{\mu} \leq 1 \tag{18.10}$$

Substituting the known values of ρ and μ for water into Eq. (18.10) and assuming a conservative velocity of 1/4 cm/s, we have d equal to 0.4 mm, which is representative of the average particle size of coarse sand.

Homogeneity and Isotropy

If the coefficient of permeability is independent of the direction of the velocity, the medium is said to be *isotropic*. Moreover, if the same value of the coefficient of permeability holds at all points within the region of flow, the medium is said to be *homogeneous* and *isotropic*. If the coefficient of permeability depends on the direction of the velocity and if this directional dependence is the same at all points of the flow region, the medium is said to be *homogeneous* and *anisotropic* (or *aleotropic*).

Streamlines and Equipotential Lines

Physically, all flow systems extend in three dimensions. However, in many problems the features of the motion are essentially planar, with the flow pattern being substantially the same in parallel planes. For these problems, for steady state, incompressible, isotropic flow in the xy plane, it can be shown [Harr, 1962] that the governing differential equation is

$$k_x\frac{\partial^2 h}{\partial x^2} = k_y\frac{\partial^2 h}{\partial y^2} = 0 \tag{18.11}$$

Here the function $h(x, y)$ is the distribution of the total head (of energy to do work), within and on the boundaries of a flow region, and k_x and k_y are the coefficients of permeability in the x and y directions, respectively. If the flow system is isotropic, $k_x = k_y$, and Eq. (18.11) reduces to

$$\frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} = 0 \tag{18.12}$$

Equation (18.12), called *Laplace's equation,* is the governing relationship for steady state, laminar-flow conditions (Darcy's law is valid). The general body of knowledge relating to Laplace's equation is called *potential theory.* Correspondingly, incompressible steady state fluid flow is often called *potential flow.* The correspondence is more evident upon the introduction of the *velocity potential* ϕ, defined as

$$\phi(x, y) = -kh + C = -k\left(\frac{p}{\gamma_w} + z\right) + C \tag{18.13}$$

where h is the total head, p/γ_w is the pressure head, z is the elevation head, and C is an arbitrary constant. It should be apparent that, for isotropic conditions,

$$v_x = \frac{\partial \phi}{\partial x} \qquad v_y = \frac{\partial \phi}{\partial y} \tag{18.14}$$

and Eq. (18.12) will produce

$$\nabla^2 \phi = \frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} = 0 \tag{18.15}$$

The particular solutions of Eqs. (18.12) or (18.15) that yield the locus of points within a porous medium of equal potential, curves along which $h(x, y)$ or $\phi(x, y)$ are equal to constants, are called *equipotential lines.*

In analyses of groundwater flow, the family of flow paths is given by the function $\psi(x, y)$, called the *stream function,* defined in two dimensions as [Harr, 1962]

$$v_x = \frac{\partial \psi}{\partial y} \qquad v_y = -\frac{\partial \psi}{\partial x} \tag{18.16}$$

where v_x and v_y are the components of the velocity in the x and y directions, respectively.

Equating the respective potential and stream functions of v_x and v_y produces

$$\frac{\partial \phi}{\partial x} = \frac{\partial \psi}{\partial y} \qquad \frac{\partial \phi}{\partial y} = -\frac{\partial \psi}{\partial x} \tag{18.17}$$

Differentiating the first of these equations with respect to y and the second with respect to x and adding, we obtain Laplace's equation:

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} = 0 \tag{18.18}$$

We shall examine the significance of this relationship following a little more discussion of the physical meaning of the stream function. Consider AB of Fig. 18.3 as the path of a particle of water passing through point P with a tangential velocity **v**. We see from the figure that

$$\frac{v_y}{v_x} = \tan\theta = \frac{dy}{dx}$$

and hence

$$v_y\, dx - v_x\, dy = 0 \tag{18.19}$$

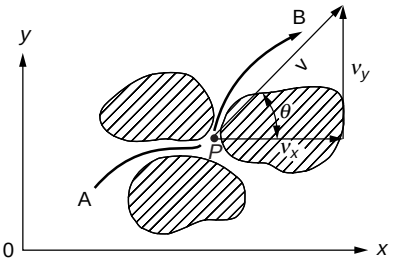

FIGURE 18.3 Path of flow.

Substituting Eq. (18.16), it follows that

$$\frac{\partial \psi}{\partial x}dx + \frac{\partial \psi}{\partial y}dy = 0$$

which states that the total differential $d\psi = 0$ and

$$\psi(x, y) = \text{constant}$$

Thus we see that the family of curves generated by the function $\psi(x, y)$ equal to a series of constants are tangent to the resultant velocity at all points in the flow region and hence define the path of flow.

The potential $[\phi = -kh + C]$ is a measure of the energy available at a point in the flow region to move the particle of water from that point to the tailwater surface. Recall that the locus of points of equal energy, say, $\phi(x, y) =$ constants, are called *equipotential lines*. The total differential along any curve $\phi(x, y) =$ constant produces

$$d\phi = \frac{\partial \phi}{\partial x}dx + \frac{\partial \phi}{\partial y}dy = 0$$

Substituting for $\partial\phi/\partial x$ and $\partial\phi/\partial y$ from Eqs. (18.16), we have

$$v_x\,dx + v_y\,dy = 0$$

and

$$\frac{dy}{dx} = -\frac{v_x}{v_y} \tag{18.20}$$

Noting the negative reciprocal relationship between their slopes, Eqs. (18.19) and (18.20), we see that, within the flow domain, the families of streamlines $\psi(x, y) =$ constants and equipotential lines $\phi(x, y) =$ constants intersect each other at right angles. It is customary to signify the sequence of constants by employing a subscript notation, such as $\phi(x, y) = \phi_i$, $\psi(x, y) = \psi_j$ (Fig. 18.4).

As only one streamline may exist at a given point within the flow medium, streamlines cannot intersect one another. Consequently, if the medium is saturated, any pair of streamlines act to form a flow channel between them. Consider the flow between the two streamlines ψ and $\psi + d\psi$ in Fig. 18.5; $\mathbf{v}$ represents the resultant velocity of flow. The quantity of flow through the flow channel per unit length normal to the plane of flow (say, cubic feet per second per foot) is

$$dQ = v_x\,ds\cos\theta - v_y\,ds\,\sin\theta = v_x\,dy - v_y\,dx = \frac{\partial \psi}{\partial y}dy + \frac{\partial \psi}{\partial x}dx$$

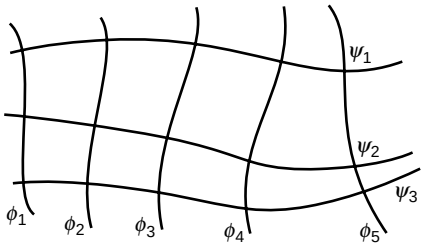

FIGURE 18.4 Streamlines and equipotential lines.

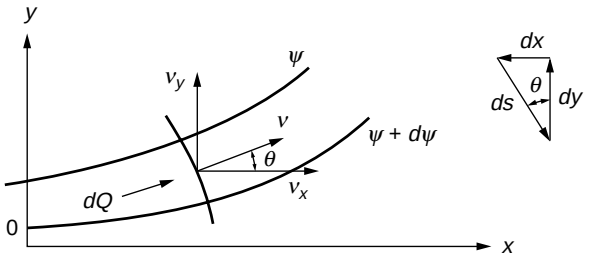

FIGURE 18.5 Flow between streamlines.

and

$$dQ = d\psi \tag{18.21}$$

Hence the quantity of flow (also called the *discharge quantity*) between any pair of streamlines is a constant whose value is numerically equal to the difference in their respective ψ values. Thus, once a sequence of streamlines of flow has been obtained, with neighboring ψ values differing by a constant amount, their plot will not only show the expected direction of flow but the relative magnitudes of the velocity along the flow channels; that is, the velocity at any point in the flow channel varies inversely with the streamline spacing in the vicinity of that point.

An equipotential line was defined previously as the locus of points where there is an expected level of available energy sufficient to move a particle of water from a point on that line to the tailwater surface. Thus, it is convenient to reduce all energy levels relative to a tailwater datum. For example, a piezometer located anywhere along an equipotential line, say at $0.75h$ in Fig. 18.6, would display a column of water extending to a height of $0.75h$ above the tailwater surface. Of course, the pressure in the water along the equipotential line would vary with its elevation.

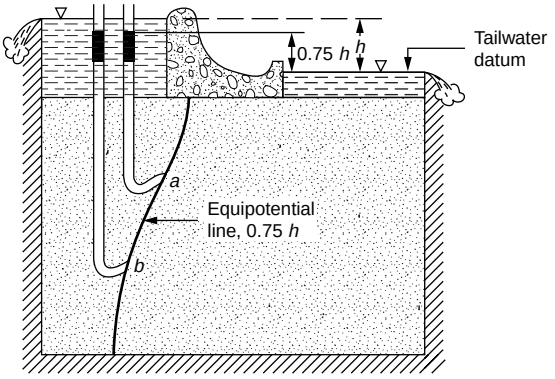

FIGURE 18.6 Pressure head along equipotential line.

18.3 The Flow Net

The graphical representation of special members of the families of streamlines and corresponding equipotential lines within a flow region form a **flow net**. The orthogonal network shown in Fig. 18.4 represents such a system. Although the construction of a flow net often requires tedious trial-and-error adjustments, it is one of the more valuable methods employed to obtain solutions for two-dimensional flow problems. Of additional importance, even a hastily drawn flow net will often provide a check on the reasonableness of solutions obtained by other means. Noting that, for steady state conditions, Laplace's equation also models the action (see Table 18.1) of thermal, electrical, acoustical, odoriferous, torsional, and other systems, the flow net is seen to be a significant tool for analysis.

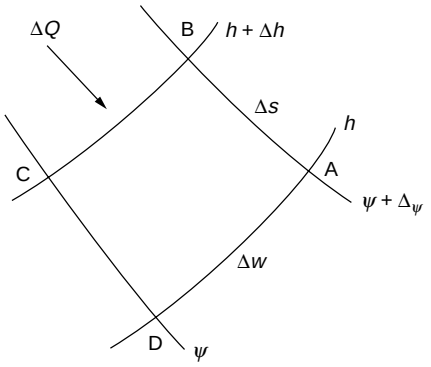

FIGURE 18.7 Flow at point.

If, in Fig. 18.7, Δw denotes the distance between a pair of adjacent streamlines and Δs is the distance between a pair of adjacent equipotential lines in the near vicinity of a point within the region of flow, the approximate velocity (in the mathematical sense) at the point, according to Darcy's law, will be

$$v \approx \frac{k\,\Delta h}{\Delta s} \approx \frac{\Delta \psi}{\Delta w} \tag{18.22}$$

As the quantity of flow between any two streamlines is a constant, ΔQ, and equal to $\Delta\psi$ (Eq. 18.21) we have

$$\Delta Q \approx k\,\frac{\Delta w}{\Delta s}\,\Delta h \tag{18.23}$$

Equations (18.22) and (18.23) are approximate. However, as the distances Δw and Δs become very small, Eq. (18.22) approaches the velocity at the point and Eq. (18.23) yields the quantity of discharge through the flow channel.

In Fig. 18.8 is shown the completed flow net for a common type of structure. We first note that there are four boundaries: the bottom impervious contour of the structure *BGHC*, the surface of the impervious layer *EF*, the headwater boundary *AB*, and the tailwater boundary *CD*. The latter two boundaries designate the equipotential lines $h = h$ and $h = 0$, respectively. For steady state conditions, the quantity

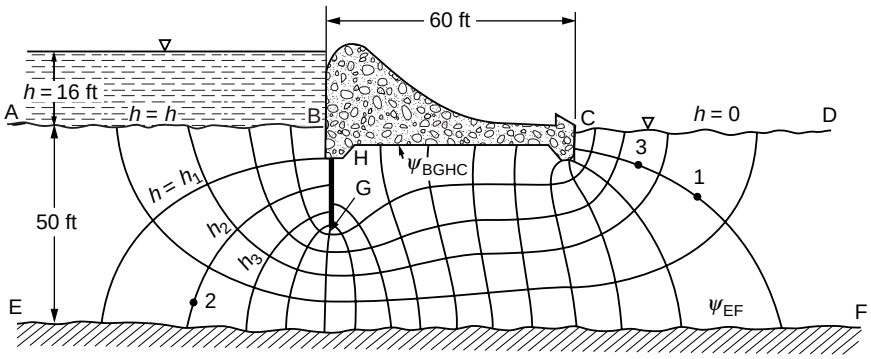

FIGURE 18.8 Example of flow net.

of discharge through the section Q and the head loss (h = 16 ft) must be constant. If the flow region is saturated, it follows that the two impervious boundaries are streamlines and their difference must be identically equal to the discharge quantity

$$Q = \psi_{BGHC} - \psi_{EF}$$

From among the infinite number of possible streamlines between the impervious boundaries, we sketch only a few, specifying the same quantity of flow between neighboring streamlines. Designating N_f as the number of flow channels, we have, from above,[1]

$$Q = N_f \Delta Q = kN_f \frac{\Delta w}{\Delta s} \Delta h$$

Similarly, from among the infinite number of possible equipotential lines between headwater and tailwater boundaries, we sketch only a few and specify the same drop in head, say, Δh, between adjacent equipotential lines. If there are N_e equipotential drops along each of the channels,

$$h = N_e \Delta h \qquad \text{and} \qquad Q = k \frac{N_f}{N_e} \frac{\Delta w}{\Delta s} h \tag{18.24}$$

If, now, we also require that the ratio $\Delta w/\Delta s$ be the same at all points in the flow region, for convenience, and because a square is most sensitive to visual inspection, we take this ratio to be unity,

$$\frac{\Delta w}{\Delta s} = 1$$

and obtain

$$Q = k \frac{N_f}{N_e} h \tag{18.25}$$

Recalling that Q, k, and h are all constants, Eq. (18.25) demonstrates that the resulting construction, with the obvious requirement that everywhere in the flow domain streamlines and equipotential lines meet at right angles, will yield a unique value for the ratio of the number of flow channels to the number of equipotential drops, N_f/N_e. In Fig. 18.8 we see that N_f equals about 5 and N_e equals 16; hence, N_f/N_e = 5/16.

The graphical technique of constructing flow nets by sketching was first suggested by Prasil [1913] although it was developed formally by Forchheimer [1930]; however, the adoption of the method by engineers followed Casagrande's classic paper in 1940. In this paper and in the highly recommended flow nets of Cedergren [1967] are to be found some of the highest examples of the art of drawing flow nets. Harr [1962] also warrants a peek!

Unfortunately, there is no "royal road" to drawing a good flow net. The speed with which a successful flow net can be drawn is highly contingent on the experience and judgment of the individual. In this regard, the beginner will do well to study the characteristics of well-drawn flow nets: *labor omnia vincit*.

In summary, a flow net is a sketch of distinct and special streamlines and equipotential lines that preserve right-angle intersections, satisfy the boundary conditions, and form curvilinear squares.[2] The following procedure is recommended:

[1]There is little to be gained by retaining the approximately equal sign ≈.

[2]We accept singular squares such as the five-sided square at point H in Fig. 18.8 and the three-sided square at point G. (It can be shown — Harr [1962], p. 84 — that a five-sided square designates a point of turbulence). With continued subdividing into smaller squares, the deviations, in the limit, act only at singular points.

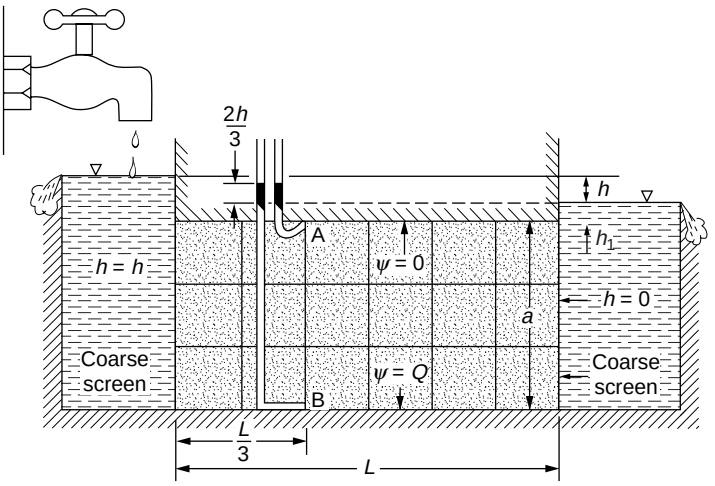

FIGURE 18.9 Example of flow regime.

1. Draw the boundaries of the flow region to a scale so that all sketched equipotential lines and streamlines terminate on the figure.
2. Sketch lightly three or four streamlines, keeping in mind that they are only a few of the infinite number of possible curves that must provide a smooth transition between the boundary streamlines.
3. Sketch the equipotential lines, bearing in mind that they must intersect all streamlines, including boundary streamlines, at right angles and that the enclosed figures must form curvilinear rectangles (except at singular points) with the same ratio of $\Delta s/\Delta s$ along a flow channel. Except for partial flow channels and partial head drops, these will form curvilinear squares with $\Delta w = \Delta s$.
4. Adjust the initial streamlines and equipotential lines to meet the required conditions. Remember that the drawing of a good flow net is a trial-and-error process, with the amount of correction being dependent upon the position selected for the initial streamlines.

Example 18.1

Obtain the quantity of discharge, Q/kh, for the section shown in Fig. 18.9.

Solution. This represents a region of horizontal flow with parallel horizontal streamlines between the impervious boundaries and vertical equipotential lines between reservoir boundaries. Hence the flow net will consist of perfect squares, and the ratio of the number of flow channels to the number of drops will be $N_f/N_e = a/L$ and $Q/kh = a/L$.

Example 18.2

Find the pressure in the water at points A and B in Fig. 18.9.

Solution. For the scheme shown in Fig. 18.9, the total head loss is linear with distance in the direction of flow. Equipotential lines are seen to be vertical. The total heads at points A and B are both equal to $2h/3$ (datum at the tailwater surface). This means that a piezometer placed at these points would show a column of water rising to an elevation of $2h/3$ above the tailwater elevation. Hence, the pressure at each point is simply the weight of water in the columns above the points in question: $p_A = (2h/3 + h_1)\gamma_w$, $p_B = (2h/3 + h_1 + a)\gamma_w$.

Example 18.3

Using flow nets obtain a plot of Q/kh as a function of the ratio s/T for the single impervious sheetpile shown in Fig. 18.10(a).

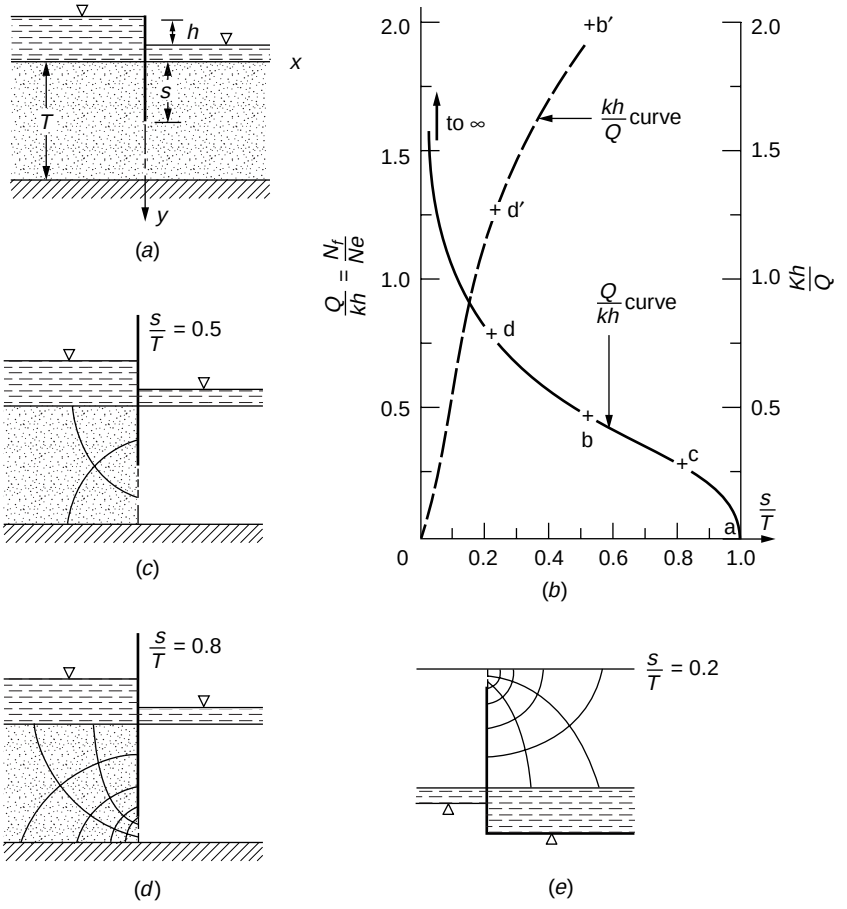

FIGURE 18.10 Example 18.3.

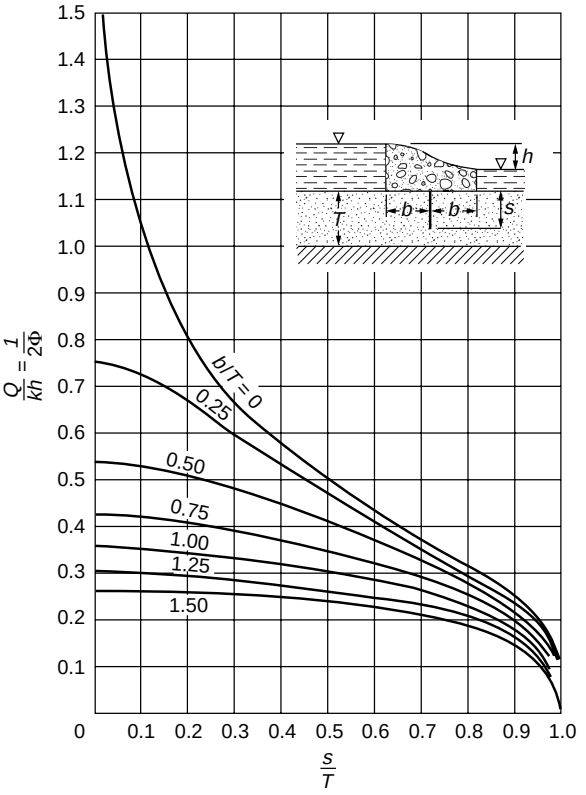
Solution. We first note that the section is symmetrical about the y axis, hence only one-half of a flow net is required. Values of the ratio s/T range from 0 to 1, with 0 indicating no penetration and 1 complete cutoff. For $s/T = 1$, $Q/kh = 0$ [see point a in Fig. 18.10(b)]. As the ratio of s/T decreases, more flow channels must be added to maintain curvilinear squares and, in the limit as s/T approaches zero, Q/kh becomes unbounded [see arrow in Fig. 18.10(b)]. If $s/T = 1/2$ [Fig. 18.10(c)], each streamline will evidence a corresponding equipotential line in the half-strip; consequently, for the whole flow region, $N_f/N_e = 1/2$ for $s/T = 1/2$ [point b in Fig. 18.10(b)]. Thus, without actually drawing a single flow net, we have learned quite a bit about the functional relationship between Q/kh and s/T. If Q/kh was known for $s/T = 0.8$ we would have another point and could sketch, with some reliability, the portion of the plot in Fig. 18.10(b) for $s/T \geq 0.5$. In Fig. 18.10(d) is shown one-half of the flow net for $s/T = 0.8$, which yields the ratio of $N_f/N_e = 0.3$ [point c in Fig. 18.10(b)]. As shown in Fig. 18.10(e), the flow net for $s/T = 0.8$ can also serve, geometrically, for the case of $s/T = 0.2$, which yields approximately $N_f/N_e = 0.8$ [plotted as point d in Fig. 18.10(b)]. The portion of the curve for values of s/T close to 0 is still in doubt. Noting that for $s/T = 0$, $kh/Q = 0$, we introduce an ordinate scale of kh/Q to the right of Fig. 18.10(b) and locate on this scale the corresponding values for $s/T = 0$, 0.2, and 0.5 (shown primed). Connecting these points (shown dotted) and obtaining the inverse, Q/kh, at desired points, the required curve can be had.

A plot giving the quantity of discharge (Q/kh) for symmetrically placed pilings as a function of depth of embedment (s/T), as well as for an impervious structure of width ($2b/T$), is shown in Fig. 18.11. This plot was obtained by Polubarinova-Kochina [1962] using a mathematical approach. The curve labeled $b/T = 0$ applies for the conditions in Example 18.3. It is interesting to note that this whole family of



$$\text{If } m = \cos\frac{\pi s}{2T}\sqrt{\tanh^2\frac{\pi b}{2T} + \tan^2\frac{\pi s}{2T}}$$

$$\text{for } m \le 0.3,\ \frac{Q}{kh} = \frac{1}{\pi}\ \ln\frac{4}{m}$$

$$\text{for } m^2 \le 0.9,\ \frac{Q}{kh} = \frac{-\pi}{2\ \ln\left(\frac{1\text{-}m^2}{16}\right)}$$

FIGURE 18.11 Quantity of flow for given geometry.

curves can be obtained, with reasonable accuracy (at least commensurate with the determination of the coefficient of permeability, k), by sketching only two additional half flow nets (for special values of b/T).

It was tacitly assumed in the foregoing that the medium was homogeneous and isotropic ($k_x = k_y$). Had isotropy not been realized, a transformation of scale (with x and y taken as the directions of maximum and minimum permeability, respectively) in the y direction of $Y = y(k_x/k_y)^{1/2}$ or in the x direction of $X = x(k_y/k_x)^{1/2}$ would render the system as an equivalent isotropic system [for details, see Harr, 1962, p. 29]. After the flow net has been established, by applying the inverse of the scaling factor, the solution can be had for the anisotropic system. The quantity of discharge for a homogeneous and anisotropic section is

$$Q = \sqrt{k_x k_y}\, h\frac{N_f}{N_e} \tag{18.26}$$

18.4 Method of Fragments

In spite of its many uses, a graphical flow net provides the solution for a particular problem only. Should one wish to investigate the influence of a range of characteristic dimensions (such as is often the case in

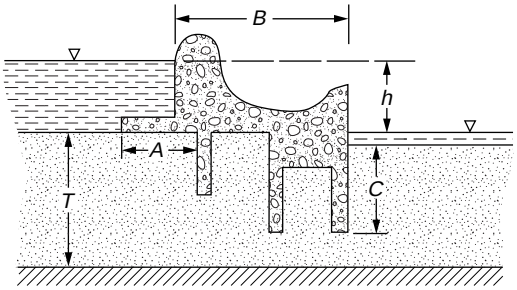


FIGURE 18.12 Example of complicated structure.

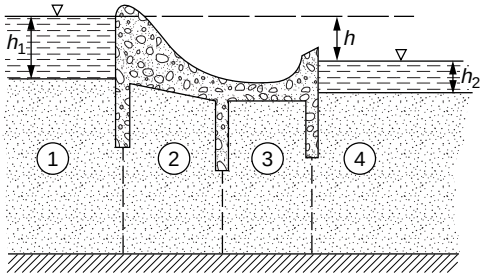

FIGURE 18.13 Four fragments.

a design problem), many flow nets would be required. Consider, for example, the section shown in Fig. 18.12, and suppose we wish to investigate the influence of the dimensions A, B, and C on the characteristics of flow, all other dimensions being fixed. Taking only three values for each of these dimensions would require 27 individual flow nets. As noted previously, a rough flow net should always be drawn as a check. In this respect it may be thought of as being analogous to a free-body diagram in mechanics, wherein the physics of a solution can be examined with respect to satisfying conditions of necessity.

An approximate analytical method of solution, directly applicable to design, was developed by Pavlovsky in 1935 [Pavlovsky, 1956] and was expanded and advanced by Harr [1962, 1977]. The underlying assumption of this method, called the **method of fragments**, is that equipotential lines at various critical parts of the flow region can be approximated by straight vertical lines (as, for example, the dotted lines in Fig. 18.13) that divide the region into sections or fragments. The groundwater flow region in Fig. 18.13 is shown divided into four fragments.

Suppose, now, that one computes the discharge in the ith fragment of a structure with m such fragments as

$$Q = \frac{kh_i}{\Phi_i} \tag{18.27}$$

where h_i is the head loss through the ith fragment and Φ_i is the dimensional form factor in the ith fragment, $\Phi_i = N_e/N_f$ in Eq. (18.25). Then, as the discharge through all fragments must be the same,

$$Q = \frac{kh_1}{\Phi_1} = \frac{kh_2}{\Phi_2} = \frac{kh_i}{\Phi_i} = \cdots = \frac{kh_m}{\Phi_m}$$

whence

$$\sum h_i = \frac{Q}{k} \sum \Phi_i$$

Fragment type	Illustration	Form factor, Φ (h is head loss through fragment)
I		$\Phi = \frac{L}{a}$
II		$\Phi = \frac{1}{2}\left(\frac{kh}{Q}\right)$, Fig. 17.11
III		$\Phi = \frac{1}{2}\left(\frac{kh}{Q}\right)$, Fig. 17.11
IV		$b \le s$: $\Phi = \ln\left(1+\frac{b}{a}\right)$ $b \ge s$: $\Phi = \ln\left(1+\frac{s}{a}\right) + \frac{b-s}{T}$

Fragment type	Illustration	Form factor, Φ (h is head loss through fragment)
V		$L \le 2s$: $\Phi = 2\ln\left(1+\frac{L}{2a}\right)$ $L \ge 2s$: $\Phi = 2\ln\left(1+\frac{s}{a}\right) + \frac{L-2s}{T}$
VI		$L \ge s'+s''$: $\Phi = \ln\left[\left(1+\frac{s'}{a'}\right)+\left(1+\frac{s''}{a''}\right)\right] + \frac{L-(s'+s'')}{T}$ $L \le s'+s''$: $\Phi = \ln\left[\left(1+\frac{b'}{a'}\right)\left(1+\frac{b''}{a''}\right)\right]$ where $b' = \frac{L+(s'-s'')}{2}$, $b'' = \frac{L-(s'-s'')}{2}$
VII		$\Phi = \frac{2L}{h_1+h_2}$ $Q = k\frac{h_1^2-h_2^2}{2L}$
VIII		$Q = k\frac{h_1-h}{\cot\alpha}\ln\frac{h_d}{h_d-h}$
IX		$Q = k\frac{a_2}{\cot\beta}\left(1+\ln\frac{a_2+h_2}{a_2}\right)$

FIGURE 18.14 Summary of fragment types and form factors.

and

$$Q = k\frac{h}{\sum_{i=1}^{m}\Phi_i} \tag{18.28}$$

where h (without subscript) is the total head loss through the section. By similar reasoning, the head loss in the ith fragment can be calculated from

$$h_i = \frac{h\Phi_i}{\sum\Phi} \tag{18.29}$$

Thus, the primary task is to implement this method by establishing a catalog of form factors. Following Pavlovsky, the various form factors will be divided into types. The results are summarized in tabular form, Fig. 18.14, for easy reference. The derivation of the form factors is well documented in the literature [Harr 1962, 1977].

Various entrance and emergence conditions for type VIII and IX fragments are shown in Fig. 18.15. Briefly, for the entrance condition, when possible the free surface will intersect the slope at right angles. However, as the elevation of the free surface represents the level of available energy along the uppermost streamline, at no point along the curve can it rise above the level of its source of energy, the headwater elevation. At the point of emergence the free surface will, if possible, exit tangent to the slope [Dachler, 1934]. As the equipotential lines are assumed to be vertical, there can be only a single value of the total head along a vertical line, and, hence, the free surface cannot curve back on itself. Thus, where unable to exit tangent to a slope, it will emerge vertical.

To determine the pressure distribution on the base of a structure (such as that along $C'CC''$) in Fig. 18.16, Pavlovsky assumed that the head loss within the fragment is linearly distributed along the impervious boundary. Thus, in Fig. 18.16, if h_m is the head loss within the fragment, the rate of loss along $E'C'CC''E''$ will be

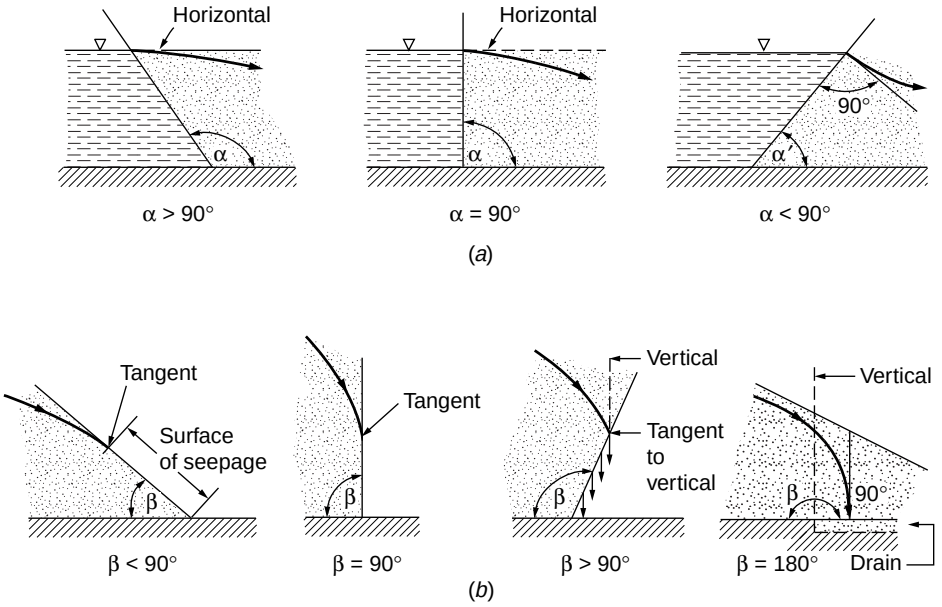

FIGURE 18.15 Entrance and emergence conditions.

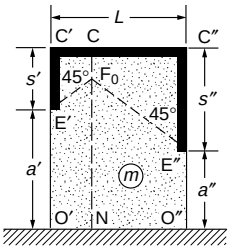

FIGURE 18.16 Illustration of Eq. (18.30).

$$R = \frac{h_m}{L + s' + s''} \tag{18.30}$$

Once the total head is known at any point, the pressure can easily be determined by subtracting the elevation head, relative to the established (tailwater) datum.

Example 18.4

For the section shown in Fig. 18.17(a), estimate (a) the discharge and (b) the uplift pressure on the base of the structure.

Solution. The division of fragments is shown in Fig. 18.17. Regions 1 and 3 are both type II fragments, and the middle section is of type V with $L = 2s$. For regions 1 and 3, we have, from Fig. 17,11, with $b/T = 0$, $\Phi_1 = \Phi_3 = 0.78$.

For region 2, as $L = 2s$, $\Phi_2 = 2 \ln (1+18/36) = 0.81$. Thus, the sum of the form factors is

$$\sum \Phi = 0.78 + 0.81 + 0.78 = 2.37$$

and the quantity of flow (Eq. 18.28) is $Q/k = 18/2.37 = 7.6$ ft.

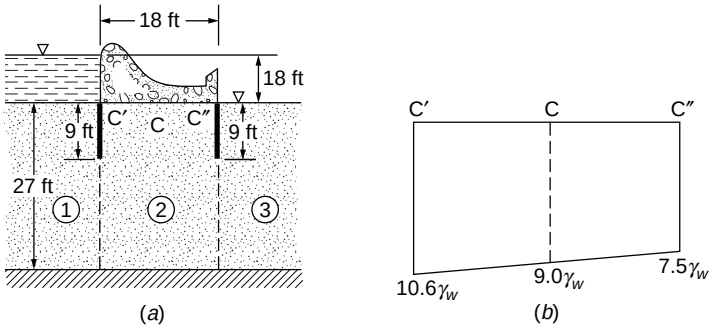

FIGURE 18.17 Example 18.4.

For the head loss in each of the sections, from Eq. (18.29) we find

$$h_1 = h_3 = \frac{0.78}{2.37}(18) = 5.9 \text{ ft}$$

$$h_2 = 6.1 \text{ft}$$

Hence the head loss rate in region 2 is (Eq. 18.30)

$$R = \frac{6.1}{36} = 17\%$$

and the pressure distribution along $C'CC''$ is shown in Fig. 18.17(b).

Example 18.5[3]

Estimate the quantity of discharge per foot of structure and the point where the free surface begins under the structure (point A) for the section shown in Fig. 18.18(a).

Solution. The line AC in Fig. 18.18(a) is taken as the vertical equipotential line that separates the flow domain into two fragments. Region 1 is a fragment of type III, with the distance B as an unknown quantity. Region 2 is a fragment of type VII, with $L = 25 - B$, $h_1 = 10$ ft, and $h_2 = 0$. Thus, we are led to a trial-and-error procedure to find B. In Fig. 18.18(b) are shown plots of Q/k versus B/T for both regions. The common point is seen to be $B = 14$ ft, which yields a quantity of flow of approximately $Q = 100k/22 = 4.5k$.

Example 18.6

Determine the quantity of flow for 100 ft of the earth dam section shown in Fig. 18.19(a), where $k = 0.002$ ft/min.

Solution. For this case, there are three regions. For region 1, a type VIII fragment $h_1 = 70$ ft, $\cot \alpha = 3$, $h_d = 80$ ft, produces

$$\frac{Q}{k} = \frac{70 - h}{3} \ln \frac{80}{80 - h} \tag{18.31}$$

For region 2, a type VII fragment produces

$$\frac{Q}{k} = \frac{h^2 - a_2^2}{2L} \tag{18.32}$$

[3]For comparisons between analytical and experimental results for mixed fragments (confined and unconfined flow) see Harr and Lewis [1965].

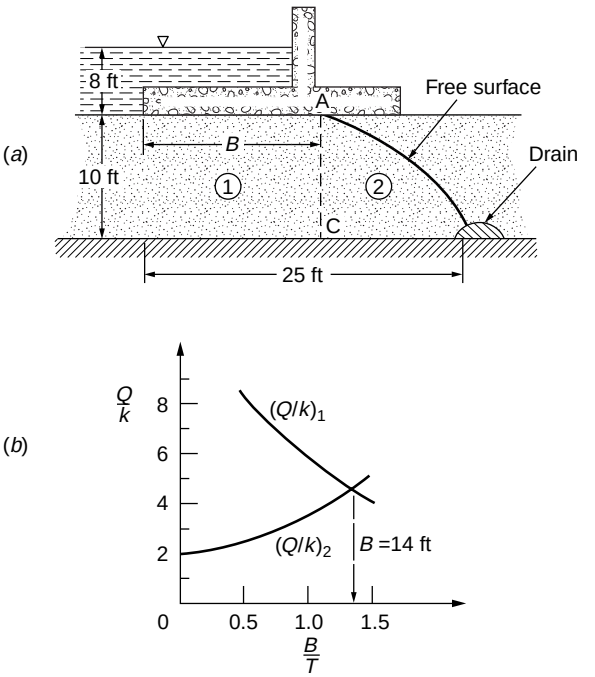

FIGURE 18.18 Example 18.5.

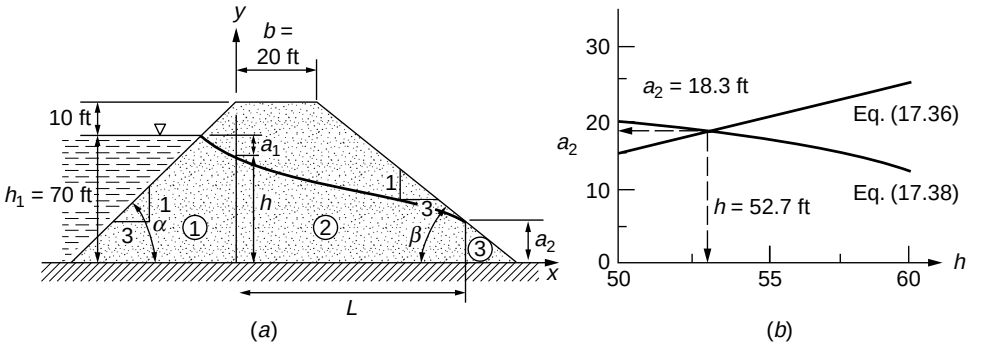

FIGURE 18.19 Example 18.6.

With tailwater absent, $h_2 = 0$, the flow in region 3, a type IX fragment, with cot β = 3 produces

$$\frac{Q}{k} = \frac{a_2}{3} \tag{18.33}$$

Finally, from the geometry of the section, we have

$$L = 20 + \cot\beta\,[h_d - a_2] = 20 + 3\,[80 - a_2] \tag{18.34}$$

The four independent equations contain only the four unknowns, h, a_2, Q/k, and L, and hence provide a complete, if not explicit, solution.

Combining Eqs. (18.32) and (18.33) and substituting for L in Eq. (18.34), we obtain, in general (b = crest width),

$$a_2 = \frac{b}{\cot\beta} + h_d - \sqrt{\left(\frac{b}{\cot\beta} + h_d\right)^2 - h^2} \tag{18.35}$$

and, in particular,

$$a_2 = \frac{20}{3} + 80 - \sqrt{\left(\frac{20}{3} + 80\right)^2 - h^2} \tag{18.36}$$

Likewise, from Eqs. (18.31) and (18.33), in general,

$$\frac{a_2 \cot\alpha}{\cot\beta} = (h_1 - h)\ln\frac{h_d}{h_d - h} \tag{18.37}$$

and, in particular,

$$a_2 = (70 - h)\ln\frac{80}{80 - h} \tag{18.38}$$

Now, Eqs. (18.36) and (18.38), and (18.35) and (18.37) in general, contain only two unknowns (a_2 and h), and hence can be solved without difficulty. For selected values of h, resulting values of a_2 are plotted for Eqs. (18.36) and (18.38) in Fig. 18.19(b). Thus, a_2 = 18.3 ft, h = 52.7 ft, and L = 205.1 ft. From Eq. (18.33), the quantity of flow per 100 ft is

$$Q = 100 \times 2 \times 10^{-3} \times \frac{18.3}{3} = 1.22\ \text{ft}^3/\text{min} = 9.1\ \text{gal/min}$$

18.5 Flow in Layered Systems

Closed-form solutions for the flow characteristics of even simple structures founded in layered media offer considerable mathematical difficulty. Polubarinova-Kochina [1962] obtained closed-form solutions for the two layered sections shown in Fig. 18.20 (with $d_1 = d_2$). In her solution she found a cluster of parameters that suggested to Harr [1962] an approximate procedure whereby the flow characteristics of structures founded in layered systems can be obtained simply and with a great degree of reliability.

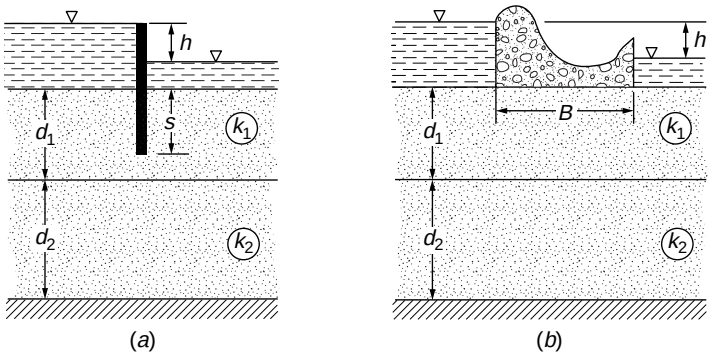

FIGURE 18.20 Examples of two-layered systems.

The flow medium in Fig. 18.20(a) consists of two horizontal layers of thickness d_1 and d_2, underlain by an impervious base. The coefficient of permeability of the upper layer is k_1 and of the lower layer k_2. The coefficients of permeability are related to a dimensionless parameter ε by the expression

$$\tan \pi\varepsilon = \sqrt{\frac{k_2}{k_1}} \tag{18.39}$$

(π is in radian measure). Thus, as the ratio of the permeabilities varies from 0 to ∞, ε ranges between 0 and 1/2. We first investigate the structures shown in Fig. 18.20(a) for some special values of ε.

1. $\varepsilon = 0$. If $k_2 = 0$, from Eq. (18.39) we have $\varepsilon = 0$. This is equivalent to having the impervious base at depth d_1. Hence, for this case the flow region is reduced to that of a single homogeneous layer for which the discharge can be obtained directly from Fig. 18.11.
2. $\varepsilon = 1/4$. If $k_1 = k_2$, the sections are reduced to a single homogeneous layer, of thickness $d_1 + d_2$, for which Fig. 18.11 is again applicable.
3. $\varepsilon = 1/2$. If $k_2 = \infty$, $\varepsilon = 1/2$. This represents a condition where there is no resistance to flow in the bottom layer. Hence, the discharge through the total section under steady state conditions is infinite, or $Q/k_1h = \infty$. However, of greater significance is the fact that the inverse of this ratio equals zero: $k_1h/Q = 0$. It can be shown [Polubarinova-Kochina, 1962] that for $k_2/k_1 \to \infty$,

$$\frac{Q}{k_1 h} = \sqrt{\frac{k_2}{k_1}} \tag{18.40}$$

Thus, we see that for the special values of $\varepsilon = 0$, $\varepsilon = 1/4$, and $\varepsilon = 1/2$, measures of the flow quantities can be easily obtained. The essence of the method then is to plot these values, on a plot of k_1h/Q versus ε, and connect the points with a smooth curve, from which intermediate values can be had.

Example 18.7

In Fig. 18.20(a), $s = 10$ ft, $d_1 = 15$ ft, $d_2 = 20$ ft, $k_1 = 4k_2 = 1 \infty 10^{-3}$ ft/min, $h = 6$ ft. Estimate Q/k_1h.

Solution. For $\varepsilon = 0$, from Fig. 18.11 with $s/T = s/d_1 = 2/3$, $b/T = 0$, $Q/k_1h = 0.39$, $k_1h/Q = 2.56$.
For $\varepsilon = 1/4$, from Fig. 18.11 with $s/T = s/(d_1 + d_2) = 2/7$, $Q/k_1h = 0.67$, $k_1h/Q = 1.49$.
For $\varepsilon = 1/2$, $k_1h/Q = 0$.

The three points are plotted in Fig. 18.21, and the required discharge, for $\varepsilon = 1/\pi \tan^{-1}. (1/4)^{1/2} = 0.15$, is $k_1h/Q = 1.92$ and $Q/k_1h = 0.52$; whence

$$\begin{aligned} Q &= 0.52 \times 1 \times 10^{-3} \times 6 \\ &= 3.1 \times 10^{-3} \text{ ft}^3/(\text{min})\,(\text{ft}) \end{aligned}$$

In combination with the method of fragments, approximate solutions can be had for very complicated structures.

Example 18.8

Estimate (a) the discharge through the section shown in Fig. 18.22(a), $k_2 = 4k_1 = 1 \times 10^{-3}$ ft/day and (b) the pressure in the water at point *P*.

Solution. The flow region is shown divided into four fragments. However, the form factors for regions 1 and 4 are the same. In Fig. 18.22(b) are given the resulting form factors for the listed conditions. In Fig. 18.22(c) is given the plot of k_1h/Q versus ε. For the required condition ($k_2 = 4k_1$), $\varepsilon = 0.35$, $k_1h/Q = 1.6$ and hence $Q = (1/1.6) \times 0.25 \times 10^{-3} \times 10 = 1.6 \times 10^{-3}$ ft³/(day) (ft).

The total head at point *P* is given in Fig. 18.22(b) as Δh for region 4; for $\varepsilon = 0$, $h_p = 2.57$ ft and for $\varepsilon = 1/4$, $h_p = 3.00$. We require h_p for $k_2 = \infty$; theoretically, there is assumed to be no resistance to the flow

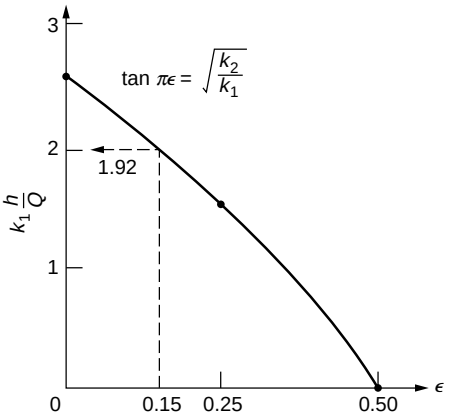

FIGURE 18.21 Example 18.7.

in the bottom layer for this condition. Hence the boundary between the two layers (*AB*) is an equipotential line with an expected value of *h*/2. Thus $h_p = 10/2 = 5$ for $\varepsilon = 1/2$. In Fig. 18.22(d) is given the plot of h_p versus ε. For $\varepsilon = 0.35$, $h_p = 2.75$ ft and the pressure in the water at point *P* is $(3.75 + 5)\gamma_w = 8.75\gamma_w$.

The above procedure may be extended to systems with more than two layers.

18.6 Piping

By virtue of the viscous friction exerted on a liquid flowing through a porous medium, an energy transfer is effected between the liquid and the solid particles. The measure of this energy is the head loss *h* between the points under consideration. The force corresponding to this energy transfer is called the *seepage force*. It is this seepage force that is responsible for the phenomenon known as *quicksand,* and its assessment is of vital importance in stability analyses of earth structures subject to the action of flowing water (seepage).

The first rational approach to the determination of the effects of seepage forces was presented by Terzaghi [1922] and forms the basis for all subsequent studies. Consider all the forces acting on a volume of particulate matter through which a liquid flows.

1. The total weight per unit volume, the mass unit weight, is

$$\gamma_m = \frac{\gamma_l (G + e)}{1 + e}$$

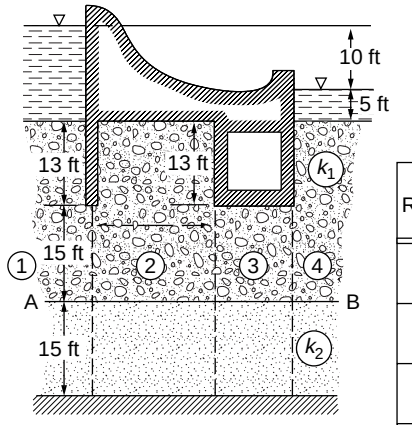
where *e* is the void ratio, *G* is the specific gravity of solids, and γ_l is the unit weight of the liquid.

2. Invoking Archimedes' principle of buoyancy (a body submerged in a liquid is buoyed up by force equal to the weight of the liquid displaced), the effective unit weight of a volume of soil, called the *submerged unit weight,* is

$$\gamma'_m = \gamma_m - \gamma_l = \frac{\gamma_l (G - 1)}{1 + e} \tag{18.41}$$

To gain a better understanding of the meaning of the submerged unit weight consider the flow condition shown in Fig. 18.23(a). If the water column (AB) is held at the same elevation as the discharge face CD ($h = 0$), the soil will be in a submerged state and the downward force acting on the screen will be

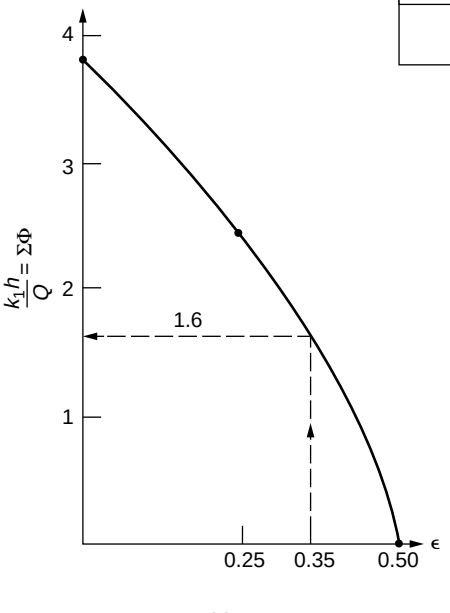
$$F\downarrow = \gamma'_m L A \tag{18.42}$$



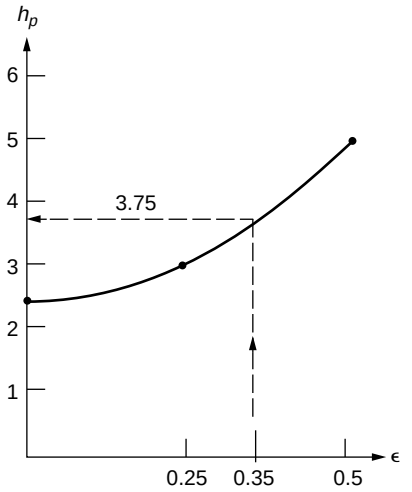
(*a*)

Region	Type	$\epsilon = 0$	$\epsilon = \frac{1}{4}$	Δh $\epsilon = 0$	Δh $\epsilon = \frac{1}{4}$
1	II	0.96	0.74	2.57	3.00
2	V	1.02	0.58	2.73	2.36
3	I	0.80	0.40	2.14	1.63
4	II	0.96	0.74	2.57	3.00
	$\Sigma\Phi$	3.74	2.46	Check: 10.0	Check: 10.0

(*b*)



(*c*)



(*d*)

FIGURE 18.22 Example 18.8.

where $\gamma'_m = \gamma_m - \gamma_w$. Now, if the water column is slowly raised (shown dotted to A′B′), water will flow up through the soil. By virtue of this upward flow, work will be done to the soil and the force acting on the screen will be reduced.

3. The change in force through the soil is due to the increased pressure acting over the area, or

$$F^+ = h\gamma_w A$$

Hence, the change in force, granted steady state conditions, is

$$\Delta F = \gamma'_m LA - h\gamma_w A \tag{18.43}$$

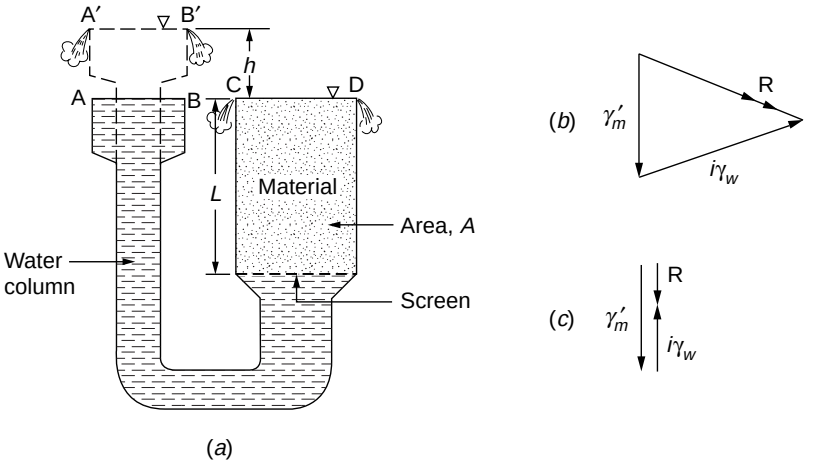


FIGURE 18.23 Piping.

Dividing by the volume AL, the resultant force per unit volume acting at a point within the flow region is

$$\mathbf{R} = \gamma'_m - i\gamma_w \tag{18.44}$$

where i is the hydraulic gradient. The quantity $i\gamma_w$ is the seepage force (force per unit volume). In general, Eq. (18.44) is a vector equation, with the seepage force acting in the direction of flow [Fig. 18.23(b)]. Of course, for the flow condition shown in Fig. 18.23(a), the seepage force will be directed vertically upward [Fig. 18.23(c)].

If the head h is increased, the resultant force **R** in Eq. (18.44) is seen to decrease. Evidently, should h be increased to the point at which $\mathbf{R} = 0$, the material would be at the point of being washed upward. Such a state is said to produce a **quick** (meaning alive) **condition**. From Eq. (18.44) it is evident that a quick condition is incipient if

$$i_{cr} = \frac{\gamma'_m}{\gamma_w} = \frac{G-1}{1+e} \tag{18.45}$$

Substituting typical values of $G = 2.65$ (quartz sand) and $e = 0.65$ (for sand, $0.57 \le e \le 0.95$), we see that as an average value the critical gradient can be taken as

$$i_{cr} \approx 1 \tag{18.46}$$

When information is lacking as to the specific gravity and void ratio of the material, the critical gradient is generally taken as unity.

At the critical gradient, there is no interparticle contact ($\mathbf{R} = 0$); the medium possesses no intrinsic strength, and will exhibit the properties of liquid of unit weight

$$\gamma_q = \left(\frac{G+e}{1+e}\right)\gamma_l \tag{18.47}$$

Substituting the above values for G, e, and $\gamma_l = \gamma_w$, $\gamma_q = 124.8$ lb/ft^3. Hence, contrary to popular belief, a person caught in quicksand would not be sucked down but would find it almost impossible to avoid floating.

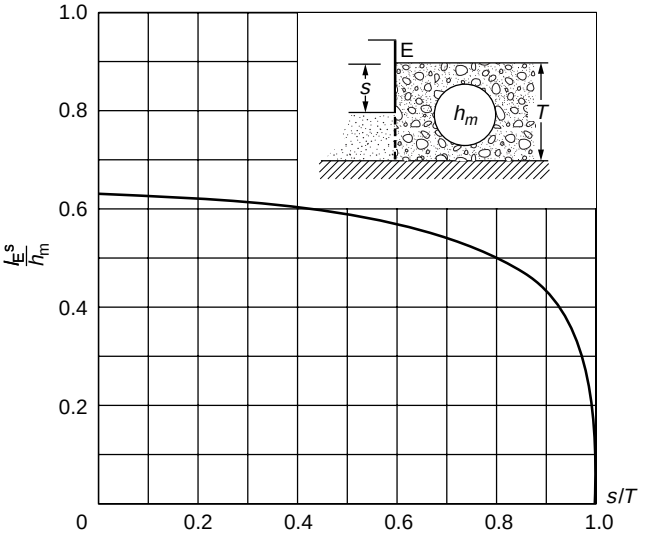

FIGURE 18.24 Exit gradient.

Many hydraulic structures, founded on soils, have failed as a result of the initiation of a local quick condition which, in a chainlike manner, led to severe internal erosion called **piping**. This condition occurs when erosion starts at the exit point of a flow line and progresses backward into the flow region forming pipe-shaped watercourses which may extend to appreciable depths under a structure. It is characteristic of piping that it needs to occur only locally and that once begun it proceeds rapidly, and is often not apparent until structural failure is imminent.

Equations (18.45) and (18.46) provide the basis for assessing the safety of hydraulic structures with respect to failure by piping. In essence, the procedure requires the determination of the maximum hydraulic gradient along a discharge boundary, called the *exit gradient,* which will yield the minimum resultant force ($\mathbf{R}_{\min}$) at this boundary. This can be done analytically, as will be demonstrated below, or from flow nets, after a method proposed by Harza [1935].

In the graphical method, the gradients along the discharge boundary are taken as the macrogradient across the contiguous squares of the flow net. As the gradients vary inversely with the distance between adjacent equipotential lines, it is evident that the maximum (exit) gradient is located where the vertical projection of this distance is a minimum, such as at the toe of the structure (point C) in Fig. 18.11. For example, the head lost in the final square of Fig. 18.11 is one-sixteenth of the total head loss of 16 ft, or 1 ft, and as this loss occurs in a vertical distance of approximately 4 ft, the exit gradient at point C is approximately 0.25. Once the magnitude of the exit gradient has been found, Harza recommended that the factor of safety be ascertained by comparing this gradient with the critical gradient of Eqs. (18.45) and (18.46). For example, the factor of safety with respect to piping for the flow conditions of Fig. 18.11 is 1.0/0.25, or 4.0. Factors of safety of 4 to 5 are generally considered reasonable for the graphical method of analysis.

The analytical method for determining the exit gradient is based on determining the exit gradient for the type II fragment, at point E in Fig. 18.14. The required value can be obtained directly from Fig. 18.24 with h_m being the head loss in the fragment.

Example 18.9

Find the exit gradient for the section shown in Fig. 18.17(a).

Solution. From the results of Example 18.4, the head loss in fragment 3 is $h_m = 5.9$ ft. With $s/T = 1/3$, from Fig. 18.24 we have $I_E s/h_m = 0.62$; hence,

$$I_E = \frac{0.62 \times 5.9}{9} = 0.41 \quad \text{or} \quad \text{FS} = \frac{1}{0.41} = 2.44$$

To account for the deviations and uncertainties in nature, Khosla et al. [1954] recommend that the following factors of safety be applied as critical values of exit gradients: gravel, 4 to 5; coarse sand, 5 to 6; and fine sand, 6 to 7.

The use of reverse filters on the downstream surface or where required serves to prevent erosion and decrease the probability of piping failures. In this regard, the Earth Manual of the U.S. Bureau of Reclamation, Washington [1974] is particularly recommended.

Defining Terms

Coefficient of permeability — Coefficient of proportionality between Darcy's velocity and the hydraulic gradient.
Flow net — Trial-and-error graphical procedure for solving seepage problems.
Hydraulic gradient — Space rate of energy dissipation.
Method of fragments — Approximate analytical method for solving seepage problems.
Piping — Development of a "pipe" within soil by virtue of internal erosion.
Quick condition — Condition when soil "liquifies."

Further Information

This chapter dealt with the conventional analysis of groundwater and seepage problems. Beginning in the mid-1970s another facet was added, motivated by federal environmental laws. These were concerned with transport processes, where chemical masses, generally toxic, are moved within the groundwater regime. This aspect of groundwater analysis gained increased emphasis with the passage of the Comprehensive Environmental Response Act of 1980, the *superfund*. Geotechnical engineers' involvement in these problems is likely to overshadow conventional problems. Several of the above references provide specific sources of information in this regard (cf. Domenico and Schwartz, Freeze and Cherry). The following are of additional interest:

Consolidation and Settlement Analysis

19.1 Components of Total Settlement
19.2 Immediate Settlement
19.3 Consolidation Settlement
Total Consolidation Settlement • Rate of Consolidation Settlement
19.4 Secondary Compression Settlement

Patrick J. Fox
Purdue University

In order to evaluate the suitability of a foundation or earth structure, it is necessary to design against both bearing capacity failure and excessive settlement. For foundations on cohesive soils, the principal design criterion is typically the latter—the control of expected settlements within the limits considered tolerable for the structure. As a result, once allowable foundation displacements have been established, the estimate of total settlement over the service life of the structure is a major factor in the choice of foundation design.

The purpose of this chapter is to present the fundamental concepts regarding settlement analysis for saturated, inorganic, cohesive soils. In addition, the recommended procedure for estimation of foundation settlements is described. Much of this chapter is based on Leonards [1968], Perloff [1975], and Holtz [1991]. Readers may refer to these works for additional information on consolidation and settlement analysis.

19.1 Components of Total Settlement

During construction, surface loads from foundations or earth structures are transmitted to the underlying soil profile. As a result, stresses increase within the soil mass and the structure undergoes a time-dependent vertical settlement. In general, this time–settlement curve can be represented conceptually as shown in Fig. 19.1. The **total settlement**, S, is calculated as the sum of the following three components:

$$S = S_i + S_c + S_s \tag{19.1}$$

where S_i is the **immediate settlement**, S_c is the **consolidation settlement**, and S_s is the **secondary compression settlement**.

Immediate settlement is time-independent and results from shear strains that occur at constant volume as the load is applied to the soil. Although this settlement component is not elastic, it is generally calculated using elastic theory for cohesive soils such as clays. Both consolidation and secondary compression settlement components are time-dependent and result from a reduction of void ratio and concurrent expulsion of water from the voids of the soil skeleton. For consolidation settlement, the rate of void ratio

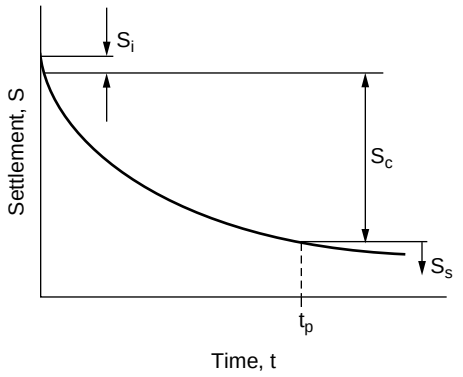

FIGURE 19.1 Time–settlement curve showing total settlement components.

reduction is controlled by the rate at which water can escape from the soil. Therefore, during consolidation, pore water pressure exceeds the steady state condition throughout the depth of the layer. Over time, the rate of consolidation settlement continuously decreases as effective stresses increase to approach their equilibrium values. Once the consolidation process is completed at time t_p, settlement continues in the form of secondary compression. During secondary compression, the rate of void ratio reduction is controlled by the rate of compression of the soil skeleton itself. As such, it is essentially a creep phenomenon that occurs at constant vertical effective stress and without sensible excess pressure in the pore water.

The time–settlement relationship shown in Fig. 19.1 is conceptually valid for all soil types. However, large differences exist in the magnitude of the components and the rate at which they occur for different soils. For granular soils, such as sands, the hydraulic conductivity is sufficiently large that consolidation occurs nearly instantaneously with the applied load. In addition, although granular soils do exhibit creep effects, secondary compression is generally insignificant. For cohesive soils, such as clays, hydraulic conductivity is very small and the consolidation of a thick deposit may require years or even decades to complete. Secondary compression can be substantial for cohesive soils. Different from both sands and clays, peats and organic soils generally undergo rapid consolidation and extensive, long-term secondary compression.

The first step in a settlement analysis is a careful study of the changes in applied loads and the selection of appropriate fractions of live load pertinent to each of the three total settlement components. Often, insufficient attention is given to this aspect of the problem. In general, immediate settlements should be computed using 100% of both live and dead loads of the structure. Consolidation and secondary compression settlements should be calculated using 100% of the dead load and permanent live load, but only a reasonable fraction of the transient live load. The proper estimate of this fraction should be made in consultation with the structural engineer on the project [Leonards, 1992].

19.2 Immediate Settlement

For saturated or nearly saturated cohesive soils, a linear elastic model is generally used for the calculation of immediate settlement. Although clays do not behave as linear elastic materials, the rationale for the use of elastic theory has been the availability of solutions for a wide variety of boundary conditions representative of foundation engineering problems. In general, the elastic approximation performs reasonably well in the case of saturated clays under monotonic loading conditions not approaching failure. In addition, for these same conditions, the elastic parameters can generally be assumed as approximately constant throughout an otherwise homogeneous soil mass [Perloff, 1975].

For cohesionless soils, in which the equivalent elastic modulus depends markedly on confinement, the use of linear elastic theory coupled with the assumption of material homogeneity is inappropriate.

Immediate settlement on granular soils is most often estimated using the procedure of Schmertmann [1970]. Holtz [1991] reviews this and other available methods in detail.

For those cases in which a linear elastic model is acceptable, solutions for stress distribution and surface deflection under a variety of flexible and rigid surface loading configurations can be found in Harr [1966], Perloff [1975], Poulos and Davis [1974], and Holtz [1991]. One particularly useful relationship is provided herein for the immediate settlement of a circular or rectangular footing at the surface of a deep isotropic stratum. In this case, the immediate vertical displacement is given by

$$S_i = C_s q B \left(\frac{1 - \nu^2}{E_u} \right) \tag{19.2}$$

where

S_i = immediate settlement of a point on the surface
C_s = shape and rigidity factor
q = equivalent uniform stress on the footing (total load/footing area)
B = characteristic dimension of the footing
ν = Poisson's ratio
E_u = undrained elastic modulus (Young's modulus)

The coefficient C_s is a function of the shape and rigidity of the loaded area and the point on the footing for which the immediate settlement estimate is desired. Thus, Eq. (19.2) can be used for both rigid and flexible footings, with the appropriate values of C_s given in Table 19.1. The characteristic footing dimension, B, is taken by convention as the diameter of a circular footing or the short side length of a rectangular footing. For saturated cohesive soils, constant volume strain is usually assumed and Poisson's ratio, ν, is set equal to 0.5. For soils that are nearly saturated, ν will be less than 0.5. However, using $\nu = 0.5$ is generally acceptable since the magnitude of computed immediate settlement is not especially sensitive to small changes in ν.

Reliable evaluation of the remaining soil parameter, the undrained elastic modulus, E_u, is critical for a good estimate of immediate settlement. In general, E_u is the slope of the undrained stress–strain curve for a stress path representative of the field condition. Figure 19.2 illustrates the measurement of E_u from a plot of principal stress difference, $\Delta\sigma$, versus axial strain, ε_a, as typically obtained from an undrained triaxial test. Principal stress difference is defined as $\sigma_1 - \sigma_3$, where σ_1 and σ_3 are the major and minor

TABLE 19.1 Values of C_s

Shape and Rigidity	Center	Corner	Edge/Middle of Long Side	Average
Circle (flexible)	1.00		0.64	0.85
Circle (rigid)	0.79		0.79	0.79
Square (flexible)	1.12	0.56	0.76	0.95
Square (rigid)	0.82	0.82	0.82	0.82
Rectangle (flexible): length/width

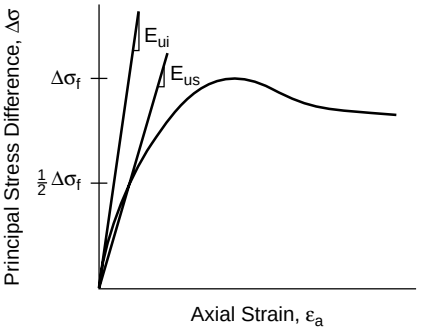

FIGURE 19.2 Definitions of the initial tangent modulus and secant modulus.

principal stresses, respectively. The initial tangent modulus, E_{ui}, is determined from the initial slope of the curve. The secant modulus, E_{us}, is sometimes used instead of E_{ui} when there is severe nonlinearity in the stress–strain relationship over the stress range of interest. Generally, the secant modulus would be taken at some predetermined stress level, such as 50% of the principal stress difference at failure, $\Delta\sigma_f$, in Fig. 19.2.

As a first approximation, the undrained elastic modulus can be estimated from the undrained shear strength using [Bjerrum, 1972]

$$E_u = 500c_u \quad \text{to} \quad E_u = 1500c_u \tag{19.3}$$

where c_u is the undrained shear strength determined from a field vane shear test. In general, E_u depends strongly on the level of shear stress. The lower value in Eq. (19.3) corresponds to highly plastic clays where the applied stress is relatively large as compared to the soil strength. The higher value is for low plasticity clays under small shear stress. In addition, the E_u/c_u ratio decreases with increasing **overconsolidation ratio** for a given stress level [Holtz and Kovacs, 1981]. Thus, Eq. (19.3) can provide a rough estimate of E_u suitable only for preliminary design computations.

In situations where a field loading test is not warranted, the undrained modulus should be estimated from a consolidated undrained (CU) triaxial test in the laboratory. The following procedure is recommended [Leonards, 1968]:

1. Obtain the highest quality soil samples. If possible, use a large-diameter piston sampler, or excavate blocks by hand from a test pit. Optimally, the laboratory test should be performed the same day as the field sampling operations.
2. Reconsolidate the specimen in the triaxial cell to the estimated initial *in situ* state of stress. If possible, anisotropic K_o consolidation is preferred to isotropic consolidation. Undrained modulus values determined from unconfined compression tests will significantly underestimate the actual value of E_u, and thereby overestimate the immediate settlement.
3. Load and unload the specimen in undrained axial compression to the expected *in situ* stress level for a minimum of 5 cycles. For field loading conditions other than a structural foundation, a different laboratory stress path may be needed to better match the actual *in situ* stress path.
4. Obtain E_u from the fifth (or greater) cycle in similar fashion to that shown in Fig. 19.2.

For sensitive clays of low plasticity, CU triaxial tests will likely yield somewhat low values of E_u, even if the specimens are allowed to undergo appreciable aging and E_u is determined at a low stress level. For highly plastic clays and organic clays, CU tests may yield stress–strain curves that are indicative of *in situ* behavior. However, it may be difficult to represent the nonlinear behavior with a single modulus value [D'Appolonia et al., 1971].

The undrained elastic modulus is best measured directly from field tests. For near surface clay deposits having a consistency that does not vary greatly with depth, E_u may be obtained from a plate load test placed at footing elevation and passed through several loading–unloading cycles (ASTM D1194). In this case, all the parameters in Eq. (19.2) are known except the factor $(1 - \nu^2)/E$, which can then be calculated. Because of the relatively shallow influence of the test, it may be advisable to use a selection of different size plates and then scale $(1 - \nu^2)/E$ to the size of the prototype foundation. In situations where the loaded stratum is deep or displays substantial heterogeneity, plate load tests may not provide a representative value for E_u. Large-scale loading tests utilizing, for example, an embankment or a large tank of water may be warranted. In this case, the immediate settlement of the proposed foundation is measured directly without requiring Eq. (19.2). Measurement of stress–strain behavior using field tests is preferred to laboratory tests because of the many difficulties in determining the appropriate modulus in the laboratory. The most important of these is the invariable disturbance of soil structure that occurs during sampling and testing. Of the many soil properties defined in geotechnical engineering, E_u is one of the most sensitive to sample disturbance effects [Ladd, 1964].

For many foundations on cohesive soils, the immediate settlement is a relatively small part of the total vertical movement. Thus, a detailed study is seldom justified unless the structure is very sensitive to distortion, footing sizes and loads vary considerably, or the shear stresses imposed by the foundation are approaching a failure condition.

19.3 Consolidation Settlement

Different from immediate settlement, consolidation settlement occurs as the result of volumetric compression within the soil. For granular soils, the consolidation process is sufficiently rapid that consolidation settlement is generally included with immediate settlement. Cohesive soils have a much lower hydraulic conductivity, and, as a result, consolidation requires a far longer time to complete. In this case, consolidation settlement is calculated separately from immediate settlement, as suggested by Eq. (19.1).

When a load is applied to the ground surface, there is a tendency for volumetric compression of the underlying soils. For saturated materials, an increase in pore water pressure occurs immediately upon load application. Consolidation is then the process by which there is a reduction in volume due to the expulsion of water from the pores of the soil. The dissipation of excess pore water pressure is accompanied by an increase in effective stress and volumetric strain. Analysis of the resulting settlement is greatly simplified if it is assumed that such strain is one-dimensional, occurring only in the vertical direction. This assumption of one-dimensional compression is considered to be reasonable when (1) the width of the loaded area exceeds four times the thickness of the clay stratum, (2) the depth to the top of the clay stratum exceeds twice the width of the loaded area, or (3) the compressible material lies between two stiffer soil strata whose presence tends to reduce the magnitude of horizontal strains [Leonards, 1976].

Employing the assumption of one-dimensional compression, the consolidation settlement of a cohesive soil stratum is generally calculated in two steps:

1. Calculate the total (or "ultimate") consolidation settlement, S_c, corresponding to the completion of the consolidation process.
2. Using the theory of one-dimensional consolidation, calculate the fraction of S_c that will have occurred by the end of the service life of the structure. This fraction is the component of consolidation settlement to be used in Eq. (19.1).

In actuality, the total amount of consolidation settlement and the rate at which this settlement occurs is a coupled problem in which neither quantity can be calculated independently from the other. However, in geotechnical engineering practice, total consolidation settlement and rate of consolidation are almost always computed independently for lack of widely accepted procedures to solve the coupled problem. This will also be the approach taken here. The calculation of total consolidation settlement will be presented first, followed by procedures to calculate the rate at which this settlement occurs.

Total Consolidation Settlement

Total one-dimensional consolidation settlement, S_c, results from a change in void ratio, Δe, over the depth of the consolidating layer. The basic equation for calculating the total consolidation settlement of a single compressible layer is

$$S_c = \frac{\Delta e H_o}{1 + e_o} \tag{19.4}$$

where e_o is the initial void ratio and H_o is the initial height of the compressible layer.

Consolidation settlement is sometimes calculated using H_o for the entire consolidating stratum and stress conditions acting at the midheight. This procedure will underestimate the actual settlement, and the error will increase with the thickness of the clay. As Δe generally varies with depth, settlement calculations can be improved by dividing the consolidating stratum into n sublayers for purposes of analysis. Equation (19.4) is then applied to each sublayer and the cumulative settlement is computed using the following equation:

$$S_c = \sum_{i=1}^{n} \frac{\Delta e_i H_{oi}}{1 + e_{oi}} \tag{19.5}$$

where Δe_i, is the change in void ratio, H_{oi} is the initial thickness, and e_{oi} is the initial void ratio of the ith sublayer.

The appropriate Δe_i for each sublayer within the compressible soil must now be determined. To begin, both the initial vertical effective stress, σ'_{vo}, and the final vertical effective stress (after excess pore pressures have fully dissipated), σ'_{vf}, are needed. The distribution of σ'_{vo} with depth is usually obtained by subtracting the *in situ* pore pressure from the vertical total stress, σ_v. Vertical total stress at a given depth is calculated using the following equation:

$$\sigma_v = \sum_{j=1}^{m} \gamma_j z_j \tag{19.6}$$

where

γ_j = unit weight of the jth stratigraphic layer
z_j = thickness of the jth stratigraphic layer
m = number of layers above the depth of interest

It should not be assumed a priori that *in situ* pore pressures are hydrostatic. Rather, significant upward or downward groundwater flow may be present. For important structures, the installation of piezometers to measure the *in situ* distribution of pore pressure is warranted. In addition, these piezometers will also provide a valuable check on the estimated initial excess pore pressures and indicate when the consolidation process is complete.

The final vertical effective stress is equal to the initial vertical effective stress plus the change of vertical effective stress, $\Delta\sigma'_v$, due to loading:

$$\sigma'_{vf} = \sigma'_{vo} + \Delta\sigma'_v \tag{19.7}$$

For truly one-dimensional loading conditions, such as a wide fill, $\Delta\sigma'_v$ is constant with depth and equal to the change in total stress applied at the surface of the soil stratum. For situations in which the load is applied over a limited surface area, such as a spread footing, $\Delta\sigma'_v$ will decrease with depth as the surface load is transmitted to increasingly larger portions of the soil mass. In this case, the theory of elasticity can be used to estimate $\Delta\sigma'_v$ as a function of depth under the center of the loaded area.

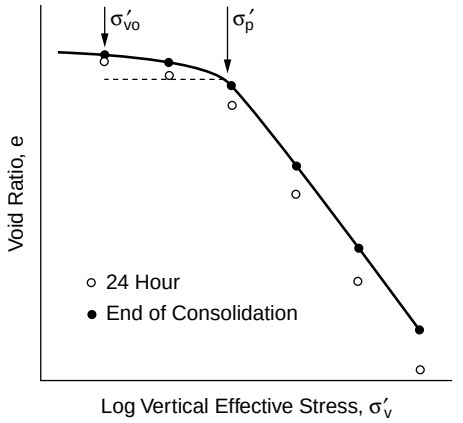

FIGURE 19.3 Typical laboratory compressibility curve.

Once initial and final stress conditions have been established, it is necessary to determine the relationship between void ratio and vertical effective stress for the *in situ* soils. This information is generally obtained from a laboratory consolidation test (ASTM D2435). The general consolidation testing procedure is to place successive loads on an undisturbed soil specimen (typically 25.4 mm high with a diameter-to-height ratio of at least 2.5 to 1) and measure the void ratio corresponding to the end of consolidation for each load increment. The load increment ratio (LIR) is defined as the added load divided by the previous total load on the specimen. The load increment duration (LID) is the elapsed time permitted for each load increment. For the standard consolidation test, the load is doubled every day, giving LIR = 1 and LID = 24 hours. Detailed procedures for specimen preparation and performance of the laboratory consolidation test are found in Bowles [1992].

A typical laboratory compressibility curve is shown in Fig. 19.3. Void ratio, e, is plotted as a function of vertical effective stress, σ'_v, on a semilogarithmic scale. The open points are void ratios measured at the end of 24 hours for each load increment. They include the contribution from all previous immediate and secondary compression settlement. The solid points represent the sum of changes in void ratio during consolidation alone, and are calculated by subtracting out the immediate and secondary compression from all previous load increments. As indicated in Fig. 19.3, the laboratory compressibility curve is best drawn through the solid points. The reason for this procedure is that S_i, S_c, and S_s are computed separately and then summed to calculate total settlement S using Eq. (19.1). Therefore, immediate and secondary compression settlements should likewise be removed from the laboratory compressibility curve to compute S_c.

For the compressibility curve in Fig. 19.3, both the **preconsolidation pressure**, σ'_p and the *in situ* initial vertical effective stress are indicated. The stress history of a soil layer is generally expressed by its **overconsolidation ratio** (OCR), which is the ratio of these two values:

$$\text{OCR} = \frac{\sigma'_p}{\sigma'_{vo}} \tag{19.8}$$

Normally consolidated soils have OCR = 1, while soils with an OCR > 1 are *preconsolidated* or *overconsolidated*. For the example shown in Fig. 19.3, the soil is overconsolidated. In addition, a soil can be underconsolidated if excess pore pressures exist within the deposit (i.e., the soil is still undergoing consolidation). With the exception of recently deposited materials, soils in the field are very often overconsolidated as a result of unloading, desiccation, secondary compression, or aging effects [Brumund et al., 1976].

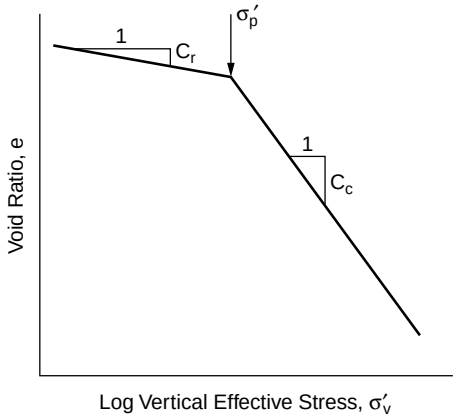

FIGURE 19.4 Simplified approximation of a laboratory compressibility curve.

The preconsolidation pressure is the stress at which the soil begins to yield in volumetric compression, and it therefore separates the region of small strains ($\sigma'_v < \sigma'_p$) from the region of large strains ($\sigma'_v > \sigma'_p$) on the $e - \log \sigma'_v$ diagram. As a result, for a given initial and final stress condition, the total consolidation settlement of a compressible layer is highly dependent on the value of the preconsolidation pressure. If a foundation applies a stress increment such that the final stress is less than σ'_p, the consolidation settlement will be relatively small. However, if the final stress is larger than σ'_p, much larger settlements will occur. Therefore, accurate determination of the preconsolidation pressure, and its variation with depth, is the most important step in a settlement analysis. The determination of σ'_p is generally performed using the Casagrande graphical construction method [Holtz and Kovacs, 1981].

For analysis purposes, the laboratory compressibility curve is usually approximated as linear (in log scale) for both the overconsolidated and normally consolidated ranges. A typical example is shown in Fig. 19.4. The slope of the overconsolidated range is the *recompression index*, C_r. Although this portion of a compressibility curve is generally not linear on the semilog plot, a line of constant C_r is usually fitted to the data for simplicity. The slope of the normally consolidated portion of the compressibility curve is the *compression index*, C_c. C_c is often constant over typical stress ranges of engineering interest. Both C_c and C_r are calculated using the same formula:

$$C_c = -\frac{\Delta e}{\Delta \log \sigma'_v} \qquad \text{normally consolidated stress range} \tag{19.9}$$

$$C_r = -\frac{\Delta e}{\Delta \log \sigma'_v} \qquad \text{overconsolidated stress range} \tag{19.10}$$

In many clay deposits, σ'_p, C_c, and C_r vary considerably with depth and the practice of performing one or two consolidation tests to evaluate the entire profile is seldom satisfactory. The following procedure is recommended for performing and interpreting the consolidation test to best obtain these parameters:

1. Obtain the highest quality undisturbed specimens, each representative of one sublayer in the profile, and begin testing the same day if possible. The value of σ'_p determined in the laboratory is very sensitive to sample disturbance and will generally be underestimated from data obtained using poor-quality soil samples.
2. Perform a consolidation test in which each load increment is placed on the specimen at the end of consolidation for the previous increment. The final void ratio obtained from each load will then directly provide the solid points in Fig. 19.3. The end of consolidation can be determined from pore pressure measurements or, less accurately, from graphical procedures such as the Casagrande log time or Taylor square root of time methods. LIR = 1 is satisfactory; however, to

more accurately measure the value of σ'_p, it may be advantageous to run a second test with smaller load increments in the vicinity of the preconsolidation pressure. If a standard consolidation test is performed using LID = 24 hours, plot the cumulative void ratio reduction during consolidation for each increment as shown by the solid dots in Fig. 19.3.

3. Obtain C_r by unloading from σ'_p to σ'_{vo} and then reloading. This path is indicated by the dashed line in Fig. 19.3. Using the initial reloading curve in Fig. 19.3 will yield too large a value of C_r. When the value of C_r is critical to a particular design, a backpressure oedometer should be used for testing. A C_r value obtained by unloading and reloading in a conventional oedometer (without backpressure) is about twice the value obtained in a backpressure oedometer due to expansion of gas within the pore water.
4. Reconstruct the *in situ* compressibility curve using the methods of Schmertmann [1955] as described in Holtz and Kovacs [1981], among others.

Once the *in situ* compressibility curve has been established for a given sublayer, the change of void ratio can be calculated knowing $\Delta\sigma'_v$. For normally consolidated conditions, the change of void ratio for the ith sublayer is

$$\Delta e_i = C_{ci} \log\left(\frac{\sigma'_{vfi}}{\sigma'_{voi}}\right) \tag{19.11}$$

Substituting Eq. (19.11) into Eq. (19.5), the ultimate consolidation settlement for a normally consolidated soil is

$$S_c = \sum_{i=1}^{n} \frac{C_{ci} H_{oi}}{1 + e_{oi}} \log\left(\frac{\sigma'_{vfi}}{\sigma'_{voi}}\right) \tag{19.12}$$

where the summation is performed over n sublayers.

In the case of overconsolidated clays, the change of void ratio for a given $\Delta\sigma'_v$ is

$$\Delta e_i = C_{ri} \log\left(\frac{\sigma'_{vfi}}{\sigma'_{voi}}\right) \tag{19.13}$$

if $\sigma'_{vf} < \sigma'_p$ and

$$\Delta e_i = C_{ri} \log\left(\frac{\sigma'_{pi}}{\sigma'_{voi}}\right) + C_{ci} \log\left(\frac{\sigma'_{vfi}}{\sigma'_{voi}}\right) \tag{19.14}$$

if $\sigma'_{vf} > \sigma'_p$. Substituting Eqs. (19.13) and (19.14) into Eq. (19.5), the total consolidation settlement of an overconsolidated soil is

$$S_c = \sum_{i=1}^{n} \frac{C_{ri} H_{oi}}{1 + e_{oi}} \log\left(\frac{\sigma'_{vfi}}{\sigma'_{voi}}\right) \tag{19.15}$$

if $\sigma'_{vf} < \sigma'_p$ and,

$$S_c = \sum_{i=1}^{n} \frac{C_{ri} H_{oi}}{1 + e_{oi}} \log\left(\frac{\sigma'_{pi}}{\sigma'_{voi}}\right) + \frac{C_{ci} H_{oi}}{1 + e_{oi}} \log\left(\frac{\sigma'_{vfi}}{\sigma'_{voi}}\right) \tag{19.16}$$

if $\sigma'_{vf} > \sigma'_p$.

As noted earlier, this discussion of consolidation settlement has been limited to conditions of one-dimensional compression. In those cases where the thickness of the compressible strata is large relative

to the dimensions of the loaded area, the three-dimensional nature of the problem may influence the magnitude and rate of consolidation settlement. The best approach for problems of this nature is a three-dimensional numerical analysis, but these have not yet become generally accepted in practice. As an alternative, the semiempirical approach of Skempton and Bjerrum [1957] and the stress path method [Lambe, 1967] are more commonly used to take these effects into account.

Rate of Consolidation Settlement

The preceding discussion has described the calculation of ultimate consolidation settlement corresponding to the complete dissipation of excess pore pressure and the return of the soil to an equilibrium stress condition. At any time during the process of consolidation, the amount of settlement is directly related to the proportion of excess pore pressure that has been dissipated. The theory of consolidation is used to predict the progress of excess pore pressure dissipation as a function of time. Therefore, the same theory is also used to predict the rate of consolidation settlement. The one-dimensional theory of Terzaghi is most commonly used for prediction of consolidation settlement rate. The assumptions of the classical Terzaghi theory are as follows:

1. Drainage and compression are one-dimensional.
2. The compressible soil layer is homogenous and completely saturated.
3. The mineral grains and pore water are incompressible.
4. Darcy's law governs the outflow of water from the soil.
5. The applied load increment produces only small strains. Therefore, the thickness of the layer remains unchanged during the consolidation process.
6. The hydraulic conductivity and compressibility of the soil are constant.
7. The relationship between void ratio and vertical effective stress is linear and unique. This assumption also implies that there is no secondary compression settlement.
8. Total stress remains constant throughout the consolidation process.

Accepting these assumptions, the fundamental governing equation for one-dimensional consolidation is

$$\frac{\partial u}{\partial t} = c_v \frac{\partial^2 u}{\partial z^2} \tag{19.17}$$

where

$$c_v = \frac{k(1 + e_o)}{\gamma_w a_v} \tag{19.18}$$

and

k = hydraulic conductivity
γ_w = unit weight of water
e_o = initial void ratio
$a_v = -de/d\sigma'_v$ = coefficient of compressibility

The parameter c_v is called the coefficient of consolidation and is mathematically analogous to the diffusion coefficient in Fick's second law. It contains material properties that govern the process of consolidation and has dimensions of area per time. In general, c_v is not constant because its component parameters vary during the consolidation process. However, in order to reduce Eq. (19.17) to a linear form that is more easily solved, c_v is assumed constant for an individual load increment.

The consolidation equation [Eq. (19.17)] can be solved analytically using the Fourier series method. In the course of the solution, the following dimensionless quantities are defined:

$$Z = \frac{z}{H_{dr}} \tag{19.19}$$

$$T = \frac{c_v t}{H_{dr}^2} \tag{19.20}$$

$$U_z = 1 - \frac{u}{u_i} \tag{19.21}$$

where

z = depth below top of the compressible stratum
H_{dr} = length of the longest pore water drainage path
t = elapsed time of consolidation
u = excess pore pressure at time t and position z
u_i = initial excess pore pressure at position z

Z is a measure of the dimensionless depth within the consolidating stratum, T is the time factor and serves as a measure of dimensionless time, and U_z is the consolidation ratio. U_z is a function of both Z and T, and thus it varies throughout the consolidation process with both time and vertical position within the layer. U_z expresses the progress of consolidation at a specific point within the consolidating layer. The value of H_{dr} depends on the boundary drainage conditions for the layer. Figure 19.5 shows the two typical drainage conditions for the consolidation problem. A single-drained layer has an impervious and pervious boundary. Pore water can escape only through the previous boundary, giving $H_{dr} = H_o$. A double-drained layer is bounded by two pervious strata. Pore water can escape to either boundary, and therefore $H_{dr} = H_o/2$.

Figure 19.6 shows the solution to Eq. (19.17) in terms of the above dimensionless parameters. For a double-drained layer, pore pressure dissipation is modeled using the entire figure. However, for a single-drained layer, only the upper or lower half is used. As expected, U_z is zero for all Z at the beginning of the consolidation process ($T = 0$). As time elapses and pore pressures dissipate, U_z gradually increases to 1.0 for all points in the layer and σ'_v increases accordingly. From Fig. 19.6, it is possible to find the consolidation ratio (and therefore u and σ'_v) at any time t and any position z within the consolidating layer after the start of loading. The time factor T can be calculated from Eq. (19.20) given the c_v for a particular deposit, the total thickness of the layer, and the boundary drainage conditions.

Figure 19.6 also provides some insight as to the progress of consolidation with time. The isochrones (curves of constant T) represent the percent consolidation for a given time throughout the compressible layer. For example, the percent consolidation at the midheight of a doubly drained layer for $T = 0.2$ is approximately 23% (see point A in Fig. 19.6). However, at $Z = 0.5$, $U_z = 44\%$ for the same time factor. Similarly, near the drainage surfaces at $Z = 0.1$, the clay is already 86% consolidated. This also means,

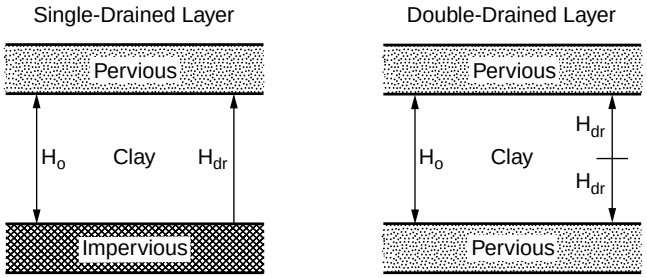

FIGURE 19.5 Boundary drainage conditions for the consolidation problem.

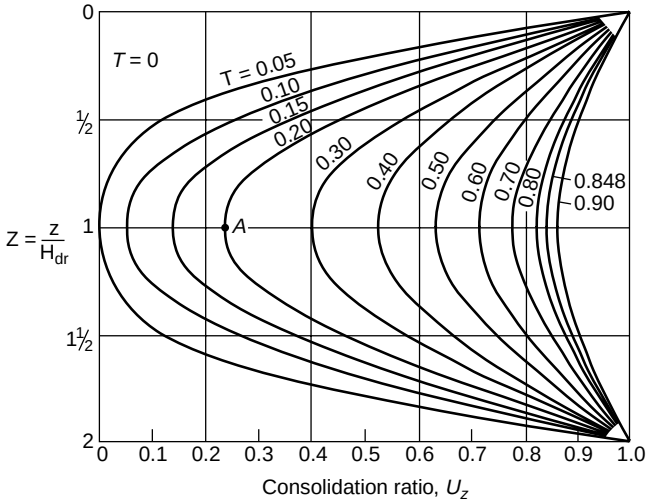

FIGURE 19.6 Consolidation ratio as a function of Z and T. (*Source:* Taylor, D. W. 1948. *Fundamentals of Soil Mechanics.* John Wiley & Sons, New York.)

at that same depth and time, 86% of the original excess pore pressure has dissipated and the effective stress has increased by a corresponding amount.

For settlement analysis, the consolidation ratio U_z is not the quantity of immediate interest. Rather, the geotechnical engineer needs to know the average degree of consolidation for the entire layer, U, defined as

$$U = \frac{s(t)}{S_c} \tag{19.22}$$

where $s(t)$ is the consolidation settlement at time t and S_c is the total (ultimate) consolidation settlement.

The following approximations can be used to calculate U. For $U < 0.60$,

$$T = \frac{\pi}{4}U^2 \tag{19.23}$$

and for $U > 0.60$,

$$T = 1.781 - 0.933 \log(100(1 - U)) \tag{19.24}$$

Provided S_c is known, Eqs. (19.22), (19.23), and (19.24) can be used to predict consolidation settlement as a function of time.

19.4 Secondary Compression Settlement

Secondary compression settlement results from the time-dependent rearrangement of soil particles under constant effective stress conditions. For highly compressible soils, such as soft clays and peats, secondary compression is important whenever there is a net increase in σ'_v due to surface loading. Although structures of any consequence would seldom be founded on these soils, highways, for example, must commonly cross areas of compressible soils that are either too deep or too extensive to excavate.

Secondary compression settlement can be predicted using the secondary compression index, C_α, defined as the change of void ratio per log cycle of time:

$$C_\alpha = -\frac{\Delta e}{\Delta \log t} \tag{19.25}$$

Laboratory values for the secondary compression index should be measured at a stress level and temperature corresponding to that expected in the subsurface.

As a first approximation, C_α can be calculated from the compression index using the ratio C_α/C_c. This method has the advantage of not requiring prolonged periods of secondary compression in the laboratory consolidation test. Recommended values for C_α/C_c are [Mesri and Castro, 1987]:

$$\frac{C_\alpha}{C_c} = 0.04 \pm 0.01 \quad \text{for soft inorganic clays} \tag{19.26}$$

$$\frac{C_\alpha}{C_c} = 0.05 \pm 0.01 \quad \text{for highly organic plastic clays} \tag{19.27}$$

Once a C_α value has been selected, secondary compression settlement S_s is calculated using the following equation:

$$S_s = \frac{C_\alpha H_o}{1 + e_o} \log \frac{t_f}{t_p} \tag{19.28}$$

where t_p is the time at the end of consolidation, and t_f is the final time for which secondary compression settlement is desired (typically the design life of the structure).

For all loading conditions, including one-dimensional compression, LIR decreases with depth. This is especially true for foundations where the load is spread over a limited surface area. For important structures, it is recommended to account for the effect of LIR on S_s. To begin, the secondary compression settlement per log cycle of time, R_s, is defined as follows,

$$R_s = \frac{\Delta S_s}{\Delta \log t} \tag{19.29}$$

Leonards and Girault [1961] demonstrated that a consistent relationship exists between R_s/S_c and LIR for Mexico City clay, as shown in Fig. 19.7. If a corresponding relationship can be obtained from laboratory consolidation tests, it can be used to estimate secondary compression settlement in the field in the following manner:

1. Divide the compressible strata into sublayers and compute the ultimate consolidation settlement S_{ci} for each ith sublayer using the procedure previously described.
2. Calculate LIR for each sublayer.
3. Obtain R_{si}/S_{ci} using the LIR for each sublayer.
4. Multiply the values of S_{ci} from step 1 by the values of R_{si}/S_{ci} obtained in step 3 to calculate R_{si} for each sublayer.
5. Sum the value of R_{si} for all sublayers to obtain R_s, the total secondary compression settlement per log cycle of time.
6. Calculate the secondary compression settlement using the following equation:

$$S_s = R_s \log \frac{t_f}{t_p} \tag{19.30}$$

Discrepancies of up to 75% may be expected using this procedure. This is indicative of the present state-of-the-art in predicting secondary compression settlement.

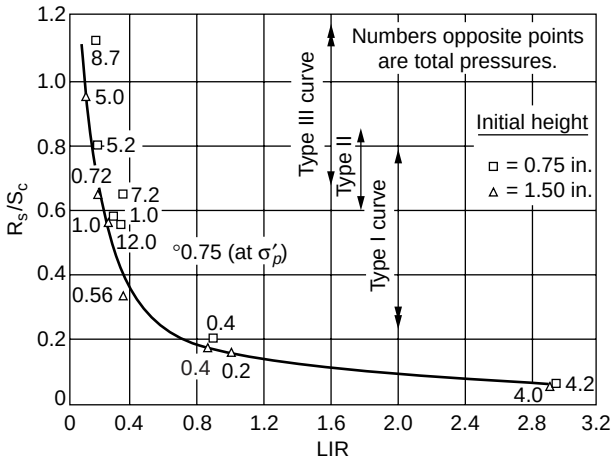

FIGURE 19.7 Effect of LIR on rate of secondary compression for undisturbed Mexico City clay. (*Source:* Leonards, G. A. and Girault, P. 1961. A study of the one-dimensional consolidation test. In *Proc. 5th Int. Conf. Soil. Mech. Found. Eng.,* Paris, 1:213–218.)

In many cases of practical interest, secondary compression is a minor effect relative to the magnitude of consolidation settlement. However, in some instances where very soft soils are involved or where deep compressible strata are subjected to small LIR, secondary compression may account for the majority of total settlement.

Defining Terms

Consolidation settlement — The time-dependent component of total settlement that results from the dissipation of excess pore pressure from within the soil mass.

Immediate settlement — The time-independent component of total settlement that occurs at constant volume as the load is applied to the soil.

Normally consolidated — A condition in which the initial vertical effective stress is equal to the preconsolidation pressure.

Overconsolidated — A condition in which the initial vertical effective stress is less than the preconsolidation pressure.

Overconsolidation ratio — The value of the preconsolidation pressure divided by the initial vertical effective stress.

Preconsolidation pressure — The vertical effective stress at which the soil begins to yield in volumetric compression.

Secondary compression — The time-dependent component of total settlement which occurs after consolidation and results from creep under constant effective stress.

Total settlement — The total vertical displacement of a foundation or earth structure that takes place after construction.

Stress Distribution

20.1 Elastic Theory (Continuum)
Three-Dimensional Systems • Two-Dimensional Systems
20.2 Particulate Medium
Two-Dimensional Systems • Three-Dimensional System • Distributed Vertical Loads at Surface

Milton E. Harr
Purdue University

From a microscopic point of view, all soil bodies are composed of discrete particles that are connected to each other by forces of mutual attraction and repulsion. Given an initial state of equilibrium, if an additional force system is applied, deformations may occur; particle arrangements may be altered; and changes in the distribution of the resultant forces may take place. Although the intensity of the generated forces may be high at points of contact, their range of influence is very short. Generally, effects extend only over a distance of molecular size or *in the very near vicinity* of the particles. The internal forces generated at these points by the induced loadings are called **stresses.**

Because stresses reflect distributional changes induced by boundary loadings, they can be thought of as providing a measure of the transmission of induced energy throughout the body. The transformation from real soil bodies, composed of discrete particles, into a form such that useful deductions can be made through the exact processes of mathematics is accomplished by introducing the abstraction of a *continuum,* or *continuous medium,* and pleading *statistical macroscopic equivalents* through the introduction of *material properties*. In concept, the soil is assumed to be continuously distributed in the region of space under consideration. This supposition then brings the continuous space required by mathematical formulations and the material points of real bodies into conformity.

This chapter will present some basic solutions for increases in vertical stresses due to some commonly encountered boundary loadings. Solutions will be presented both from the linear theory of elasticity and from particulate mechanics. Special efforts have been made to present the results in easy-to-use form. Many solutions can also be found in computer software packages.

20.1 Elastic Theory (Continuum)

Three-Dimensional Systems

Soil in the neighborhood of a point is called **isotropic** if its defining parameters are the same in all directions emanating from that point. Isotropy reduces the number of elastic constants at a point to two: E, the *modulus of elasticity;* and μ, *Poisson's ratio* [Harr, 1966]. If the elastic constants are the same at all points within a region of a soil body, that region is said to be **homogeneous.** Invoking *linear constitutive* equations produces

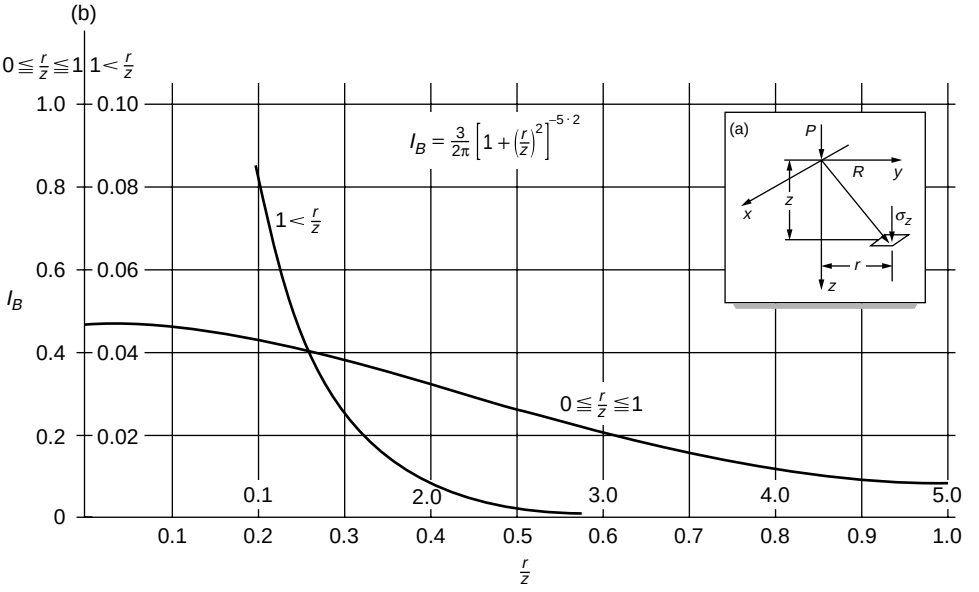

FIGURE 20.1 Concentrated force acting at and normal to surface; $\sigma_z = I_B P/z^2$.

$$
\begin{aligned}
\varepsilon_x &= \frac{1}{E}[\sigma_x - \mu(\sigma_y - \sigma_z)] \\
\varepsilon_y &= \frac{1}{E}[\sigma_y - \mu(\sigma_x - \sigma_z)] \\
\varepsilon_z &= \frac{1}{E}[\sigma_z - \mu(\sigma_x - \sigma_y)] \\
\gamma_{yz} &= \frac{2(1+\mu)}{E}\tau_{yz} \\
\gamma_{xz} &= \frac{2(1+\mu)}{E}\tau_{xz} \\
\gamma_{xy} &= \frac{2(1+\mu)}{E}\tau_{xy}
\end{aligned}
\tag{20.1}
$$

where ε_i and σ_i are the normal **strains** and stresses, respectively, and γ_i and τ_i are the shearing strains and stresses in the $i = x, y, z$ directions, respectively.

Force Normal to Surface (Boussinesq Problem)

Assuming that the z direction coincides with the direction of gravity, the vertical stress under a concentrated load P as shown in Fig. 20.1(a), where $R^2 = x^2 + y^2 + z^2$, is [Boussinesq, 1885]

$$
\sigma_z = \frac{3Pz^3}{2\pi R^5} \tag{20.2}
$$

It should be noted that the vertical normal stress (σ_z) is independent of the so-called elastic parameters. Equation (20.2) can also be written as

$$
\sigma_z = I_B \frac{P}{z^2} \tag{20.3}
$$

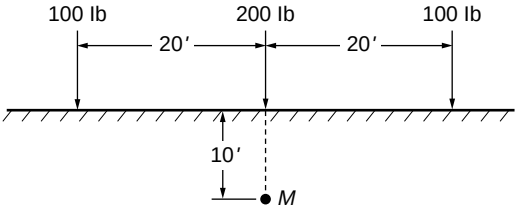

FIGURE 20.2 Example 20.1.

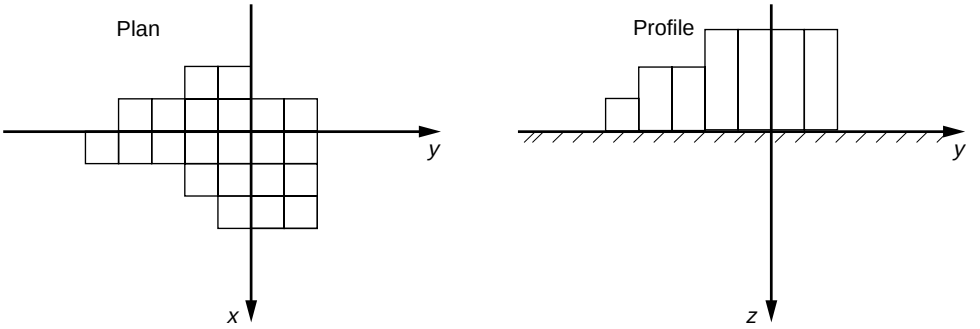

FIGURE 20.3 Distributed loads.

where

$$I_B = \frac{3}{2\pi}\left[1 + \left(\frac{r}{z}\right)^2\right]^{-5/2}$$

A plot of the **influence factor** I_B is given in Fig. 20.1(b).

Because superposition is valid, the effects of a number of normal forces acting on the surface of a body can be accounted for by adding their relative influence values.

Example 20.1

Find the vertical stress at point M in Fig. 20.2 due to the three loads shown acting in a line at the surface.

Solution. For the 200 lb force $r/z = 0$ and, from Fig. 20.1(b), $I_B = 0.478$. For the 100 lb forces, $r/z = 20/10 = 2$, $I_B = 0.009$. Hence, the corresponding vertical stress at point M is

$$\sigma_z = \frac{200(0.478)}{100} + \frac{2(100)(0.009)}{100} = 0.974 \text{ lb/ft}^2$$

By applying the principle of superposition, the increased stress due to distributed loadings over flexible areas at the surface can be obtained by dividing the loading into increments (see Fig. 20.3) and treating each increment as a concentrated force.

For a concentrated force parallel to the boundary surface (Fig. 20.4), the vertical stress [Cerruti, 1882] is

$$\sigma_z = \frac{3Qxz^2}{2\pi R^5} \tag{20.4}$$

By combining Eqs. (20.2) and (20.4), the increase in vertical stress, consistent with the assumptions of linear elasticity, can be determined for a concentrated force at the surface with any inclination.

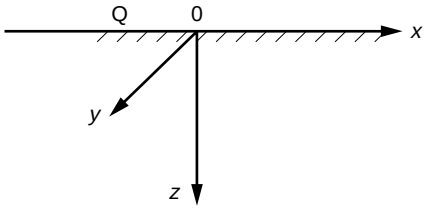

FIGURE 20.4 Concentrated force parallel to surface.

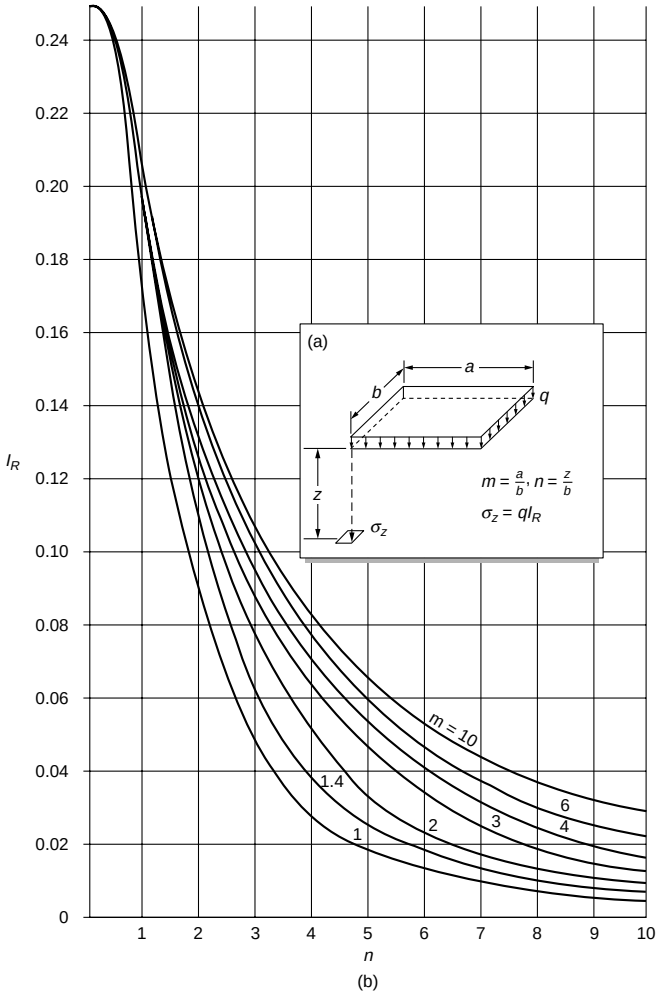

FIGURE 20.5 Normal uniform load over rectangular area. *Source:* After Steinbrenner, W. 1936 A rational method for the determination of the vertical normal stresses under foundations. *Proc. 1st Int. Conf. Soil Mech. Found. Eng.*, Vol. 2.

Uniform Flexible Load over Rectangular Area

The vertical stress under the corner of a flexible, uniformly loaded, rectangular area with sides a by b, as in Fig. 20.5(a), is

$$\sigma_z = \frac{q}{2\pi}\left[\frac{mn}{\sqrt{1+m^2+n^2}}\,\frac{1+m^2+2n^2}{(1+n^2)(m^2+n^2)} + \sin^{-1}\frac{m}{\sqrt{m^2+mn^2}\sqrt{1+n^2}}\right] \tag{20.5}$$

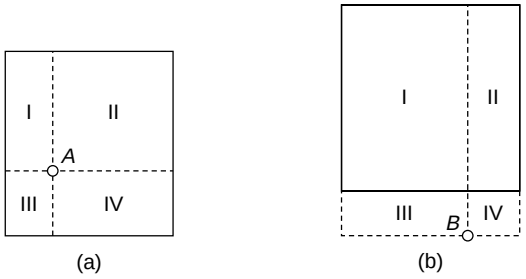

FIGURE 20.6 Vertical stress. (a) Interior. (b) Exterior.

where $m = a/b$ and $n = z/b$. This can also be written as

$$\sigma_z = qI_R$$

where I_R is a dimensionless influence factor. Figure 20.5(b) gives a plot of I_R as a function of the dimensionless ratios m and n. This form of the solution was given by Steinbrenner [1936].

By superposition, the distribution of vertical stress can be obtained anywhere under uniformly loaded, flexible, rectangular loadings. Two cases will be examined.

Vertical Stress for a Point Interior to a Loaded Area

For this case, Fig. 20.6(a), the influence factor I_R is determined from Fig. 20.5(b) for each of the rectangular areas (Roman numerals) with their corresponding m and n values and add them to obtain

$$\sigma_{zA} = q(I_{RI} - I_{RII} + I_{RIII} + I_{RIV})$$

Vertical Stress for a Point Exterior to a Loaded Area

For a point such as B in Fig. 20.6(b), the stress is computed as

$$\sigma_{zB} = q(I_{RI+III} + I_{RII+IV} - I_{RIII} - I_{RIV})$$

Influence Chart Normal Load

Although the above procedure can also be used to approximate irregularly shaped loadings, an influence chart, developed by Newmark [1942] greatly reduces the work required. Such a chart is shown in Fig. 20.7. To use the chart, the shape of the loading is drawn (generally on tracing paper) to scale so that the length AB on the chart represents the depth z at which the vertical stress is desired. The scaled drawing is then oriented so that the point under which the stress is sought is directly over the center of the circles on the chart. The number of blocks covered by the area of loading multiplied by the influence value (each square is $0.001q$ for this chart) yields, for the vertical stress, that part of the uniformly distributed load. By repeating this procedure and varying the size of the drawings, the complete distribution of vertical stresses can be found with depth. A separate drawing of the area is required for each depth. Although the chart was developed for uniform loadings over the whole area, the effects of varying loads can be treated as a series of uniform loadings.

Two-Dimensional Systems

In soil mechanics and foundation engineering, problems such as the analysis of retaining walls or of continuous footings and slopes generally offer one dimension very large in comparison with the other two. Hence, if boundary forces are perpendicular to and independent of this dimension, all cross sections will be the same. In Fig. 20.8 the y dimension is taken to be large, and it is assumed that the state of affairs existing in the xz plane holds for all planes parallel to it. These conditions are said to define the state of **plane strain.**

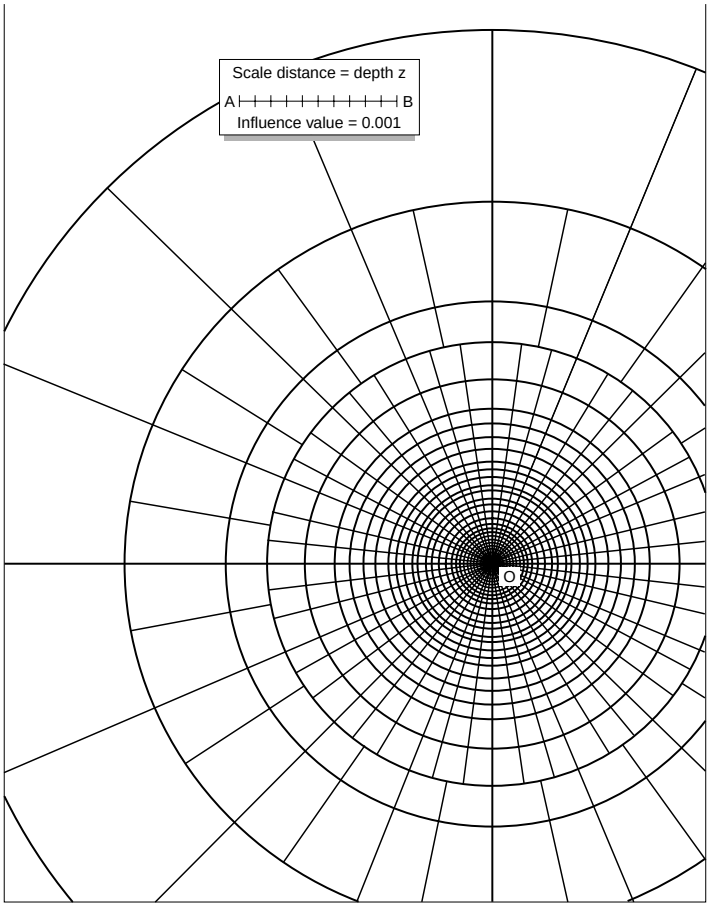

FIGURE 20.7 Influence chart for uniform vertical normal stress. *Source:* After Newmark, N. M. 1942. Influence charts for computation of stresses in elastic foundations. *Univ. of Illinois Bull. 338.*

Infinite Line Load Normal to Surface (Flamant Problem)

Figure 20.9(a) shows a semi-infinite plane with a concentrated load (line load) of intensity P (per unit run) normal to the surface. The solution, given by Flamant [1892], is

$$\sigma_z = \frac{2Pz^3}{\pi(x^2 + z^2)^2} \tag{20.6}$$

In Fig. 20.9(b) is given a plot of this equation taken as $\sigma_z = I_{\sigma z}(P/z)$. Also plotted are the influence factors for $I_{\sigma x}$ and the tangential stress, I_τ.

Example 20.2

Find the vertical normal stress at a depth corresponding to point A in Fig. 20.10, due to the three normal line forces N_1, N_2 and N_3.

Solution. The influence curve is oriented so that the origin (point O) is directly above point A (as shown). The magnitude of the force multiplied by the ordinate of the σ_z curve immediately under it for $P = 1$ (such as $\overline{B_1C_1}$ under N_1) gives that part of the stress at point A due to the particular force. By superposition the total vertical stress at point A is obtained as the algebraic sum of the contributions of each of the

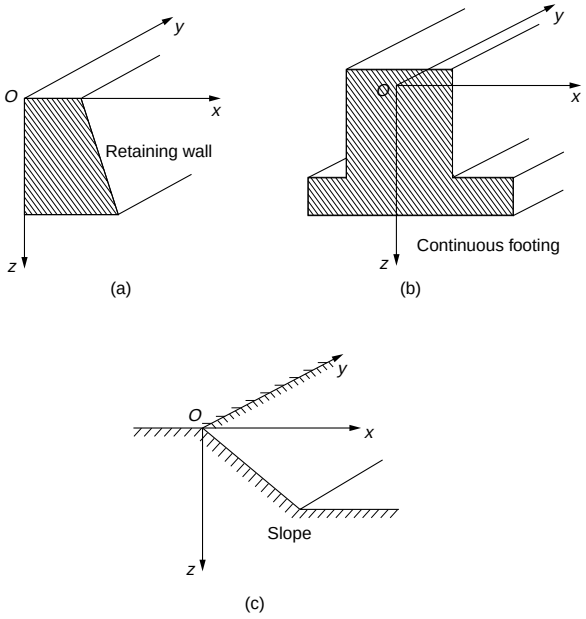

FIGURE 20.8 Examples of plane strain models.

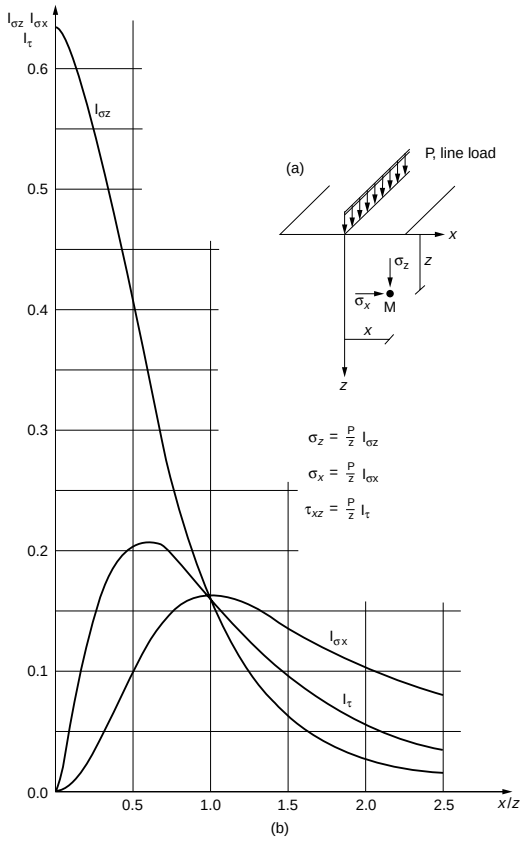

FIGURE 20.9 Infinite line load, normal to surface.

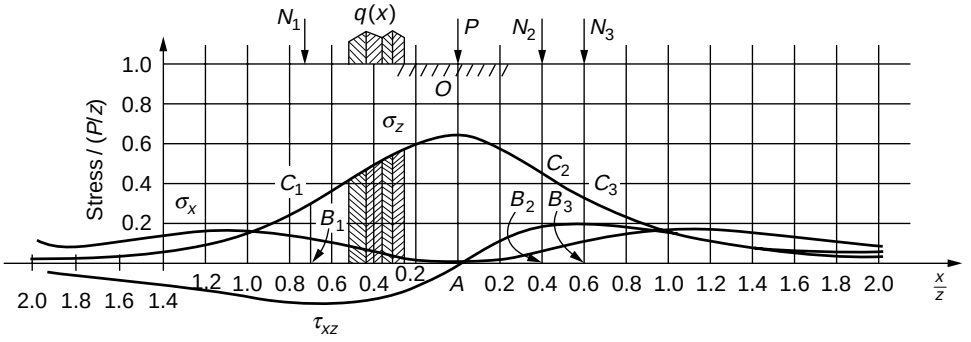

FIGURE 20.10 Example 20.2.

forces. Thus, for the three forces N_1, N_2, and N_3, the increase in vertical stress at point A is $\sigma_{zA} = (N_1(\overline{B_1C_1}) + N_2(\overline{B_2C_2}) + N_3(\overline{B_3C_3}))$.

Superposition also permits the determination of the stress under any distribution of flexible surface loading. For example, to obtain the vertical stress at point A in Fig. 20.10 under the distributed line load $q(x)$, the load is first divided into a number of increments, and each increment is then treated, as just described, as a concentrated force.

Infinite Strip of Width *b*

An influence chart [Giroud, 1973] provides the stress σ_z at point $P(x, z)$ in Fig. 20.11, due to the distributed vertical load q over a flexible strip of width b in the form

$$\sigma_z = I_{\sigma z} \cdot q \tag{20.7}$$

Plots of this equation as well as the influence factor $I_{\sigma x}$ are also shown.

20.2 Particulate Medium

Two-Dimensional Systems

Infinite Line Load Normal to Surface

On the basis of a probabilistic model, Harr [1977] gave the expression for the vertical stress due to a concentrated load (line load) of intensity P (per unit run) normal to the surface (see Fig. 20.9) as

$$\bar{s}_z = \frac{P}{z\sqrt{2\nu\pi}} \exp\left[-\frac{x^2}{2\nu z^2}\right] \tag{20.8}$$

The symbol $\bar{s}_z$ will be used to designate the vertical normal stress for the probabilistic model. The overlaid bar implies that this is the expected value of the stress. The customary symbol σ_z will be reserved for the linear theory of elasticity. Harr called the parameter ν (Greek nu) the *coefficient of lateral stress* and showed that it can be approximated by the conventional *coefficient of lateral earth pressure, K*. For comparisons with the linear theory of elasticity, $\nu \approx 1/3$.

Example 20.3

Compare the distribution of the vertical normal stress of the particulate theory with that given by the theory of elasticity, Eq.(20.6), using $\nu = K_{active} = 1/3$.

Solution. Some numerical values of these two functions are given in Table 20.1. The correspondence is seen to be very good.

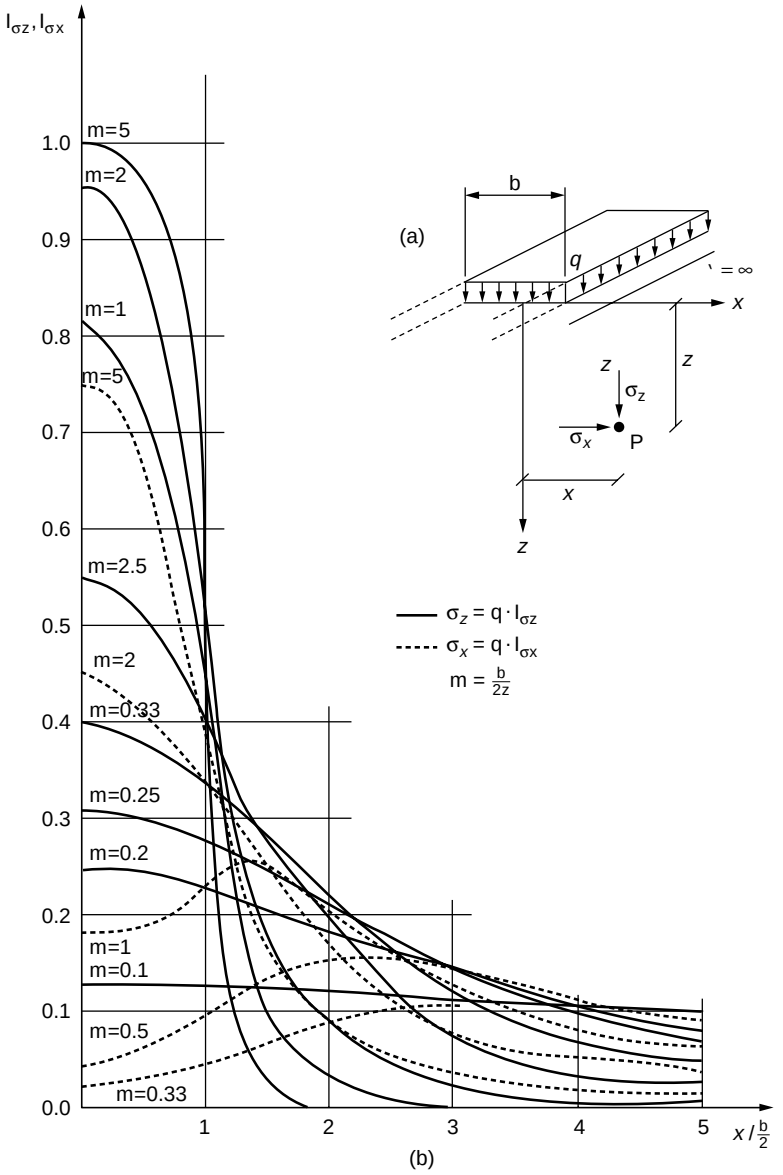

FIGURE 20.11 Stresses under infinite strip loading. *Source:* Giroud, J. P. 1973. *Tables pour le Calcul des Fondations.* 2 Vols. Dunod, Paris.

Infinite Strip of Width *b*

The counterpart of Eq. (20.7), Fig. 20.11, for the particulate model is

$$\bar{s}_z = q\left\{\psi\left[\frac{x + b/2}{z\sqrt{\nu}}\right] - \psi\left[\frac{x - b/2}{z\sqrt{\nu}}\right]\right\} \tag{20.9a}$$

and under the center line ($x = 0$),

$$\bar{s}_z(0) = 2q\psi\left[\frac{b}{2z\sqrt{\nu}}\right] \tag{20.9b}$$

TABLE 20.1 Comparison of Particulate and Elastic Solutions (Infinite Normal Line Load)

$\frac{x}{z}$	$z\bar{s}_z/P = \left(\frac{1}{2\nu\pi}\right)^{1/2} \exp\left[-\frac{x^2}{2\nu z^2}\right]$	$z\sigma_z/P = \left(\frac{2}{\pi}\right)\left[1+\frac{x^2}{z^2}\right]^{-2}$
0.0	0.69	0.64
0.1	0.68	0.62

2.0	0.004	0.03

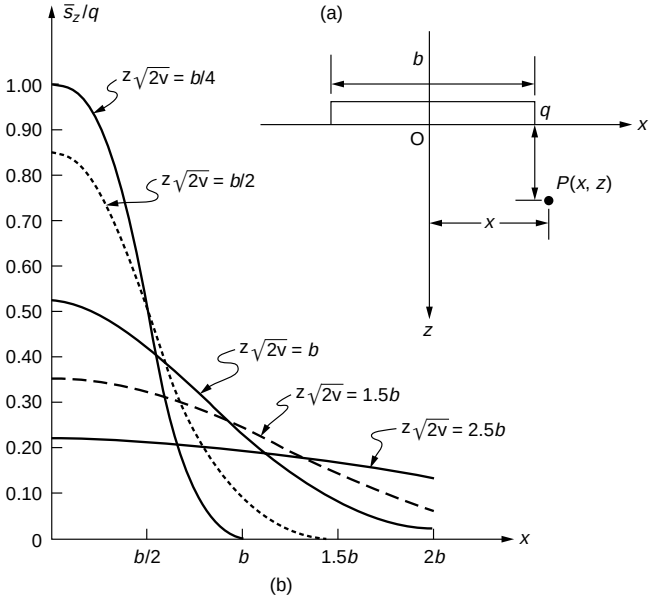

FIGURE 20.12 Uniform normal load over strip.

Values of the function $\psi[\ ]$ are given in Table 16.3 of Chapter 16. For example, $\psi[0.92] = 0.321$. In Fig. 20.12 a plot of $\bar{s}_z/q$ is given for a range of values (compare with Fig. 20.11 for $\nu = 1/3$).

Example 20.4

Find the expected value for the vertical normal stress at point $x = 2$ ft, $z = 4$ ft for a uniformly distributed load $q = 100$ lb/ft^2 acting over a strip 8 ft wide. Take $\nu = \pi/8$.

Solution. Equation (20.9a) becomes for this case

$$\bar{s}_z = 100\left\{\psi\left[\frac{2+4}{4(0.63)}\right] - \psi\left[\frac{(2-4)}{4(0.63)}\right]\right\}$$

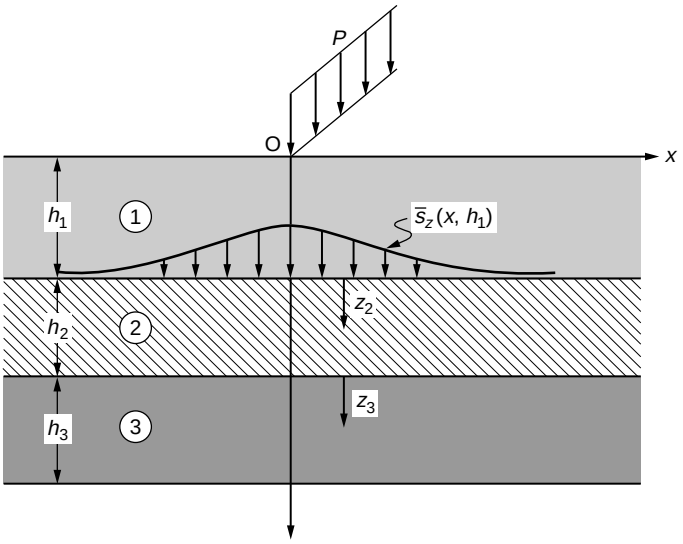

FIGURE 20.13 Multilayer system.

From Table 16.3 of Chapter 16,

$$\bar{s}_z = 100\{0.4916 + 0.2881\} = 78.0 \text{ lb/ft}^2$$

The theory of elasticity gives for the vertical stress in this case, from Fig. 20.11, $\sigma_z = 73$ lb/ft^2.

Multilayer System

Given a system with N layers in which the ith layer has thickness h_i and coefficient of lateral stress ν_i, Fig. 20.13, Kandaurov [1966] showed that the equivalent thickness for the upper $N - 1$ layers can be found as

$$\bar{h}_{N-1} = h_1\sqrt{\frac{\nu_1}{\nu_N}} + h_2\sqrt{\frac{\nu_2}{\nu_N}} + \cdots + h_{N-1}\sqrt{\frac{\nu_{N-1}}{\nu_N}} \tag{20.10}$$

Hence, the expected vertical normal stress in the Nth layer (z_N is the vertical distance into the Nth layer as measured from its upper boundary), for a line load P normal to the layers, will be

$$\bar{s}_z(x, z) = \frac{P}{h_{N-1} + z_N}\sqrt{\frac{1}{2\pi\nu_N}}\exp\left[-\frac{x^2}{2\nu_N(h_{N-1} + z_N)^2}\right] \tag{20.11}$$

Example 20.5

A three-layer system is subjected to a line load of 9000 lb/ft with the following information: $h_1 = 1$ ft, $\nu_1 = 0.4$; $h_2 = 2$ ft, $\nu_2 = 0.3$; $\nu_3 = 0.2$, h_3 is unbounded. Find the expected value for the vertical normal stress 3 ft into the third layer immediately under the line load.

Solution. From Eq. (20.10), the equivalent thickness is

$$\bar{h} = 1\sqrt{\frac{0.4}{0.2}} + 2\sqrt{\frac{0.3}{0.2}} = 3.86 \text{ ft}$$

Thus, from Eq. (20.11) the expected vertical normal stress at a depth of 3 ft in the third layer, immediately under the line load ($x = 0$), is

$$\bar{s}_z = \frac{9000}{3.86 + 3}\sqrt{\frac{1}{2\pi(0.2)}} = 1169.7 \text{ lb/ft}^2$$

The theory of elasticity would give for this case, assuming a single homogeneous layer, Eq. (20.6), $\sigma_z = 954.9$ lb/ft^2.

Three-Dimensional System

Force Normal to Surface

The probabilistic counterpart of the Boussinesq solution, Eq. (20.2), for the expected vertical normal stress is

$$\bar{s}_z = \frac{P}{2\pi\nu z^2}\exp\left[-\frac{r^2}{2\nu z^2}\right] \tag{20.12}$$

where $r^2 = x^2 + y^2$.

Example 20.6

Find the coefficient ν in Eq. (20.12) that would yield the same value for the maximum expected value of normal vertical stress as that given by the theory of elasticity.

Solution. For the theory of elasticity Eq. (20.2) gives as the maximum vertical stress

$$\sigma_{z_{\max}} = \frac{3P}{2\pi z^2}$$

Equation (20.12) gives

$$\bar{s}_{z_{\max}} = \frac{P}{2\pi\nu z^2}$$

Equating the two produces $\nu = 1/3$.

Example 20.7

Compare the lateral attenuation of vertical normal stress for the probabilistic theory with that given by the theory of elasticity (for three dimensions) using $\nu = 1/3$.

Solution. Substituting $\nu = 1/3$ into Eq. (20.12) obtains

$$\bar{s}_z = 3P/2\pi z^2 \exp[-3r^2/z^2]$$

The theory of elasticity, Eq. (20.2), yields $\sigma_z = 3P/2\pi z^2(1 + r^2/z^2)^{-5/2}$. Some values of the two functions are given in Table 20.2. In Fig. 20.14 a nomograph of the expected vertical normal stress is given for a range of ν values.

Example 20.8

Find the expected value of the vertical normal stress at the point $r = 6$ ft, $z = 10$ ft if $\nu = 1/5$ under a concentrated vertical force of 100 lb.

Solution. The arrow in Fig. 20.14 indicates that for the given conditions $vz^2\bar{s}_z/P = 0.06$. Hence, the expected value of the vertical normal stress is $\bar{s}_z = 0.065(100)(5)(1/100) = 0.33$ lb/ft^2. The theory of elasticity gives for this case, Fig. 20.1, $\sigma_z = 0.22$ lb/ft^2.

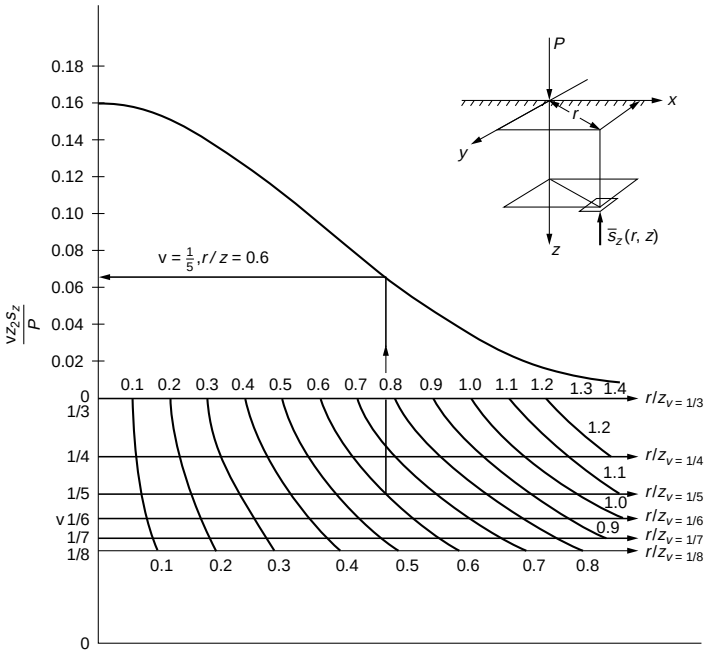

FIGURE 20.14 Expected value of vertical stress, particulate model.

TABLE 20.2 Comparison of Particulate and Elastic Solutions (Normal Point Load)

r/z	$z^2\bar{s}_z/P$	$z^2\sigma_z/P$
0.0	0.48	0.48
0.1	0.47	0.47
0.2	0.45	0.43
0.4	0.38	0.33
0.6	0.28	0.22
0.8	0.18	0.14

1.2	0.06	0.05
1.5	0.02	0.03
2.0	0.001	0.01

Distributed Vertical Loads at Surface

Normal Uniform Load over a Rectangular Area

The probabilistic counterpart of Eq. (20.5) for the expected vertical normal stress under the corner of a rectangular area with sides a by b, as in Fig. 20.5(a), is

$$\bar{s}_z/q = \psi\left[\frac{a}{z\sqrt{v}}\right]\psi\left[\frac{b}{z\sqrt{v}}\right] \tag{20.13}$$

Values of the function $\psi[\,]$ are given in Table 16.3 of Chapter 16.

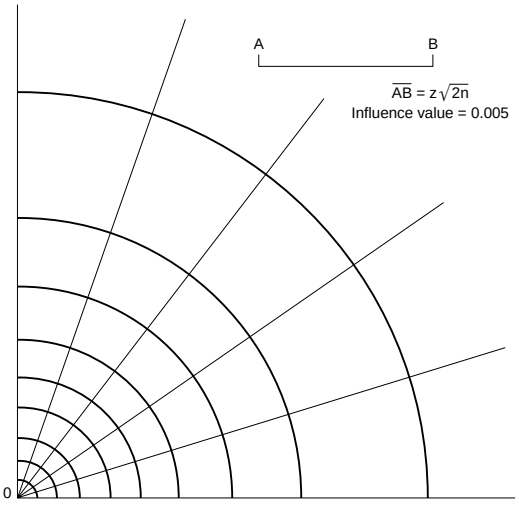

FIGURE 20.15 Influence chart.

Example 20.9

A uniformly distributed vertical load of magnitude 25 lb/ft^2 acts over an area 4 ft by 8 ft at the surface of a particulate medium. Find the expected vertical normal stress 6 ft below the center of the area. Take $\nu = 1/3$.

Solution. From Eq. (20.13), taking the 4×8 ft area as four areas, each with sides 2×4 ft, we have

$$\bar{s}_z = 4(25)\psi\left[\frac{2}{6\sqrt{1/3}}\right]\psi\left[\frac{4}{6\sqrt{1/3}}\right] = 100\,\psi[0.58]\,\psi[1.15] = 100(0.219)(0.375)$$

and $\bar{s}_z = 8.2$ lb/ft^2. The theory of elasticity, as shown in Fig. 5(b), yields for this case $\sigma_z = 7.3$ lb/ft^2.

Uniform Normal Load over Circular Area

The expected vertical normal stress under the center of a circular area, of radius a, subject to a uniform normal load q was obtained by Kandaurov [1959] as

$$\bar{s}_z(z) = q\left[1 - \exp\left(-\frac{a^2}{2\nu z^2}\right)\right] \tag{20.14}$$

The theory of elasticity gives for this case [Harr, 1966]

$$\sigma_z(z) = q\left[1 - \frac{1}{[(a/z)^2 + 1]^{3/2}}\right] \tag{20.15}$$

The influence chart shown in Fig. 20.15 was prepared using Eq. (20.14). The chart is used in the same way as was previously explained in reference to Fig. 20.7. For layered systems, the equivalent depth $\overline{h}_{N-1} + z_N$, Eq. (20.10) can be substituted for z.

Example 20.10

Compare Eqs. (20.14) and (20.15) for $\nu = 1/3$.

Solution. Some values are given in Table 20.3. Again we see that for $\nu = 1/3$ the correspondence between the two is very good for the special value of the coefficient of lateral stress.

TABLE 20.3 Comparison of Particulate and Elastic Solutions (Normal Vertical Distributed Load)

a/z	$\bar{s}_z/q$	σ_z/q
0.2	0.06	0.06
0.4	0.21	0.20
0.6	0.42	0.37
0.8	0.62	0.52
1.0	0.78	0.65
1.2	0.88	0.74
1.4	0.95	0.80
2.0	1.00	0.91

Parabolic Loading over Circular Area

The parabolic form of the loading on the surface is defined as

$$\bar{s}_z(r, 0) = \begin{cases} q\left(1 - \dfrac{r^2}{a^2}\right) & 0 \le r \le a \\ 0 & r > a \end{cases} \tag{20.16a}$$

For the special, but important, case under the center of the loading ($r = 0$), the expected vertical stress reduces to the expression

$$\bar{s}_z(0, z) = q\left\{1 - \frac{2\nu z^2}{a^2}\left[1 - \exp\left(-\frac{a^2}{2\nu z^2}\right)\right]\right\} \tag{20.16b}$$

Tangential (Horizontal Force at Surface)

For a concentrated force of intensity Q parallel to the boundary surface (the equivalent of Cerruti's solution, Fig. 20.4), Muller [1962] obtained the expression

$$\bar{s}_x = \frac{Q}{2\pi\nu x^2}\exp\left[-\frac{y^2 + z^2}{2\nu x^2}\right] \tag{20.17}$$

Example 20.11

Compare the expression for the vertical stress in Eq. (20.17) with that given by Cerruti (Eq. 20.4) for the line $y = 0$, $z = 1$.

Solution. Cerruti obtained $\sigma_z = 3Qxz^2/2\pi R^5$ where $R^2 = x^2 + y^2 + z^2$. From Eq. (20.17) for $y = 0$, $z = 1$,

$$\frac{2\pi\bar{s}_z}{Q} = \frac{1}{\nu x^2}\exp\left[-\frac{1}{2\nu x^2}\right]$$

It can be shown that $\lim_{x\to 0}\bar{s}_z = 0$. Some numerical values for two values of ν are given in Table 20.4. It is seen that the vertical stresses for the developed theory are smaller than those given by the theory of elasticity in the near vicinity of the applied load. However, the general patterns of the distributions are quite similar away from the point of loading.

TABLE 20.4 Comparison of Particulate and Elastic Solutions (Concentrated Force Parallel to Boundary Surface)

		$2\pi\bar{s}_z/Q$	
x	$2\pi\sigma_z/Q$	$\nu = 1/3$	$\nu = 1/2$

2.0	0.11	0.52	0.39
2.5	0.05	0.38	0.27

Defining Terms

Homogeneous — Having elastic parameters the same at all points in a region of a body.

Influence factor — A dimensionless cluster of factors generally obtained from a graphical presentation.

Isotropic — Having defining parameters the same in all directions emanating from a point.

Plane strain — A two-dimensional simplification used when there is little or no variation in strain in the direction normal to the plane.

Strain — Changes in displacements due to changes in stress.

Stress — Intensity of internal forces within a soil body induced by loadings. In the classical theory of elasticity stress is single-valued. The particulate theory deals with a distribution, the best measure of which is the *expected* (mean) value.

21.1 Introduction

Slope stability analysis is performed to assess the potential for failure of the slope by rupture. Slopes that are typically assessed fall into a number of categories, as illustrated in Fig. 21.1. The primary objective of a stability analysis is to determine the factor of safety (FS) of a particular slope, to predict when failure is imminent, and to assess remedial treatments when necessary. In many practical situations, an analytical assessment of stability can be made. Other situations do not lend themselves to convenient analytical solutions. Analytical techniques can be applied to slope failures where peak strength occurs essentially simultaneously at every point along single or multiple failure surfaces and the mass moves as a unit or group of units. The sliding surface may be circular, planar, or irregular.

Slope failure forms that cannot be analyzed in the present state of the art include avalanches, flows, failure by lateral spreading, and progressive failure. All of these forms can be initiated by a slide failure at the toe of the mass. The only defense against these failure forms is recognition that their potential exists [Hunt, 1984].

Deformations can be a concern in slopes and embankments due to the effects on surface or buried structures, and because they often precede failure. The finite element method (FEM) has been used to approximate deformations in earth-dam embankments and rock slopes, but only infrequently in natural and cut slopes in soils [Vulliet and Hutter, 1988]. In any case, it is necessary to closely define material properties, slope geometry, and the initial state of stress, which often are difficult to assess accurately. The most common analytical approaches currently used by practitioners to assess slope stability are based on the limiting equilibrium method. It is an approximate solution that considers a state of equilibrium between the forces acting to cause failure (driving forces) and the forces resisting failure (mobilized shear stresses). Two general cases are illustrated in Fig. 21.2.

Limit equilibrium analyses assume the following:

1. The failure surface is of simple geometric shape (planar, circular, log-spiral).
2. The distribution of stresses acting along the failure surface causing failure are determinate.
3. The same percentage of mobilized shear strength acts simultaneously along the entire failure surface.

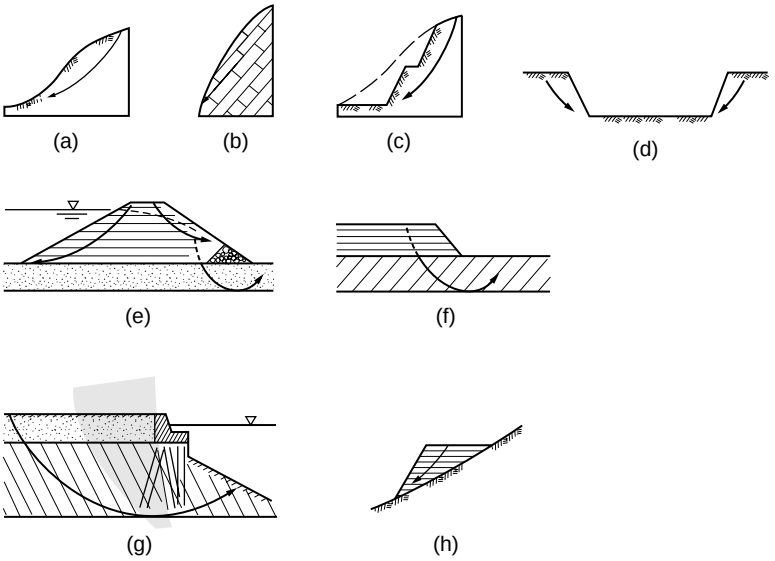

FIGURE 21.1 Categories of slope stability problems: (a) natural soil slope; (b) natural rock slope; (c) cut slope; (d) open excavation; (e) earth dam embankment; (f) embankment over soft soils; (g) waterfront structure; (h) sidehill fill. FIGURE 21.2 Forces acting on cylindrical failure surfaces. (a) Rotational cylindrical failure surface with length *L*. Safety factor against sliding FS. (b) Simple wedge failure on planar surface with length *L*. *Note:* The expression for FS is generally considered unsatisfactory (see text).

Limit equilibrium methods of analysis typically use the Mohr–Coulomb failure criterion, in which (see Table 21.1)

$$s = c + \sigma_n \tan \phi$$

where s is the shearing resistance, c is the cohesion, σ_n is the normal stress, and ϕ is the angle of internal friction. Appropriate total stress or effective stress strength parameters for specific loading conditions are provided in Table 21.2.

The factor of safety has been expressed in a number of forms, examples of which are given in Fig. 21.2 (see Table 21.3). In slope stability analysis, FS can be considered as the ratio of the total shearing strength

TABLE 21.1 Field Conditions and Strength Parameters Acting at Failure

Material	Field Conditions	Strength Parameter[a]
Cohesionless sands	Dry	f (i = f)
	Submerged slope	f (i = f ¢)
	Slope seepage with top flow line coincident with and parallel to slow surface	f (i = f ¢2)
Clays (except stiff fissured clays and clay shales)	Undrained conditions	S_u (f = 0)
	Drained conditions	c¢[b]
Stiff fissured clays and clay shales and existing failure surfaces	Without slope seepage	f ¢(i a f ¢)[b]
	With slope seepage	f ¢(i a f ¢2[b])
Cohesive mixtures	Undrained conditions	c_u, f $_u$
	Drained conditions	c¢ f [b]
Rock joints	Clean surfaces	f or f + j[c]
	With fillings	c¢ f , or f ¢
	Clean but irregular surfaces after failure	f $_t$ + j[c]

[a] i = stable slope angle.

[b] Pore-water pressures: reduce frictional resistance in accordance with (N – U) tan f .

[c] j = angle of asperities.

TABLE 21.2 Total versus Effective Stress Analysis

Condition	Preferred Method	Comment
Stability at intermediate times	$\bar{c}$, $\bar{f}$ analysis with estimated pore pressures	Actual pore pressures must be field-checked.
End of construction; partially saturated soil; construction period short compared to soil consolidation time	Either method: $\bar{c}_u$, $\bar{f}_u$ from CU tests, or $\bar{c}$, $\bar{f}$ plus estimated pore pressures	$\bar{c}$, $\bar{f}$ analysis permits check during construction using actual pore pressures
End of construction; saturated soil; construction period short compared to consolidation time	Total stress or s_u analysis with f = 0 and $c = s_u$	$\bar{c}$, $\bar{f}$ analysis permits check during construction using actual pore pressures
Long-term stability	$\bar{c}$, $\bar{f}$ analysis with pore pressures given by equilibrium ground-water conditions	Stability depends on amount of water-table rise and pore-pressure increase

Source: After Lambe, T. W., and Whitman, R. V. 1969. *Soil Mechanics*. John Wiley & Sons, New York.

available along the sliding surface to the total shearing stresses required to maintain limiting equilibrium, given as

$$\text{FS} = \frac{cL + N \tan f}{c_m L + N \tan f_m}$$

where L is the length of the failure surface, N is the normal force on the assumed failure surface, c_m is the mobilized cohesion at equilibrium, f $_m$ is the mobilized friction angle at equilibrium, and c/c_m = f /f $_m$.

21.2 Factors to Consider

Selection of the proper method to be applied to the analysis of a slope problem requires consideration of a number of factors. Specific details can be found in the referenced works.

- Type of slope to be analyzed, such as natural or cut slope in soil [Bjerrum, 1973; Patton and Hendron, 1974; Brand, 1982; Leonards, 1979, 1982] or rock [Deere, 1976], earth-dam embankments [Lowe, 1967], embankments over soft ground [Chirapuntu and Duncan, 1976; Ladd, 1991], or sidehill fills.

TABLE 21.3 Minimum Values for FS for Earth and Rock-fill Dams[a,b]

Case	Design Conditions	FS_{min}	Shear Strength[c]	Remarks
I	End of construction	1.3[d]	*Q* or *S*[e]	Upstream and downstream slopes
II	Sudden drawdown from maximum pool	1.0[f]	*R*, *S*	Upstream slope only, use composite envelope
III	Sudden drawdown from spillway crest	1.2[f]	R, S	Upstream slope only, use composite envelope
IV	Partial pool with steady seepage	1.5	$(R + S)/2$ for $R < S$	Upstream slope only, use intermediate envelope
V	Steady seepage with maximum pool	1.5	$(R + S)/2$ for $R < S$	Downstream slope only, use intermediate envelope
VI	Earthquake (Cases I, IV, and V with seismic loading)	1.0	—[g]	Upstream and downstream slopes

[a] *Source:* From Wilson, S. D., and Marsal, R. J. 1979. *Current Trends in Design and Construction of Embankment Dams*. ASCE, New York.

[b] Not applicable to embankments on clay shale foundations; higher FS values should be used for these conditions.

[c] *Q* = quick (unconsolidated-undrained test), *S* = slow (consolidated-drained test), and *R* = intermediate (consolidated-undrained test).

[d] For embankments more than 50 ft high over relatively weak foundation use $FS_{min} = 1.4$.

[e] In zones where no excess pore-water pressures are anticipated use *S* strength.

[f] FS should not be less than 1.5 when drawdown rate and pore-water pressures developed from flow nets are used in stability analysis

[g] Use shear strength for case analyzed without earthquake. (Values for FS are based on pseudostatic approach.)

- Location, orientation, and shape of a potential or existing failure surface which is controlled by material type and structural features. The shape of the rupture zone can have single or multiple surfaces, and can be composed of single or multiple wedges. Failure surfaces can be planar, cylindrical or log-spiral, or irregular.
- Material distribution (stratigraphy) within and beneath the slope, divided generally into homogeneous zones wherein the properties are more or less similar in all directions, and nonhomogeneous zones wherein soils are stratified and rock masses contain major discontinuities.
- Material types and representative shear strength parameters; angle of internal friction ϕ, cohesion *c*, residual strength ϕ_r, and undrained strength s_u (see Table 21.1).
- Drainage conditions; appropriateness for either drained or undrained analysis, which depends on the relative rates of construction and pore pressure dissipation. Often considered as short-term (during construction) or long-term (postconstruction or natural slope) conditions; that is, total versus effective stress analysis (see Table 21.2).
- Distribution of piezometric levels (pore- or cleft-water pressures) along the potential failure surface and an estimate of the maximum value that may prevail.
- Potential earthquake loadings, which are a transient factor.

Hunt [1984, 1986] provides a detailed discussion of these necessary considerations for the various slope types.

21.3 Analytical Approaches

Most slope stability analyses are computationally intensive. Many computer programs have been developed to perform stability analyses on personal computers. Commonly used packages include PCSTABL (Purdue University) and UTEXAS3 (University of Texas). Data is input for the problem geometry, material stratigraphy, and the phreatic surface based on a coordinate system, and material properties are then entered. The programs search for the potential failure surface that produces the lowest value for FS. These

programs are used routinely in virtually all geotechnical consulting offices. The following discussion is intended to present the salient features of the assumptions and analytical approach used to perform the stability analysis.

General

Failure, sudden or gradual, results when the mobilized stresses in a slope or its foundation equal the available strength. Limit equilibrium analysis is the basis for most methods available for slope stability evaluations. Consideration is given to a free body of the soil mass bounded by the slope and an assumed "slip" or failure surface. The known or assumed forces acting on the body and the shearing resistance required for stability are estimated. Most practical problems are statically indeterminate and require simplifying assumptions regarding the position and direction of forces to render the problem determinate.

The primary assumption of the limit equilibrium method is that the assumed strength can be mobilized throughout the length of the failure surface simultaneously. Strain compatibility is not considered. This assumption is applicable for stress–strain conditions that can be modeled as perfectly plastic at the failure strength. When soils have some post-peak strength reduction (as with most natural soil), engineering judgment is required to select appropriate strength parameters and safety factors.

Two common free-body assumptions are illustrated in Fig. 21.2. In the cylindrical form shown in Fig. 21.2(a), the mass weight W acting through lever arm E produces a driving moment. This moment is resisted by strength S mobilized along the failure surface of length L that acts through a lever arm R. In the simple wedge [Fig. 21.2(b)], strength S acting along the planar surface of length L resists the driving forces resulting from gravity acting on weight W. A plane strain condition is assumed in most analytical methods currently in use so the potential failure mass is analyzed per unit width. Resistance that would be generated at the lateral extremities of the failure zone are considered insignificant compared to the area of the potential failure surface. When three-dimensional analyses are performed, FS(3-D) > FS(2-D) [Duncan, 1992] for most cases; therefore, two-dimensional analysis normally is conservative.

Common methods of analysis consider a system of forces. The soil mass is divided into a system of "slices," "blocks," or "wedges," and force and/or moment equilibrium conditions are evaluated for the individual components of the soil mass. The soil strength is uniformly adjusted by a scaling factor until the system is in a state of equilibrium. The actual soil strength divided by the strength required to satisfy equilibrium is defined as the factor of safety.

Slices as Free Bodies

In modern force systems the sliding mass is divided into "slices" as shown in Fig. 21.3(a), which illustrates a "finite" slope with a circular failure surface. The forces that act on a slice [Fig. 21.3(b)] include the material weight W, normal force N, and shear force T distributed along an assumed failure surface; water pressure force U; water pressure V acting in a tension crack; and forces E_r, X_r, E_L, and X_L acting along

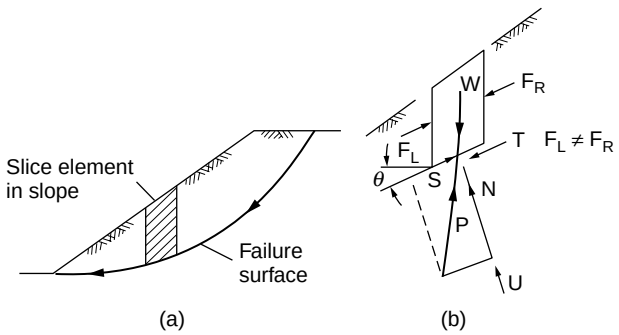

FIGURE 21.3 Finite slope with cylindrical failure surface (a) and forces on an element (b).

the sides of the slice. A discussion of the treatment of tension cracks can be found in Tschebotarioff [1973] and Spencer [1967]. Earthquakes impose dynamic forces in the form of the acceleration of gravity acting on the mass component.

Planar Surfaces, Blocks, and Wedges

Simple planar failures involve a single surface which can define a wedge in soil or rock [Fig. 21.2(b)], a sliding block, or a wedge in rock with a tension crack. The force system is similar to that given in Fig. 21.3, except that the side forces are neglected. Complex planar failures involve a number of planes dividing the mass into two or more blocks, and in addition to the force system for the single block, these solutions provide for interblock forces.

Infinite Slope

The infinite slope pertains where the depth to a planar failure surface is small compared to its length, which is considered as unlimited. Such conditions are found in slopes composed of the following:

- Cohesionless materials, such as clean sands
- Cohesive soils, such as residuum or colluvium, over a sloping rock surface at shallow depth
- OC fissured clays or clay shales with a uniformly deep, weathered zone
- Large slabs of sloping rock layers underlain by a weakness plane

Circular Failure Surfaces

General

In rotational slide failures, methods are available to analyze a circular or log-spiral failure surface, or a surface of any general shape. The location of the critical failure surface is found by determining the lowest value of safety factor obtained from a large number of assumed failure surface positions.

Slice Methods

Common to all slice methods is the assumption that the assumed soil mass and failure surface can be divided into a finite number of slices. Equilibrium conditions are considered for all slices. The problem is strongly indeterminate, requiring several basic assumptions regarding the location of application or resultant directions of applied forces.

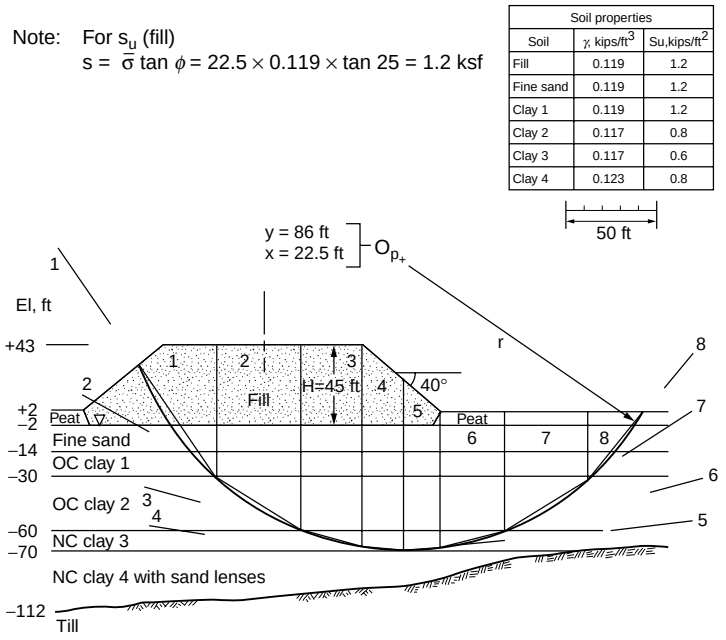
The slice methods can be divided into two groups: nonrigorous and rigorous. Nonrigorous methods satisfy either force or moment equilibrium, whereas rigorous methods satisfy both force and moment equilibrium. The factor of safety estimated from rigorous methods is relatively insensitive to the assumptions made to obtain determinacy [Duncan, 1992; Espinoza et al., 1992, 1994]. However, nonrigorous solutions can produce significantly different estimates of safety depending on the assumptions made. In general, a nonrigorous solution satisfying only moment equilibrium is superior to one satisfying only force equilibrium and will provide solutions close to a rigorous method.

Ordinary Method of Slices

The ordinary method of slices, also known as the Swedish method, was developed by Fellenius [1936] to analyze failures in homogeneous clays occurring along Swedish railways in the 1920s. The solution is a trial-and-error technique that locates the critical failure surface, or that circle with the lowest value for FS.

The ordinary method is not a rigorous solution because the shear and normal stresses and pore-water pressures acting on the sides of the slice are not considered. In general the results are conservative. In slopes with low ϕ angles and moderate inclinations, FS may be 10 to 15% below the range of the more exact solutions; with high ϕ and slope inclination, FS can be underestimated by as much as 60%.

For the $\phi = 0$ case, normal stresses do not influence strength, and the ordinary method provides results similar to rigorous methods [Johnson, 1974]. An example analysis using the ordinary method for the $\phi = 0$ case as applied to an embankment over soft ground is given in Fig. 21.4.



Slice	s_u, ksf	ΔL, ft	$S_u \Delta L$	θ, degrees	W, kips*	$W \sin\theta$
1	1.2	76	91.2	56	203.39	168.62
2	0.8	58	46.4	32	359.73	190.63
3	0.6	34	20.4	17	399.74	116.87
4	0.6	24	14.4	5	187.15	16.31
5	0.6	21	12.6	−5	117.60	−10.25
6	0.6	39	23.4	−14	128.46	−31.08
7	0.8	58	46.4	−32	113.40	−60.09
8	1.2	42	50.4	−51	30.24	−23.50
L = 352		Σ = 305.2			Σ = 367.5	

$$FS = \frac{\Sigma S_u \Delta L}{\Sigma W \sin\theta}$$

$$FS = \frac{305.2}{367.5} = 0.83$$

FIGURE 21.4 Embankment over soft clay: stability analysis for $\phi = 0$ case using ordinary method of slices. (*Source:* Hunt, R. E. 1986. *Geotechnical Engineering Techniques and Practices*. McGraw-Hill, New York. Reprinted with permission of McGraw-Hill Book Co.)

A counterberm added to increase stability (Fig. 21.5) must be of adequate width to cause the critical circle to pass beyond the toe with an acceptable value for FS.

Bishop Slice Methods

The rigorous Bishop method [Bishop, 1955] considers the complete system of forces acting on a slice, as shown in Fig. 21.6. In addition to N, U_i, and T_i, included along each side of the slice are shear stresses (x_i with width b_i), effective normal stresses (E_i), and pore-water pressures (U_L and U_r). In analysis, distributions of $(x_i - x_{i+1})$ are found by successive approximation until a number of equilibrium conditions are satisfied. Computations are considerable even with a computer.

The modified (simplified) Bishop method [Bishop, 1955; Janbu et al., 1956] is a simplification of the rigorous method. In the modified method it is assumed that the total influence of the tangential forces on the slice sides is small enough to be neglected.

Other Slice Methods

A number of other methods have been developed that differ in the statics employed to determine FS and the assumptions used to render the problem determinate. Included are Spencer's method [Spencer, 1967], Janbu's rigorous and simplified methods [Janbu et al., 1956], and the Morganstern–Price method

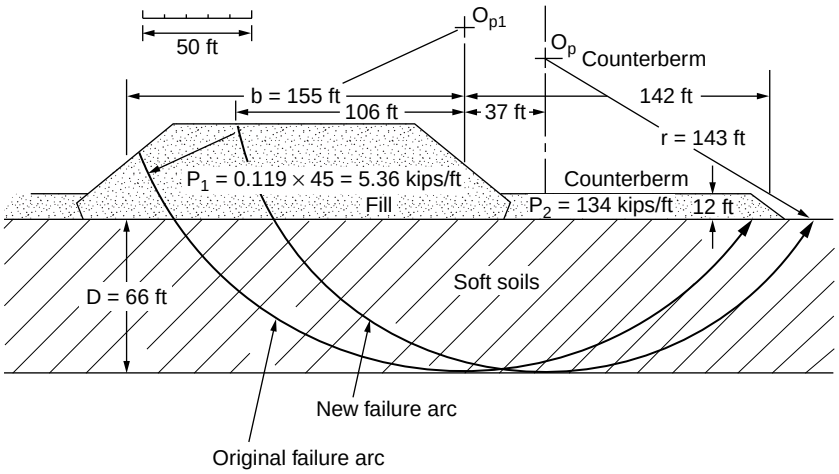


FIGURE 21.5 Counterberm to provide stability for embankment shown in Fig. 21.3. FS = 1.2. (*Source:* Hunt, R. E. 1986. *Geotechnical Engineering Techniques and Practices*. McGraw-Hill, New York. Reprinted with permission of McGraw-Hill Book Co.)

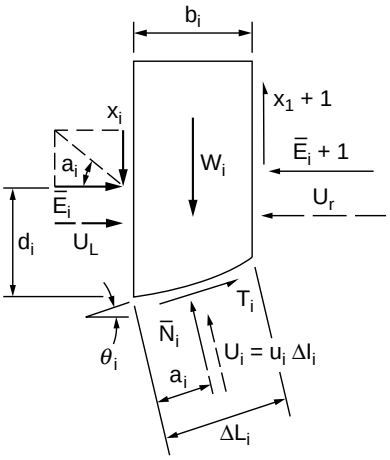

FIGURE 21.6 Complete force system acting on a slice. (*Source:* Lambe, T. W., and Whitman, R. V. 1969. *Soil Mechanics.* John Wiley & Sons, New York. Used with permission of John Wiley & Sons, Inc.)

[Morganstern and Price, 1965]. Espinoza et al. [1992, 1994] present a general framework to evaluate all limit equilibrium methods of stability analysis and illustrate the variability among methods for circular and irregular failure surfaces.

Chart Solutions for Homogeneous Slopes

Various chart solutions have been developed for simple homogeneous slopes, including Taylor [1937, 1948], Janbu [1968], Hunter and Schuster [1968], and Cousins [1978]. They are useful for preliminary analysis of the $\phi = 0$ case, and discussion and examples can be found in NAVFAC [1982] and Duncan et al. [1987].

Irregular and Planar Failure Surfaces

Geological conditions in many slopes are not amenable to circular failures, particularly when the potential failure surface is shallow relative to its length. Several methods are suitable for analyses of these conditions,

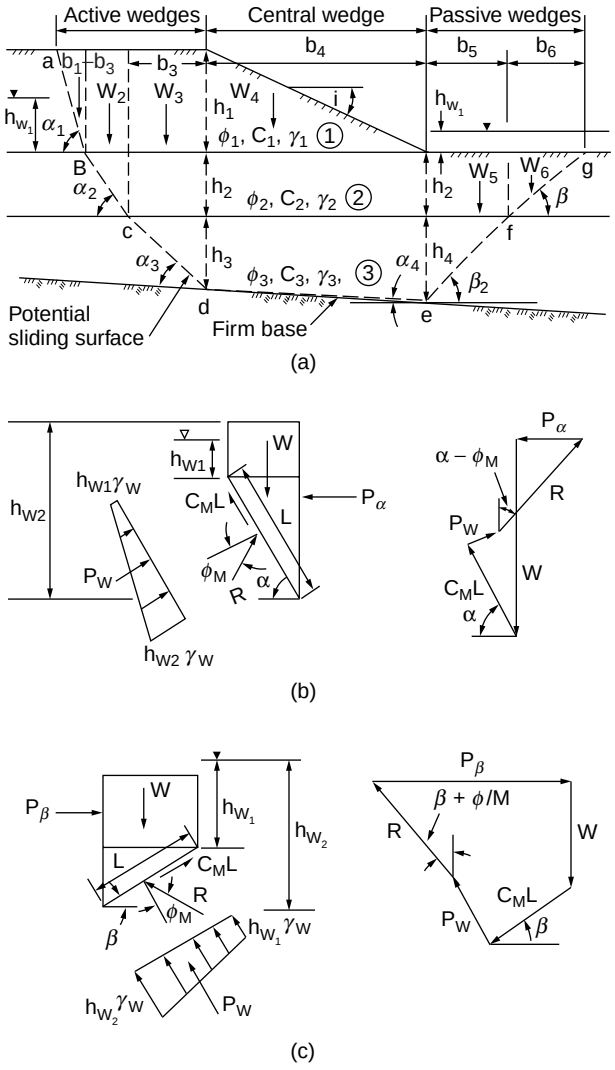

FIGURE 21.7 Stability analysis of translational failure (a). The resultant horizontal force for a wedge sliding along surface *abcde* is P_a (b), and for sliding along surface *efg* is P_b (c). (*Source:* NAVFAC. 1982. *Design Manual, Soil Mechanics, Foundations and Earth Structures, DM-7*. Naval Facilities Engineering Command, Alexandria, VA.)

including Spencer's method [Spencer, 1967], the Morganstern–Price method [Morganstern and Price, 1965], and Janbu's method [Janbu et al., 1956; Janbu, 1973].

In many natural situations the failure surface is planar and can be approximated by one or more straight lines which divide the mass into wedges or blocks. Solutions for one-, two-, and three-block problems are available in many sources, including Hunt [1986], Huang [1983], and NAVFAC [1982]. A detailed discussion of the analysis of blocks as applied to rock slopes is given in Hoek and Bray [1977].

The translation failure method [NAVFAC, 1982] is based on earth pressures and is suitable for multiple blocks, although interwedge forces are ignored. It is useful where soil conditions consist of several masses with different parameters such as in the case illustrated in Fig. 21.7.

Three-dimensional or tetrahedral wedge failures are common in open-pit mines on heights of one or two benches (60 to 100 ft) but become progressively less prevalent as slope height increases. Failure seems to be associated with weakness planes that are of the same order of size as the slope height involved, with

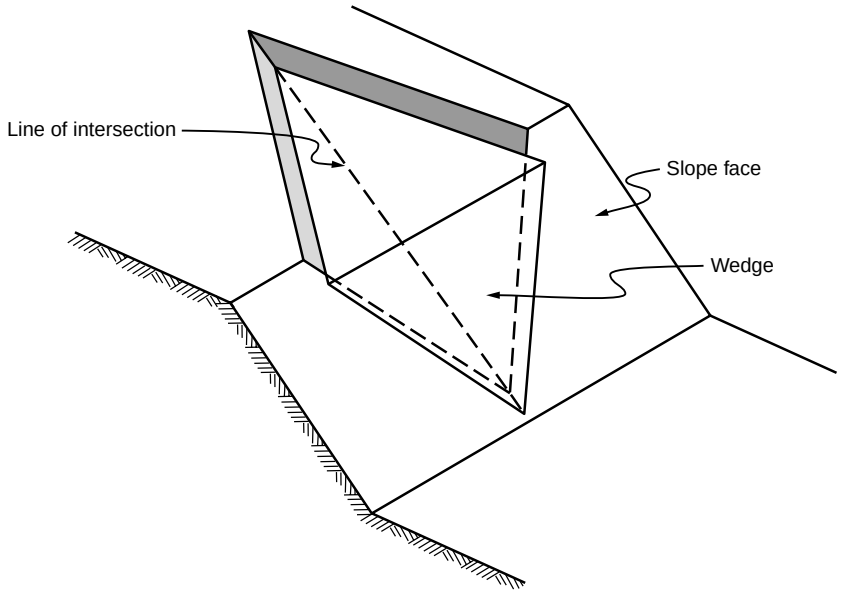

FIGURE 21.8 Geometry of a triangular wedge failure. (*Source:* Hoek, E., and Bray, J. W. 1977. *Rock Slope Engineering,* 2nd ed. The Institute of Mining and Metallurgy, London.)

the planes representing three or more intersecting joint sets. The "free blocks" approach tetrahedrons in shape, as shown in Fig. 21.8. A discussion of the analysis of the tetrahedral wedge can be found in Hoek and Bray [1977].

Earthquake Forces

Earthquake forces include cyclic loads which decrease the stability of a slope by increasing shear stresses, pore air and water pressures, and decreasing soil strength. In the extreme case, increases in pore pressure can lead to liquefaction. Sensitive clays and loose fine-grained granular soils above or below groundwater level (GWL), and metastable soils such as loess even when dry, are very susceptible to failure during cyclic loading. The presence of even a thin layer of saturated fine-grained soil, such as silt or clayey silt, can lead quickly to instability in any slope. Embankments over fine-grained saturated soils are particularly susceptible to failure, especially in areas where lateral restraint is limited.

Natural slopes composed of low-sensitivity clay, dense granular soils above or below GWL, or loose coarse-grained soils below GWL generally are stable even during strong ground shaking. Earth-dam embankments can withstand moderate to strong shaking when well-built to modern standards. The greatest risk of damage or failure lies with dams constructed of saturated fine-grained cohesionless materials. The general effect of ground shaking on embankments is slope bulging and crest settlement.

Pseudostatic Analysis

In the conventional approach, stability is determined as for static loading conditions and the effects of an earthquake are accounted for by including an equivalent horizontal force acting on the mass. The horizontal force, as shown in Fig. 21.9, is expressed as the product of the weight and a seismic coefficient k, which is related to induced accelerations. The effects on pore pressure are not considered, and a decrease in soil strength is accounted for only indirectly. Hall and Newmark [1977] developed design accelerations for horizontal ground motion for slope stability studies as related to magnitude, as given in Table 21.3. Augello et al. [1994] provide additional guidance for selecting appropriate design accelerations.

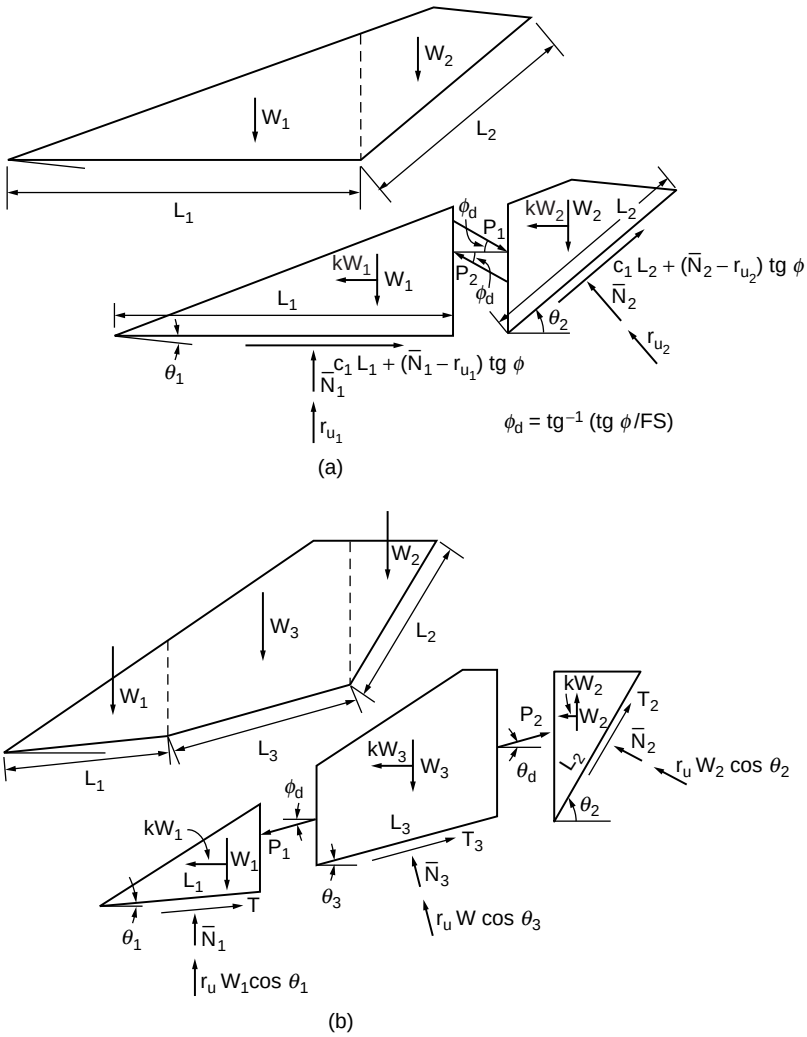

FIGURE 21.9 Complex wedge systems: (a) free-body diagrams for two blocks and (b) free-body diagrams for three blocks. (*Source:* After Huang, Y. H. 1983. *Stability Analysis of Earth Slopes.* Van Nostrand-Reinhold, New York.)

Time–History Dependence

Pseudostatic analysis is based on peak accelerations producing dynamic inertial forces. They may be sufficiently large to drop FS below unity for brief intervals during which displacements occur, but movement ceases when accelerations drop. The time element of the dynamic loadings is extremely significant and is not typically considered in analysis. Augello et al. [1995] and Bray et al. [1995] evaluate the time–history-dependent movements associated with stability of landfill slopes.

If dynamic loads are applied in cycles with small periods, but relatively long duration, soil will not have time to drain between loadings, pore pressures will continue to increase, and failure by liquefaction may occur. The Alaskan event of 1964 lasted almost three minutes, causing disastrous slides at Turnagain Heights where previous earthquakes of equal magnitude but shorter duration had caused little damage.

Dynamic Analysis

Dynamic analysis of embankments is performed employing finite element methods [Newmark, 1965; Seed, 1966; Seed et al., 1975; Byrne, 1991; Finn, 1993]. Embankment response to base excitation is

evaluated and the dynamic stresses included in representative elements of the embankment are computed incorporating nonlinear dynamic material properties by using strain-dependent shear modulus and damping values. Recent work includes the generation of excess pore-water pressure during dynamic loading and the onset of liquefaction. Both the overall deformations and the stability of the embankment section are evaluated.

21.4 Treatments to Improve Stability

General Concepts

Selection Basis

Slope treatments can be placed in one of two broad categories:

- Preventive treatments applied to stable, but potentially unstable natural slopes, slopes to be cut, sidehill fills to be placed, or embankments to be constructed
- Remedial or corrective treatments applied to existing unstable, moving slopes, or to failed slopes

The slope treatment selected is a function of the degree of the hazard and the risk to the public. In natural slopes these factors are very much related to the form of slope failure (fall, slump, avalanche, or flow), the identification of which requires evaluation and prediction by an experienced engineering geologist.

Rating the Hazard and the Risk

Hazard degree relates to the potential failure itself in terms of its possible magnitude and probability of occurrence. Magnitudes can range from a small displacement and material volume, as is common in slump slides, to a large displacement and material volume, such as in a massive debris avalanche. Probability can range from certain to remote. Risk degree relates to the consequences of failure, such as a small volume of material covering portions of a roadway but not endangering lives, to the high risk from the failure of an earth dam resulting in the loss of many lives and much property damage. Safe but economical construction is always the desired result, but the acceptable degree of safety varies with the degree of hazard and risk. An example of a rating system for hazard and risk is given in Hunt [1984].

Treatment Options

Avoid the High-Risk Hazard

There are natural conditions where slope failure is essentially unpredictable and not preventable by reasonable means and the consequences are potentially disastrous. It is best to avoid construction in mountainous terrain subject to massive planar slides or avalanches, slopes in tropical climates subject to debris avalanches, or slopes subject to liquefaction and flows.

Accept the Failure Hazard

In some cases, low to moderate hazards may be acceptable because postfailure cleanup is less costly than some stabilization treatment. Examples are partial temporary closure of a roadway, which is often the approach in underdeveloped countries, or a slide in an open-pit mine where failure is predictable but prevention is considered uneconomical.

In many cases, failures are self-correcting, and eventually a slope may reach a stable condition or work back to where failures do not affect construction. An innovation being used in southern California to protect homes against debris slides, avalanches, and flows is the "A" wall [Hollingsworth and Kovacs, 1981] illustrated in Fig. 21.10. The purpose of the wall is to deflect moving earth masses away from the building.

Eliminate or Reduce the Hazard

Where failure is essentially predictable and preventable, or is occurring or has occurred and is suitable for treatment, slope stabilization methods are applied. For low-to-moderate-risk conditions, the approach can be either to eliminate or to reduce the hazard, depending on comparative economics. For high-risk

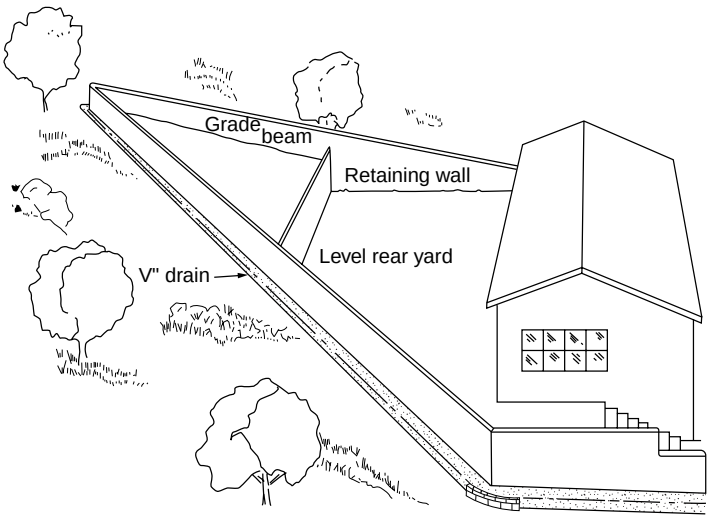

FIGURE 21.10 Typical A-wall layout to deflect debris slides, avalanches, and flows. (*Source:* Hollingsworth, R., and Kovacs, G. S. 1981. Soil slumps and debris flows: Prediction and protection. *Bul. Assoc. Eng. Geol.* 18(1):17–28.)

conditions the hazard should be eliminated. The generally acceptable safety factor determined by stability analysis can be taken as follows: low risk, FS = 1.3; significant risk, FS = 1.4; high risk, FS = 1.5.

Slope Stabilization

Slope stabilization methods may be placed in five general categories, as follows (Fig. 21.11):

1. Change slope geometry to decrease the driving forces or increase the resisting forces.
2. Control surface water to prevent erosion, and infiltration to reduce seepage forces.
3. Control internal seepage to reduce the driving forces.
4. Increase material strengths to increase resisting forces.
5. Provide retention to increase the resisting forces.

Where slopes are in the process of failing, the time factor must be considered. Time may not be available for carrying out measures that will eliminate the hazard; therefore, the hazard should be reduced and perhaps eliminated at a later date. The objective is to arrest the immediate movement. Where possible, treatments should be performed during the dry season, when movements will not affect remediation such as breaking horizontal drains.

Changing Slope Geometry

Natural Slope Inclinations

In many cases the natural slope represents the maximum long-term inclination, but there are cases where the slope is not stable and is moving. The inclination of existing slopes should be noted during field reconnaissance, since an increase in inclination by cutting may result in failure.

Cut Slopes in Rock

The objective of any cut slope is to form a stable inclination without retention. Controlled blasting procedures are required in rock masses to avoid excessive rock breakage resulting in extensive fracturing. Line drilling and presplitting during blasting operations minimize disturbance of the rock face.

Hard masses of igneous or metamorphic rocks, widely jointed, are commonly cut to 1H:4V (76°) [Terzaghi, 1962] [Fig. 21.12(a)]. Hard rock masses with joints, shears, or bedding representing major discontinuities dipping downslope are excavated along the dip of the discontinuity, as shown in

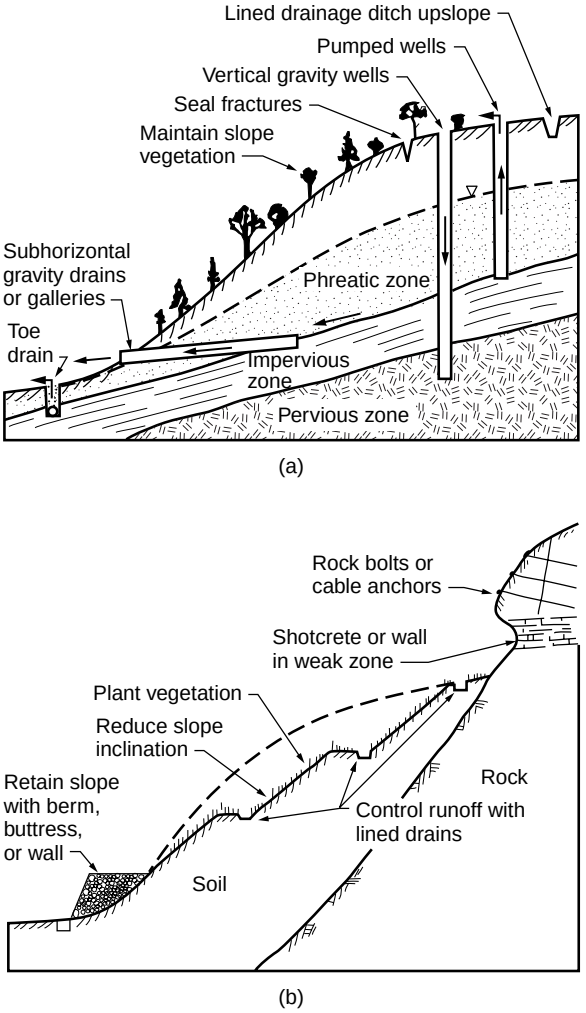

FIGURE 21.11 The general methods of slope stabilization: (a) control of seepage forces, (b) reducing the driving forces and increasing the resisting forces. (*Source:* Hunt, R. E. 1984. *Geotechnical Engineering Investigation Manual*. McGraw-Hill, New York.)

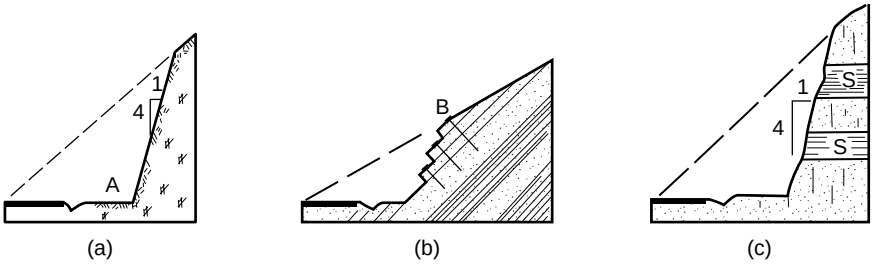

FIGURE 21.12 Typical cut slopes in hard rock for a roadway. Leave space at *A* for storage of block falls and topples and scale slope of loose blocks. (a) Closely jointed, competent rock. (b) Dipping beds; follow the dip unless excessively flat, in which case retain with bolts *B*. (c) Horizontally bedded sandstones and shales; apply gunite to the shales *S* if subjected to differential weathering. (*Source:* Hunt, R. E. 1986. *Geotechnical Engineering Techniques and Practices*. McGraw-Hill, New York. Reprinted with permission of McGraw-Hill Book Co.)

Fig. 21.12(b). All material should be removed until the original slope is intercepted. If the dip is too shallow for economical excavation, slabs can be retained with rock bolts (see "Retention," later in this chapter).

Hard sedimentary rocks with bedding dipping vertically or into the face, or horizontally interbedded hard sandstones and shales [Fig. 21.12(c)], are often cut to 1H:4V, but in the latter case, the shales should be protected from weathering with shotcrete or gunite to retard differential weathering. Weathered or closely jointed masses (except clay shales and dipping major discontinuities) require a reduction in inclination to between 1H:2V to 1H:1V (63° to 45°) depending on conditions, or require some form of retention. Clay shales, unless interbedded with sandstones, are often excavated to 6H:1V (9.5°).

Benching has been common practice in high rock cuts but there is disagreement among practitioners as to its value. Some consider benches to be undesirable because they provide takeoff points for falling blocks [Chassie and Goughnor, 1976]. To provide for storage they must be of adequate width. Block storage space should always be provided at the slope toe with adequate shoulder width to protect the roadway from falls and topples.

Cut Slopes in Soils

Most soil formations are commonly cut to an average inclination of 2H:1V (26°) but consideration must be given to seepage forces and other physical and environmental factors to determine if retention is required. Soil cuts are normally designed with benches, especially for cuts over 25 to 30 ft high. Because the slope angle between benches may be increased, benches reduce the amount of excavation necessary to achieve overall lower inclinations. Drains are installed as standard practice along the slopes and the benches to control runoff, as illustrated in Fig. 21.11(b) and Fig. 21.13.

In soil–rock transition (strong residual soils to weathered rock) such as in Fig. 21.13, cuts are often excavated to between 1H:2V to 1H:1V (63° to 45°) although potential failure along relict discontinuities must be considered. Where there is thin soil cover over rock the soil should be removed or retained as the condition normally will be unstable in cut. Figure 21.13 illustrates an ideal case, often misinterpreted from test boring data, and not present in the slope. In mountainous terrain all of the formations may be dipping, as shown on Fig. 21.14, a potentially very unstable condition. In such conditions, downslope seismic refraction surveys are valuable to define stratigraphy.

Failing Slopes

If a slope is failing and undergoing substantial movement, the removal of material from the head to reduce the driving forces can be the quickest method of arresting movement, and benching may be effective in the early stages. Placing material at the toe to form a counterberm increases the resisting forces. An alternative is to remove debris from the toe and permit failure to occur. Eventually the mass may naturally attain a stable inclination.

Changing slope geometry to achieve stability once failure has begun usually requires either the removal of very large volumes or the implementation of other methods. Space is seldom available in critical situations to permit placement of material at the toe, since very large volumes normally are required. As will be discussed, subhorizontal drains are often a very effective intermediate solution.

Surface Water Control

Purpose

Surface water is controlled to eliminate or reduce infiltration and to provide erosion protection. External measures are generally effective, however, only if the slope is stable and there is no internal source of water to cause excessive seepage forces.

Infiltration and Erosion Protection

Planting the slope with thick, fast-growing native vegetation strengthens the shallow soils with root systems and discourages desiccation, which causes fissuring. Not all vegetation works equally well, and

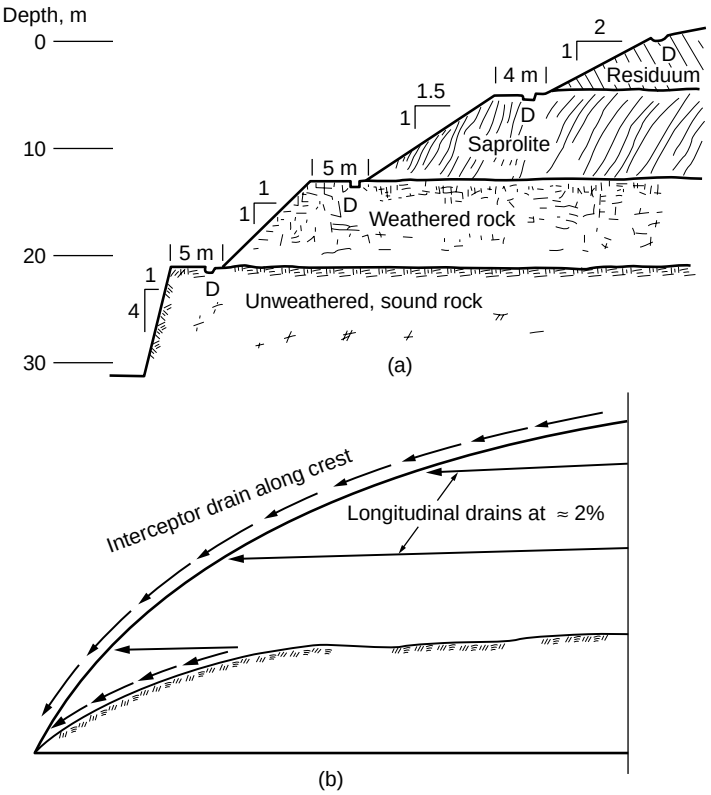

FIGURE 21.13 Benching a cut slope. (a) Typical section with drains located at *D*. Slope in weathered rock varies with rock quality; in saprolite, varies with orientation of foliations. Attempt is made to place benches on contact between material types. (b) General scheme to control runoff and drainage shown in face view. (*Source:* Hunt, R. E. 1986. *Geotechnical Engineering Techniques and Practices*. McGraw-Hill, New York. Reprinted with permission of McGraw-Hill Book Co.)

selection requires experience. In the Los Angeles area of California, for example, Algerian ivy has been found to be quite effective in stabilizing steep slopes [Sunset, 1978]. Newly cut slopes should be immediately planted and seeded. Burlap bags or sprayed mulch helps increase growth rate and provide protection against erosion during early growth stages. In addition to plantings, erosion protection along the slope can be achieved with wattling bundles, as illustrated in Fig. 21.15.

Sealing cracks and fissures with asphalt or soil cement will reduce infiltration but will not stabilize a moving slope since the cracks will continue to open. Grading a moving area results in filling cracks with soil, which helps reduce infiltration.

Surface Drainage Systems

Cut slopes should be protected with interceptor drains installed along the crest of the cut, along benches, and along the toe (Figs. 21.11 and 21.13). On long cuts the interceptors are connected to downslope collectors [Fig. 21.13(b)]. All drains should be lined with nonerodible materials, free of cracks or other openings, and designed to direct all concentrated runoff to discharge offslope.

With failing slopes, installation of an interceptor along the crest beyond the head of the slide area will reduce runoff into the slide. But the interceptor is a temporary expedient, since in time it may break up and cease to function as the slide disturbance progresses upslope.

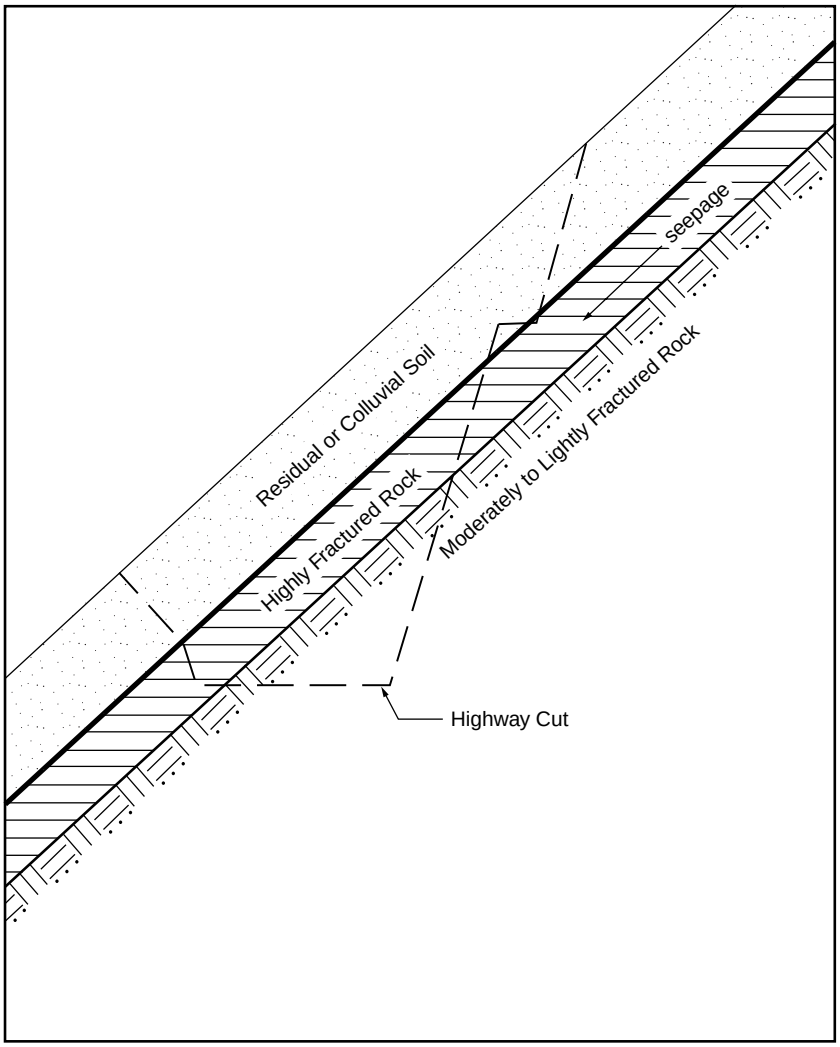

FIGURE 21.14 Slope conditions common along steep slopes in mountainous terrain.

Internal Seepage Control

General

Internal drainage systems are installed to lower the piezometric level below the potential or existing sliding surface. Selection of the drainage method is based on consideration of the geologic materials, structure, and groundwater conditions (static, perched, or artesian), and the location of the phreatic surface.

As the drains are installed, the piezometric head is monitored by piezometers and the efficiency of the drains is evaluated. The season of the year and the potential for increased flow during wet seasons must be considered, and if piezometric levels are observed to rise to dangerous values (as determined by stability analysis, or from monitoring slope movements), the installation of additional drains is required.

Cut Slopes

Systems to relieve seepage forces in cut slopes are seldom installed in practice, but they should be considered more frequently, since there are many conditions where they would aid significantly in maintaining stability.

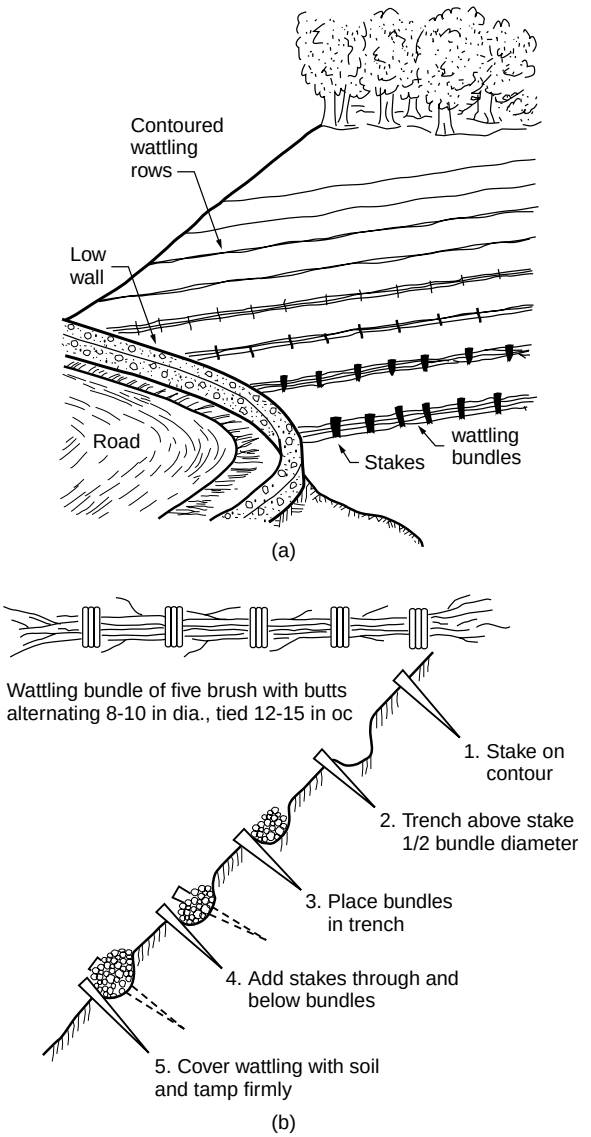

FIGURE 21.15 Erosion protection by installation of wattling bundles along contours of slope face. (a) Contoured wattling on slope face. (b) Sequence of operations for installing wattling on slope face. Work starts at bottom of cut or fill with each contour line proceeding from step 1 through 5. Cigar-shaped bundles of live brush of species which root are buried and staked along slope. They eventually root and become part of the permanent slope cover. (After Gray *et. al.*, 1980. Adapted with the permission of the American Society of Civil Engineers.)

Failing Slopes

The relief of seepage pressures is often the most expedient means of stabilizing a moving mass. The primary problem is that, as mass movement continues, the drains will be cut off and cease to function; therefore, it is often necessary to install the drains in stages over a period of time. Installation must be planned and performed with care, since the use of water during drilling could possibly trigger a total failure.

Methods

Deep wells have been used to stabilize many deep-seated slide masses, but they are costly since continuous or frequent pumping is required. Check valves normally are installed so that when the water level rises, pumping begins. Deep wells are most effective if installed in relatively free-draining material below the failing mass.

Vertical gravity drains are useful in perched water-table conditions where an impervious stratum overlies an open, free-draining stratum with a lower piezometric level. The drains permit seepage by gravity through the confining stratum and thus relieve hydrostatic pressures. Clay strata over granular soils, or clays or shales over open-jointed rock, offer favorable conditions for gravity drains where a perched water table exists.

Subhorizontal drains are one of the most effective methods to improve stability of a cut slope, or to stabilize a failing slope. Installed at a slight angle upslope to penetrate the phreatic zone and permit gravity flow, they usually consist of perforated pipe, 2 in. diameter or larger, forced into a predrilled hole of slightly larger diameter than the pipe. Horizontal drains have been installed to lengths of more than 300 ft. Spacing depends on the type of material being drained; fine-grained soils may require spacing as close as 10 to 30 ft, whereas for more permeable materials, 30 to 50 ft may suffice.

Drainage galleries are very effective for draining large moving masses but their installation is difficult and costly. They are used mostly in rock masses where roof support is less of a problem than in soils. Installed below the failure zone to be effective, they are often backfilled with stone. Vertical holes drilled into the galleries from above provide for drainage from the failure zone into the galleries.

Interceptor trench drains can be installed upslope to intercept groundwater flowing into a cut or sliding mass, but they must be sufficiently deep. Perforated pipe is laid in the trench bottom, embedded in sand, and covered with free-draining material, then sealed at the surface. Interceptor trench drains are generally not practical on steep, heavily vegetated slopes because installation of the drains and access roads requires stripping the vegetation, which will tend to decrease stability.

Relief trenches relieve pore pressures at the slope toe. They are relatively simple to install. Excavation should be made in sections and quickly backfilled with stone so as not to reduce the slope stability and possibly cause a total failure. Generally, relief trenches are most effective for small slump slides where high seepage forces in the toe area are the major cause of instability.

Electroosmosis has been used occasionally to stabilize silts and clayey silts, but the method is relatively costly, and not a permanent solution unless operation is maintained.

Increased Strength

Chemicals have sometimes been injected to increase soil strength. In a number of instances the injection of a quicklime slurry into predrilled holes has arrested slope movements as a result of the strength increase from chemical reaction with clays [Handy and Williams, 1967; Broms and Boman, 1979]. Strength increase in saltwater clays, however, was found to be low.

Resistance along an existing or potential failure surface can be increased with drilled piers [Oakland and Chameau, 1989; Lippomann, 1989], shear pins (reinforced concrete dowels), or stone columns. In the latter case the increased resistance is obtained from a significantly higher friction angle obtained in the stone along its width intercepting the failure surface.

Sidehill Fills

Failures

Construction of a sidehill embankment using slow-draining materials can be expected to block natural drainage and evaporation. As seepage pressures increase, particularly at the toe (as shown in Fig. 21.16), the embankment strains and concentric tension cracks form. The movements develop finally into a rotational failure. Fills placed on moderately steep to steep slopes of residual or colluvial soils, in particular,

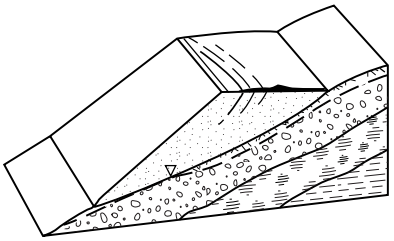

FIGURE 21.16 Early failure stage in sidehill fill as concentric cracks form in the pavement.

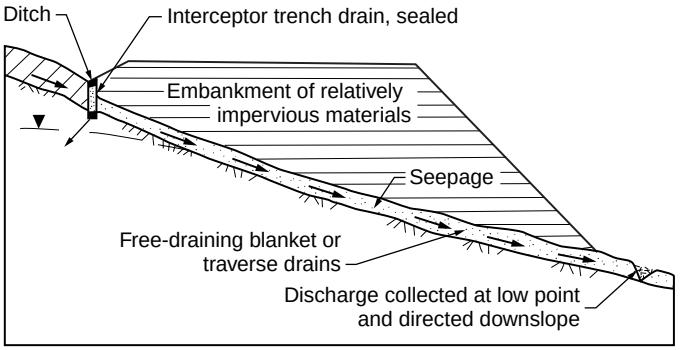

FIGURE 21.17 Proper drainage provisions for a sidehill fill *A* constructed of relatively impervious materials over relatively impervious natural soils *S* subject to surface creep. Upper soils are stripped and replaced with free-draining blanket *B*. Interceptor trench drain *C* installed and sealed with lined ditch *D*. Groundwater discharge collected at low point *E* and directed downslope. (*Source:* Hunt, R. E. 1986. *Geotechnical Engineering Techniques and Practices*. McGraw-Hill, New York. Reprinted with permission of McGraw-Hill Book Co.)

are prone to be unstable unless seepage is properly controlled, or the embankment is supported by a retaining structure.

Preventive Treatments

Interceptor trench drains should be installed along the upslope side of all sidehill fills as standard practice to intercept flow, as shown in Fig. 21.17. Perforated pipe is laid in the trench bottom, embedded in sand, covered by free-draining materials, and then sealed at the surface. Surface flow is collected in open drains and all discharge, including that from the trench drains, is directed away from the fill area.

Where anticipated flows are low to moderate, transverse drains extending downslope and connecting with the interceptor ditches upslope, parallel to the roadway, may provide adequate subfill drainage. Wherever either the fill or the natural soils are slow-draining, however, a free-draining blanket should be installed over the entire area between the fill and the natural slope materials to relieve seepage pressures from shallow groundwater conditions (Fig. 21.17). It is prudent to strip potentially unstable upper soils, which are often creeping on moderately steep to steep slopes, to a depth where stronger soils are encountered. Stepped excavations improve stability. Discharge should be collected at the low point of the fill and drained downslope in a manner that will provide erosion protection.

Retaining structures may be economical on steep slopes that continue for some distance beyond the fill, if stability is uncertain.

Corrective Treatments

If movement downslope has begun in a slow initial failure stage, subhorizontal drains may be adequate to stabilize the embankment if closely spaced. They should be installed during the dry season, if practical, since the use of water to drill holes during the wet season may accelerate total failure. An alternative is

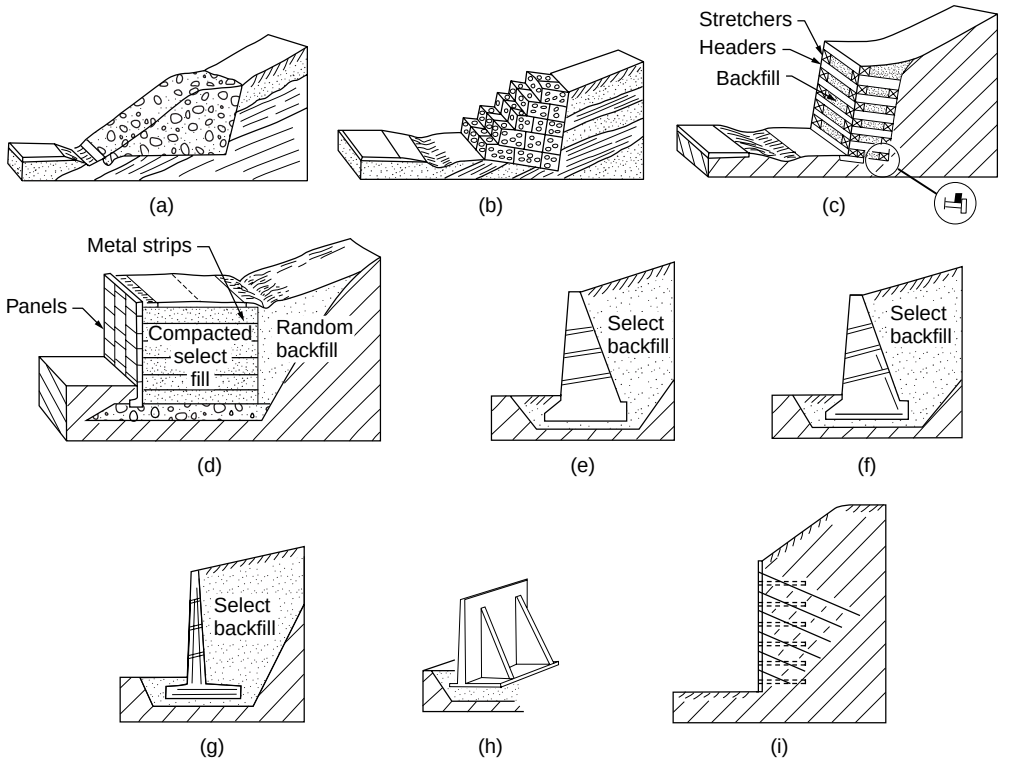

FIGURE 21.18 Various types of retaining walls: (a) rock-filled buttress; (b) gabion wall; (c) crib wall; (d) reinforced earth wall; (e) concrete gravity wall; (f) concrete-reinforced semigravity wall; (g) cantilever wall; (h) counterfort wall; (i) anchored curtain wall. (*Source:* Hunt, R. E. 1986. *Geotechnical Engineering Techniques and Practices*. McGraw-Hill, New York. Reprinted with permission of McGraw-Hill Book Co.)

to retain the fill with an anchored curtain wall (Fig. 21.18). After total failure, the most practical solutions are either reconstruction of the embankment with proper drainage, or retention with a wall.

Retention

Rock Slopes

Various methods of retaining hard rock slopes are illustrated in Fig. 21.19. They can be described briefly as follows.

- Concrete pedestals are used to support overhangs, where their removal is not practical because of danger to existing construction downslope [Fig. 21.19(a)].
- Rock bolts are used to reinforce jointed rock masses or slabs on a sloping surface [Fig. 21.19(b)]. Ordinary or temporary rock bolts, and fully grouted or permanent rock bolts are described by Lang [1972].
- Concrete straps and rock bolts are used to support loose or soft rock zones or to reduce the number of bolts [Fig. 21.19(c)].
- Cable anchors are used to reinforce thick rock masses [Fig. 21.19(d)]. The reinforcement of a single block by bolts or cables is shown in Fig. 21.20.

Shotcrete, when applied to rock slopes, usually consists of a wet-mix mortar with aggregate as large as 2 cm (3/4 in.) which is projected by air jet directly onto the slope face. The force of the jet compacts the mortar in place, bonding it to the rock, which first must be cleaned of loose particles and loose blocks.

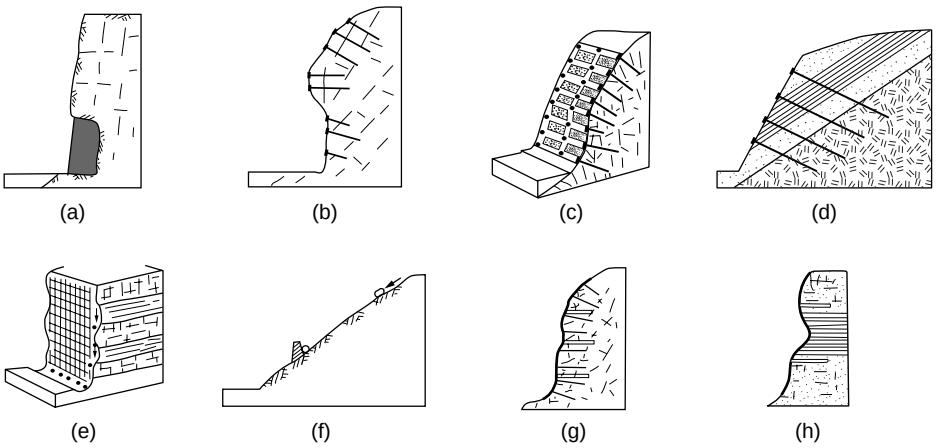

FIGURE 21.19 Various methods of retaining hard rock slopes: (a) concrete pedestals for overhangs; (b) rock bolts for jointed masses; (c) bolts and concrete straps for intensely jointed masses; (d) cable anchors to increase support depth; (e) wire mesh to constrain falls; (f) impact walls to deflect or contain rolling blocks; (g) shotcrete to reinforce loose rock, with bolts and drains; (h) shotcrete to retard weathering and slaking of shales. (*Source:* Hunt, R.E. 1984. *Geotechnical Engineering Investigation Manual.* McGraw-Hill, New York.)

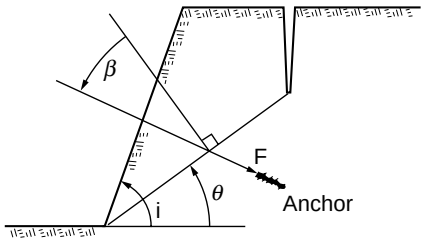

FIGURE 21.20 Definition of angle b for reinforcement of a single rock block with rock bolts. (*Source:* Hunt, R. E. 1986. *Geotechnical Engineering Techniques and Practices.* McGraw-Hill, New York. Reprinted with permission of McGraw-Hill Book Co.)

Application is in 3- to 4-in. layers, each of which is permitted to set before application of subsequent layers. Weep holes are installed to relieve seepage pressures behind the face. Since shotcrete acts as reinforcing and not as support, it is used often in conjunction with rock bolts. The tensile strength can be increased significantly by adding 25-mm-long wire fibers to the concrete mix.

Soil Slopes

Walls are used to retain earth slopes where space is not available for a flat enough slope or excessive volumes of excavation are required, or to obtain more positive stability under certain conditions. Except for anchored concrete curtain walls, wall types which require cutting into the slope for construction are seldom suitable for retention of a failing slope.

Various types of walls are illustrated in Fig. 21.18. They may be divided into four general classes, with some wall types included in more than one class: gravity walls, nongravity walls, rigid walls, and flexible walls.

Gravity walls provide slope retention by either their weight alone, or their weight combined with the weight of a soil mass acting on a portion of their base or by the weight of a composite system. They are free to move at the top, thereby mobilizing active earth pressure. Included are concrete gravity walls, cantilever walls, counterfort walls, rock-filled buttresses, gabion walls, crib walls, and reinforced earth walls. With the advent of geosynthetics there are many variations of "reinforced earth" [Koerner, 1993], and other innovations such as "soil nailing" [FHWA, 1993].

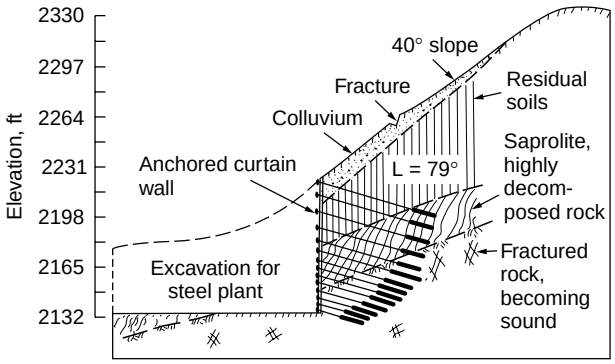

FIGURE 21.21 Section through a 25.5 m (85 ft) high anchored curtain wall constructed to retain a steep slope with a history of landslides. Joao Monlavade, M. G. Brazil. (*Source:* Hunt, R. E., and da Costa Nunes, A. J. 1978. Retaining walls: Taking it from the top. *Civ. Eng., ASCE,* May, 73–75.)

Nongravity walls are restrained at the top and not free to move. They include basement walls, some bridge abutments, and anchored concrete curtain walls. Anchored concrete curtain walls, such as the one illustrated in Fig. 21.21, can be constructed to substantial heights and have a very high retention capacity. As illustrated in Fig. 21.22, they are constructed from the top down by excavation of a series of benches into the slope and formation of a section of wall, retained by anchors, in each bench along the slope. Since the slope is thus retained completely during the wall construction, the system is particularly suited to potentially unstable or unstable slopes. A variation of the anchored curtain wall consists of anchored premolded concrete panels. The advantage of the system is that the wall easily conforms to the slope configuration.

Rigid walls include concrete walls, gravity and semigravity walls, cantilever walls, and counterfort walls. Anchored concrete curtain walls are considered as semirigid. Flexible walls include rock-filled buttresses, gabion walls, crib walls, reinforced earth walls, and anchored sheet-pile walls.

Embankments

Earth Dams

During design and construction of earth dams, stability is provided by controlled compaction of the embankment materials, adequate support by founding materials, and control of seepage through and beneath the embankment. Stable slope inclinations are related to the materials used to construct the embankment, and to the foundation materials. Relatively weak foundation materials either require removal by excavation or the flattening of embankment slopes.

Control of seepage through, beneath, and around the embankment is a critical aspect of design and construction. In addition to water loss in a reservoir, uncontrolled seepage can result in internal erosion of the embankment or high uplift pressures in the foundation, either of which can lead to complete failure.

Embankments over Soft Ground

Failures usually occur during or shortly after construction when embankments are raised over soft foundation soils. The major postconstruction concern is long-term settlements. In most situations it is desirable to avoid failure because the remolding of the soils that occurs significantly decreases their strength, worsening the situation. Therefore, embankments are constructed in stages. During each stage consolidation and strength increase occurs in the foundation soils, enabling the construction of subsequent stages [Ladd, 1991]. Vertical drains, such as wick drains, significantly increase the rate of consolidation and shorten the time interval between stages.

Geosynthetics are used to improve embankment strength. They may be placed on the soft ground prior to placing the first lift, and then subsequently placed within the embankment. Hird [1986] and Low et al. [1990] provide methods for assessing stability of reinforced embankments on soft ground. Construction of counterberms (Fig. 21.5) also improves stability.

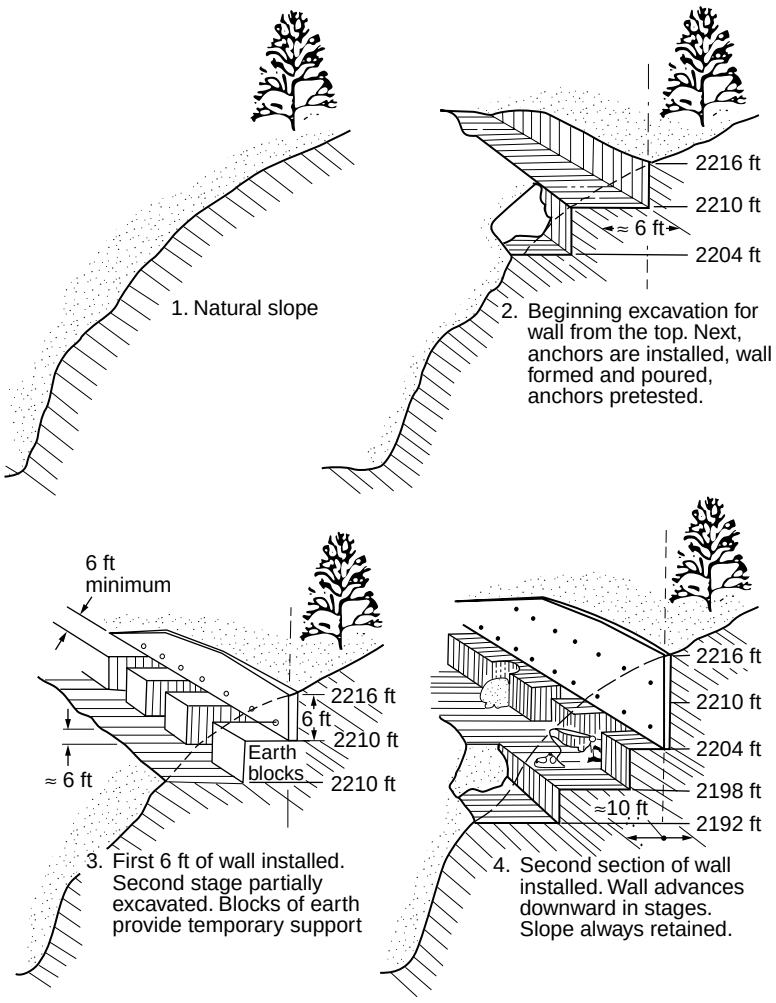

FIGURE 21.22 The "Brazilian method" of construction of an anchored curtain wall from the top down. (*Source:* Hunt, R. E., and da Costa Nunes, A. J. 1978. Retaining walls: Taking it from the top. *Civ. Eng., ASCE,* May, 73–75.)

21.5 Investigation and Monitoring

Exploration

Preliminary Phases

The objectives of the preliminary phases of investigation are to identify potential forms, magnitudes, and incidences of slope failures, and to plan an exploration program. The study scope includes collection of existing data, generation of new data through terrain analysis, and field reconnaissance. Data to be collected include site geology, topographic maps, and remotely sensed imagery, and historical information on regional and local slope failures, climatic conditions of precipitation and temperature, and seismicity.

Using the topographic maps and remotely sensed imagery (air-photo interpretation techniques) terrain analysis is performed to identify unstable and potentially unstable areas, and to establish preliminary conclusions regarding geologic conditions. For a large study area, a preliminary map is prepared on which is shown topography, drainage, active and ancient failures, and geology. The preliminary map is developed

into a hazard map after field reconnaissance. At the project location, more detailed maps are prepared illustrating the foregoing items. The methodology identifies the significant features to be examined during field reconnaissance.

The site location is visited and notations are made regarding seepage points, vegetation, creep indications (tilted and bent tree trunks), tension cracks, failure scars, hummocky ground, natural slope inclinations, exposed geology, and prevailing and recent weather conditions.

From the data collected, preliminary evaluations are made regarding slope conditions and an exploration program is planned. The entire slope should be explored, not only the specific area of failure or area to be cut.

Explorations

Seismic refraction profiling is useful to determine the depth to sound rock and the probable groundwater table, and is most useful in differentiating between colluvial or residual soils and the fractured-rock zone. Surveys are made both longitudinal and transverse to the slope. They are particularly valuable on steep slopes with a deep weathering profile where test borings are time-consuming and costly.

Resistivity profiling may be performed to determine the depth to groundwater and to rock. Profiling is generally only applicable to depths of about 15 to 30 ft, but very useful in areas of difficult access. In the soft, sensitive clays of Sweden, the failure surface or potential failure surface is often located by resistivity measurements since the salt content, and therefore the resistivity, often changes suddenly at the slip surface [Broms, 1975].

Test borings are made to confirm the stratigraphy determined by the geophysical explorations, to recover samples of the various materials, and to provide holes for the installation of instrumentation. Borings should extend to adequate penetration below the depth of a cut, and below the depth of any potential failure surface. Sampling should be continuous through a potential or existing rupture zone, and in residual soils and rock masses care should be taken to identify slickensided surfaces. Groundwater conditions must be defined carefully and the static water table, perched, and artesian conditions noted. It is important to remember that the conditions existing at the time of investigation are not likely to be those during failure.

Evaluations

Evaluations are made of the safety factor against total failure on the basis of existing topographic conditions, then under conditions of the imposed cut or fill. For preliminary studies, shear strengths may be estimated from published data, or measured by laboratory or *in situ* testing. In the selection of the strength parameters, consideration is given to field conditions as well as to changes that may occur with time (reduction from weathering, leaching, solution). Other transient conditions such as weather and earthquakes also require consideration, especially if the safety factor for the entire slope is low and could go below unity with some environmental change.

Instrumentation and Monitoring

Purpose

Where movement is occurring, where safety factors against sliding are low, or where a major work would become endangered by a slope failure, instrumentation is required to monitor changing conditions and provide early warning of impending failure.

Slope–stability analysis is far from an exact science, regardless of the adequacy of the data available, and sometimes the provision for an absolutely safe slope is prohibitively costly.

In cut slopes, instrumentation monitors movements and changing stress conditions to provide early warning and permit invoking contingency plans for remedial measures when low safety factors are accepted in design. In unstable or moving slopes, instrumentation is installed to locate the failure surface and determine pore-water pressures for analysis, and to measure surface and subsurface movements, velocities, and accelerations which provide indications of impending total failure.

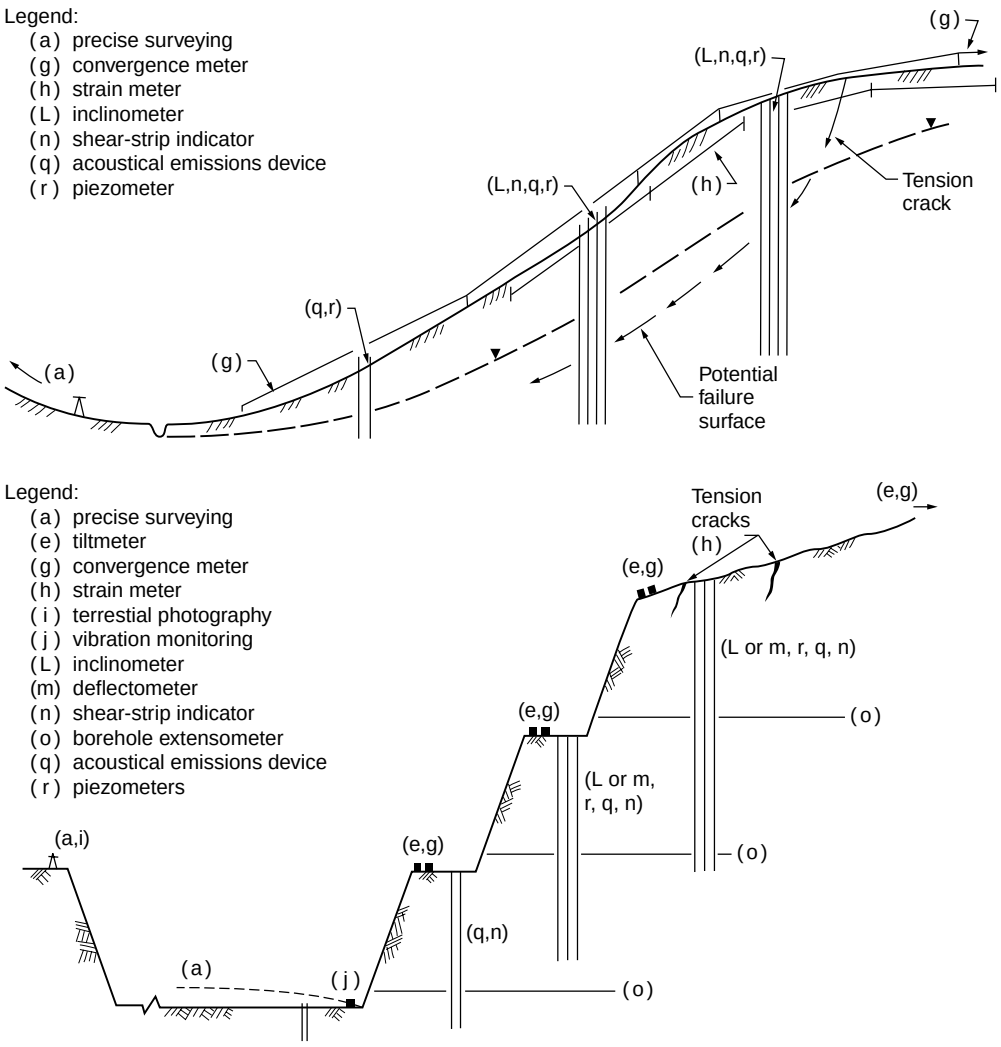

FIGURE 21.23 Slope instrumentation and monitoring: (a) potentially unstable soil slope and (b) rock cut. (*Source:* Hunt, R. E. 1984. *Geotechnical Engineering Investigation Manual.* McGraw-Hill, New York.)

Methods Summarized

Instrumentation is discussed in detail in Hunt [1984] and Dunnicliff [1988], and for slopes is illustrated in Fig. 21.23. Surface movements are monitored by survey nets, tiltmeters (on benches), convergence meters, surface extensometers, and terrestrial photography. Subsurface deformations are monitored with inclinometers, deflectometers, shear-strip indicators, steel wire and weights in boreholes, and the acoustical emissions device. Pore-water pressures are monitored with piezometers.

All instruments should be monitored periodically and the data plotted as it is obtained to show changing conditions. Movement accelerations are most significant.

22.1 Introduction

Civil engineering projects often require the construction of systems that retain earth materials. An excavation support system for a cut-and-cover trench for utilities installation is an example of a temporary retaining structure. A reinforced concrete retaining wall utilized in a highway project to accommodate a change in elevation over a limited distance is an example of a permanent retaining structure. Numerous earth retention systems have been developed over the years and a few systems are shown in Fig. 22.1. The design of retaining structures requires an evaluation of the loads likely to act on the system during its design life and the strength, load-deformation, and volume-change response of the materials to the imposed loads. Lateral pressures develop on retaining structures as a result of the adjacent earth mass, surcharge, water, and equipment. The development of lateral earth pressures and the transfer of these pressures to the retaining system are inherently governed by soil-structure interaction considerations. Hence, the analytical procedure should consider the relative rigidity/flexibility of the earth retention system. In this chapter, retaining structures will be broadly classified as either *rigid* or *flexible*. Before applicable design procedures are discussed, **lateral earth pressure** concepts will be reviewed.

22.2 Lateral Earth Pressures

The at-rest lateral earth pressure within a level earth mass of large areal extent can be estimated using the following relationship:

$$\sigma'_h = K_0 \sigma'_v \tag{22.1}$$

where σ'_h is the horizontal effective pressure, σ'_v is the vertical effective pressure, and K_0 is the **lateral earth pressure coefficient at rest**. Note that this relationship is valid in terms of effective stress only. The parameter K_0 is difficult to evaluate. Based on Jaky [1944], K_0 for normally consolidated soils, $K_{0,nc}$, can be approximated as

$$K_{0,nc} \approx 1 - \sin\phi' \tag{22.2}$$

where ϕ' is the effective friction angle. This correlation appears to be more reasonable for clays and less reasonable for sands, but it is widely used in practice [see data presented in Mayne and Kulhawy, 1982].

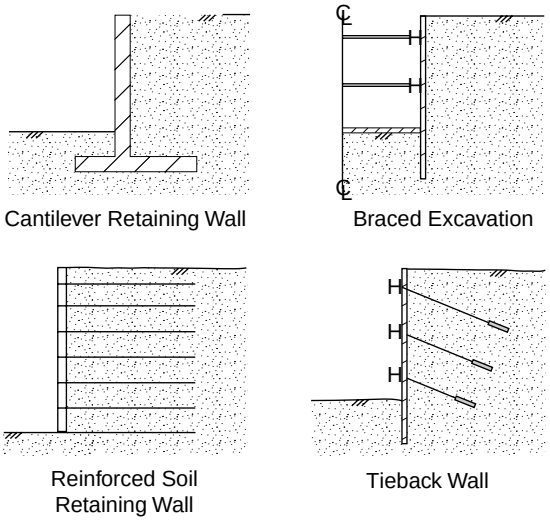

FIGURE 22.1 Examples of earth retention systems.

A strong case could be made for just using $K_0 \approx 0.4$ for most normally consolidated sands. Schmidt's [1966] relationship as modified by Mayne and Kulhawy [1982] can be used to estimate the coefficient of lateral earth pressure at rest during unloading, $K_{0,u}$, as

$$K_{0,u} \approx K_{0,nc}(\mathrm{OCR})^{\sin\phi'} \tag{22.3}$$

where OCR is the **overconsolidation ratio**. The at-rest lateral earth pressure coefficient during reloading is not known precisely, but it can be approximated as halfway between $K_{0,u}$ and $K_{0,nc}$ [Clough and Duncan, 1991]. K_0 may also be estimated on a site-specific basis using *in situ* test devices, such as the pressure meter or dilatometer [see Kulhawy and Mayne, 1990].

If a perfectly rigid vertical wall was wished into place (i.e., no lateral deformation occurred), then the at-rest *in situ* pressure distribution would be preserved. In homogeneous, dry soil with a constant K_0 and unit weight, γ, the horizontal effective stress would increase linearly with depth, z, proportional to the linearly increasing vertical effective stress (i.e., $\sigma'_h = K_0 \gamma z$). This would result in a triangular pressure distribution. With the presence of a level water table, the total lateral pressure would consist of two components: horizontal effective earth pressure and water pressure ($u = \gamma_w \cdot z_w$, where u = pore water pressure, γ_w = unit weight of water, and z_w = depth below water table). Layered soil profiles can be easily handled by calculating the vertical effective stress at the depth of interest and multiplying this value by the parameter K_0 that best represents the soil layer at this depth. The compaction of earth fill behind a rigid wall that does not move will lock in higher lateral earth pressures than the at-rest condition [see Duncan and Seed, 1986].

If the rigid vertical retaining wall discussed above translates outward the lateral earth pressure on the back of the wall reduces, since the adjacent earth mass mobilizes strength as it deforms to follow the outward wall movement. The minimum active lateral earth pressure is reached when the soil has mobilized its maximum shear strength. Conversely, if the rigid wall translates inward, the lateral earth pressure on the back of the wall increases as the adjacent earth mass mobilizes strength and resists the inward wall translation. At the limiting state, the maximum passive lateral earth pressure is attained. Hence, a range of possible magnitudes for the lateral earth pressure on the back of the wall exist, depending on the direction and magnitude of wall movement (see Fig. 22.2). The **minimum active earth pressure** defined by $p'_a = K_a \sigma'_v$ and the **maximum passive earth pressure** defined by $p'_p = K_p \sigma'_v$ represent only the limiting states of the possible lateral pressure range. Note that p'_a is attained at relatively low wall

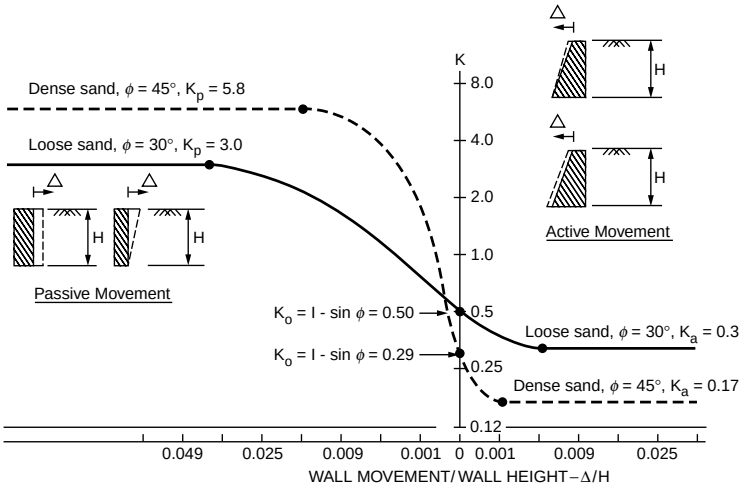

FIGURE 22.2 Relationship between wall movement and earth pressure. (After Clough, G. W., and Duncan, J. M. 1991. Earth Pressures. In *Foundation Engineering Handbook,* ed. H-Y. Fang, pp. 224–235. Van Nostrand Reinhold, New York.)

displacements, and that an order of magnitude more wall displacement is required to reach p'_a. Consequently, engineers often design retaining structures for the full active state when the earth retaining wall can move outward, but only for a fraction of the full passive state when the retaining wall moves inward.

22.3 Earth Pressure Theories

Rankine Theory

If the vertical wall is frictionless and the retained earth materials are level, homogeneous, isotropic, and characterized by the Mohr–Coulomb strength criterion (i.e., $s = c' + \sigma'_n \tan \phi'$), the limiting states of stress can be estimated using Rankine [1857] earth pressure theory. The minimum active earth pressure is

$$p'_a = K_a \sigma'_v - 2c' \sqrt{K_a} \tag{22.4}$$

where $K_a = \tan^2(45 - \phi'/2)$. Note that the vertical effective stress can include the effects of any applied surcharge as well as the gravity load of the earth materials. Typically, only the destabilizing effects of the active earth pressure (i.e., $p'_a > 0$) are included in developing design pressures, and a tension crack filled with water is conservatively assumed to exist down to the depth at which $p'_a = 0$. Layered soil profiles can be easily handled by calculating p'_a at the top and bottom of each soil layer and realizing that the lateral earth pressure varies linearly between these points. With freely draining cohesionless materials, effective strength parameters should be used and the earth and water pressure distributions should be computed separately. In a short-term undrained analysis of cohesive soils, total strength parameters may be used, but now the earth and water pressures will be calculated together since the total strength parameters include pore water effects.

The Rankine maximum passive earth pressure is

$$p'_p = K_p \sigma'_v + 2c' \sqrt{K_p} \tag{22.5}$$

where $K_p = \tan^2(45 + \phi'/2)$. Rankine theory underestimates the actual maximum passive earth pressure, so engineers often use the full Rankine passive earth pressure in design.

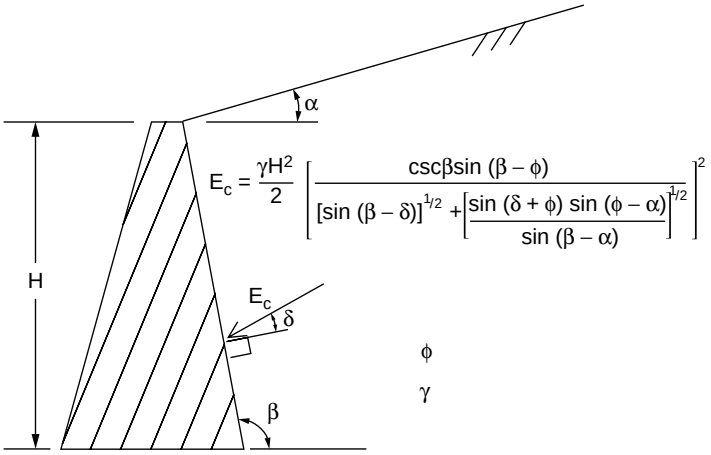

FIGURE 22.3 Closed-form solution for Coulomb minimum active earth force.

Coulomb Theory

Coulomb [1776] solved the lateral earth pressure problem assuming a homogeneous, isotropic material, rough wall, planar failure surface, and Mohr–Coulomb strength criterion. A wide range of earth pressure problems can be solved using the force polygon technique implied in Coulomb's method. The closed-form solution for the minimum active earth force for a general case including dry, cohesionless material, inclined rough wall, and sloping backfill is presented in Fig. 22.3. Coulomb theory can overestimate the actual maximum passive earth pressure acting on a rough wall with the wall friction angle, δ, greater than half of ϕ′, so its use should be avoided. The use of log-spiral failure surfaces, as opposed to planar failure surfaces, provides good estimates of minimum active and maximum passive earth pressures, and graphical solution charts are available (see Fig. 22.4).

Example 22.1 — Lateral Earth Pressure

Calculate the resultant active earth pressure by Rankine theory for the case shown in Fig. 22.5(a).

Solution.

Sand ($\phi' = 30°$, $c' = 0$): $K_a = \tan^2(45° - \phi'/2) = \tan^2(45° - 30°/2) = 0.333$; $p'_a = K_a\gamma' z = K_a\rho' gz$

Clay ($\phi = 0°$, $c = 24$ kPa): $K_a = \tan^2(45 - 0°/2) = 1.0$; $p_a = \rho_t gz - 2c$

At $z = 3$ m, $p'_a = K_a\rho' gz = (0.333)\ (2.0\ \text{Mg/m}^3)\ (9.81\ \text{m/s}^2)\ (3\ \text{m}) = 19.6$ kPa

At $z = 6^-$ m, $p'_a = 19.6\ \text{kPa} + (0.333)\ (2.0 - 1.0\ \text{Mg/m}^3)\ (9.81\ \text{m/s}^2)(3\ \text{m}) = 29.4$ kPa

At $z = 6^-$ m, $u = \rho_w gz_w = (1\ \text{Mg/m}^3)\ (9.81\ \text{m/s}^2)\ (3\ \text{m}) = 29.4$ kPa

At $z = 6^+$ m, $p_a = \rho_t gz - 2c = (2\ \text{Mg/m}^3)\ (9.81\ \text{m/s}^2)\ (6\ \text{m}) - 2(24\ \text{kPa}) = 69.7$ kPa

At $z = 12^-$ m, $p_a = 69.7\ \text{kPa} + (1.8\ \text{Mg/m}^3)\ (9.81\ \text{m/s}^2)\ (6\ \text{m}) = 175.6$ kPa

$$P_{ae} = \tfrac{1}{2}(19.6\ \text{kN/m}^2)\ (3\ \text{m}) + \tfrac{1}{2}(19.6 + 29.4\ \text{kN/m}^2)\ (3\ \text{m}) + \tfrac{1}{2}(69.7 + 175.6\ \text{kN/m}^2)\ (6\ \text{m})$$
$$= 839\ \text{kN/m}$$

$$P_w = \tfrac{1}{2}(29.4\ \text{kN/m}^2)\ (3\ \text{m}) = 44\ \text{kN/m}$$

See Fig. 22.5(b) for pressure diagram.

22.4 Rigid Retaining Walls

Design lateral active earth pressures for low retaining walls (i.e., height <6 m) are often estimated using conservative design charts [see Department of the Navy, 1982] or using equivalent fluid pressures. The equivalent fluid unit weight, γ_{eq}, equals the product of the minimum active earth pressure coefficient and the backfill material's unit weight (i.e., $\gamma_{eq} = K_a \cdot \gamma$), and

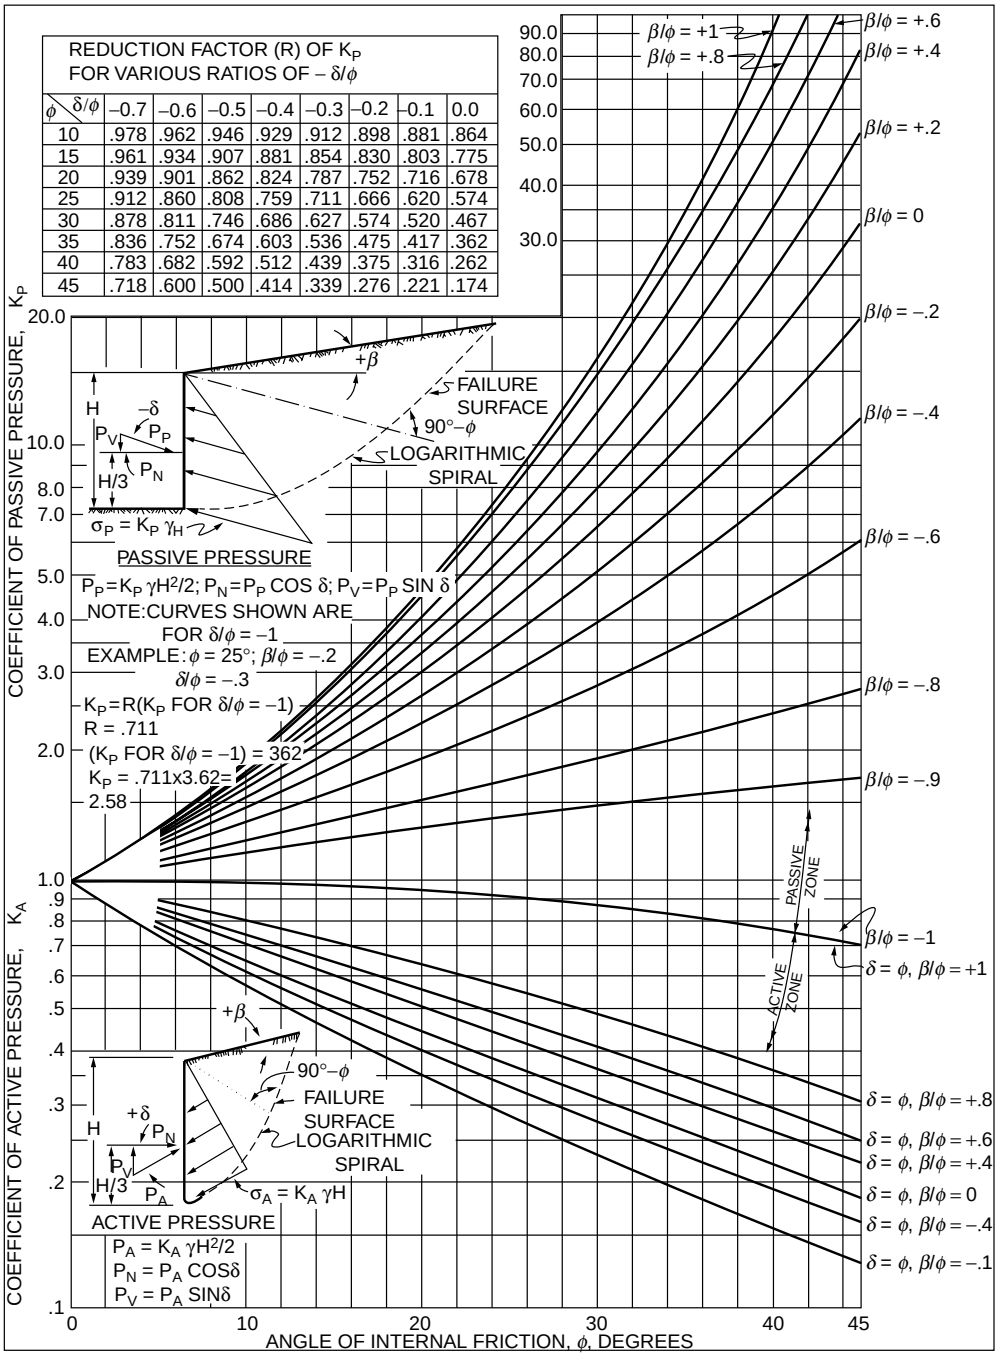

FIGURE 22.4 Minimum active and maximum passive lateral earth pressure coefficients developed from log-spiral solution techniques. (After Department of the Navy. 1982. *Foundations and Earth Structures: Design Manual 7.2.* NAVFAC DM-7.2, May.)

$$p_a = \gamma_{eq} \cdot z \tag{22.6}$$

Conservative estimates of γ_{eq} for a variety of backfill materials are listed in Table 22.1. All earth retention structures should be designed to sustain potential surcharge loadings, and typically a minimum surcharge

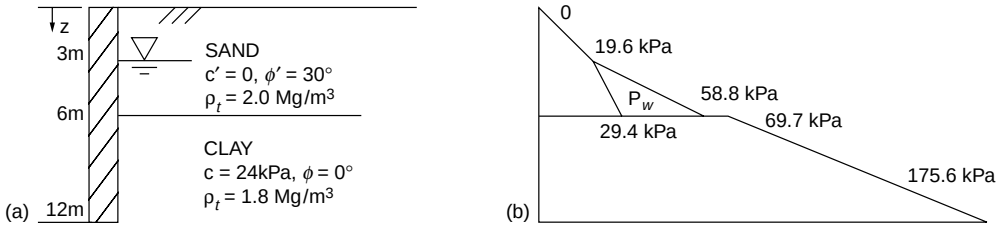

FIGURE 22.5 Example 22.1.

TABLE 22.1 Equivalent Fluid Unit Weights (kN/m3) for Design of Low Retaining Walls

	Level Backfill		2H:IV Backfill

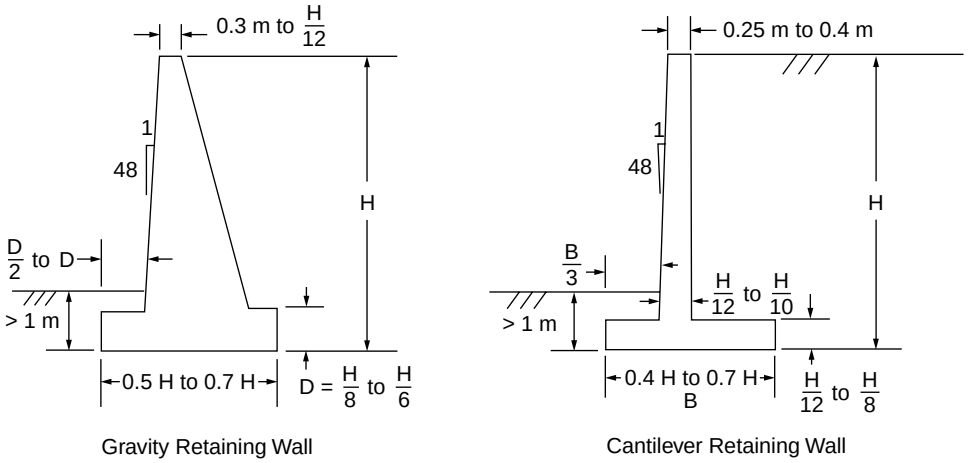

FIGURE 22.6 Tentative gravity and cantilever wall dimensions.

load equivalent to an additional 0.6-m thickness of backfill is specified. Retaining walls should be constructed with free-draining backfill materials and with effective drainage systems, because if water can pond behind the wall the additional water pressure will dramatically increase the load on the wall. If ponding cannot be precluded, the wall should be designed to resist the higher total pressures.

The general design procedure for gravity and cantilever retaining walls follows:

1. Characterize project site and subsurface conditions. Pay particular attention to groundwater and surface water, site geology, availability of free-draining backfill soils, and potentially weak seams.
2. Select tentative wall dimensions (see Fig. 22.6).
3. Estimate the forces acting on the retaining wall (i.e., active earth pressure, weight, surcharge, and resultant).
4. Check overturning stability; the resultant force should act within the middle third of the base of the wall.

5. Check bearing capacity; maximum earth pressure on the wall base should be less than the allowable earth pressure regarding bearing capacity or permissible settlement.
6. Check sliding; horizontal frictional resisting force on the base of the wall should be at least 1.5 times the horizontal driving force.
7. Check for excessive settlement from deeper soil deposits.
8. Check the overall stability of the earth mass that contains the retaining structure.
9. Apply load factors and compute reactions, shears, and moments in the wall.
10. Compute the ultimate strength of the structural components.
11. Check adequacy of structural components against applied factored forces and moments.

Design procedures differ for retaining systems built of reinforced soil [see Mitchell and Villet, 1987].

Example 22.2 — Cantilever Retaining Wall

Check the adequacy of the cantilever retaining wall shown in Fig. 22.7 regarding overturning, bearing capacity, and sliding. The allowable bearing pressure is 360 kPa.

Solution. (a) The overall dimensions of the wall appear to be appropriate (see Fig. 22.6).

(b) Estimate the forces acting on wall:

$W_1 = \rho_c g A = (2.4\ \text{Mg/m}^3)(9.81\ \text{m/s}^2)(0.25\ \text{m} \cdot 8\ \text{m}) = 47.1\ \text{kN/m}$
$W_2 = (2.4\ \text{Mg/m}^3)(9.81\ \text{m/s}^2)(0.5 \cdot 0.45\ \text{m} \cdot 8\ \text{m}) = 42.4\ \text{kN/m}$
$W_3 = (2.4\ \text{Mg/m}^3)(9.81\ \text{m/s}^2)(0.6\ \text{m} \cdot 4.5\ \text{m}) = 63.6\ \text{kN/m}$
$W_4 = \rho_t g A \approx (1.9\ \text{Mg/m}^3)(9.81\ \text{m/s}^2)(8.5\ \text{m} \cdot 2.8\ \text{m}) = 444\ \text{kN/m}$
$W_5 = (1.9\ \text{Mg/m}^3)\ (9.81\ \text{m/s}^2)\ (0.9\ \text{m} \cdot 1.0\ \text{m}) = 16.8\ \text{kN/m}$
$W_T = \sum W_i = 614\ \text{kN/m}$

Add 0.6 m of soil behind the wall to account for surcharge; hence, $H = 0.6\ \text{m} + 8\ \text{m} + 1\ \text{m} + 0.6\ \text{m} = 10.2\ \text{m}$. Conservatively assume $P_p \approx 0$. Use the log-spiral solution for the sloping backfill to estimate K_a (see Fig. 22.4).

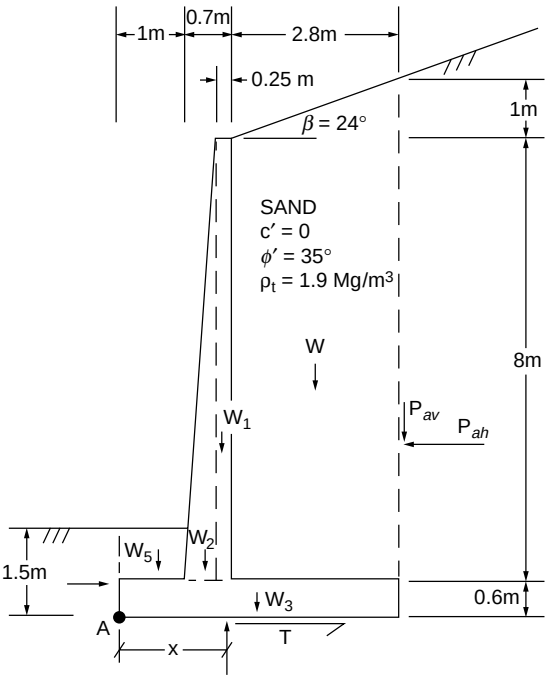

FIGURE 22.7 Example 22.2.

$\beta/\phi = 24°/35° \cong 0.7$ and $\phi' = 35°$ with $\delta = \phi' \rightarrow K_a = 0.38$
$P_a = K_a \gamma H^2/2 = (0.38)(1.9\ \text{Mg/m}^3)(9.81\ \text{m/s}^2)(10.2\ \text{m})^2/2 = 368\ \text{kN/m}$
$P_{ah} = P_a \cos \delta = (368\ \text{kN/m}) \cos 35° = 301\ \text{kN/m}$
$P_{av} = P_a \sin \delta = (368\ \text{kN/m}) \sin 35° = 211\ \text{kN/m}$
$N = W_T + P_{av} = 614\ \text{kN/m} + 211\ \text{kN/m} = 825\ \text{kN/m}$
$T = N \tan \delta_b = (825\ \text{kN/m}) \tan 35° = 578\ \text{kN/m}$

Location of resultant, *N*:

$$\begin{aligned}\sum M_A = 0 &= (47.1\ \text{kN/m})(1.575\ \text{m}) + (42.4\ \text{kN/m})(1.3\ \text{m}) \\ &\quad + (63.6\ \text{kN/m})(2.25\ \text{m}) + (444\ \text{kN/m})(3.1\ \text{m}) \\ &\quad + (16.8\ \text{kN/m})(0.5\ \text{m}) + (211\ \text{kN/m})(4.5\ \text{m}) \\ &\quad - (301\ \text{kN/m})(3.2\ \text{m}) - (825\ \text{kN/m})(x) \\ x &= 2.0\ \text{m}\end{aligned}$$

(c) Check overturning:

$$B/3 = 4.5\ \text{m}/3 = 1.5\ \text{m} \qquad 2B/3 = 2 \cdot 1.5\ \text{m} = 3\ \text{m}$$

$1.5\ \text{m} < 2.0\ \text{m} < 3\ \text{m}$ OK, since *N* acts within middle third of base

(d) Check bearing capacity:

$$e = \left|\frac{B}{2} - x\right| = \left|\frac{4.5\ \text{m}}{2} - 2.0\ \text{m}\right| = 0.25\ \text{m}$$

$$P_{\max} = \frac{N}{B}\left(1 + \frac{6e}{B}\right) = \frac{825\ \text{kN/m}}{4.5\ \text{m}}\left(1 + \frac{6 \cdot 0.25\ \text{m}}{4.5\ \text{m}}\right) = 245\ \text{kPa}$$

$$P_{\max} = 245\ \text{kPa} < q_a = 360\ \text{kPa} \quad \text{OK}$$

(e) Check sliding:

$$\text{FS} = \frac{T}{P_{ah}} = \frac{578\ \text{kN/m}}{301\ \text{kN/m}} = 1.9 > 1.5 \quad \text{OK}$$

22.5 Flexible Retaining Structures

Flexible retaining structures include systems used in braced excavations, tie-back cuts, and anchored bulkheads. In this section, braced excavation systems will be discussed. Braced excavation support systems include walls, which may be steel sheetpiles, soldier piles with wood lagging, slurry placed tremie concrete, or secant/tangent piles; and supports, which may be cross-lot struts, rakers, diagonal bracing, tiebacks, or the earth itself in cantilever walls. Active earth pressure theories cannot be used directly to develop estimates of the lateral earth pressure acting on flexible retention structures. The pattern of wall movements during the excavation process does not satisfy Rankine-type assumptions of rigid wall translation or rigid wall rotation about its toe. With respect to the active Rankine state, the movement at the top of the wall is less and the movement at the base of the wall is more. Terzaghi [1943] showed that the resultant force on the flexible retaining structure is about 10% greater than the active Rankine resultant force and that the resultant force is located nearer to midheight of the wall rather than at its lower-third point. Theory is inadequate, since much depends on construction procedures, soil-structure interaction, and stress transfer. Moreover, more conservatism is desirable to guard against a progressive failure of the

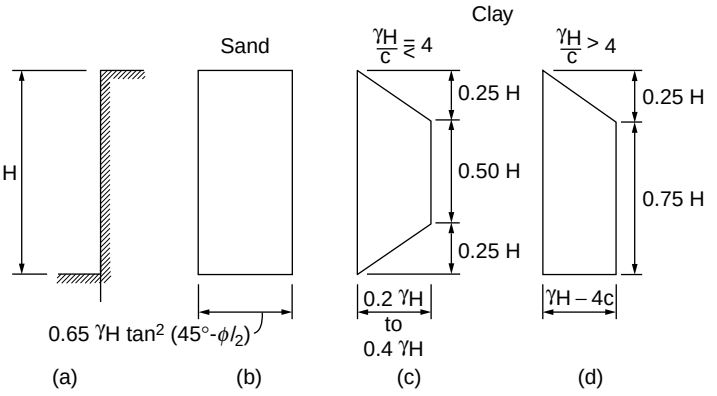

FIGURE 22.8 Lateral pressure distribution for computation of strut loads in braced excavation systems. (After Terzaghi, K., and Peck, R. 1967. *Soil Mechanics in Engineering Practice*. John Wiley & Sons, New York. Copyright © 1967 John Wiley & Sons, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

support system. Consequently, **apparent lateral earth pressure** diagrams, which envelop the maximum strut loads measured for excavation systems (in specific subsurface conditions), are used.

Terzaghi and Peck [1967] have developed the apparent pressure diagrams shown in Fig. 22.8 for sand and clay sites [see Tschebotarioff, 1951 for other diagrams]. Note that for sand, the ratio of the resultant force due to the apparent pressure distribution shown in Fig. 22.8 to that due to active Rankine earth pressures is 1.3. The corresponding ratio for clay is about 1.7. Individual strut loads are computed based on the associated tributary area of the apparent pressure diagram. This is merely a reversal of the procedure used to develop the apparent pressure diagrams. The apparent pressure diagrams are based on field measurements of maximum strut loads, so normal surcharge loads are already included. Some engineers increase the strength of the upper struts by 15% to guard against surcharge overload.

The design wall and wale moments are typically calculated using the assumption that the wall and wale are simply supported between adjacent wales and struts, respectively. If the wall or wale is continuous over at least three supports, then the moment formula for a continuous beam can be used to calculate moments. Since the design of the wall and wale do not require the level of conservatism needed to guard against progressive failure of the struts, only two-thirds of the magnitude of the apparent pressure diagram is used in the computation. Hence, the maximum wall or wale moment, M_{max}, can be calculated by the following formula:

$$M_{max} = \frac{\frac{2}{3} \cdot \text{AP} \cdot l_{max}^2}{(8 \text{ or } 10)} \tag{22.7}$$

where AP = apparent distributed load, l_{max} = maximum span length, and the denominator is 8 for the simply supported condition or 10 for the continuous beam condition. Excavations in deep soft to medium stiff clays may present situations in which the maximum wall moment occurs prior to installing the bottom strut, so wall moments should not just be computed for the final bracing configuration. Lastly, structural details are critically important in braced excavation systems. Typically, stiffeners are added to the wales at strut locations, and long internal struts are braced at points along their length.

The overall stability of the excavation must also be evaluated. Some potential failure mechanisms that should be investigated include **base heave**, bottom blowout, and piping. Calculating the factor of safety against base heave in deep clay deposits is especially important because a low safety factor indicates marginal stability and the potential for excessive movements (see Fig. 22.9). The engineer's primary concern in urban areas or where sensitive structures are near the excavation is often limiting ground movements.

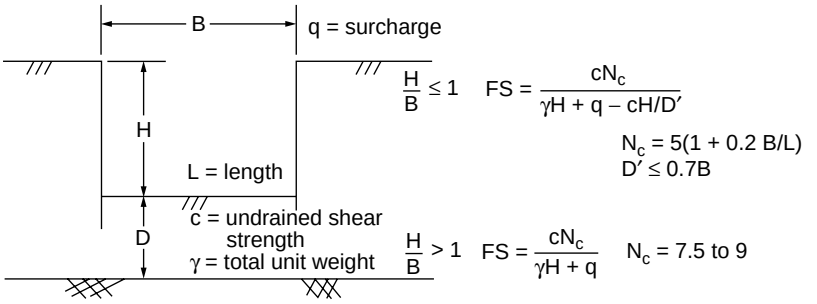

FIGURE 22.9 Factor of safety against base heave.

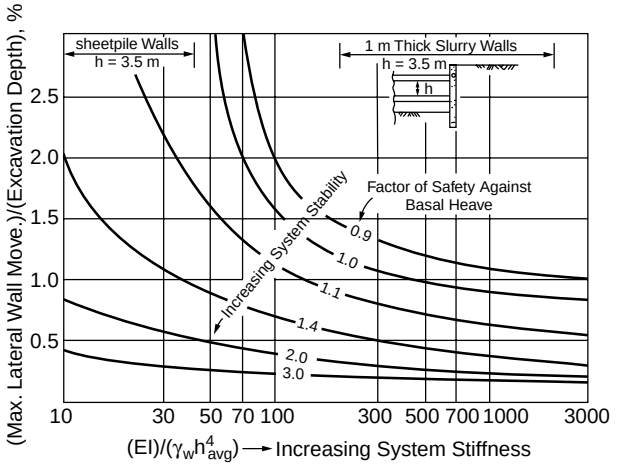

FIGURE 22.10 Design curves to obtain maximum lateral wall movement for soft to medium stiff clays. (After Clough, G.W., Smith, E.M., and Sweeny, B.P. 1989. Movement Control of Excavation Support Systems by Iterative Design. *Proc. ASCE Foundation Engineering: Current Principles and Practices,* 2: 869–884. Reproduced by permission of ASCE.)

Clough and O'Rourke [1990] present empirical data and analytical results that assist engineers in estimating excavation-induced ground movements. The maximum lateral wall movement, $\Delta_{h,m}$, in well-constructed excavations in stiff clays, residual soils, and sands is typically 0.1% to 0.5% of the height of the excavation, H, with most of the data suggesting $\Delta_{h,m} \approx 0.2\%H$. The stiffness of the support system is not critically important in those soil deposits. Conversely, the support system stiffness is important in controlling movements with excavations in soft to medium stiff clays. In soft to medium stiff clays, the maximum lateral wall movement can range from 0.3%H to over 3%H depending on the factor of safety against base heave and the support system stiffness (see Fig. 22.10). When the factor of safety against base heave is less than 1.5, special care should be exercised in controlling the excavation procedures to minimize movements. Preloading struts, not allowing overexcavation, and employing good construction details (e.g., steel shims) have proven useful in minimizing ground movements. Vertical movements of the ground surface, Δ_v, surrounding the excavation are largely a function of the lateral wall movements, and $\Delta_{v,m} \approx \Delta_{h,m}$. However, vertical ground movements can be much higher if excavation dewatering induces consolidation settlement in underlying clay deposits. Driving sheetpiles in loose sands can also induce significant ground settlement [see Clough and O'Rourke, 1990].

The design of tieback walls used in temporary excavations is similar to that described previously for braced excavations, but there are a number of significant differences [see Juran and Elias, 1991]. Tieback systems often permit less movement because they use higher preloads, positive connections, smaller support spacing, and less overexcavation. The tieback anchor itself, however, is more flexible than an

internal strut, and its capacity depends greatly on the bond developed between the soil and grouted anchorage. Tieback systems consequently require good soil conditions and the absence of obstructions in the surrounding ground. Typically, the tieback system is checked against anchor pullout by proof testing each anchor to 100 to 150% of the design load, and the required lengths of the anchors are determined by ensuring their anchorage zones are located behind potential failure surfaces. Because preloading anchors to roughly 80% of their design load maintains a nearly at-rest stress state in the ground, lateral earth pressures are often assumed to be near at-rest pressures. Numerous other support systems have been developed and, depending on the availability of specialized contractors, these systems may be advantageous. For example, in good soils, soil nailing with a reinforced shotcrete wall has proved to be effective and cost-efficient.

Example 22.3 — Braced Excavation

For the braced excavation shown in Fig. 22.11(a), develop estimates of the strut loads, maximum wale moment, maximum wall moment, and maximum excavation-induced ground movements.

Solution. (a) Apparent pressures:

$$\text{Stability number } N = \frac{\gamma H}{c} = \frac{(2\ \text{Mg/m}^3)(9.81\ \text{m/s}^2)(8\ \text{m})}{35\ \text{kPa}} = 4.5$$

Since N is only slightly larger than 4, both Terzaghi and Peck [1967] clay apparent pressure diagrams should be calculated. The one with the largest resultant should be used (i.e., the left one in which R = 283 kN/m).

(b) Strut loads:

$$S1 = 1.15[\tfrac{1}{2}(47.1\ \text{kPa})(2\ \text{m}) + (47.1\ \text{kPa})(1.5\ \text{m})]6\ \text{m} = 810\ \text{kN}$$

$$S2 = [(47.1\ \text{kPa})(2.5\ \text{m}) + \tfrac{1}{2}(47.1\ \text{kPa} + 35.4\ \text{kPa})(0.5\ \text{m})]6\ \text{m} = 830\ \text{kN}$$

$$\text{Stability number } N = \frac{\gamma H}{c} = \frac{(2\ \text{Mg/m}^3)(9.81\ \text{m/s}^2)(8\ \text{m})}{35\ \text{kPa}} = 4.5$$

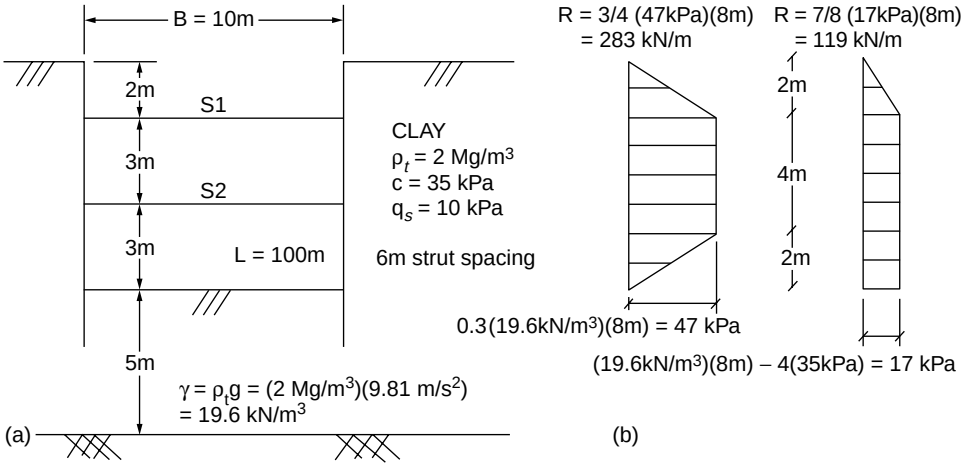

FIGURE 22.11 Example 22.3.

(c) Maximum wale moment:

$$M_{max} = \frac{\left(\frac{2}{3}\,\mathrm{AP}\right)l_{max}^2}{10} = \frac{\left(\frac{2}{3}\cdot\frac{830\ \mathrm{kN}}{6\ \mathrm{m}}\right)(6\ \mathrm{m})^2}{10} = 330\ \mathrm{kN\text{-}m}$$

(d) Maximum wall moment:

$$M_{max} = \frac{\left(\frac{2}{3}\,\mathrm{AP}\right)l_{max}^2}{8} = \frac{\left(\frac{2}{3}\cdot 47.1\ \mathrm{kPa}\right)(3\ \mathrm{m})^2}{8} = 35\ \mathrm{kN\text{-}m/m}$$

(e) Estimate ground movements:

$$N_c = 5(1 + 0.2B/L) = 5(1 + (0.2)(10\ \mathrm{m})/100\ \mathrm{m}) = 5.1$$

$$D' = 5\ \mathrm{m} \le 0.7(10\ \mathrm{m}) = 7\ \mathrm{m}$$

$$\mathrm{FS}_{BH} = \frac{cN_C}{\gamma H + q - cH/D'}$$

$$= \frac{(35\ \mathrm{kPa})(5.1)}{(2\ \mathrm{Mg/m^3})(9.81\mathrm{m/s^2})(8\ \mathrm{m}) + 10\ \mathrm{kPa} - (35\ \mathrm{kPa})(8\ \mathrm{m})/5\ \mathrm{m}} = 1.6$$

Using Fig. 22.10, for a typical sheetpile wall with $\mathrm{FS}_{BH} \approx 1.6$, $\Delta_{h,m} \approx 1.0\%H$, or $\Delta_{h,m} \approx 0.01(8\ \mathrm{m}) = 0.08\ \mathrm{m} = 8\ \mathrm{cm}$.

In urban areas, maximum wall movements should normally be kept less than 5 cm. A heavy sheetpile wall (e.g., PZ 40) or a relatively stiff concrete slurry wall could be used to increase the system stiffness and reduce ground movements.

22.6 Summary

The analytical techniques presented in this section for retaining structures are based on simple models that have been empirically calibrated. Much depends on the method of construction of these systems and the quality of the workmanship involved. Hence, sound engineering judgment should be exercised and local experience in similar ground conditions is invaluable. Much can be gained by implementing an integrated approach that uniquely considers the project's subsurface conditions, site constraints, and excavation procedures [see Bray et al., 1993]. Finite element programs [e.g., SOILSTRUCT, Filz et al., 1990], which capture the unique soil-structure response of each excavation system, can provide salient insights and assist in identifying critical aspects of a particular project. The monitoring of field instrumentation (e.g., inclinometers) during excavation allows the engineer to verify the reasonableness of the analysis and to employ the observational method to optimize the design during construction.

Defining Terms

Apparent lateral earth pressure — Lateral earth pressure acting on tributary area of flexible retaining wall that is necessary to develop measured strut loads.

Base heave — Upward movement of base of excavation and associated inward movement of retaining wall due to bearing capacity-type instability of base soil.

Lateral earth pressure coefficient — Horizontal effective stress divided by vertical effective stress at a point.

Lateral earth pressure coefficient at rest — Lateral earth pressure coefficient when the lateral strain in the soil is zero. Realized for case of 1-D vertical compression (e.g., level ground).

Maximum passive earth pressure coefficient — Maximum value of the lateral earth pressure coefficient. Realized when soil compresses laterally and its full strength is mobilized.

Minimum active earth pressure coefficient — Minimum value of the lateral earth pressure coefficient. Realized when soil expands laterally and its full strength is mobilized.

Overconsolidation ratio — Maximum vertical effective stress in the past divided by the current vertical effective stress.

Further Information

Foundation Engineering by Peck et al. [1974] provides a good overview of earth pressure theories and retaining structures, with illustrated design examples.

Retaining walls and abutments are discussed in Barker et al. [1991], and reinforcement of earth slopes and embankments are discussed by Mitchell and Villet [1987].

The design of anchored bulkheads is presented in Department of the Navy [1982].

State-of-the-art papers on the design and performance of earth retaining structures are presented in Lambe and Hansen [1990].

Before a foundation design can be undertaken, the associated soil profile must be well established. The soil profile is compiled from three cornerstones of information: borehole records with laboratory classification and testing, piezometer observations, and assessment of the overall geology at the site. Projects where construction difficulties, disputes, and litigation arise often have one thing in common: Copies of borehole field records were thought to determine the soil profile.

An essential part of the foundation design is to come up with a foundation type and size which will have acceptable values of deformation (settlement) and an adequate margin of safety to failure (the degree of engaging the soil strength). Deformation is a function of *change* of effective stress, and soil strength is *proportional* to effective stress. Therefore, all applications of foundation design start with determining the effective stress distribution of the soil around and below the foundation unit. The distribution then serves as basis for the design analysis.

23.1 Effective Stress

Effective stress is the total stress minus the **pore pressure** (the water pressure in the voids). The common method of calculating the effective stress, $\Delta\sigma'$, contributed by a soil layer is to multiply the buoyant unit weight, γ', of the soil with the layer thickness, Δh. Usually, the buoyant unit weight is determined as the bulk unit weight of the soil, γ_t, minus the unit weight of water, γ_w, which presupposes that there is no vertical gradient of water flow in the soil.

$$\Delta\sigma' = \gamma'\Delta h \tag{23.1a}$$

The effective stress at a depth, σ'_z, is the sum of the contributions from the soil layers above.

$$\sigma_z' = \Sigma(\gamma' \Delta h) \tag{23.1b}$$

However, most sites display vertical water gradients: either an upward flow, maybe even artesian (the head is greater than the depth from the ground surface), or a downward flow, and the buoyant unit weight is a function of the gradient, *i*, in the soil, as follows.

$$\gamma' = \gamma_t - \gamma_w (1 - i) \tag{23.1c}$$

The gradient is defined as the difference in head between two points divided by the distance the water has to flow between these two points. Upward flow gradient is negative and downward flow is positive. For example, if for a particular case of artesian condition the gradient is nearly equal to –1, then, the buoyant weight is nearly zero. Therefore, the effective stress is close to zero, too, and the soil has little or no strength. This is the case of so-called quicksand, which is not a particular type of sand, but a soil, usually a silty fine sand, subjected to a particular pore pressure condition.

The gradient in a nonhydrostatic condition is often awkward to determine. However, the difficulty can be avoided, because the effective stress is most easily determined by calculating the total stress and the pore water pressure separately. The effective stress is then obtained by simple subtraction of the latter from the former.

Note the difference in terminology — effective *stress* and pore *pressure* — which reflects the fundamental difference between forces in soil as opposed to in water. Soil stress is directional; that is, the stress changes depending on the orientation of the plane of action in the soil. In contrast, water pressure is omnidirectional, that is, independent of the orientation of the plane. The soil stress and water pressures are determined, as follows.

The *total vertical stress* (symbol σ_z) at a point in the soil profile (also called total overburden stress) is calculated as the stress exerted by a soil column with a certain weight, or bulk unit weight, and height (or the sum of separate values where the soil profile is made up of a series of separate soil layers having different bulk unit weights). The symbol for bulk unit weight is γ_t (the subscript *t* stands for "total," because the bulk unit weight is also called *total unit weight*).

$$\sigma_z = \gamma_t z \tag{23.2}$$

or

$$\sigma_z = \Sigma \Delta \sigma_z = \Sigma(\gamma_t \Delta h)$$

Similarly, the pore pressure (symbol *u*), if measured in a stand-pipe, is equal to the unit weight of water, γ_w, times the height of the water column, *h*, in the stand-pipe. (If the pore pressure is measured directly, the head of water is equal to the pressure divided by the unit weight of water, γ_w.)

$$u = \gamma_w h \tag{23.3}$$

The height of the column of water (the head) representing the water pressure is rarely the distance to the ground surface or, even, to the groundwater table. For this reason, the height is usually referred to as the *phreatic height* or the *piezometric height* to separate it from the depth below the groundwater table or depth below the ground surface.

The groundwater table is defined as the uppermost level of zero pore pressure. Notice that the soil can be saturated with water also above the groundwater table without pore pressure being greater than zero. Actually, because of capillary action, pore pressures in the partially saturated zone above the groundwater table may be negative.

The pore pressure distribution is determined by applying that (in stationary situations) the pore pressure distribution is linear in each individual soil layer, and, in pervious soil layers that are "sandwiched" between less pervious layers, the pore pressure is hydrostatic (that is, the vertical gradient is zero).

The *effective overburden stress* (symbol σ'_z) is then obtained as the difference between total stress and pore pressure.

$$\sigma'_z = \sigma_z - u_z = \gamma_t z - \gamma_w h \tag{23.4}$$

Usually, the geotechnical engineer provides the density (symbol ρ) instead of unit weight, γ. The unit weight is then the density times the gravitational constant, g. (For most foundation engineering purposes, the gravitational constant can be taken to be 10 m/s^2 rather than the overly exact value of 9.81 m/s^2.)

$$\gamma = \rho g \tag{23.5}$$

Many soil reports do not indicate the total soil density, ρ_t, only water content, w, and dry density, ρ'_d. For saturated soils, the total density can then be calculated as

$$\rho_t = \rho_d (1 + w) \tag{23.6}$$

The principles of effective stress calculation are illustrated by the calculations involved in the following soil profile: an upper 4 m thick layer of normally consolidated sandy silt, 17 m of soft, compressible, slightly overconsolidated clay, followed by 6 m of medium dense silty sand and a thick deposit of medium dense to very dense sandy ablation glacial till. The groundwater table lies at a depth of 1.0 m. For *original conditions,* the pore pressure is hydrostatically distributed throughout the soil profile. For *final conditions,* the pore pressure in the sand is not hydrostatically distributed, but artesian with a phreatic height above ground of 5 m, which means that the pore pressure in the clay is non-hydrostatic (but linear, assuming that the final condition is long term). The pore pressure in the glacial till is also hydrostatically distributed. A 1.5 m thick earth fill is to be placed over a square area with a 36 m side. The densities of the four soil layers and the earth fill are: 2000 kg/m^3, 1700 kg/m^3, 2100 kg/m^3, 2200 kg/m^3, and 2000 kg/m^3, respectively.

Calculate the distribution of total and effective stresses as well as pore pressure underneath the center of the earth fill before and after placing the earth fill. Distribute the earth fill by means of the 2:1 method; that is, distribute the load from the fill area evenly over an area that increases in width and length by an amount equal to the depth below the base of the fill area.

Table 23.1 presents the results of the stress calculation for the example conditions. The calculations have been made with the Unisettle program [Goudreault and Fellenius, 1993] and the results are presented in the format of a "hand calculation" to ease verifying the computer calculations. Notice that performing the calculations at every meter depth is normally not necessary. The table includes a comparison between the non-hydrostatic pore pressure values and the hydrostatic, as well as the effect of the earth fill, which can be seen from the difference in the values of total stress for original and final conditions.

The stress distribution below the center of the loaded area was calculated by means of the 2:1 method. However, the 2:1 method is rather approximate and limited in use. Compare, for example, the vertical stress below a loaded footing that is either a square or a circle with a side or diameter of B. For the same contact stress, q_0, the 2:1 method, strictly applied to the side and diameter values, indicates that the vertical distributions of stress, $[q_z = q_0/(B + z)^2]$, are equal for the square and the circular footings. Yet, the total applied load on the square footing is $4/\pi = 1.27$ times larger than the total load on the circular footing. Therefore, if applying the 2:1 method to circles and other non-rectangular areas, they should be modeled as a rectangle of an equal size ("equivalent") area. Thus, a circle is modeled as an equivalent square with a side equal to the circle radius times $\sqrt{\pi}$.

More important, the 2:1 method is inappropriate to use for determining the stress distribution along a vertical line below a point at any other location than the center of the loaded area. For this reason, it can not be used to combine stress from two or more loaded areas unless the areas have the same center. To calculate the stresses induced from more than one loaded area and/or below an off-center location, more elaborate methods, such as the Boussinesq distribution (Chapter 20) are required.

A footing is usually placed in an excavation and fill is often placed next to the footing. When calculating the stress increase from one or more footing loads, the changes in effective stress from the excavations

TABLE 23.1 Stress Distribution (2:1 Method) at Center of Earth Fill

Depth (m)	Original Condition (no earth fill) σ_t (kPa)	u (kPa)	σ' (kPa)	Final Condition (with earth fill) σ_t (kPa)	u (kPa)	σ' (kPa)
	Layer 1 Sandy Silt $\rho = 2000$ kg/m^3

Note: Calculations by means of UNISETTLE.

and fills must be included which therefore precludes the use of the 2:1 method (unless all such excavations and fills surround and are concentric with the footing).

A small diameter footing, of about 1 meter width, can normally be assumed to distribute the stress evenly over the footing contact area. However, this cannot be assumed to be the case for wider footings. The Boussinesq distribution assumes ideally flexible footings (and ideally elastic soil). Kany [1959] showed that below a so-called characteristic point, the vertical stress distribution is equal for flexible

and stiff footings. The characteristic point is located at a distance of $0.37B$ and $0.37L$ from the center of a rectangular footing of sides B and L and at a radius of $0.37R$ from the center of a circular footing of radius R. When applying Boussinesq method of stress distribution to regularly shaped footings, the stress below this point is normally used rather than the stress below the center of the footing.

Calculation of the stress distribution below a point within or outside the footprint of a footing by means of the Boussinesq method is time-consuming, in particular if the stress from several loaded areas are to be combined. The geotechnical profession has for many years simplified the calculation effort by using nomograms over "influence values for vertical stress" at certain locations within the footprint of a footing. The Newmark influence chart [Newmark, 1935, 1942] is a classic. The calculations are still rather time consuming. However, since the advent of the computer, several computer programs are available which greatly simplify and speed up the calculation effort — for example, Unisettle by Goudreault and Fellenius [1993].

23.2 Settlement of Foundations

A **foundation** is a constructed unit that transfers the load from a superstructure to the ground. With regard to vertical loads, most foundations receive a more or less concentrated load from the structure and transfer this load to the soil underneath the foundation, distributing the load as a stress over a certain area. Part of the soil structure interaction is then the condition that the stress must not give rise to a deformation of the soil in excess of what the superstructure can tolerate.

The amount of deformation for a given contact stress depends on the distribution of the stress over the affected soil mass in relation to the existing stress (the imposed change of effective stress) and the compressibility of the soil layer. The change of effective stress is the difference between the initial (original) effective stress and the final effective stress, as illustrated in Table 23.1. The stress distribution has been discussed in the foregoing. The compressibility of the soil mass can be expressed in either simple or complex terms. For simple cases, the soil can be assumed to have a linear stress–strain behavior and the compressibility can be expressed by an elastic modulus.

Linear stress–strain behavior follows Hooke's law:

$$\varepsilon = \frac{\Delta\sigma'}{E} \tag{23.7}$$

where ε = induced strain in a soil layer
$\Delta\sigma'$ = imposed change of effective stress in the soil layer
E = elastic modulus of the soil layer

Often the elastic modulus is called *Young's modulus*. Strictly speaking, however, Young's modulus is the modulus for when lateral expansion is allowed, which may be the case for soil loaded by a small footing, but not when loading a larger area. In the latter case, the lateral expansion is constrained. The constrained modulus, D, is larger than the E-modulus. The constrained modulus is also called the *oedometer modulus*. For ideally elastic soils, the ratio between D and E is:

$$\frac{D}{E} = \frac{(1-\nu)}{(1+\nu)(1-2\nu)} \tag{23.8}$$

where ν = Poisson's ratio. For example, for a soil material with a Poisson's ratio of 0.3, a common value, the constrained modulus is 35% larger than the Young's modulus. (Notice also that the concrete inside a concrete-filled pipe pile behaves as a constrained material as opposed to the concrete in a concrete pile. Therefore, when analyzing the deformation under load, use the constrained modulus for the former and the Young's modulus for the latter.)

The deformation of a soil layer, s, is the strain, ε, times the thickness, h, of the layer. The settlement, S, of the foundation is the sum of the deformations of the soil layers below the foundation.

$$S = \sum s = \sum (\varepsilon h) \tag{23.9}$$

However, stress–strain behavior is nonlinear for most soils. The nonlinearity cannot be disregarded when analyzing compressible soils, such as silts and clays; that is, the elastic modulus approach is not appropriate for these soils. Nonlinear stress–strain behavior of compressible soils is conventionally modeled by Eq. (23.10):

$$\varepsilon = \frac{C_c}{1 + e_0} \lg \frac{\sigma_1'}{\sigma_0'} \tag{23.10}$$

where σ_0' = original (or initial) effective stress
σ_1' = final effective stress
C_c = compression index
e = void ratio

The compression index and the void ratio parameters C_c and e_0 are determined by means of oedometer tests in the laboratory.

If the soil is overconsolidated, that is, consolidated to a stress (called "preconsolidation stress") larger than the existing effective stress, Eq. (23.10) changes to

$$\varepsilon = \frac{1}{1 + e_0} \left[C_{cr} \lg \frac{\sigma_p'}{\sigma_0'} + C_c \lg \frac{\sigma_1'}{\sigma_p'} \right] \tag{23.11}$$

where σ_p' = preconsolidation stress and C_{cr} = recompression index.

Thus, in conventional engineering practice of settlement design, two compression parameters need to be established. This is an inconvenience that can be avoided by characterizing the soil with the ratios $C_c/(1 + e_0)$ and $C_{cr}/(1 + e_0)$ as single parameters (usually called compression ratio, CR, and recompression ratio, RR, respectively), but few do. Actually, on surprisingly many occasions, geotechnical engineers only report the C_c parameter — neglecting to include the e_0 value — or worse, report the C_c from the oedometer test and the e_0 from a different soil specimen than used for determining the compression index! This is not acceptable, of course. The undesirable challenge of ascertaining what C_c value goes with what e_0 value is removed by using the Janbu tangent modulus approach instead of the C_c and e_0 approach, applying a modulus number, m, instead.

The Janbu tangent modulus approach, proposed by Janbu [1963, 1965, 1967] and referenced by the Canadian Foundation Engineering Manual, (CFEM) [Canadian Geotechnical Society, 1985], applies the same basic principle of nonlinear stress–strain behavior to all soils, clays as well as sand. By this method, the relation between stress and strain is a function of two nondimensional parameters which are unique for a soil: a stress exponent, j, and a modulus number, m.

In cohesionless soils, $j > 0$, the following simple formula governs:

$$\varepsilon = \frac{1}{mj} \left[\left(\frac{\sigma_1'}{\sigma_r'} \right)^j - \left(\frac{\sigma_0'}{\sigma_r'} \right)^j \right] \tag{23.12}$$

where ε = strain induced by increase of effective stress
σ_0' = the original effective stress
σ_1' = the final effective stress
j = the stress exponent
m = the modulus number, which is determined from laboratory and/or field testing
σ_r' = a reference stress, a constant, which is equal to 100 kPa (= 1 tsf = 1 kg/cm^2)

In an essentially cohesionless, sandy or silty soil, the stress exponent is close to a value of 0.5. By inserting this value and considering that the reference stress is equal to 100 kPa, Eq. (23.12) is simplified to

$$\varepsilon = \frac{1}{5m}\left(\sqrt{\sigma_1'} - \sqrt{\sigma_0'}\right). \tag{23.13a}$$

Notice that Eq. (23.13a) is *not* independent of the choice of units; the stress values must be inserted in kPa. That is, a value of 5 MPa is to be inserted as the number 5000 and a value of 300 Pa as the number 0.3. In English units, Eq. (23.13a) becomes

$$\varepsilon = \frac{2}{m}\left(\sqrt{\sigma_1'} - \sqrt{\sigma_0'}\right). \tag{23.13b}$$

Again, the equation is not independent of units: Because the reference stress converts to 1.0 tsf, Eq. (23.13b) requires that the stress values be inserted in units of tsf.

If the soil is overconsolidated and the final stress exceeds the preconsolidation stress, Eqs. (23.13a) and (23.13b) change to

$$\varepsilon = \frac{1}{5m_r}\left(\sqrt{\sigma_p'} - \sqrt{\sigma_0'}\right) + \frac{1}{5m}\left(\sqrt{\sigma_1'} - \sqrt{\sigma_p'}\right) \tag{23.14a}$$

$$\varepsilon = \frac{2}{m_r}\left(\sqrt{\sigma_p'} - \sqrt{\sigma_0'}\right) + \frac{2}{m}\left(\sqrt{\sigma_1'} - \sqrt{\sigma_p'}\right) \tag{23.14b}$$

where σ_0' = original effective stress (kPa or tsf)
σ_p' = preconsolidation stress (kPa or tsf)
σ_1' = final effective stress (kPa or tsf)
m = modulus number (dimensionless)
m_r = recompression modulus number (dimensionless)

Equation (23.14a) requires stress units in kPa and Eq. (23.14b) stress units in tsf.

If the imposed stress does not result in a new (final) stress that exceeds the preconsolidation stress, Eqs. (23.13a) and (23.13b) become

$$\varepsilon = \frac{1}{5m_r}\left(\sqrt{\sigma_1'} - \sqrt{\sigma_0'}\right) \tag{23.15a}$$

$$\varepsilon = \frac{2}{m_r}\left(\sqrt{\sigma_1'} - \sqrt{\sigma_0'}\right) \tag{23.15b}$$

Equation (23.15a) requires stress units in kPa and Eq. (23.15b) units in tsf.

In cohesive soils, the stress exponent is zero, $j = 0$. Then, in a normally consolidated cohesive soil:

$$\varepsilon = \frac{1}{m}\ln\left(\frac{\sigma_1'}{\sigma_0'}\right) \tag{23.16}$$

and in an overconsolidated cohesive soil

$$\varepsilon = \frac{1}{m_r}\ln\left(\frac{\sigma_p'}{\sigma_0'}\right) + \frac{1}{m}\ln\left(\frac{\sigma_1'}{\sigma_p'}\right) \tag{23.17}$$

TABLE 23.2 Typical and Normally Conservative Modulus Numbers

Soil Type		Modulus Number	Stress Exp.
Till, very dense to dense		1000–300	($j = 1$)
Gravel		400–40	($j = 0.5$)
Sand	Dense	400–250	($j = 0.5$)
	Compact	250–150	″
	Loose	150–100	″
Silt	Dense	200–80	($j = 0.5$)
	Compact	80–60	″
	Loose	60–40	″
	Clays		
Silty clay	Hard, stiff	60–20	($j = 0$)
and	Stiff, firm	20–10	″
clayey silt	Soft	10–5	″
Soft marine clays and organic clays		20–5	($j = 0$)
Peat		5–1	($j = 0$)

Notice that the ratio (σ'_p/σ'_0) is equal to the overconsolidation ratio, OCR. Of course, the extent of overconsolidation may also be expressed as a fixed stress-unit value, $\sigma'_p - \sigma'_0$.

If the imposed stress does not result in a new stress that exceeds the preconsolidation stress, Eq. (23.17) becomes

$$\varepsilon = \frac{1}{m_r} \ln\left(\frac{\sigma'_1}{\sigma'_0}\right) \tag{23.18}$$

By means of Eqs. (23.10) through (23.18), settlement calculations can be performed without resorting to simplifications such as that of a constant elastic modulus. Apart from having knowledge of the original effective stress, the increase of stress, and the type of soil involved, without which knowledge no reliable settlement analysis can ever be made, the only soil parameter required is the modulus number. The modulus numbers to use in a particular case can be determined from conventional laboratory testing, as well as *in situ* tests. As a reference, Table 23.2 shows a range of normally conservative values, in particular for the coarse-grained soil types, which are typical of various soil types (quoted from the CFEM [Canadian Geotechnical Society, 1985]).

In a cohesionless soil, where previous experience exists from settlement analysis using the elastic modulus approach — Eqs. (23.7) and (23.9) — a direct conversion can be made between E and m, which results in Eq. (23.19a).

$$m = \frac{E}{5(\sigma'_1 + \sigma'_0)} = \frac{E}{10\bar{\sigma}'} \tag{23.19a}$$

Equation (23.19a) is valid when the calculations are made using SI units. Notice, stress and E-modulus must be expressed in the same units, usually kPa. When using English units (stress and E-modulus in tsf), Eq. (23.19b) applies.

$$m = \frac{2E}{(\sigma'_1 + \sigma'_0)} = \frac{E}{\bar{\sigma}'} \tag{23.19b}$$

Notice that most natural soils have aged and become overconsolidated with an overconsolidation ratio, OCR, that often exceeds a value of 2. For clays and silts, the recompression modulus, m_r, is often five to ten times greater than the virgin modulus, m, listed in Table 23.2.

The conventional C_c and e_0 method and the Janbu modulus approach are identical in a cohesive soil. A direct conversion factor as given in Eq. (23.20) transfers values of one method to the other.

$$m = \ln 10\left(\frac{1+e_0}{C_c}\right) = 2.30\left(\frac{1+e_0}{C_c}\right) \tag{23.20}$$

Designing for settlement of a foundation is a prediction exercise. The quality of the prediction — that is, the agreement between the calculated and the actual settlement value — depends on how accurately the soil profile and stress distributions applied to the analysis represent the site conditions, and how closely the loads, fills, and excavations considered resemble those actually occurring. The quality depends also, of course, on the quality of the soil parameters used as input to the analysis. Soil parameters for cohesive soils depend on the quality of the sampling and laboratory testing. Clay samples tested in the laboratory should be from carefully obtained "undisturbed" piston samples. Paradoxically, the more disturbed the sample is, the less compressible the clay appears to be. The error which this could cause is to a degree "compensated for" by the simultaneous apparent reduction in the overconsolidation ratio. Furthermore, high-quality sampling and oedometer tests are costly, which limits the amounts of information procured for a routine project. The designer usually runs the tests on the "worst" samples and arrives at a conservative prediction. This is acceptable, but only too often is the word "conservative" nothing but a disguise for the more appropriate terms of "erroneous" and "unrepresentative" and the end results may not even be on the "safe side."

Non-cohesive soils cannot easily be sampled and tested. Therefore, settlement analysis of foundations in such soils must rely on empirical relations derived from *in situ* tests and experience values. Usually, these soils are less compressible than cohesive soils and have a more pronounced overconsolidation. However, considering the current tendency toward larger loads and contact stresses, foundation design must prudently address the settlement expected in these soils as well. Regardless of the methods that are used for prediction of the settlement, it is necessary to refer the results of the analyses back to basics. That is, the settlement values arrived at in the design analysis should be evaluated to indicate what corresponding compressibility parameters (Janbu modulus numbers) they represent for the actual soil profile and conditions of effective stress and load. This effort will provide a check on the reasonableness of the results as well as assist in building up a reference database for future analyses.

Time-Dependent Settlement

Because soil solids compress very little, settlement is mostly the result of a change of pore volume. Compression of the solids is called *initial compression*. It occurs quickly and it is usually considered elastic in behavior. In contrast, the change of pore volume will not occur before the water occupying the pores is squeezed out by an increase of stress. The process is rapid in coarse-grained soils and slow in fine-grained soils. In fine clays, the process can take a longer time than the life expectancy of the building, or of the designing engineer, at least. The process is called *consolidation* and it usually occurs with an increase of both undrained and drained soil shear strength. By analogy with heat dissipation in solid materials, the Terzaghi consolidation theory indicates simple relations for the time required for the consolidation. The most commonly applied theory builds on the assumption that water is able to drain out of the soil at one surface boundary and not at all at the opposite boundary. The consolidation is fast in the beginning, when the driving pore pressures are greater, and slows down with time. The analysis makes use of the relative amount of consolidation obtained at a certain time, called *average degree of consolidation,* which is defined as follows:

$$\bar{U} = \frac{S_t}{S_f} = 1 - \frac{\bar{u}_t}{\bar{u}_0} \tag{23.21}$$

where $\bar{U}$ = *average* degree of consolidation
S_t = settlement at time t
S_f = final settlement at full consolidation
$\bar{u}_t$ = *average* pore pressure at time t
$\bar{u}_0$ = initial *average* pore pressure (on application of the load; time $t = 0$)

Notice that the pore pressure varies throughout the soil layer and Eq. (23.21) assumes average values. In contrast, the settlement values are not the average, but the accumulated values.

The time for achieving certain degree consolidation is then, as follows:

$$t = T_v \frac{H^2}{c_v} \tag{23.22}$$

where t = time to obtain a certain degree of consolidation
T_v = a dimensionless time coefficient
c_v = coefficient of consolidation
H = length of the longest drainage path

The time coefficient, T_v, is a function of the type of pore pressure distribution. Of course, the shape of the distribution affects the average pore pressure values and a parabolic shape is usually assumed. The coefficient of consolidation is determined in the laboratory oedometer test (some *in situ* tests can also provide c_v values) and it can rarely be obtained more accurately than within a ratio range of 2 or 3. The length of the longest drainage path, H, for a soil layer that drains at both surface boundaries is half the layer thickness. If drainage only occurs at one boundary, H is equal to the full layer thickness. Naturally, in layered soils, the value of H is difficult to ascertain.

Approximate values of T_v for different degrees of consolidation are given below. For more exact values and values to use when the pore pressure distribution is different, see, for example, Holtz and Kovacs [1981].

U(%)	25	50	70	80	90	100
T_v	0.05	0.20	0.30	0.40	0.60	1.00

In partially saturated soils, consolidation determined from observed settlement is initially seemingly rapid, because gas (air) will readily compress when subjected to an increase of pressure. This settlement is often mistaken for the initial compression of the grain solids. However, because the pore pressure will not diminish to a similar degree, initial consolidation determined from observed pore pressures will not appear to be as large. In these soils and in seemingly saturated soils that have a high organic content, gas is present as bubbles in the pore water, and the bubbles will compress readily. Moreover, some of the gas may go into solution in the water as a consequence of the pressure increase. Inorganic soils below the groundwater surface are usually saturated and contain no gas. In contrast, organic soils will invariably contain gas in the form of small bubbles (as well as gas dissolved in the water, which becomes free gas on release of confining pressure when sampling the soil) and these soils will appear to have a fast initial consolidation. Toward the end of the consolidation process, when the pore pressure has diminished, the bubbles will return to the original size and the consolidation process will appear to have slowed.

Generally, the determination — prediction — of the time for a settlement to develop is filled with uncertainty and it is very difficult to reliably estimate the amount of settlement occurring within a specific time after the load application. The prediction is not any easier when one has to consider the development during the build-up of the load. For details on the subject, see Ladd [1991].

The rather long consolidation time in clay soils can be shortened considerably by means of vertical drains. Vertical drains installed at spacings ranging from about 1.2 m through 2.0 m have been very successful in accelerating consolidation from years to months. In the past, vertical drains consisted of sand drains and installation disturbance in some soils often made the drains cause more problems than

they solved. However, the sand drain is now replaced by premanufactured band-shaped drains, wick drains, which do not share the difficulties and adverse behavior of sand drains.

Theoretically, when vertical drains have been installed, the drainage is in the horizontal direction and design formulas have been developed as based on radial drainage. However, vertical drains connect horizontal layers of greater permeability, which frequently are interspersed in natural soils, which make the theoretical calculations quite uncertain. Some practical aspects of the use of vertical drains are described in the CFEM [Canadian Geotechnical Society, 1985].

The settlement will continue after the end of the consolidation. This type of settlement is called *creep* or *secondary compression*. Creep is a function of a coefficient of secondary compression, C_α, and the ratio of the time considered after full consolidation and the time for full consolidation to develop:

$$\varepsilon_{creep} = \frac{C_\alpha}{(1 + e_0)} \ln \frac{t_\alpha}{t_{100}} \tag{23.23}$$

where C_α = coefficient of secondary compression
t_α = time after end of consolidation
t_{100} = time for achieving primary compression

In most soils, creep is small in relation to the consolidation settlement and is therefore neglected. However, in organic soils, creep may be substantial.

Magnitude of Acceptable Settlement

For many years, settlement analysis was limited to ascertaining that the expected settlement should not exceed one inch. (Realizing that 25.4 mm is too precise a value — as is 25 mm when transferring this limit to the SI system — some have argued whether the "metric inch" should be 20 mm or 30 mm). Furthermore, both total settlement and differential settlement must be evaluated. The *Canadian Foundation Engineering Manual* [Canadian Geotechnical Society, 1985] lists allowable displacement criteria in terms of maximum deflection between point supports, maximum slope of continuous structures, and rotation limits for structures. The multitude of limits demonstrate clearly that the acceptable settlement varies with the type and size of structure considered. Moreover, modern structures often have small tolerance for settlement and, therefore, require a more thorough settlement analysis. The advent of the computer and development of sophisticated yet simple to use design software have enabled the structural engineers to be very precise in the analysis of deformations and the effect of deformations on the stress and strain in various parts of a structure. As a not so surprising consequence, requests for "settlement-free" foundations have increased. When the geotechnical engineer is vague on the predicted settlement, the structural designer "plays it safe" and increases the size of footings or changes the foundation type, which may increase the costs of the structure. These days, in fact, the geotechnical engineer cannot just estimate a "less than one inch" value, but must provide a more accurate value by performing a thorough analysis considering soil compressibility, soil layering, and load variations. Moreover, the analysis must be put into the context of the structure, which necessitates a continuous communication between the geotechnical and structural engineers during the design effort. Building codes have started to recognize the complexity of the problem and mandate that the designers collaborate continuously. See, for example, the 1993 Canadian Highway Bridge Design Code.

23.3 Bearing Capacity of Shallow Foundations

When society started building and imposing large concentrated loads onto the soil, occasionally the structure would fail catastrophically. Initially, the understanding of foundation behavior progressed from one failure to the next. Later, tests were run of model footings in different soils and the test results were extrapolated to the behavior of full-scale foundations. For example, loading tests on model size footings

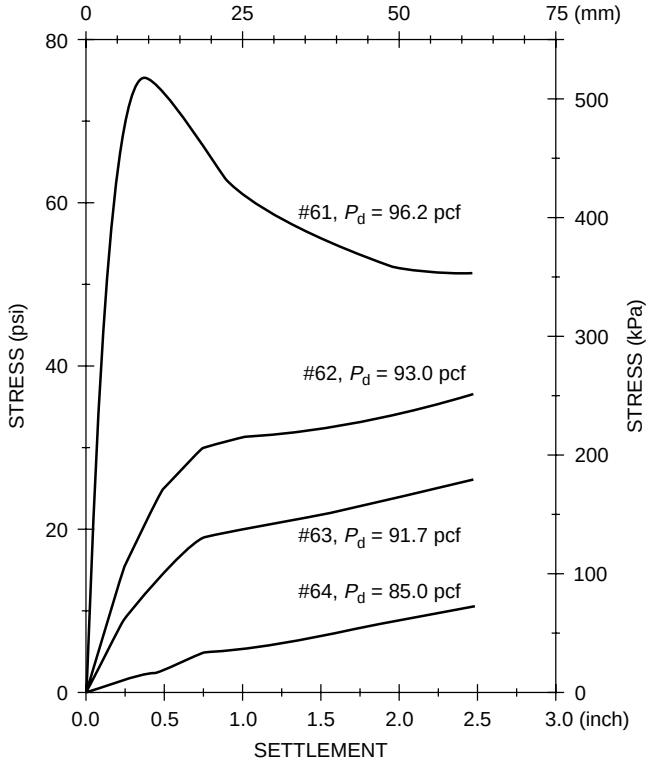

FIGURE 23.1 Contact stress vs. settlement of 150-mm footings. (*Source:* Vesic, 1967.)

in normally consolidated clay showed load-movement curves where the load increased to a distinct peak value — bearing capacity failure — indicating that the capacity (not the settlement) of a footing in clay is independent of the footing size.

The behavior of footing in clay differs from the behavior of footings in sand, however. Figure 23.1 presents results from loading tests on a 150-mm diameter footing in dry sand of densities varying from very dense to loose. In the dense sand, a peak value is evident. In less dense sands, no such peak is found.

The capacity and the load movement of a footing in sand are almost directly proportional to the footing size. This is illustrated in Fig. 23.2, which shows some recent test results on footings of different size in a fine sand. Generally, eccentric loading, inclined loading, footing shape, and foundation depth influence the behavior of footings. Early on, Terzaghi developed the theoretical explanations to observed behaviors into a "full bearing capacity formula," as given in Eq. (23.24a) and applicable to a continuous footing:

$$r_u = c'N_c + q'(N_q - 1) + 0.5B\,\gamma'N_\gamma \tag{23.24a}$$

where r_u = ultimate unit resistance of the footing
c' = effective cohesion intercept
B = footing width
q' = overburden effective stress at the foundation level
γ' = average effective unit weight of the soil below the foundation
N_c, N_q, N_γ = nondimensional bearing capacity factors

The **bearing capacity** factors are a function of the effective friction angle of the soil. Such factors were first originated by Terzaghi, later modified by Meyerhof, Berezantsev, and others. As presented in the *Canadian Foundation Engineering Manual* [Canadian Geotechnical Society, 1985], the bearing capacity factors are somewhat interrelated, as follows.

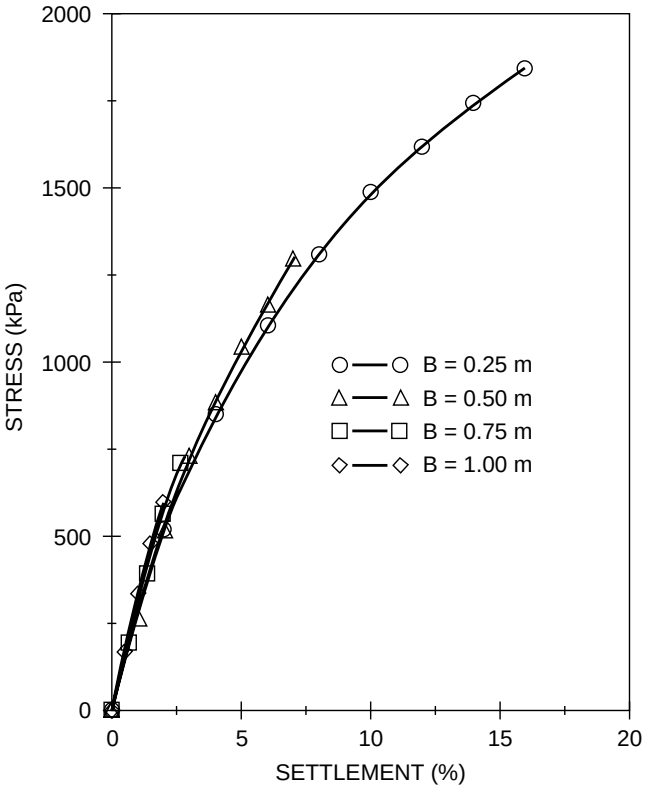

FIGURE 23.2 Stress vs. normalized settlement. (Data from Ismael, 1985.)

$$N_q = (e^{\pi \tan \varphi'})\left(\frac{1 + \sin \varphi'}{1 - \sin \varphi'}\right) \qquad \varphi' \to 0 \quad N_q \to 1 \tag{23.24b}$$

$$N_c = (N_q - 1)(\cot \varphi') \qquad \varphi' \to 0 \quad N_c \to 5.14 \tag{23.24c}$$

$$N_\gamma = 1.5(N_q - 1)(\tan \varphi') \qquad \varphi' \to 0 \quad N_\gamma \to 0 \tag{23.24d}$$

For friction angles larger than about 37°, the bearing capacity factors increase rapidly and the formula loses in relevance.

For a footing of width B subjected to a load Q, the applied contact stress is q $(= Q/B)$ per unit length and the applied contact stress mobilizes an equally large soil resistance, r. Of course, the soil resistance can not exceed the strength of the soil. Equation (23.24a) indicates the maximum available (ultimate) resistance, r_u. In the design of a footing for bearing capacity, the applied load is only allowed to reach a certain portion of the ultimate resistance. That is, as is the case for all foundation designs, the design must include a margin of safety against failure. In most geotechnical applications, this margin is achieved by applying a factor of safety defined as the available soil strength divided by the mobilized shear. The available strength is either cohesion, c, friction, tan φ, or both combined. (Notice that friction is not the friction angle, φ, but its tangent, tan φ). However, in bearing capacity problems, the factor of safety is usually defined somewhat differently and as given by Eq. (23.24e):

$$F_s = r_u / q_{\text{allow}} \tag{23.24e}$$

where F_s = factor of safety
r_u = ultimate unit resistance (unit bearing capacity)
q_{allow} = the allowable bearing stress

The factor of safety applied to the bearing capacity formula is usually recommended to be no smaller than 3.0, usually equal to 4.0. There is some confusion whether, in the bearing capacity calculated according to Eq. (23.24a), the relation $(N_q - 1)$ should be used in lieu of N_q and, then, whether or not the allowable bearing stress should be the "net" stress, that is, the value exceeding the existing stress at the footing base. More importantly, however, is that the definition of factor of safety given by Eq. (23.24e) is not the same as the factor of safety applied to the shear strength, because the ultimate resistance determined by the bearing capacity formula includes several aspects other than soil shear strength, particularly so for foundations in soil having a substantial friction component. Depending on the details of each case, a value of 3 to 4 for the factor defined by Eq. (23.24e) corresponds, very approximately, to a factor of safety on shear strength in the range of 1.5 through 2.0.

In fact, the bearing capacity formula is wrought with much uncertainty and the factor of safety, be it 3 or 4, applied to a bearing capacity formula is really a "factor of ignorance" and does not always guarantee an adequate safety against failure. Therefore, in the design of footings, be it in clays or sands, the settlement analysis should be given more weight than the bearing capacity formula calculation.

Footings are rarely loaded only vertically and concentrically. Figure 23.3(b) illustrates the general case of a footing subjected to both inclined and eccentric load. Eq. (23.24a) changes to

$$r_u = s_c i_c c' N_c + s_q i_q q' N_q + s_\gamma i_\gamma 0.5 B' \gamma' N_\gamma \tag{23.24f}$$

where factors not defined earlier are

s_c, s_q, s_γ = nondimensional shape factors
i_c, i_q, i_γ = nondimensional inclination factors
B' = equivalent or effective footing width

The shape factors are

$$s_c = s_q = 1 + (B'/L')(N_q/N_c) \tag{23.24g}$$

where L' = equivalent or effective footing length.

$$s_\gamma = 1 - 0.4(B'/L') \tag{23.24h}$$

The inclination factors are

$$i_c = i_q = (1 - \delta/90°)^2 \tag{23.24i}$$

$$i_\gamma = (1 - \delta/\varphi')^2 \tag{23.24j}$$

An inclined load can have a significant reducing effect on the bearing capacity of a footing. Directly, first, as reflected by the inclination factor and then also because the resultant to the load on most occasions acts off center. An off-center load will cause increased stress, edge stress, on one side and a decreased stress on the opposing side. A large edge stress can be the starting point of a failure. In fact, most footings, when they fail, fail by tilting, which is an indication of excessive edge stress. To reduce the risk for failure, the bearing capacity formula (which assumes a uniform load) applies the term B' in Eq. (23.24f), the effective footing width, which is the width of a smaller footing having the resultant load in its center. That is, the calculated ultimate resistance is decreased because of the reduced width (γ component) and the applied stress is increased because it is calculated over the effective area [as $q = Q/(B'/L')$]. The approach is approximate and its application is limited to the requirement that the contact stress must not be reduced beyond a zero value at the opposite edge ("No tension at the heel"). This means that the resultant must fall within the middle third of the footing, or the eccentricity must not be greater than $B/6$.

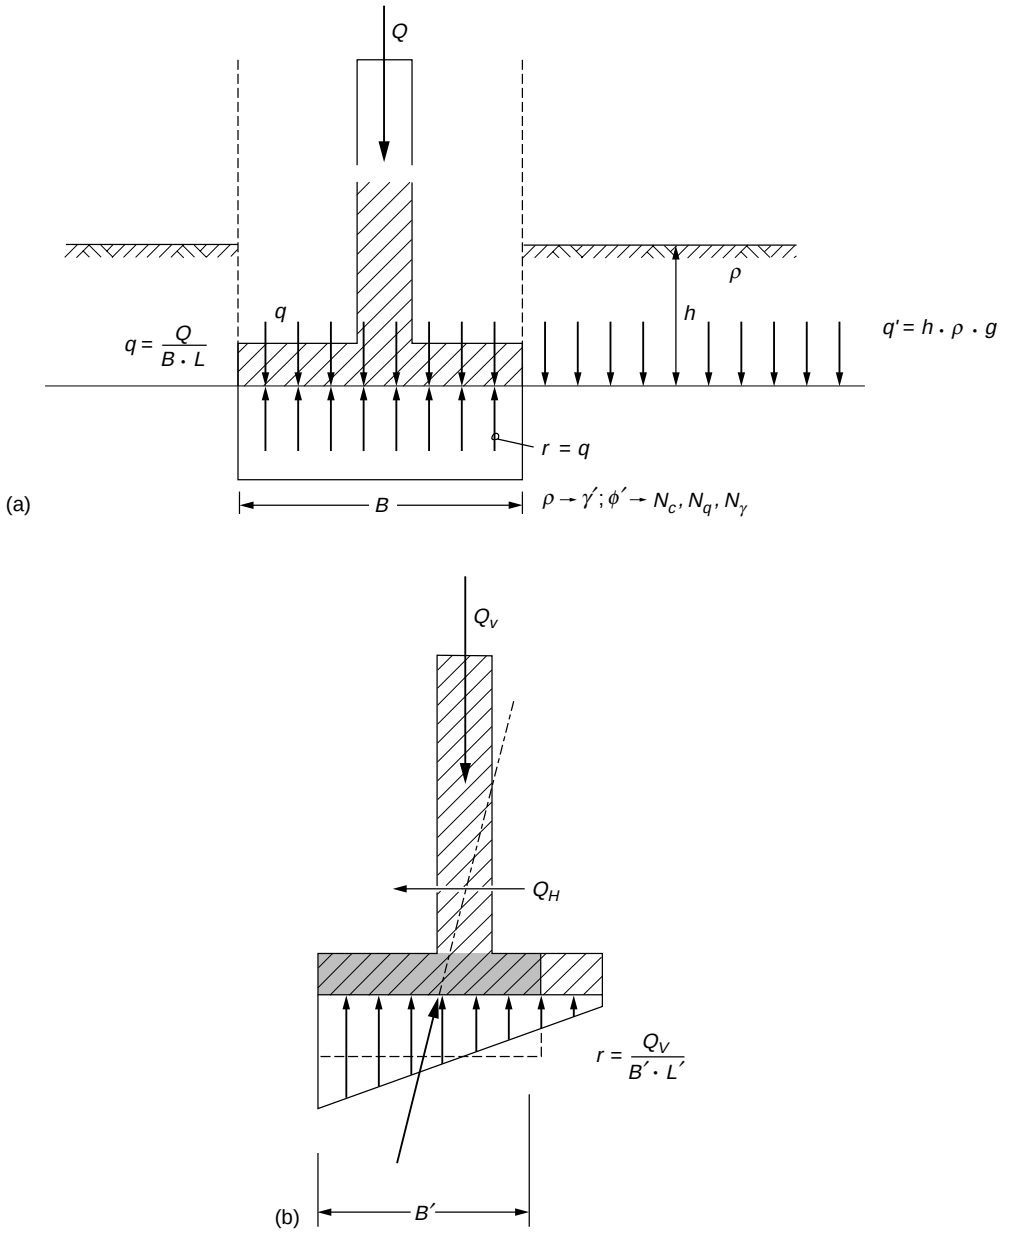

FIGURE 23.3 Input to the bearing capacity formula applied to a strip footing. (a) Concentric and vertical loading. (b) Vertical and horizontal loading.

When the load forms an angle with both sides of a footing or is eccentric in the directions of both the short and long sides of the footing, the calculation must be made twice, exchanging B' and L'.

The inclined load has a horizontal component and the calculation of a footing stability must check that the safety against sliding is sufficient. The calculation is simple and consists of determining the ratio between the horizontal and vertical loads, Q_h/Q_v. This ratio must be smaller than the soil strength (friction, $\tan\varphi'$, and/or cohesion, c') at the interface between the footing underside and the soil. Usually, a factor of safety of 1.5 through 1.8 applied to the soil strength is considered satisfactory.

In summary, the bearing capacity calculation of a footing is governed by the bearing capacity of a uniformly loaded equivalent footing, with a check for excessive edge stress (eccentricity) and safety against sliding. In some texts, an analysis of "overturning" is mentioned, which consists of taking the moment of forces at the edge of the footing and applying a factor of safety to the equilibrium. This is an incorrect approach, because long before the moment equilibrium has been reached, the footing fails due to excessive edge stress. (It is also redundant, because the requirement for the resultant to be located within the middle third takes care of the "overturning.") In fact, "overturning" failure will occur already at a calculated "factor of safety" as large as about 1.3 on the moment equilibrium. Notice that the factor of safety approach absolutely requires that the calculation of the stability of the structure indicates that it is stable also at a factor of safety very close to unity — theoretically stable, that is.

The bearing capacity calculations are illustrated in the example presented in Fig. 23.4. The example involves a 10.0 m long and 8.0 m high, vertically and horizontally loaded retaining wall (bridge abutment). The wall is placed on the surface of a "natural" coarse-grained soil and backfilled with a coarse material. A 1.0 m thick backfill is placed in front of the wall and over the front slab. The groundwater table lies close to the ground surface at the base of the wall. Figure 23.4(a) presents the data to include in an analysis.

In any analysis of a foundation case, a free-body diagram is necessary to ensure that all forces are accounted for in the analysis, such as shown in Fig. 23.4(b). Although the length of the wall is finite, it is normally advantageous to calculate the forces per unit length of the wall. To simplify the computations, the weight of the slab and the wall is ignored (or the slab weight is assumed included in the soil weights, and the weight of the wall [stem] is assumed included in the vertical load applied to the top of the wall).

The vertical forces denoted Q_1 and Q_2 are the load on the back slab of the wall. The two horizontal forces denoted P_1 and P_2 are the active earth pressure forces acting on a fictitious wall rising from the heel of the back slab, which wall is the boundary of the free body. Because this fictitious wall is soil, there is no wall friction to consider in the earth pressure calculation. Naturally, earth pressure also acts on the footing stem (the wall itself). Here, however, wall friction does exist, rotating the earth pressure resultant from the horizontal direction. Because of compaction of the backfill and the inherent stiffness of the stem, the earth pressure coefficient to use for earth pressure against the stem is larger than active pressure coefficient. This earth pressure is of importance for the structural design of the stem and it is quite different from the earth pressure to consider in the stability analysis of the wall.

Figure 23.4(b) does not indicate any earth pressure in front of the wall. It would have been developed on the passive side (the design assumes that movements may be large enough to develop active earth pressure behind the wall, but not large enough to develop fully the passive earth pressure against the front of the wall). In many projects a more or less narrow trench for burying pipes and other conduits is often dug in front of the wall. This, of course, eliminates the passive earth pressure, albeit temporarily.

The design calculations show that the factors of safety against bearing failure and against sliding are 3.29 and 2.09, respectively. The resultant acts at a point on the base of the footing at a distance of 0.50 m from the center, which is smaller than the limit of 1.00 m. Thus, it appears as if the footing is safe and stable and the edge stress acceptable. However, a calculation result must always be reviewed in a "what if" situation. That is, what if for some reason the backfill in front of the wall were to be removed over a larger area? Well, this seemingly minor change results in a reduction of the calculated factor of safety to 0.69. The possibility that this fill is removed at some time during the life of the structure is real. Therefore — although under the given conditions for the design problem, the factor of safety for the footing is adequate — the structure may not be safe.

Some words of caution: As mentioned above, footing design must emphasize settlement analysis. The bearing capacity formula approach is very approximate and should never be taken as anything beyond a simple estimate for purpose of comparing a footing design to previous designs. When concerns for capacity are at hand, the capacity analysis should include calculation using results from *in situ* testing (piezocone penetrometer and pressuremeter). Finite element analysis may serve as a very useful tool provided that a proven soil model is applied. Critical design calculations should never be permitted to rely solely on information from simple borehole data and N values (SPT-test data) applied to bearing capacity formulas.

23.4 Pile Foundations

Where using shallow foundations would mean unacceptable settlement, or where scour and other environmental risks exist which could impair the structure in the future, deep foundations are used. Deep foundations usually consist of piles, which are slender structural units installed by driving or by *in situ* construction methods through soft compressible soil layers into competent soils. Piles can be made of wood, concrete, or steel, or be composite, such as concrete-filled steel pipes or an upper concrete section connected to a lower steel or wood section. They can be round, square, hexagonal, octagonal, even triangular in shape, and straight shafted, step tapered, or conical. In order to arrive at a reliable design, the particulars of the pile must be considered, most important, the pile material and the method of construction.

Pile foundation design starts with an analysis of how the load applied to the pile head is transferred to the soil. This analysis is the basis for a settlement analysis, because in contrast to the design of shallow foundations, settlement analysis of piles cannot be separated from a load-transfer analysis. The load-transfer analysis is often called *static analysis* or *capacity analysis*. Total stress analysis using undrained shear strength (so-called α-method) has very limited application, because the load transfer between a pile and the soil is governed by effective stress behavior. In an effective stress analysis (also called β-method), the resistance is proportional to the effective overburden stress. Sometimes, an adhesion (cohesion) component is added. (The adhesion component is normally not applicable to driven piles, but may be useful for cast *in situ* piles). The total stress and effective stress approaches refer to both **shaft** and **toe resistances**, although the equivalent terms, "α-method" and "β-method" usually refer to shaft resistance, specifically.

Shaft Resistance

The general numerical relation for the unit shaft resistance, r_s, is

$$r_s = c' + \beta\sigma'_z \tag{23.25a}$$

The adhesion component, c', is normally set to zero for driven piles and Eq. (23.25a) then expresses that unit shaft resistance is directly proportional to the effective overburden stress.

The accumulated (total) shaft resistance, R_s, is

$$R_s = \int A_s r_s dz = \int A_s (c' + \beta\sigma'_z) dz \tag{23.25b}$$

The beta coefficient varies with soil gradation, mineralogical composition, density, and soil strength within a fairly narrow range. Table 23.3 shows the approximate range of values to expect from basic soil types.

TABLE 23.3 Approximate Range of Beta Coefficients

Soil Type	Phi	Beta
Clay	25–30	0.25–0.35
Silt	28–34	0.27–0.50
Sand	32–40	0.30–0.60
Gravel	35–45	0.35–0.80

Toe Resistance

Also the unit toe resistance, r_t, is proportional to the effective stress, that is, the effective stress at the **pile toe** ($z = D$). The proportionality coefficient has the symbol N_t. Its value is sometimes stated to be of some relation to the conventional bearing capacity coefficient, N_q, but such relation is far from strict. The toe resistance, r_t, is

$$r_t = N_t \, \sigma'_{z\,=D}. \tag{23.26a}$$

The total toe resistance, R_t, acting on a pile with a toe area equal to A_t is

$$R_t = A_t r_t = A_t N_t \, \sigma'_{z\,=D}. \tag{23.26b}$$

In contrast to the β-coefficient, the toe coefficient, N_t, varies widely. Table 23.4 shows an approximate range of values for the four basic soil types.

TABLE 23.4 Approximate Range of N_t Coefficients

Soil Type	Phi	N_t
Clay	25–30	3–30
Silt	28–34	20–40
Sand	32–40	30–150
Gravel	35–45	60–300

Ultimate Resistance — Capacity

The capacity of the pile, Q_{ult} (alternatively, R_{ult}), is the sum of the shaft and toe resistances.

$$Q_{ult} = R_s + R_t \tag{23.27}$$

When the shaft and toe resistances are fully mobilized, the load in pile, Q_z, (as in the case of a static loading test brought to "failure") varies, as follows:

$$Q_z = Q_u - \int A_s \beta \sigma'_z dz = Q_u - R_s \tag{23.28}$$

Equation (23.28) is also called the *resistance distribution curve*. At the depth $z = D$, Eq. (23.28), of course, states that $Q_z = R_t$.

Notice that the commonly used term "ultimate capacity" is a misnomer and a tautology: a mix of the words "ultimate resistance" and "capacity". Although one cannot be mistaken about the meaning of ultimate capacity, the adjective should not be used, because it makes other adjectives seem proper, such as "load capacity," "allowable capacity," "design capacity," which are at best awkward and at worst misleading, because what is meant is not clear. Sometimes not even the person using these adjectives with "capacity" knows the meaning.

During service conditions, loads from the structure will be applied to the pile head via a pile cap. The loads are normally permanent (or "dead") loads, Q_d, and transient (or "live") loads Q_l. Not generally recognized is that even if soil settlement is small — too small to be noticeable — the soil will in the majority of cases move down in relation to the pile and in the process transfer load to the pile by negative skin friction. (The exception refers to piles in swelling soils and it is then limited to the length of pile in the swelling zone.) Already the extremely small relative movements always occurring between a pile shaft and the soil are sufficient to develop either shaft resistance or negative skin friction. Therefore, every pile develops an equilibrium of forces between, on the one side, the sum of dead load applied to the pile head, Q_d, and dragload, Q_n, induced by negative skin friction in the upper part of the pile, and, on the other side, the sum of positive shaft resistance and toe resistance in the lower part of the pile. The point of equilibrium, called the neutral plane, is the depth where the shear stress along the pile changes over from negative skin friction into positive shaft resistance. This is also where there is no relative displacement between the pile and the soil.

The key aspect of the foregoing is that the development of a neutral plane and negative skin friction is an always occurring phenomenon in piles and not only of importance in the context of large settlement of the soil around the piles.

Normally, the neutral plane lies below the midpoint of a pile. The extreme case is for a pile on rock, where the location of the neutral plane is at the bedrock elevation. For a dominantly shaft-bearing pile "floating" in a homogeneous soil with linearly increasing shear resistance, the neutral plane lies at a depth which is about equal to the lower third point of the pile embedment length.

The larger the toe resistance, the deeper the elevation of the neutral plane. And, the larger the dead load, the shallower the elevation of the neutral plane.

The load distribution in the pile during long-term conditions down to the neutral plane is given by the following load-transfer relation. [Below the neutral plane, Q_z follows Eq. (23.28).]

$$Q_z = Q_d + \int A_s q_n dz = Q_d + Q_n \tag{23.29}$$

The transition between the load-resistance curve [Eq. (23.27)] and the load-transfer curve [Eq. (23.28)] is in reality not the sudden kink the equations suggest, but a smooth transition over some length of pile, about 4 to 8 pile diameters above and below the neutral plane. (The length of this transition zone varies with the type of soil at the neutral plane.) Thus, the theoretically calculated value of the maximum load in the pile is higher than the real value. That is, it is easy to overestimate the magnitude of the dragload.

Critical Depth

Many texts suggest the existence of a so-called "critical depth" below which the shaft and toe resistances would be constant and independent of the increasing effective stress. This concept is a fallacy based on past incorrect interpretation of test data and should not be applied.

Effect of Installation

Whether a pile is installed by driving or by other means, the installation affects, disturbs, the soil. It is difficult to determine the magnitude of the shaft and toe resistances existing before the disturbance from the pile installation has subsided. For instance, presence of dissipating excess pore pressures causes uncertainity in the magnitude of the effective stress in the soil, ongoing strength gain due to reconsolidation is hard to estimate, etc. Such installation effects can take a long time to disappear, especially in clays. They can be estimated in an effective stress analysis using suitable assumptions as to the distribution of pore pressure along the pile at any particular time. Usually, to calculate the installation effect, a good estimate can be obtained by imposing excess pore pressures in the fine-grained soil layers, taking care that the pore pressure must not exceed the total overburden stress. By restoring the pore pressure values to the original conditions, which will prevail when the induced excess pore pressures have dissipated, the long-term capacity is found.

Residual Load

The dissipation of induced excess pore pressures is called *reconsolidation*. Reconsolidation after installation of a pile imposes load (residual load) in the pile by negative skin friction in the upper part of the pile, which is resisted by positive shaft resistance in the lower part of the pile and some toe resistance. The quantitative effect of including, as opposed to not to, the residual load in the analysis is that the shaft resistance becomes smaller and the toe resistance becomes larger. If the residual load is not recognized in the evaluation of results from a static loading test, totally erroneous conclusions will be drawn from the test: The shaft resistance appears larger than the true value, while the toe resistance appears correspondingly smaller, and if the resistance distribution is determined from a force gauge in the pile, zeroed at the start of the test, a "critical depth" will seem to exist. For more details on this effect and how to analyze the force gauge data to account for the residual load, see Altaee et al. [1992, 1993].

Analysis of Capacity for Tapered Piles

Many piles are not cylindrical or otherwise uniform in shape throughout the length. The most common example is the wood pile, which is conical in shape. Step-tapered piles are also common, consisting of two or more concrete-filled steel pipes of different diameters connected to each other, the larger above the smaller. Sometimes a pile can consist of a steel pipe with a conical section immediately above the pile toe, for example, the Monotube pile, which typically has a 25 feet (7.6 m) long conical end section, tapering the diameter down from 14 inches (355 mm) to 8 inches (203 mm). Piles can have an upper solid concrete section and a bottom H-pile extension.

For the step-tapered piles, obviously each "step" provides an extra resistance point, which needs to be considered in an analysis. (The GRLWEAP wave equation program [GRL, 1993], for example, can model a pile with one diameter change as having a second pile toe at the location of the step). Similarly, in a static analysis, each such step can be considered as a donut-shaped extra pile toe and assigned a corresponding

toe resistance per Eq. (23.26). Each such extra toe resistance value is then added to the shaft resistance calculated using the actual pile diameter.

Piles with a continuous taper (conical piles) are less easy to analyze. Nordlund [1963] suggested a taper correction factor to use to increase the unit shaft resistance in sand for conical piles. The correction factor is a function of the taper angle and the soil friction angle. A taper angle of 1° (0.25 inch/foot) in a sand with a 35° friction angle would give a correction factor of about 4. At an angle of 0.5°, the factor would be about 2.

A more direct calculation method is to "step" the calculation in sub-layers of some thickness and at the bottom of each such sub-layer project the donut-shaped diameter change, which then is treated as an extra toe similar to the analysis of the step-taper pile. The shaft resistance is calculated using the mean diameter of the pile over the same "stepped" length. The shaft resistance over each such particular length consists of the sum of the shaft resistance and the extra-toe resistance. This method requires that a toe coefficient, N_t, be assigned to each soil layer.

The taper does not come into play for negative skin friction. This means that, when determining the dragload, the effect of the taper should be excluded. Below the neutral plane, however, the effect should be included. Therefore, the taper will influence the location of the neutral plane (because the taper increases the positive shaft resistance below the neutral plane).

Factor of Safety

In a pile design, one must distinguish between the design for bearing capacity and design for structural strength. The former is considered by applying a factor of safety to the pile capacity according to Eq. (23.27). The capacity is determined considering positive shaft resistance developed along the full length of the pile plus full toe resistance. Notice that no allowance is given for the dragload. If design is based on only theoretical analysis, the usual factor of safety is about 3.0. If based on the results of a loading test, static or dynamic, the factor of safety is reduced, depending on reliance on and confidence in the capacity value, and importance and sensitivity of the structure to foundation deformations. Factors of safety as low as 1.8 have then been used in actual design, but usually the lower bound is 2.0.

Design for structural strength applies to a factor of safety applied to the loads acting at the pile head and at the neutral plane. At the pile head, the loads consist of dead and live load combined with bending at the pile head, but no dragload. At the neutral plane, the loads consist of dead load and dragload, but no live load. Live load and dragload cannot occur at the same time and must, therefore, not be combined in the analysis. It is recommended that for *straight and undamaged piles* the allowable maximum load at the neutral plane be limited to 70% of the pile strength. For composite piles, such as concrete-filled pipe piles, the load should be limited to a value that induces a maximum compression strain of 1.0 millistrain into the pile with no material becoming stressed beyond 70% of its strength. The calculations are interactive inasmuch a change of the load applied to a pile will change the location of the neutral plane and the magnitude of the maximum load in the pile.

The third aspect in the design, calculation of settlement, pertains more to pile groups than to single piles. In extending the approach to a pile group, it must be recognized that a pile group is made up of a number of individual piles which have different embedment lengths and which have mobilized the toe resistance to a different degree. The piles in the group have two things in common, however: They are connected to the same stiff pile cap and, therefore, all pile heads move equally, and the piles must all have developed a neutral plane at the same depth somewhere down in the soil (long-term condition, of course).

Therefore, it is impossible to ensure that the neutral plane is common for the piles in the group, with the mentioned variation of length, etc., unless the dead load applied to the pile head from the cap differs between the piles. This approach can be used to discuss the variation of load within a group of stiffly connected piles. A pile with a longer embedment below the neutral plane or one having mobilized a larger toe resistance as opposed to other piles will carry a greater portion of the dead load on the group. On the other hand, a shorter pile, or one with a smaller toe resistance as opposed to other piles in the

group, will carry a smaller portion of the dead load. If a pile is damaged at the toe, it is possible that the pile exerts a negative — pulling — force at the cap and thus increases the total load on the pile cap.

An obvious result of the development of the neutral plane is that no portion of the dead load is transferred to the soil via the pile cap, unless, of course, the neutral plane lies right at the pile cap and the entire pile group is failing.

Above the neutral plane, the soil moves down relative to the pile; below the neutral plane, the pile moves down into the soil. Therefore, at the neutral plane, the relative movement between the pile and the soil is zero, or, in other words, whatever the settlement of the soil that occurs at the neutral plane is equal to the settlement of the pile (the pile group) at the neutral plane. Between the pile head and the neutral plane, only deformation of the pile due to load occurs and this is usually minor. Therefore, settlement of the pile and the pile group is governed by the settlement of the soil at and below the neutral plane. The latter is influenced by the stress increase from the permanent load on the pile group and other causes of load, such as the fill. A simple method of calculation is to exchange the pile group for an equivalent footing of area equal to the area of the pile cap placed at the depth of the neutral plane. The load on the pile group load is then distributed as a stress on this footing calculating the settlement of this footing stress in combination with all other stress changes at the site, such as the earth fill, potential groundwater table changes, adjacent excavations, etc. Notice that the portion of the soil between the neutral plane and the pile toe depth is "reinforced" with the piles and, therefore, not very compressible. In most cases, the equivalent footing is best placed at the pile toe depth (or at the level of the average of the pile toe depths).

Empirical Methods for Determining Axial Pile Capacity

For many years, the *N*-index of standard penetration test has been used to calculate capacity of piles. Meyerhof [1976] compiled and rationalized some of the wealth of experience available and recommended that the capacity be a function of the *N*-index, as follows:

$$R = R_t + R_s = mNA_t + nNA_sD \tag{23.30}$$

where m = a toe coefficient
n = a shaft coefficient
N = *N*-index at the pile toe
N = average *N*-index along the pile shaft
A_t = pile toe area
A_s = unit shaft area; circumferential area
D = embedment depth

For values inserted into Eq. (23.30) using base SI units — that is, R in newton, D in meter, and A in m^2 — the toe and shaft coefficients, m and n, become:

$m = 400 \cdot 10^3$ for driven piles and $120 \cdot 10^3$ for bored piles (N/m^2)
$n = 2 \cdot 10^3$ for driven piles and $1 \cdot 10^3$ for bored piles (N/m^3)

For values inserted into Eq. (23.30) using English units with R in ton, D in feet, and A in ft^2, the toe and shaft coefficients, m and n, become:

m = 4 for driven piles and 1.2 for bored piles (N/m^2)
n = 0.02 for driven piles and 0.01 for bored piles (N/m^3)

The standard penetration test (SPT) is a subjective and highly variable test. The test and the *N*-index have substantial qualitative value, but should be used only very cautiously for quantitative analysis. The *Canadian Foundation Engineering Manual* [Canadian Geotechnical Society, 1985] includes a listing of

the numerous irrational factors influencing the *N*-index. However, when the use of the *N*-index is considered with the sample of the soil obtained and related to a site- and area-specific experience, the crude and decried SPT test does not come out worse than other methods of analyses.

The static cone penetrometer resembles a pile. There is shaft resistance in the form of so-called local friction measured immediately above the cone point, and there is toe resistance in the form of the directly applied and measured cone-point pressure.

When applying cone penetrometer data to a pile analysis, both the local friction and the point pressure may be used as direct measures of shaft and toe resistances, respectively. However, both values can show a considerable scatter. Furthermore, the cone-point resistance, (the cone-point being small compared to a pile toe) may be misleadingly high in gravel and layered soils. Schmertmann [1978] has indicated an averaging procedure to be used for offsetting scatter, whether caused by natural (real) variation in the soil or inherent in the test.

The piezocone, which is a cone penetrometer equipped with pore pressure measurement devices at the point, is a considerable advancement on the static cone. By means of the piezocone, the cone information can be related more dependably to soil parameters and a more detailed analysis can be performed. Soil is variable, however, and the increased and more representative information obtained also means that a certain digestive judgment can and must be exercised to filter the data for computation of pile capacity. In other words, the designer is back to square one: more thoroughly informed and less liable to jump to false conclusions, but certainly not independent of site-specific experience. Eslami and Fellenius (1997) and Fellenius and Eslami (2000) have presented comprehensive information on soil profiling and analysis on pile capacity based on CPT data.

The Lambda Method

Vijayvergiya and Focht [1972] compiled a large number of results from static loading tests on essentially shaft-bearing piles in reasonably uniform soil and found that, for these test results, the mean unit shaft resistance is a function of depth and can be correlated to the sum of the mean overburden effective stress plus twice the mean undrained shear strength within the embedment depth, as follows.

$$r_s = \lambda(\sigma'_m + 2c_m) \tag{23.31}$$

where r_m = mean shaft resistance along the pile
λ = the lambda correlation coefficient
σ_m = mean overburden effective stress
c_m = mean undrained shear strength

The correlation factor is called “lambda” and it is a function of pile embedment depth, reducing with increasing depth, as shown in Table 23.5.

The lambda method is almost exclusively applied to determining the shaft resistance for heavily loaded pipe piles for offshore structures in relatively uniform soils.

TABLE 23.5 Approximate Values of λ

Embedment (ft)	Embedment (m)	λ (–)
0	0	0.50
10	3	0.36
25	7	0.27
50	15	0.22
75	23	0.17
100	30	0.15
200	60	0.12

Field Testing for Determining Axial Pile Capacity

The capacity of a pile is of most reliable value when determined in a full-scale field test. However, despite the numerous static loading tests that have been carried out and the many papers that have reported on such tests and their analyses, the understanding of static pile testing in current engineering practice leaves much to be desired. The reason is that engineers have concerned themselves with mainly one question — "Does the pile have a certain least capacity?" — finding little of practical value in analyzing the pile–soil interaction, the load transfer.

A static loading test is performed by loading a pile with a gradually or stepwise increasing force while monitoring the movement of the pile head. The force is obtained by means of a hydraulic jack reacting against a loaded platform or anchors.

The American Society for Testing and Materials, ASTM, publishes three standards, D-1143, D-3689, and D-3966, for static testing of a single pile in axial compression, axial uplift, and lateral loading, respectively. The ASTM standards detail how to arrange and perform the pile test. Wisely, they do not include how to interpret the tests, because this is the responsibility of the engineer in charge, who is the only one with all the site- and project-specific information necessary for the interpretation.

The most common test procedure is the slow maintained load method referred to as the "standard loading procedure" in the ASTM Designation D-1143 and D-3689, in which the pile is loaded in eight equal increments up to a maximum load, usually twice a predetermined allowable load. Each load level is maintained until zero movement is reached, defined as 0.25 mm/hr (0.01 in./hr). The final load, the 200 percent load, is maintained for a duration of 24 hours. The "standard method" is very time-consuming, requiring from 30 to 70 hours to complete. It should be realized that the words "zero movement" are very misleading: The "zero" movement rate mentioned is equal to a movement of more than 2 m (7 ft) per year!

Each of the eight load increments is placed onto the pile very rapidly; as fast as the pump can raise the load, which usually takes about 20 seconds to 2 minutes. The size of the load increment in the "standard procedure" — 12.5 percent of the maximum load — means that each such increase of load is a shock to the pile and the soil. Smaller increments that are placed more frequently disturb the pile less, and the average increase of load on the pile during the test is about the same. Such loading methods provide more consistent, reliable, and representative data for analysis.

Tests that consist of load increments applied at constant time intervals of 5, 10, or 15 minutes are called quick maintained-load tests or just "quick tests." In a quick test, the maximum load is not normally kept on the pile longer than any other load before the pile is unloaded. Unloading is done in about ten steps of no longer duration than a few minutes per load level. The quick test allows for applying one or more load increments beyond the minimum number that the particular test is designed for, that is, making use of the margin built into the test. In short, the quick test is, from the technical, practical, and economic points of view, superior to the "standard loading procedure."

A quick test should aim for 25 to 40 increments with the maximum load determined by the amount of reaction load available or the capacity of the pile. For routine cases, it may be preferable to stay at a maximum load of 200 percent of the intended allowable load. For ordinary test arrangements, where only the load and the pile head movement are monitored, time intervals of 10 minutes are suitable and allow for the taking of 2 to 4 readings for each increment. When testing instrumented piles, where the instruments take a while to read (scan), the time interval may have to be increased. To go beyond 20 minutes, however, should not be necessary. Nor is it advisable, because of the potential risk for influence of time-dependent movements, which may impair the test results. Usually, a quick test is completed within three to six hours.

In routine tests, cyclic loading or even single unloading and loading phases must be avoided, as they do little more than destroy the possibility of a meaningful analysis of the test results. There is absolutely no logic in believing that anything of value on load distribution and toe resistance can be obtained from an occasional unloading or from one or a few "resting periods" at certain load levels, when considering that we are testing a unit that is subjected to the influence of several soil types, is subjected to residual

stress of unknown magnitude, exhibits progressive failure, etc., and when all we know is what is applied and measured at the pile head.

Interpretation of Failure Load

For a pile that is stronger than the soil, the failure load is reached when rapid movement occurs under sustained or slightly increased load (the pile plunges). However, this definition is inadequate, because plunging requires large movements. To be useful, a definition of failure load must be based on some mathematical rule and generate a repeatable value that is independent of scale relations and the opinions of the individual interpreter. Furthermore, it has to consider the shape of the load-movement curve or, if not, it must consider the length of the pile (which the shape of the curve indirectly does).

Fellenius [1975, 1980] compiled several methods used for interpreting failure or limit loads from a load-movement curve of a static loading test. The most well-known method is the offset limit method proposed by Davisson [1972]. This limit load is defined as the load corresponding to the movement that exceeds the elastic compression of the pile by an offset of 4 mm (0.15 inch) plus a value equal to the diameter of the pile divided by 120. It must be realized, however, that the offset limit load is a deformation limit that is determined taking into account the stiffness and length of the pile. It is not necessarily equal to the failure load of the pile.

The offset limit has the merit of allowing the engineer, when proof testing a pile for a certain allowable load, to determine *in advance* the maximum allowable movement for this load with consideration of the length and size of the pile. Thus, contract specifications can be drawn up including an acceptance criterion for piles proof tested according to quick-testing methods. The specifications can simply call for a test to at least twice the design load, as usual, and declare that at a test load equal to a factor F times the design load the movement shall be smaller than the Davisson offset from the elastic column compression of the pile. Normally, F would be chosen within a range of 1.8 to 2.0. The acceptance criterion could be supplemented with the requirement that the safety factor should also be smaller than a certain minimum value calculated on pile bearing failure defined according to the 80% criterion or other preferred criterion.

Influence of Errors

A static loading test is usually considered a reliable method for determining the capacity of a pile. However, even when using new manometers and jacks and calibrating them together, the applied loads is usually substantially overestimated. The error is usually about 10% to 15% of the applied load. Errors as large as 30% to 40% are not uncommon.

The reason for the error is that the jacking system is required to both provide the load and to measure it, and because load cells with moving parts are considerably less accurate than those without moving parts. For example, when calibrating testing equipment in the laboratory, one ensures that no eccentric loading, bending moments, or temperature variations influence the calibration. In contrast, all of these adverse factors are at hand in the field and influence the test results to an unknown extent, unless a load cell is used.

The above deals with the error of the applied load. The error in movement measurement can also be critical. Such errors do not originate in the precision of the reading — the usual precision is more than adequate — but in undesirable influences, such as heave or settlement of the reference beam during unloading the ground when loading the pile. For instance, one of the greatest spoilers of a loading test is the sun: The reference beam must be shielded from sunshine at all times.

Dynamic Analysis and Testing

The penetration resistance of driven piles provides a direct means of determining bearing capacity of a pile. In impacting a pile, a short-duration force wave is induced in the pile, giving the pile a downward velocity and resulting in a small penetration of the pile. Obviously, the larger the number of blows necessary to achieve a certain penetration, the stronger the soil. Using this basic principle, a large number of so-called pile-driving formulas have been developed for determining pile-bearing capacity. All these

formulas are based on equalizing potential energy available for driving in terms of weight of hammer times its height of fall (stroke) with the capacity times penetration ("set") for the blow. The penetration value often includes a loss term.

The principle of the dynamic formulas is fundamentally wrong as wave action is neglected along with a number of other aspects influencing the penetration resistance of the pile. Nevertheless, pile-driving formulas have been used for many years and with some degree of success. However, success has been due less to the theoretical correctness of the particular formulas used and more to the fact that the users possessed adequate practical experience to go by. When applied to single-acting hammers, use of a dynamic formula may have some justification. However, dynamic formulas are the epitome of an outmoded level of technology and they have been or must be replaced by modern methods, such as the wave equation analysis and dynamic measurements, which are described below.

Pile-driving formulas or any other formula applied to vibratory hammers are based on a misconception. Vibratory driving works by eliminating resistance to penetration, not by overcoming it. Therefore, records of penetration combined with frequency, energy, amplitudes, and so on can relate only to the resistance not eliminated, not to the static pile capacity after the end of driving.

Pile-driving hammers are rated by the maximum potential energy determined as the ram weight times the maximum ram travel. However, diesel hammers and double-acting air/steam hammers, but also single-acting air/steam hammers, develop their maximum potential energy only during favorable combinations with the pile and the soil. Then, again, the energy actually transferred to the pile may vary due to variation in cushion properties, pile length, toe conditions, etc. Therefore, a relation between the hammer rated energy and measured transferred energy provides only very little information on the hammer.

For reliable analysis, all aspects influencing the pile driving and penetration resistance must be considered: hammer mass and travel, combustion in a diesel hammer, helmet mass, cushion stiffness, hammer efficiency, soil strength, viscous behavior of the soil, and elastic properties of the pile, to mention some. This analysis is made by means of commercially available wave equation programs, such as the GRLWEAP [GRL, 1993].

However, the parameters used as input into a wave equation program are really variables with certain ranges of values and the number of parameters included in the analysis is large. Therefore, the result of an analysis is only qualitatively correct, and not necessarily quantitatively correct, unless it is correlated to observations. The full power of the wave equation analysis is only realized when combined with dynamic measurements during pile driving by means of transducers attached to the pile head. The impact by the pile-driving hammer produces strain and acceleration in the pile which are picked up by the transducers and transmitted via a cable to a data acquisition unit (the Pile Driving Analyzer), which is placed in a nearby monitoring station. The complete generic field-testing procedure is described in the American Society for Testing and Materials, Standard for Dynamic Measurements, ASTM D-4945.

Dynamic testing, also called dynamic monitoring, is performed with the Pile Driving Analyzer (PDA). The PDA measurements provide much more information than just the value of the capacity of the pile, such as the energy transferred into the pile, the stresses in the pile, and the hammer performance. The dynamic data can be subjected to special analyses and provide invaluable information for determining that the piles are installed correctly, that the soil response is what was assumed in the design, and much more. For details, see Rausche et al. [1985] and Hannigan [1990]. Should difficulties develop with the pile driving at the site, the dynamic measurements can normally determine the reason for the difficulties and how to eliminate them. In the process, the frequent occurrence of having difficulties grow into a dispute between the contractor, the engineer, and the owner is avoided.

The dynamic measurements provide quantitative information of how the pile hammer functions, the compression and tension stresses that are imposed on the pile during the driving, and how the soil responds to the driving of the pile, including information pile static capacity. The dynamic measurements can also be used to investigate damage and defects in the pile, such as voids, cracks, spalling, local buckling, etc.

Dynamic records are routinely subjected to a detailed analysis called the CAPWAP signal matching analysis [Rausche et al., 1972]. The CAPWAP analysis provides, first of all, a calculated static capacity and the distribution of resistance along the pile. However, it also provides several additional data, for example, the movement necessary to mobilize the full shear resistance in the soil (the quake) and damping values for input in a wave equation analysis.

Pile Group Example: Axial Design

The design approach is illustrated in the following example: A group of 25 piles consisting of 355-mm diameter, closed-end steel pipes are to be driven at equal spacing and in a square configuration at a site with the soil profile equal to that described earlier as background to Table 23.1. The 1.5-m earth fill over 36 m^2 area will be placed symmetrically around the pile group. The pile cap is 9.0 m^2 and placed level with the ground surface.

Each pile will be subjected to dead and live loads of 800 kN and 200 kN, respectively. The soils investigation has established a range of values of the soil parameters necessary for the calculations, such as density, compressibility, consolidation coefficient, as well as the parameters (β and N_t) used in the effective stress calculations of load transfer. A load-transfer analysis is best performed using a range (boundary values) of β and N_t parameters, which differentiate upper and lower limits of reasonable values. The analysis must include several steps in approximately the following order.

Determine first the range of installation length (using the range of effective stress parameters) as based on the required at-least capacity, which is stated, say, to be at least equal to the sum of the loads times a factor of safety of 3.0: $3.0(800 + 200) = 3000$ kN.

To obtain a capacity of 3000 kN, applying the lower boundary of β and N_t, the piles have to be installed to a penetration into the sandy till layer of 5 m, that is, to a depth of 32 m. Table 23.6 presents the results of the load-transfer calculations for this embedment depth. The calculations have been made with the Unipile program [Goudreault and Fellenius, 1990] and the results are presented in the format of a hand calculation to ease verifying the computer calculations. The precision indicated by stress values given with two decimals is to assist in the verification of the calculations and does not suggest a corresponding level of accuracy. Moreover, the effect of the 9 m^2 "hole" in the fill for the pile cap was ignored in the calculation. Were its effect to be included in the calculations, the calculated capacity would reduce by 93 kN or the required embedment length increase by 0.35 m.

The calculated values have been plotted in Fig. 23.5 in the form of two curves: a resistance curve giving the load transfer as in a static loading test to failure (3000 kN); and a load curve for long-term conditions, starting at the dead load of 800 kN and increasing due to negative skin friction to a maximum at the neutral plane. The load and resistance distributions for the example pile follow Eqs. (23.27) and (23.28).

Pile Group Settlement

The piles have reached well into the sand layers, which will not compress much for the increase of effective stress. Therefore, settlement of the pile group will be minimal and will not govern the design.

Installation Phase

The calculations shown above pertain to the service condition of the pile and are not quite representative for the installation (construction) phase. First, when installing the piles (these piles will be driven), the earth fill is not yet placed, which means that the effective stress in the soil is smaller than during the service conditions. More important, during the pile driving, large excess pore pressures are induced in the soft clay layer and, probably, also in the silty sand, which further reduces the effective stress. An analysis imposing increased pore pressures in these layers suggests that the capacity is about 2200 kN at the end of the initial driving (EOID) using the depth and effective stress parameters indicated in Table 23.6 for the 32 m installation depth. The subsequent dissipation of the pore pressures will result in an about 600-kN soil increase of capacity due to set-up. (The stress increase due to the earth fill will provide the additional about 200 kN to reach the 3000-kN service capacity.)

TABLE 23.6 Calculation of Pile Capacity

	Live Load, Q_l = 200 kN	Shaft Resistance, R_s = 1817 kN
Area A_s = 1.115 m²/m	Dead Load, Q_d = 800 kN	Toe Resistance, R_t = 1205 kN
Area A_t = 0.009 m²	Total Load = 1000 kN	Total Resistance, R_u = 3021 kN
Factor of Safety = 3.2	Depth to Neutral Plane = 26.51 m	Load at Neutral Plane = 1911 kN

Note: Calculations by means of UNIPILE.

The design must include the selection of the pile-driving hammer, which requires the use of software for wave equation analysis, called WEAP analysis [Goble et al., 1980; GRL, 1993; Hannigan, 1990]. This analysis requires input of soil resistance in the form as result of static load-transfer analysis. For the installation (initial driving) conditions, the input is calculated considering the induced pore pressures. For restriking conditions, the analysis should consider the effect of soil set-up.

By means of wave equation analysis, pile capacity at initial driving — in particular the EOID — and restriking (RSTR) can be estimated. However, the analysis also provides information on what driving

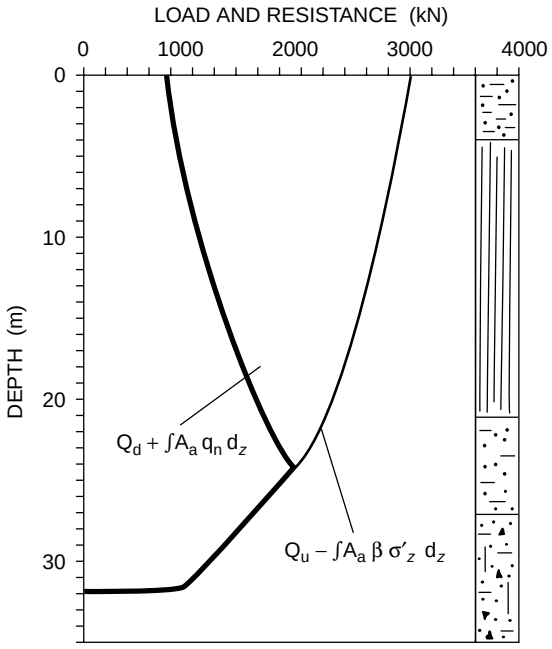

FIGURE 23.5 Load-transfer and resistance curves.

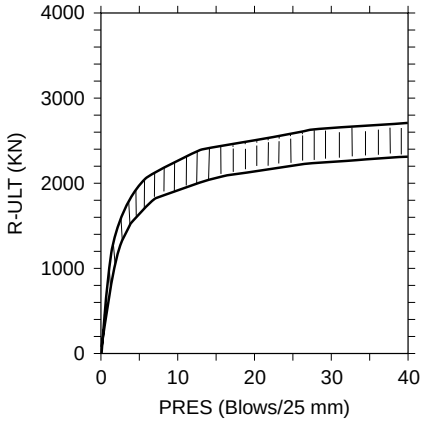

FIGURE 23.6 Bearing graph from WEAP analysis.

stresses to expect, indeed, even the length of time and the number of blows necessary to drive the pile. The most commonly used result is the bearing graph, that is, a curve showing the ultimate resistance (capacity) versus the penetration resistance (blow count) as illustrated in Fig. 23.6. As in the case of the static analysis, the parameters to input to a wave equation analysis can vary within upper and lower limits, which results in not one curve but a band of curves within envelopes as shown in Fig. 23.6. The input parameters consist of the particular hammer to use with its expected efficiency, the static resistance variation, dynamic parameters for the soil, such as damping and quake values, and many other parameters. It should be obvious that no one should expect a single answer to the analysis. Figure 23.6 shows that at EOID for the subject example, when the predicted capacity is about 2200 kN, the penetration resistance (PRES) will be about 10 blows/25 mm through about 20 blows/25 mm.

Notice that the wave equation analysis postulates observation of the actual penetration resistance when driving the piles, as well as a preceding static analysis. Then, common practice is to combine the analyses with a factor of safety ranging from 2.5 through 3.0.

Figure 23.6 demonstrates that the hammer selected for the driving cannot drive the pile against the 3000-kN capacity expected after full set-up. That is, restriking cannot prove out the capacity. This is a common occurrence. Bringing in a larger hammer may be a costly proposition. It may also be quite unnecessary. If the soil profile is well known, the static analysis correlated to the soil profile and to careful observation during the entire installation driving for a few piles, sufficient information is usually obtained to support a satisfactory analysis of the pile capacity and load transfer. That is, the capacity after set-up is inferred and sufficient for the required factor of safety.

When conditions are less consistent, when savings may result, and when safety otherwise suggests it to be good practice, the pile capacity is tested directly. Conventionally, this is accomplished by means of a static loading test. Since about 1975, dynamic tests have likewise often been performed. Static tests are costly and time-consuming, and are therefore usually limited to one or a few piles. In contrast, dynamic tests can be obtained quickly and economically and can be performed on several piles, thus providing assurance in numbers. For larger projects, static and dynamic tests are often combined. More recently, a new testing method called Statnamic has been proposed [Bermingham and Janes, 1989]. The Statnamic method is particularly intended for high-capacity bored piles (drilled piers). The Osterberg O-Cell (Fellenius, 2001) is a very useful new tool for the geotechnical engineer to use when reliable separation of shaft and toe resistances is required. The O-cell is suitable for testing of both bored and drive piles.

When the capacity is determined by direct testing, the factor of safety of the design is reduced. The usual range is from 2.0 to 2.2. When the design and the installation are tested by means of static or dynamic proof testing on the site, the factor of safety is often reduced to the range of 1.8 through 2.0. Notice that results of the tests must not just be given in terms of a capacity value (which can vary depending on how the ultimate resistance is defined); the load transfer should also be included in the analysis.

All analyses for a project must apply the same factor of safety. Therefore, for the subject example, when the designer knows that the capacity will be verified by means of a direct test, the minimum factor of safety to apply reduces to about 2.2, say. That is, the piles need only be driven to a final (after set-up) capacity of 2000 kN or 2200 kN. Considering the initial driving conditions, the capacity at EOID could be limited to about 1600 kN and this should be obtainable at a penetration into the till of slightly less than one meter and a penetration resistance of 4 to 5 blow/25 mm. Then, the subsequent increase due to set-up to 2200 kN is verified in a dynamic of static test *combined* with restriking to verify that the PRES values have increased to beyond about 10 blows/25 mm.

Summary of Axial Design of Piles

In summary, pile design consists of the following steps.

1. Compile soil data and perform a static analysis of the load transfer.
2. Verify that the ultimate pile resistance (capacity) is at least equal to the factor of safety times the sum of the dead and the live load (do not include the dragload in this calculation).
3. Verify that the maximum load in the pile, which is the sum of the dead load and the dragload is smaller than the structural strength of the pile divided by the appropriate factor of safety (usually 1.5) times. (Do not include the live load in this calculation.)
4. Verify that the pile group settlement does not exceed the maximum deformation permitted by the structural design.
5. Perform wave equation analysis to select the pile-driving hammer and to decide on the driving and termination criteria (for driven piles).
6. Observe carefully the pile driving (construction) and verify that the work proceeds as anticipated. Document the observations (that is, keep a complete and carefully prepared log!).
7. When the factor of safety needs to be 2.5 or smaller, verify pile capacity by means of static or dynamic testing.

Design of Piles for Horizontal Loading

Because foundation loads act in many different directions depending on the load combination, piles are rarely loaded in true axial direction only. Therefore, a more or less significant lateral component of the total pile load always acts in combination with an axial load. The imposed lateral component is resisted by the bending stiffness of the pile and the shear resistance mobilized in the soil surrounding the pile.

An imposed horizontal load can also be carried by means of inclined piles, if the horizontal component of the axial pile load is at least equal to and acting in the opposite direction to the imposed horizontal load. Obviously, this approach has its limits, as the inclination cannot be impractically large. It should, preferably, not be greater than 4 (vertical) to 1 (horizontal). Also, only one load combination can provide the optimal lateral resistance.

In general, it is not correct to resist lateral loads by means of combining the soil resistance for the piles (inclined as well as vertical) with the lateral component of the vertical load for the inclined piles. The reason is that resisting an imposed lateral load by means of soil shear requires the pile to move against the soil. The pile will rotate due to such movement and an inclined pile will then either push up against or pull down from the pile cap, which will substantially change the axial load in the pile.

In design of vertical piles installed in a homogeneous soil and subjected to horizontal loads, an approximate and usually conservative approach is to assume that each pile can sustain a horizontal load equal to the passive earth pressure acting on an equivalent wall with depth of $6b$ and width $3b$, where b is the pile diameter or face-to-face distance [Canadian Geotechnical Society, 1985].

Similarly, the lateral resistance of a pile group may be approximated by the soil resistance on the group calculated as the passive earth pressure over an equivalent wall with depth equal to $6b$ and width equal to:

$$L_e = L + 2b \tag{23.32}$$

where L_e = equivalent width
L = the length, center-to-center, of the pile group in plan perpendicular to the direction of the imposed loads
b = the width of the equivalent area of the group in plan parallel to the direction of the imposed loads

The lateral resistance calculated according to Eq. (23.32) must not exceed the sum of the lateral resistance of the individual piles in the group. That is, for a group of n piles, the equivalent width of the group, L_e, must be smaller than n times the equivalent width of the individual pile, $6b$. For an imposed load not parallel to a side of the group, calculate for two cases, applying the components of the imposed load that are parallel to the sides.

The very simplified approach expressed above does not give any indication of movement. Nor does it differentiate between piles with fixed heads and those with heads free to rotate; that is, no consideration is given to the influence of pile bending stiffness. Because the governing design aspect with regard to lateral behavior of piles is lateral displacement, and the lateral capacity or ultimate resistance is of secondary importance, the usefulness of the simplified approach is very limited in engineering practice.

The analysis of lateral behavior of piles must involve two aspects:

1. *Pile response.* The bending stiffness of the pile, how the head is connected (free head, or fully or partially fixed head).
2. *Soil response*. The input in the analysis must include the soil resistance as a function of the magnitude of lateral movement.

The first aspect is modeled by treating the pile as a beam on an "elastic" foundation, which is accomplished by solving a fourth-degree differential equation with input of axial load on the pile, material properties of the pile, and the soil resistance as a nonlinear function of the pile displacement.

The derivation of lateral stress may make use of a simple concept called *coefficient of subgrade reaction* having the dimension of force per volume [Terzaghi, 1955]. The coefficient is a function of the soil density

or strength, the depth below the ground surface, and the diameter (side) of the pile. In cohesionless soils, the following relation is used:

$$k_s = n_h \frac{z}{b} \tag{23.33}$$

where k_s = coefficient of horizontal subgrade reaction
n_h = coefficient related to soil density
z = depth
b = pile diameter

The intensity of the lateral stress, p_z, mobilized on the pile at depth z is then as follows:

$$p_z = k_s y_z b \tag{23.34}$$

where y_z = the horizontal displacement of the pile at depth z. Combining Eqs. (23.33) and (23.34), we get

$$p_z = n_h y_z z. \tag{23.35}$$

The relation governing the behavior of a laterally loaded pile is then as follows:

$$Q_h = EI \frac{d^4 y}{dx^4} + Q_v \frac{d^2 y}{dx^2} - p \tag{23.36}$$

where Q_h = lateral load on the pile
EI = bending stiffness (flexural rigidity)
Q_v = axial load on the pile

Design charts have been developed that, for an input of imposed load, basic pile data, and soil coefficients, provide values of displacement and bending moment. See, for instance, the *Canadian Foundation Engineering Manual* [Canadian Geotechnical Society, 1985].

The design charts cannot consider all the many variations possible in an actual case. For instance, the $p - y$ curve can be a smooth rising curve, can have an ideal elastic-plastic shape, or can be decaying after a peak value. As an analysis without simplifying shortcuts is very tedious and time-consuming, resort to charts has been necessary in the past. However, with the advent of the personal computer, special software has been developed, which makes the calculations easy and fast. In fact, as in the case of pile-driving analysis and wave equation programs, engineering design today has no need for computational simplifications. Exact solutions can be obtained as easily as approximate ones. Several proprietary and public domain programs are available for analysis of laterally loaded piles.

One must not be led to believe that, because an analysis is theoretically correct, the results also predict the true behavior of the pile or pile group. The results must be correlated to pertinent experience and, lacking this, to a full-scale test at the site. If the experience is limited and funds are lacking for a full-scale correlation test, then a prudent choice is necessary of input data, as well as of margins and factors of safety.

Designing and analyzing a lateral test is much more complex than for the case of axial behavior of piles. In service, a laterally loaded pile almost always has a fixed-head condition. However, a fixed-head test is more difficult and costly to perform as opposed to a free-head test. A lateral test without inclusion of measurement of lateral deflection down the pile (bending) is of limited value. While an axial test should not include unloading cycles, a lateral test should be a cyclic test and include a large number of cycles at different load levels. The laterally tested pile is much more sensitive to the influence of neighboring piles than is the axially tested pile. Finally, the analysis of the test results is very complex and requires the use of a computer and appropriate software.

Seismic Design of Lateral Pile Behavior

Seismic design of lateral pile behavior is often taken as being the same as the conventional lateral design. A common approach is to assume that the induced lateral force to be resisted by piles is static and equal to a proportion, usually 10% of the vertical force acting on the foundation. If all the horizontal force is designed to be resisted by inclined piles, and all piles — including the vertical ones — are designed to resist significant bending at the pile cap, this approach is normally safe, albeit costly.

The seismic wave appears to the pile foundation as a soil movement forcing the piles to move with the soil. The movement is resisted by the pile cap; bending and shear are induced in the piles; and a horizontal force develops in the foundation, starting it to move in the direction of the wave. A half period later, the soil swings back, but the foundation is still moving in the first direction, and therefore the forces increase. This situation is not the same as the one originated by a static force.

Seismic lateral pile design consists of determining the probable amplitude and frequency of the seismic wave as well as the natural frequency of the foundation and structure supported by the piles. The first requirement is, as in all seismic design, that the natural frequency must not be the same as that of the seismic wave. Then the probable maximum displacement, bending, and shear induced at the pile cap are estimated. Finally the pile connection and the pile cap are designed to resist the induced forces.

There is at present a rapid development of computer software for use in detailed seismic design.

Defining Terms

Capacity — The maximum or ultimate soil resistance mobilized by a foundation unit.

Capacity, bearing — The maximum or ultimate soil resistance mobilized by a foundation unit subjected to downward loading.

Dragload — The load transferred to a deep foundation unit from negative skin friction.

Factor of safety — The ratio of maximum available resistance or of the capacity to the allowable stress or load.

Foundation — A system or arrangement of structural members through which the loads are transferred to supporting soil or rock.

Groundwater table — The upper surface of the zone of saturation in the ground.

Load, allowable — The maximum load that may be safely applied to a foundation unit under expected loading and soil conditions and determined as the capacity divided by the factor of safety.

Neutral plane — The location where equilibrium exists between the sum of downward acting permanent load applied to the pile and dragload due to negative skin friction and the sum of upward acting positive shaft resistance and mobilized toe resistance. The neutral plane is also where the relative movement between the pile and the soil is zero.

Pile — A slender deep foundation unit, made of wood, steel, concrete, or combinations thereof, which is either premanufactured and placed by driving, jacking, jetting, or screwing, or cast *in situ* in a hole formed by driving, excavating, or boring. A pile can be a non-displacement, low-displacement, or displacement type.

Pile head — The uppermost end of a pile.

Pile point — A special type of pile shoe.

Pile shaft — The portion of the pile between the pile head and the pile toe.

Pile shoe — A separate reinforcement attached to the pile toe of a pile to facilitate driving, to protect the lower end of the pile, and/or to improve the toe resistance of the pile.

Pile toe — The lowermost end of a pile. (Use of terms such as pile tip, pile point, or pile end in the same sense as pile toe is discouraged).

Pore pressure — Pressure in the water and gas present in the voids between the soil grains minus the atmospheric pressure.

Pore pressure, artesian — Pore pressure in a confined body of water having a level of hydrostatic pressure higher than the level of the ground surface.

Pore pressure, hydrostatic — Pore pressure varying directly with a free-standing column of water.

Pore pressure elevation, phreatic — The elevation of a groundwater table corresponding to a hydrostatic pore pressure equal to the actual pore pressure.

Pressure — Omnidirectional force per unit area. (Compare stress.)

Settlement — The downward movement of a foundation unit or soil layer due to rapidly or slowly occurring compression of the soils located below the foundation unit or soil layer, when the compression is caused by an increase of effective stress.

Shaft resistance, negative — Soil resistance acting downward along the pile shaft because of an applied uplift load.

Shaft resistance, positive — Soil resistance acting upward along the pile shaft because of an applied compressive load.

Skin friction, negative — Soil resistance acting downward along the pile shaft as a result of downdrag and inducing compression in the pile.

Skin friction, positive — Soil resistance acting upward along the pile shaft caused by swelling of the soil and inducing tension in the pile.

Stress — Unidirectional force per unit area. (Compare pressure.)

Stress, effective — The total stress in a particular direction minus the pore pressure.

Toe resistance — Soil resistance acting against the pile toe.

24.1 Introduction

In only a very few years, geosynthetics (geotextiles, geogrids, and geomembranes) have joined the list of traditional civil engineering construction materials. Often the use of a geosynthetic can significantly increase the safety factor, improve performance, and reduce costs in comparison with conventional construction alternatives. In the case of embankments on extremely soft foundations, geosynthetics can permit construction to take place at sites where conventional construction alternatives would be either impossible or prohibitively expensive.

Two recent conferences dealt specifically with geosynthetics and soil improvement, and their proceedings deserve special mention (see Holtz [1988a] and Borden et al. [1992]).

After an introduction to geosynthetic types and properties, recent developments in the use of geosynthetics for the improvement of soils in foundations and slopes will be summarized. Primary applications are to drainage and erosion control systems, temporary and permanent roadways and railroads, soil reinforcement, and waste containment systems.

There are a number of **geotextile**-related materials, such as webs, mats, nets, grids, and sheets, which may be made of plastic, metal, bamboo, or wood, but so far there is no ASTM (American Society for Testing and Materials) definition for these materials. They are "geotextile-related" because they are used in a similar manner, especially in reinforcement and stabilization situations, to geotextiles.

Geotextiles and related products such as nets and grids can be combined with **geomembranes** and other synthetics to take advantage of the best attributes of each component. These products are called *geocomposites,* and they may be composites of geotextile–geonets, geotextile–geogrids, geotextile–geomembranes, geomembrane–geonets, geotextile–polymeric cores, and even three-dimensional polymeric cell structures. There is almost no limit to the variety of geocomposites that are possible and useful. The general generic term encompassing all these materials is *geosynthetic*.

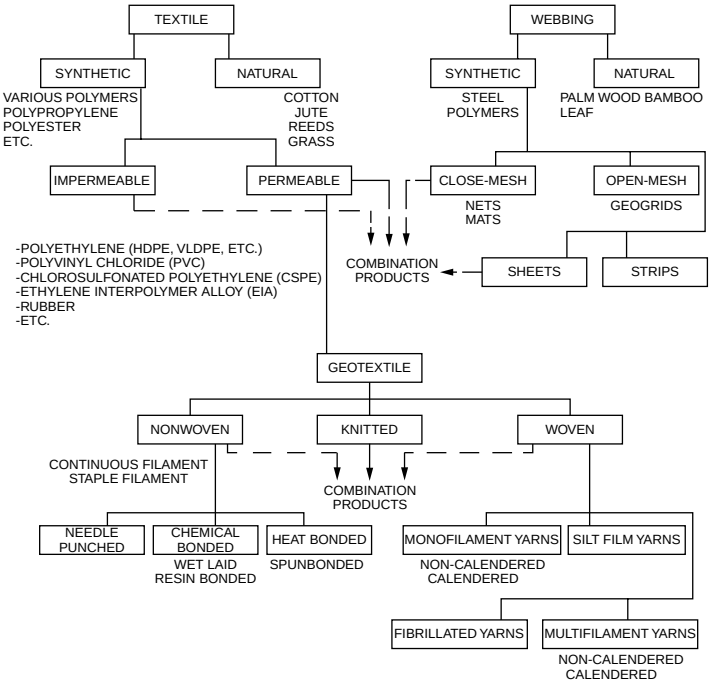

FIGURE 24.1 Classification of geosynthetics. [Adapted (from Rankilor, P. R. 1981. *Membranes in Ground Engineering*. John Wiley & Sons, New York) by Christopher, B. R., and Holtz, R. D. 1989. *Geotextile Design and Construction Guidelines*. U.S. Federal Highway Administration, National Highway Institute, Report No. FHWA-HI-90-001.]

Types and Manufacture

A convenient classification for geosynthetics is given in Fig. 24.1. For details on the composition, materials, and manufacture of geotextiles and related materials, see Koerner and Welsh [1980], Rankilor [1981], Giroud and Carroll [1983], Christopher and Holtz [1985], Veldhuijzen van Zanten [1986], Ingold and Miller [1988], and Koerner [1990a]. Most geosynthetics are made from synthetic polymers such as polypropylene, polyester, polyethylene, polyamide, and PVC. These materials are highly resistant to biological and chemical degradation. Natural fibers such as cotton, jute, and bamboo can be used as geotextiles and geogrids, especially for temporary applications, but they have not been promoted or researched as widely as geotextiles made from synthetic polymeric materials.

Applications and Functions

More than 150 separate applications of geosynthetics have been identified [Koerner, 1990a]. Table 24.1 lists those for geotextiles and related products, and the primary application areas are filtration and drainage, erosion protection and control, roadways and asphalt pavement overlays, and reinforced walls, slopes, and embankments. The primary geotextile functions are filtration, drainage, separation, and reinforcement. In virtually every application, the geotextile also provides one or more secondary functions of filtration, drainage, separation, and reinforcement (see Table 24.1). Geogrids, nets, webs, fascines, and so on are primarily used for roadway stabilization and all types of earth reinforcement. They also have significant applications in waste containment systems when used together with geotextile filters and geomembranes (geocomposites).

Historical and Recent Developments

Giroud [1986] and Fluet [1988] give interesting accounts of the history of geosynthetics. Few developments have had such a rapid growth and strong influence on so many aspects of civil engineering practice.

TABLE 24.1 Representative Applications and Controlling Functions of Geotextiles

Primary Function	Application	Secondary Functions
Separation	Unpaved roads (temporary and permanent)	Filter, drains, reinforcement
	Paved roads (secondary and primary)	Filter, drains
	Construction access roads	Filter, drains, reinforcement
	Working platforms	Filter, drains, reinforcement
	Railroads (new construction)	Filter, drains, reinforcement
	Railroads (rehabilitation)	Filter, drains, reinforcement
	Landfill covers	Drains, reinforcement
	Preloading (stabilization)	Drains, reinforcement
	Marine causeways	Filter, drains, reinforcement
	General fill areas	Filter, drains, reinforcement
	Paved and unpaved parking facilities	Filter, drains, reinforcement
	Cattle corrals	Filter, drains, reinforcement
	Coastal and river protection	Filter, drains, reinforcement
	Sports fields	Filter, drains
Drainage-transmission	Retaining walls	Separation, filter
	Vertical drains	Separation, filter
	Horizontal drains	Reinforcement
	Below membranes (drainage of gas and water)	Reinforcement
	Earth dams	Filter
	Below concrete (decking and slabs)	—
Reinforcement	Pavement overlays	—
	Concrete overlays	—
	Subbase reinforcement in roadways and railways	Filter
	Retaining structures	Drains
	Membrane support	Separation, drains, filter
	Embankment reinforcement	Drains
	Fill reinforcement	Drains
	Foundation support	Drains
	Soil encapsulation	Drains, filter separation
	Net against rockfalls	Drains
	Fabric retention systems	Drains
	Sandbags	—
	Reinforcement of membranes	—
	Load redistribution	Separation
	Bridging nonuniformity soft soil areas	Separation
	Encapsulated hydraulic fills	Separation
	Bridge piles for fill placement	—
Filter	Trench drains	Separation, drains
	Pipe wrapping	Separation, drains
	Base course drains	Separation, drains
	Frost protection	Separation, drainage, reinforcement
	Structural drains	Separation, drains
	Toe drains in dams	Separation, drains
	High embankments	Drains
	Filter below fabric-form	Separation, drains
	Silt fences	Separation, drains
	Silt screens	Separation
	Culvert outlets	Separation
	Reverse filters for erosion control:	
	Seeding and mulching	
	Beneath gabions	
	Ditch amoring	
	Embankment protection, coastal	
	Embankment protection, rivers and streams	
	Embankment protection, lakes	
	Vertical drains (wicks)	Separation

Source: Christopher, B. R., and Holtz, R. D. 1989. *Geotextile Design and Construction Guidelines.,* U.S. Federal Highway Administration, National Highway Institute, Report No. FHWA-HI-90-001.

In 1970, there were only five or six geotextiles available. Today more than 250 different materials are sold in the U.S. as geotextiles and geogrids; worldwide, the number probably exceeds 400. The size of the geotextile market, both in terms of square meters produced and their dollar value, is indicative of their influence. For example, in 1991, more than 300 million square meters of geotextiles and related materials such as geogrids were sold in North America. The worldwide consumption was probably more than twice this amount. The value of these materials is probably close to $500 million. Since the total cost of the construction is at least four or five times the cost of the geosynthetic itself, the impact of these materials on civil engineering construction is very large indeed.

Another important recent development is the rapid growth of the literature on geosynthetics. This literature includes books, conference proceedings, and technical journals devoted to various aspects of geosynthetics. A listing of geosynthetic literature can be found in Holtz and Paulson [1988] and Cazzuffi and Anzani [1992].

Design and Selection

In the early days of geotextiles, selection and specification were primarily by type or brand name. This was satisfactory as long as there were only a few geotextiles on the market and the choices available to the designer were limited. Today, however, with such a wide variety of geosynthetics available, this approach is inappropriate. The recommended approach for designing, selecting, and specifying geosynthetics is no different than what is commonly practiced in any geotechnical engineering design. First, the design should be made *without* geosynthetics to see if they really are needed. If conventional solutions are impractical or uneconomical, design calculations using reasonable engineering estimates of the required geosynthetic properties are carried out. Next, generic or performance type specifications are written so that the most appropriate and economical geosynthetic is selected, consistent with the properties required for its function, constructibility, and endurance. In addition to conventional soils and materials testing, geosynthetic testing will very likely be required. Finally, as with any other construction, design with geosynthetics is not complete until construction has been satisfactorily carried out. Therefore, careful field inspection during construction is essential for a successful project.

Properties and Tests

Because of the wide variety of geosynthetics available (Fig. 24.1), along with their different polymers, filaments, bonding mechanisms, thicknesses, masses, and so on, they have a wide range of physical and mechanical properties. A further complicating factor is the variability of some properties, even within the same manufactured lot or roll. Differences may sometimes be due to the test procedures themselves.

Many of our current geosynthetic tests were developed by the textile and polymer industries, often for quality control of the manufacturing process. Consequently the test values from these tests may not relate well to the civil engineering conditions of a particular application. Furthermore, soil confinement or interaction is not accounted for in most geosynthetics testing. Research is now underway to provide test procedures and soil–geosynthetic interaction properties which are more appropriate for design. Geotextile testing is discussed in detail by Christopher and Holtz [1985] and Koerner [1990a].

Specifications

Good specifications are essential for the success of any civil engineering project, and this is even more critical for projects in which geosynthetics are to be used. Christopher and DiMaggio [1984] provide some guidance on writing generic and performance-based geotextile specifications.

24.2 Filtration, Drainage, and Erosion Control

One of the most important uses for geotextiles is as a filter in drainage and erosion control applications. Drainage examples include trench and French drains, interceptor drains, blanket drains, pavement edge

drains, and structural drains, to name just a few. Permanent erosion control applications include coastal and lakeshore revetments, stream and canal banks, cut and fill slope protection, and scour protection. In all these applications, geotextiles are used to replace graded granular filters used in conjunction with the drainage aggregate, perforated pipe, rip rap, and so on. When properly designed, geotextiles can provide comparable performance at less cost, provide consistent filtration characteristics, and they are easier and therefore cheaper to install. Although erosion control technically does not improve the soil, prevention of both external and internal erosion in residual and structured soils is an important design consideration.

Geotextiles can also be used to temporarily control and minimize erosion or transport of sediment from unprotected construction sites. In some cases, geotextiles provide temporary protection after seeding and mulching but before vegetative ground cover can be established. Geotextiles may also be used as armor materials in diversion ditches and at the ends of culverts to prevent erosion. Probably the most common application is for silt fences, which are a substitute for hay bales or brush piles, to remove suspended particles from sediment-laden runoff water.

Filtration Design Concepts

For a geotextile to satisfactorily replace a graded granular filter, it must perform the same functions as a graded granular filter: (1) prevent soil particles from going into suspension; (2) allow soil particles already in suspension to pass the filter (to prevent clogging or blinding); and (3) have a sufficiently high permeability and flow rate so that no back pressure develops in the soil being protected.

How a geotextile filter functions is discussed in detail by Bell et al. [1980, 1982], Rankilor [1981], Christopher and Holtz [1985], and Koerner [1990a]. The factors that control the design and performance of a geotextile filter are (1) physical properties of the geotextile, (2) soil characteristics, (3) hydraulic conditions, and (4) external stress conditions.

After a detailed study of research carried out here and in Europe on both conventional and geotextile filters, Christopher and Holtz [1985] developed a widely used design procedure for geotextile filters for drainage and permanent erosion-control applications. The level of design required depends on the critical nature of the project and the severity of the hydraulic and soil conditions. Especially for critical projects, consideration of the risks involved and the consequences of possible failure of the geotextile filter require great care in selecting the appropriate geotextile. For such projects and for severe hydraulic conditions, very conservative designs are recommended. As the cost of the geotextile is usually a minor part of the total project or system cost, geotextile selection should not be based on the lowest material cost. Also, expenses should not be reduced by eliminating laboratory soil–geotextile performance testing when such testing is recommended by the design procedure.

The three design criteria which must be satisfied are (1) soil retention (piping resistance), (2) permeability, and (3) clogging criteria. For both permeability and clogging, different approaches are recommended for critical/severe applications. Furthermore, laboratory filtration tests must be performed to determine clogging resistance. It is not sufficient to simply rely on retention and permeability to control clogging potential. Finally, mechanical and index property requirements for durability and constructibility are given. Constructibility is sometimes called *survivability,* and it depends on the installation conditions. The best geotextile filter design in the world is useless if the geotextile does not survive the construction operations.

Fischer et al. [1990] have proposed a design procedure based on the pore size distribution of the geotextile filter.

Applications

The more common applications of geotextiles in drainage and erosion control are shown in Figs. 24.2, 24.3, and 24.4. Construction of geotextile filters in these applications is described in detail by Christopher and Holtz [1985, 1989].

Prefabricated Drains

In the last few years, prefabricated geocomposite drainage materials have become available as a substitute for conventional drains with and without geotextiles. Geocomposites are probably most practical for lateral drainage situations [Figs. 24.2(b), (c), and (e)] and in waste containment systems in conjunction with clay or geomembrane liners [Koerner, 1990a]. Another important soil improvement application of

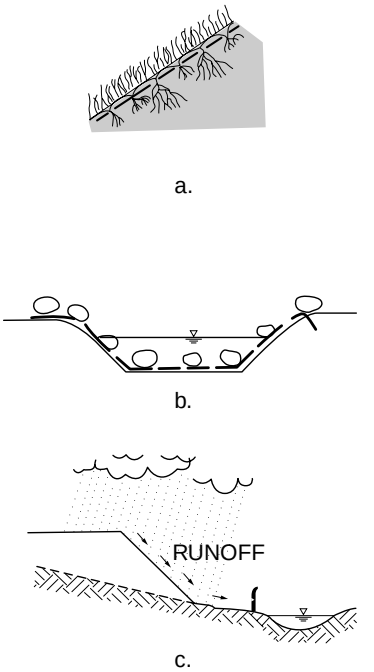

FIGURE 24.4 Temporary erosion control applications: (a) vegetative cover, (b) diversion ditches, and (c) silt fences. (*Source:* Christopher, B. R., and Holtz, R. D. 1989. *Geotextile Design and Construction Guidelines*. U.S. Federal Highway Administration, National Highway Institute, Report No. FHWA-HI-90-001.)

geocomposites is the use of prefabricated vertical ("wick") drains to accelerate the consolidation of soft compressible cohesive soil layers. Because they are much less expensive to install, geocomposite drains have made conventional sand drains obsolete. Design principles and installation techniques are given by Holtz et al. [1991].

24.3 Geosynthetics in Temporary and Permanent Roadways and Railroads

A very important use of geosynthetics is to stabilize roadways and railroads. The primary function of the geosynthetic in these applications is that of separation; secondary functions such as filtration, drainage, and possibly reinforcement may also be more or less present. Recommended references on geotextiles in various aspects of roads and railroads are Steward et al. [1977], Rankilor [1981], Christopher and Holtz [1985, 1989], Fluet [1986], and Koerner [1990a].

In the early days of geotextiles, a number of design procedures were developed to use geotextiles in temporary facilities such as haul roads, contractor staging yards, mine and timber storage and haulage facilities, temporary construction platforms, and so on. Virtually all methods provided design charts which indicated that the use of a geotextile could reduce the thickness of aggregate required for a given subgrade and traffic condition. Unfortunately, most of these design methods permitted some rutting to occur in the subgrade even with the geotextile in place; obviously, rutting is not desirable for permanent facilities. Although the geotextile functions are similar for both temporary and permanent roadways, because of the difference in performance requirements, design methods for temporary roads should *not* be used to design permanent roads. However, as noted by Christopher and Holtz [1985], there still are a number of significant advantages to using geotextiles in permanent roadways.

Geosynthetics in roadways are most cost effective on soft subgrades (CBR values less than 2) with sensitive silty or clayey soils (CH, ML, MH, A-6, A-7, etc.), and at sites with the water table near the ground surface and where there is poor equipment mobility. If such conditions are present in residual and structured soil subgrades, geotextiles should also be effective stabilizers of subgrades on these soils. One important consequence of using geotextiles in roadway construction is that the contractors are required to be more careful during construction to avoid damaging the geotextile. Such care usually results in reduced stress and damage to the subgrade soils, which is especially appropriate for residual and structured soil subgrades.

Although there is strong evidence that the primary function of geotextiles in roadways is separation [Steward et al., 1977], research has suggested a number of possible geosynthetic reinforcement mechanisms [Christopher and Holtz, 1985]. For example, a geogrid placed in the aggregate base course will provide a significant increase in load-carrying capacity [Haas et al., 1988].

Design Approaches

Design of geosynthetics in both temporary and permanent roadways is discussed at length by Christopher and Holtz [1985, 1989] and Koerner [1990a]. Recommended temporary road design methods are discussed by Steward, et al. [1977], Bender and Barenberg [1978], Giroud and Noiray [1981], Haliburton and Barron [1983], Houlsby et al. [1989], and Milligan et al. [1989]. The last two papers are summarized by Jewell [1990].

Because most of the available design methods for permanent roadways lack field or controlled experimental verification, Christopher and Holtz [1991] proposed a simple procedure which assumes that the first aggregate stabilization layer often required to permit construction at very soft, wet sites acts as an unpaved road subjected to only a few passes of construction equipment. The geotextile acts primarily as a separator, and geotextile survivability must be taken into account [Christopher and Holtz, 1985, 1989]. It should be noted that no structural support is attributed to the geotextile in this design procedure. The method does not change the design thickness required for traffic or other design considerations. It only allows aggregate to be saved which would otherwise be consumed in constructing the first stabilization lift.

Detailed guidelines for the construction of roads using geotextiles are given by Christopher and Holtz [1985, 1989].

24.4 Geosynthetics for Reinforcement

One of the most important applications of geosynthetics in geotechnical engineering is soil reinforcement, an important aspect of soil improvement. Applications include reinforcing the base of embankments constructed on very soft foundations, increasing the stability and steepness of slopes, and reducing the earth pressures behind retaining walls and abutments. In the first two applications, geosynthetics permit construction that otherwise would be cost-prohibitive or in some cases impossible. In the case of retaining walls, significant cost savings are possible in comparison with conventional retaining wall construction.

Other reinforcement and stabilization applications in which geosynthetics have also proven to be very effective include large area stabilization and natural slope reinforcement.

Reinforced Embankments

In only a few years, geosynthetic reinforcement has joined the list of the more traditional soil improvement methods for increasing the stability of embankments on very soft foundations. Concepts for using geosynthetics for reinforcement are indicated in Fig. 24.5. Discussion of these concepts as well as detailed design procedures are given by Christopher and Holtz [1985, 1989], Bonaparte et al. [1987], Bonaparte and Christopher [1987], Holtz [1989a, 1989b, 1990], and Humphrey and Rowe [1991]. As our approach is to design against failure, types of unsatisfactory behavior (Fig. 24.6) which are likely to require reinforcement must be assumed so that an appropriate stability analysis may be carried out.

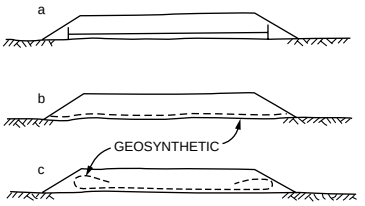

FIGURE 24.5 Concepts for using geosynthetics to reinforce embankments. (*Source:* Holtz, R. D. 1990. Design and construction of geosynthetically reinforced embankments on very soft soils. In *Performance of Reinforced Soil Structures, Proc. Int. Reinforced Soil Conf.* Glasgow, British Geotechnical Society, pp. 391–402.)

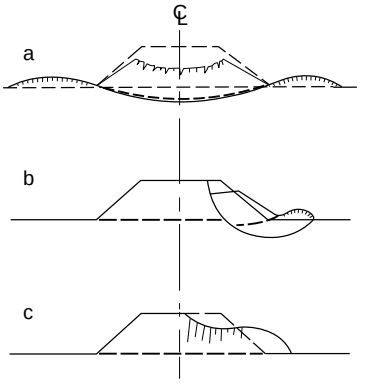

FIGURE 24.6 Unsatisfactory behavior that may occur in reinforced embankments. (*Source:* Christopher, B. R., and Holtz, R. D. 1989. *Geotextile Design and Construction Guidelines.* U.S. Federal Highway Administration, National Highway Institute, Report No. FHWA-HI-90-001.)

The design steps are as follows:

1. Check overall bearing capacity.
2. Check edge bearing capacity or edge slope stability.
3. Conduct a sliding wedge analysis for embankment spreading.
4. Perform an analysis to limit geosynthetic deformations.
5. Determine geosynthetic strength requirements in the longitudinal direction.

Based on these stability calculations, the minimum geosynthetic strengths required for stability at an appropriate factor of safety can be determined. A detailed discussion of geosynthetic properties and specifications is given in the references cited above.

The importance of proper construction procedures for geosynthetic reinforced embankments cannot be overemphasized. A specific construction sequence is usually required in order to avoid failures during construction. Appropriate site preparation, low ground pressure equipment, small initial lift thicknesses, and partially loaded hauling vehicles may be required. Fill placement, spreading, and compaction procedures are also very important. A detailed discussion of construction procedures for reinforced embankments on very soft foundations is given by Christopher and Holtz [1985, 1989].

It should be noted that all geosynthetic seams must be positively joined. For geotextiles, this means sewing; for geogrids, some type of positive clamping arrangement must be used. Careful inspection is essential, as the seams are the "weak link" in the system and seam failures are common in embankments which are improperly constructed.

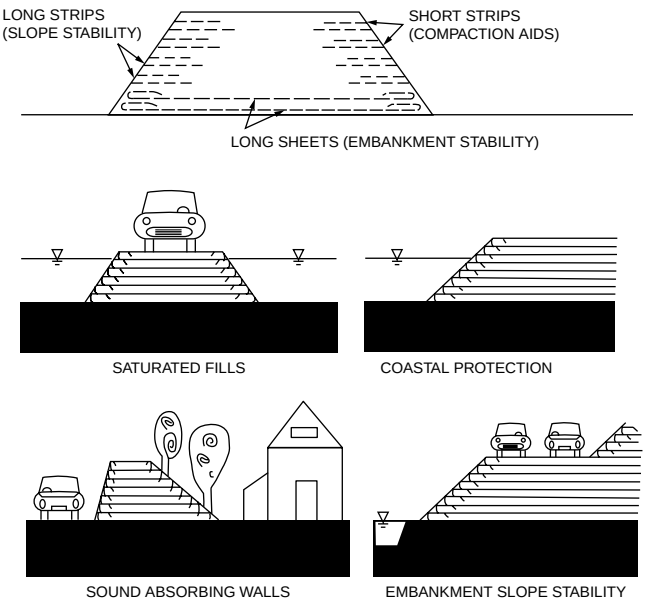

FIGURE 24.7 Examples of multilayer geosynthetic slope reinforcement. (*Source:* Christopher, B. R., and Holtz, R. D. 1985. *Geotextile Engineering Manual*. STS Consultants Ltd., Northbrook, IL; U.S. Federal Highway Administration, Report No. FHWA-TS-86/203.)

Slope Stability

Geosynthetics have been very effectively used many times both here and abroad to stabilize failed slopes. Cost savings result because the slide debris is reused together with geosynthetic reinforcement in the reinstatement of the slope. It is also possible that even though foundation conditions are satisfactory, slopes of a compacted embankment fill may be unstable at the desired slope angle. Costs of fill and right-of-way plus other considerations may require a steeper slope than is stable in compacted soils. Typically, embankment slope reinforcement is placed in layers as the embankment is constructed in lifts (see Fig. 24.7).

Embankment slope stability analyses have been developed by Murray [1982], Jewell et al. [1984], Schneider and Holtz [1986], Schmertmann et al. [1987], Verduin and Holtz [1989], Christopher et al. [1989], and Christopher and Leshchinsky [1991].

Reinforced Retaining Walls and Abutments

Retaining walls are used where a slope is uneconomical or not technically feasible. Retaining walls with reinforced backfills are very cost-effective, especially for higher walls; also, they are more flexible and thus more suitable for poor foundation conditions. The concept was developed in France by H. Vidal in the mid-1960s. His system, called *reinforced earth,* is shown in Fig. 24.8. Steel strips or ties are used to reduce the earth pressure against the wall face ("skin"). The design and construction of Vidal-type reinforced earth walls are now well established, and many thousands have been successfully built throughout the world in the last 25 years.

The use of geotextiles as reinforcing elements started in the early 1970s because of questions about possible corrosion of the metallic strips in reinforced earth. Systems using sheets of geosynthetics rather than steel strips are shown in Fig. 24.9. The most commonly used system is shown in Fig. 24.9(a), in which the geosynthetic provides the facing as well as the reinforcing elements in the wall.

Most designs of geotextile reinforced retaining walls utilize classical earth pressure theory combined with tensile-resistance *tiebacks,* in which the reinforcement extends back beyond the assumed failure

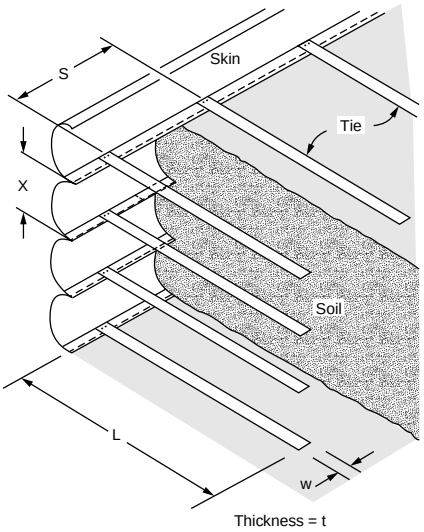

FIGURE 24.8 Components of reinforced earth. (*Source:* Lee, K. L., Adams, B. D., and Vagneron, J. M. J. 1973. Reinforced earth retaining walls. *J. Soil Mech. Found., ASCE.* 99(SM10):745–764.)

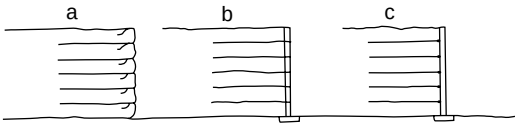

FIGURE 24.9 Reinforced retaining wall systems using geosynthetics: (a) with wraparound geosynthetic facing, (b) with segmented precast concrete or timber panels, and (c) with full height ("propped") precast panels.

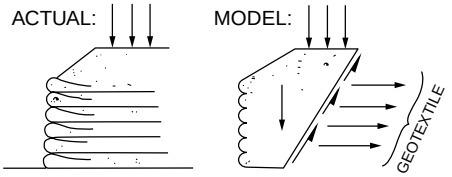

FIGURE 24.10 Actual geosynthetic-reinforced wall compared to its analytical model. (*Source:* Christopher, B. R., and Holtz, R. D. 1985. *Geotextile Engineering Manual.* STS Consultants Ltd., Northbrook, IL; U.S. Federal Highway Administration, Report No. FHWA-TS-86/203.)

plane (see Fig. 24.10). This approach is discussed by Christopher and Holtz [1985, 1989], Bonaparte et al. [1987], Christopher et al. [1989], and Allen and Holtz [1991]. Both internal and external stability must be considered. Failure modes and geosynthetic properties required for design are given in Table 24.2; these are patterned after the failure modes for reinforced earth. Christopher and Holtz [1985, 1989], Bonaparte et al. [1987], and Christopher et al. [1989] discuss how these properties may be obtained by laboratory and other tests.

Typically, sliding of the entire reinforced mass controls the length of the reinforcing elements. Thus Christopher and Holtz [1989] and Christopher et al. [1989] recommend starting with a sliding analysis first (considering surcharges, etc.) and then designing for internal stability before proceeding to check the other components of external stability (bearing capacity, overturning, and slope stability). Surcharges may be considered in the usual manner, and both stiff and flexible facings are possible. For design, K_0 and K_A may be assumed, depending on the rigidity of the facing and the amount of yielding likely to occur during construction.

TABLE 24.2 Failure Modes in Geosynthetically Reinforced Retaining Walls

Geosynthetic Failure Mode	Corresponding Reinforced Earth Failure Mode	Property Required
Geosynthetic rupture	Ties break	Geosynthetic tensile strength
Geosynthetic pullout	Ties pull out	Soil-geosynthetic friction
Creep	Creep	Creep resistance

Backfill for geosynthetically reinforced walls should be free draining. This is important for stability considerations and because an impervious permanent facing is often used; thus, drainage outward through the wall face may not be possible. For permanent construction, some type of permanent facing is required because of possible deterioration of the geosynthetic due to ultraviolet radiation. This is the only application in which the geosynthetic is not entirely buried, and consequently, some ultraviolet deterioration and loss of stability, at least locally, is possible. Permanent facings which have been successfully used include shotcrete, sprayed asphalt emulsion, precast concrete elements hung on the wall, segmented precast concrete blocks, and separate timber or precast concrete facades.

Construction procedures for geosynthetic reinforced walls and abutments are quite straightforward. Details are given by Steward et al. [1977] and Christopher and Holtz [1985, 1989].

24.5 Geosynthetics in Waste Containment Systems

Geomembranes and geocomposite drainage systems are commonly used today in the construction and remediation of containment and disposal systems for hazardous, industrial, and domestic wastes. Although not directly part of soil improvement, their importance in environmental geotechnology deserves special mention. Tremendous advances have been made in recent years in geomembrane technology, yet the seams and joints between sheets of geomembrane are still the weak link in these systems. Inspection during construction is crucial; improper installation or damage to the membrane during construction operations may compromise the integrity of the entire containment system. Helpful references on geomembrane technology and related systems include Koerner [1990a, 1990b], Bonaparte [1990], and Rollin and Rigo [1991].

Defining Terms

Geomembrane — Continuous membrane-type liners and barriers composed of asphaltic, polymeric, or a combination of asphaltic and polymeric materials with sufficiently low permeability so as to control fluid migration in a geotechnical engineering-related man-made project, structure, or system.

Geotextile — The American Society for Testing and Materials (ASTM) has defined a *geotextile* as any permeable textile material used with foundation, soil, rock, earth, or any other geotechnical engineering-related material as an integral part of a man-made project, structure, or system.

25.1 Introduction

Geotechnical factors often exert a major influence on damage patterns and loss of life in earthquake events. For example, the localized patterns of heavy damage during the 1985 Mexico City and 1989 Loma Prieta, California, earthquakes provide grave illustrations of the importance of understanding the seismic response of deep clay deposits and loose, saturated sand deposits. The near failure of the Lower San Fernando dam in 1971 due to liquefaction of the upstream shell materials is another grave reminder that we must strive to understand the seismic response of critical earth structures. The characteristics and distribution of earth materials at a project site significantly influence the characteristics of the earthquake ground motions, and hence significantly influence the seismic response of the constructed facilities at a site. Moreover, the composition and geometry of earth structures, such as earth dams and solid waste landfills, significantly affect their seismic response. Geotechnical considerations therefore play an integral role in the development of sound earthquake-resistant designs. In this chapter, geotechnical earthquake engineering phenomena such as site-specific amplification, soil liquefaction, and seismic slope stability are discussed. Case histories are used to illustrate how earthquakes affect engineered systems, and established, simplified empirical procedures that assist engineers in assessing the effects of these phenomena are presented. The field of earthquake engineering is quite complex, so the need for exercising engineering judgment based on appropriate experience is emphasized.

25.2 Earthquake Strong Shaking

The development and transmission of earthquake energy through the underlying geology is quite complex, and a site-specific seismic response study requires an assessment of the primary factors influencing the ground motion characteristics at a site. They are

- Earthquake source mechanism
- Travel path geology

- Topographic effects
- Earthquake magnitude
- Distance from zone of energy release
- Local soil conditions

Earthquakes are produced in a particular geologic setting due to specific physical processes. A midplate earthquake (e.g., New Madrid) will differ from a plate margin earthquake (e.g., San Andreas) [see Nuttli, 1982]. The principal descriptive qualities of the earthquake source are the type of fault displacement (strike-slip, normal, or reverse), depth of the rupture, length of the rupture, and duration of the rupturing. The characteristics of the rock which the seismic waves travel through influence the frequency content of the seismic energy. Significant topographic features (e.g., basins) can focus and hence amplify earthquake motions. The **magnitude** of an earthquake is related to the amount of energy released during the event. The difference between earthquakes of different magnitudes is significant; for example, a magnitude 7 earthquake event releases nearly a thousand times more energy than a magnitude 5 event. The potential for seismic damage will typically increase with earthquake events of greater magnitude. Seismic energy attenuates as it travels away from the zone of energy release and spreads out over a greater volume of material. Hence, the intensity of the bedrock motion will typically decrease as the distance of a particular site from the zone of energy release increases. A number of **attenuation relationships** based on earthquake magnitude and distance from the earthquake fault rupture are available [e.g., Nuttli and Herrmann, 1984; Joyner and Boore, 1988; Idriss, 1991]. Local soil conditions may significantly amplify ground shaking, and some soil deposits may undergo severe strength loss resulting in ground failure during earthquake shaking. The last three factors listed above (magnitude, distance, local soil conditions) are usually the most important factors, and most seismic studies focus on these factors.

There are several earthquake magnitude scales, so it is important to use these scales consistently. The earliest magnitude scale, local magnitude (M_L), was developed by Richter [1935] and is defined as the logarithm of the maximum amplitude on a Wood-Anderson torsion seismogram located at a distance of 100 km from the earthquake source [Richter, 1958]. Other related magnitude scales include surface wave magnitude, M_s, and body wave magnitudes, m_b and m_B [Gutenberg and Richter, 1956]. These magnitude scales are based on measurement of the amplitude of the seismic wave at different periods (M_L at 0.8 s, m_b and m_B between 1 s and 5 s, and M_s at 20 s), and hence they are not equivalent. The moment magnitude, M_w, is different from these other magnitude scales because it is directly related to the dimensions and characteristics of the fault rupture. Moment magnitude is defined as

$$M_w = \frac{2}{3} \log M_0 - 10.7 \tag{25.1}$$

where M_0 is the seismic moment in dyne-cm, with $M_0 = \mu \cdot A_f \cdot D$; μ = shear modulus of material along the fault plane (typically 3×10^{11} dyne/cm^2), A_f = area of fault rupture in cm^2, and D = average slip over the fault rupture in cm [Hanks and Kanamori, 1979]. Heaton et al. [1982] has shown that these magnitude scales are roughly equivalent up to $M_w = 6$, but that magnitude scales other than M_w reach limiting values for higher moment magnitude earthquake events (i.e., $\max m_b \approx 6$, $\max M_L \approx 7$, $\max m_B \approx 7.5$, and $\max M_s \approx 8$). Thus, the use of moment magnitude is preferred, but the engineer must use the appropriate magnitude scale in available correlations between engineering parameters and earthquake magnitude.

The earthquake motion characteristics of engineering importance are

- Intensity
- Frequency content
- Duration

The intensity of ground shaking is usually portrayed by the **maximum horizontal ground acceleration (MHA)**, but since velocity is a better indicator of the earthquake energy that must be dissipated by an engineered system, it should be used as well. The MHA developed from a site-specific seismicity study

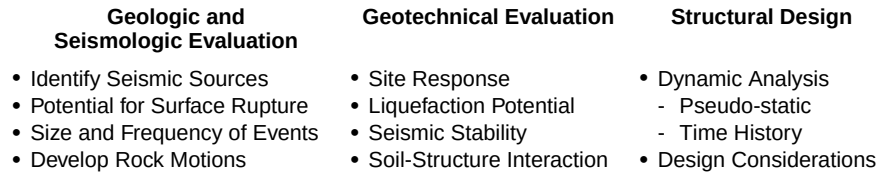

FIGURE 25.1 Seismic hazard assessment.

should be compared to that presented in the U.S. Geological Survey maps prepared by Algermissen et al. [1991] and the seismic zone factor (Z) given in the Uniform Building Code. The frequency content of the ground motions is typically characterized by its **predominant period** ($\mathbf{T_p}$). The predominant period of the ground motions at a site tends to increase with higher magnitude events and with greater distances from the zone of energy release [see Idriss, 1991]. Earthquake rock motions with a concentration of energy near the fundamental periods of the overlying soil deposit and structure have a greater potential for producing amplified shaking and seismic damage. Lastly, the **duration of strong shaking** is related to the earthquake's magnitude and is typically described by the duration of the earthquake record in which the intensity is sufficiently high to be of engineering importance (i.e., MHA exceeding around 0.05g) or the equivalent number of cycles of strong shaking [see Seed and Idriss, 1982].

A seismic hazard assessment generally involves those items listed in Fig. 25.1. Earthquake engineering is a multidisciplinary field that requires a coordinated effort. The success of the geotechnical evaluation depends greatly on the results of the geological and seismological evaluation, and the results of the geotechnical evaluation must be compatible with the requirements of the structural design.

25.3 Site-Specific Amplification

The localized patterns of heavy damage during the 1989 Loma Prieta earthquake in northern California demonstrate the importance of understanding the seismic response of deep soil deposits. Well over half of the economic damage and more than 80% of the loss of life occurred on considerably less than 1% of the land within 80 km of the fault rupture zone largely as a result of site-specific effects [Seed et al., 1990]. For example, in the Oakland area, which is 70 km away from the rupture zone, maximum horizontal ground accelerations were amplified by a factor of 2 to 4 and spectral accelerations at some frequencies were amplified by a factor of 3 to 8 [Bray et al., 1992]. The dramatic collapse of the elevated highway I-880 structure, in which 38 people died, is attributed in part to these amplified strong motions [Hough et al., 1990]. Hundreds of buildings in the San Francisco Bay area sustained significant damage because of earthquake strong shaking. These observations are critical to many cities as deep soil deposits exist in many earthquake-prone areas around the world. For example, records of the January 31, 1986 northeastern Ohio earthquake suggest that similar site-specific amplification effects could occur in the central U.S. and produce heavy damage during a major event in the New Madrid seismic zone [Nuttli, 1987].

Response spectra are typically used to portray the characteristics of the earthquake shaking at a site. The **response spectrum** shows the maximum response induced by the ground motions in damped single-degree-of-freedom structures of different **fundamental periods**. Each structure has a unique fundamental period at which the structure tends to vibrate when it is allowed to vibrate freely without any external excitation. The response spectrum indicates how a particular structure with its inherent fundamental period would respond to the earthquake ground motion. For example, referring to Fig. 25.2, a low-period structure (say, $T = 0.1$ s) at the SCT building site would experience a maximum acceleration of 0.14g, whereas a higher-period structure (say, $T = 2.0$ s) at the SCT site would experience a maximum acceleration of 0.74g for the same ground motions.

The response spectra shown in Fig. 25.2 illustrate the pronounced influence of local soil conditions on the characteristics of the observed earthquake ground motions. Since Mexico City was located approximately 400 km away from the earthquake's epicenter, the observed response at rock and hard soil sites

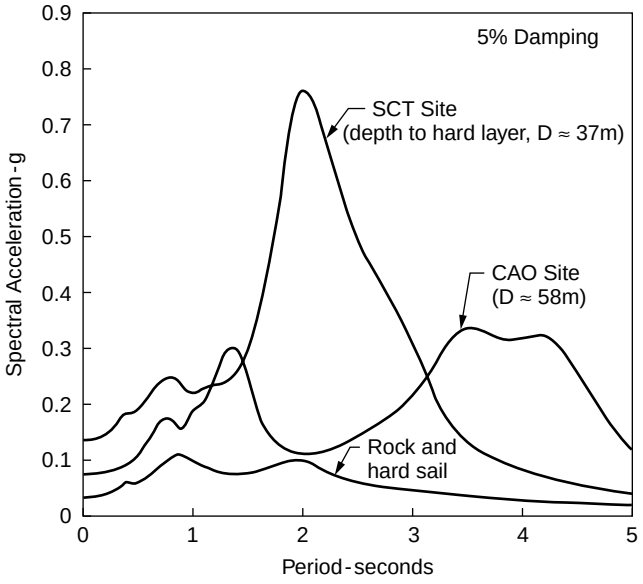

FIGURE 25.2 Acceleration response spectra for motions recorded in Mexico City during the 1985 Mexico City earthquake (after Seed, H. B., Romo, M. P., Sun, J., Jaime, A., and Lysmer, J. 1987. Relationships between Soil Conditions and Earthquake Ground Motions in Mexico City in the Earthquake of Sept. 19, 1985. Earthquake Engineering Research Center, Report No. UCB/EERC-87/15, University of California, Berkeley).

was fairly low (i.e., the spectral accelerations were less than 0.1*g* at all periods). Damage was correspondingly negligible at these sites. At the Central Market site (CAO), spectral accelerations were significantly amplified at periods of around 1.3 s and within the range of 3.5 s to 4.5 s. Since buildings at the CAO site did not generally have fundamental periods within these ranges, damage was fairly minor. The motion recorded at the SCT building site, however, indicated significant amplification of the underlying bedrock motions with a maximum horizontal ground acceleration (the spectral acceleration at a period of zero) over four times that of the rock and hard soil sites and with a spectral acceleration at $T = 2.0$ s over seven times that of the rock and hard soil sites. Major damage, including collapse, occurred to structures with fundamental periods ranging from about 1 s to 2 s near the SCT building site and in areas with similar subsurface conditions. At these locations, the soil deposit's fundamental period *matched* that of the overlying structures, creating a resonance condition that amplified strong shaking and caused heavy damage.

The 1991 Uniform Building Code (UBC) utilizes site coefficients in its pseudostatic design base shear procedure to limit damage due to local soil conditions (see Table 25.1). For example, the site coefficient for soil characteristics (S factor) is increased to 2.0 for the soft soil profile S_4, and an S factor of 1.0 is used at rock sites where no soil-induced amplification occurs. However, a deposit of stiff clay greater than 61 m thick, such as those that underlay Oakland, would be categorized as soil profile S_2 with an S factor of only 1.2. The seismic response of the deep stiff clay sites during the 1989 Loma Prieta earthquake with spectral amplification factors on the order of 3 to 8 suggest that we may be currently underestimating the seismic hazard at these sites. Earthquake engineering is a relatively young field of study, and additional research is required to support the evolution of safer building codes.

The UBC also allows dynamic analyses of structural systems and provides the normalized response spectra shown in Fig. 25.3. The spectral acceleration of a structure can be estimated from this figure given an estimate of the system's fundamental period (T), the peak ground acceleration (MHA) of the design event, and the classification of the subsurface soil conditions. At longer periods ($T > 0.5$ s), the spectral accelerations for deep soil sites (soil type 2) and soft soil sites (soil type 3) are significantly higher than that for rock and stiff soils (soil type 1). The engineer can also use wave propagation analyses [e.g., SHAKE91; see Idriss and Sun, 1992] to develop a site-specific design response spectrum based on the

TABLE 25.1 1991 UBC Site Coefficients[a,b]

Type	Description	*S* factor
S_1	A soil profile with either (a) a rock-like material characterized by a shear wave velocity greater than 762 mps or by other suitable means of classification, or (b) stiff or dense soil condition where the soil depth is less than 61 m	1.0
S_2	A soil profile with dense or stiff soil conditions where the soil depth exceeds 61 m	1.2
S_3	A soil profile 21 m or more in depth and containing more than 6 m of soft to medium stiff clay but not more than 12 m of soft clay	1.5
S_4	A soil profile containing more than 12 m of soft clay characterized by a shear wave velocity less than 152 mps	2.0

[a] The site factor shall be established from properly substantiated geotechnical data. In location where the soil properties are not known in sufficient detail to determine the soil profile type, soil profile S_1 shall be used. Soil profile S_4 need not be assumed unless the building official determines that soil profile S_4 may be present at the site, or in the event soil profile S_4 is established by geotechnical data.

[b] The total design base shear (V) is determined from the formula $V = Z \cdot I \cdot C \cdot W/R_w$, where $C = 1.225S/T^{2/3} \leq 2.75$. Z = seismic zone factor, I = importance factor, S = site coefficient, T = fundamental period of structure, W = total seismic dead load, and R_w = reduction coefficient based on the lateral load-resisting system (see UBC). Hence $V \propto S$ if $C < 2.75$.

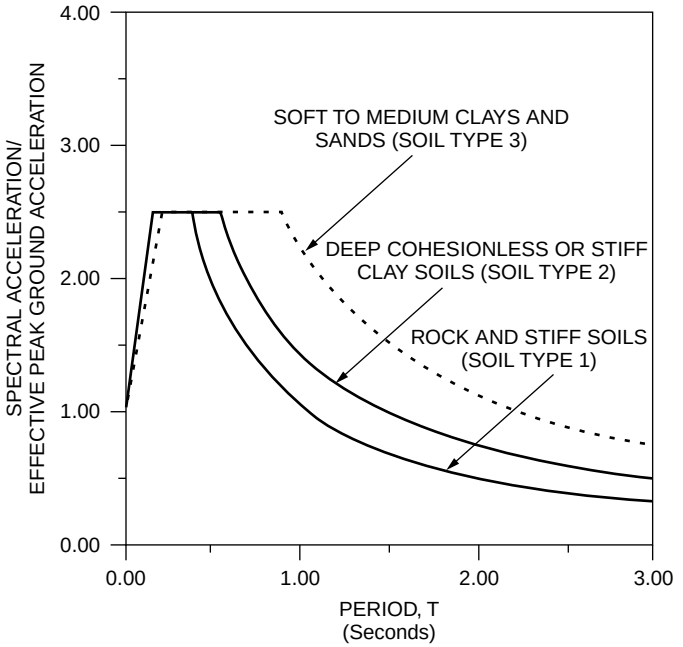

FIGURE 25.3 1991 UBC normalized acceleration response spectra.

geologic, seismologic, and soil characteristics associated with the project site. The seismic response of earth materials is dictated primarily by geometric considerations and by the soil's dynamic properties (e.g., shear modulus and damping characteristics). The shear modulus gives an indication of the stiffness of the soil system, whereas the **damping ratio** provides a measure of the soil system's ability to dissipate energy under cyclic loading. Soils exhibit strain-dependent dynamic properties so that as earthquake strong shaking increases and the strain induced in the soil increases, the material's damping ratio increases and its shear modulus decreases [see Seed et al., 1984; Vucetic and Dobry, 1991]. As material damping increases, the soil-induced amplification tends to decrease. As the material stiffness decreases, however, the fundamental period of the soil system increases, and this may affect the amplification of higher-period motions.

The amplification of higher-period ground motions that may match the fundamental period of the building located at the site is one of the most critical concerns in seismic site response studies. If the building's fundamental period is close to that of the site, an earthquake with a concentration of energy around this period would have the potential to produce heavy damage to this structure. The matching of the building and site fundamental periods creates a resonant condition that can amplify shaking. Consideration of a different structural system whose fundamental period does not match that of the underlying soil deposit might be prudent. Otherwise, the design criteria should be more stringent to limit damage to the building during an earthquake event.

Illustrative Site Response Problem

Problem 25.1

An eight-story building will be constructed at a deep soil site in Tennessee. As shown in Fig. 25.4, the deep soil site contains surficial deposits of loose, saturated sand overlying a thick clay deposit. The design earthquake is a magnitude (m_B) 7.5 event occurring at a distance of 130 km from the site. Develop a preliminary estimate of the maximum horizontal acceleration (MHA) at the site and evaluate the potential for soil-induced amplification of earthquake shaking near the building's fundamental period.

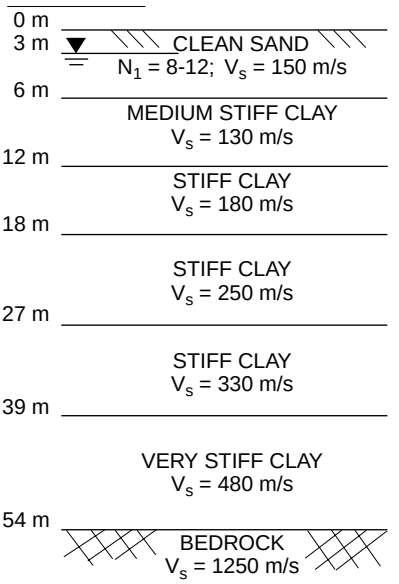

FIGURE 25.4 Subsurface conditions of project site discussed in Problem 25.1.

Earthquake Strong Shaking

Limited data is available to develop attenuation curves for the deeper-focus eastern-U.S. earthquakes, and hence this is an area of ongoing research. Nuttli and Herrmann [1984] proposed the attenuation curve shown in Fig. 25.5 for earthquakes likely to occur in the eastern and central U.S. For a site located 130 km from the zone of energy release for an m_B = 7.5 event, the bedrock MHA would be on the order of 0.1*g*. This magnitude of MHA is comparable with what established building codes (e.g., BOCA, SBCCI, and UBC) would recommend for the central part of the state of Tennessee. At this distance (130 km), a magnitude 7.5 earthquake would tend to produce bedrock strong shaking with a predominant period within the range of 0.4 s to 0.7 s [Idriss, 1991].

Site-Specific Amplification

Comparisons between MHA recorded at deep clay soil sites and those recorded at rock sites indicate that MHA at deep clay soil sites can be 1 to 3 times greater than those at rock sites when $MHA_{rock} \approx 0.1g$ [Bray et al., 1992; Idriss, 1991]. The results of one-dimensional (columnar) dynamic response analyses also suggest MHA amplification factors on the order of 1 to 3 for deep clay sites at low values of MHA_{rock}. A proposed relationship between the MHA at soft clay sites and the MHA at rock sites is shown in Fig. 25.6. The estimated rock site MHA value of 0.1*g* would be increased to 0.2*g* for this deep clay site using the average site amplification factor of 2.

The fundamental period of typical buildings can be estimated using the 1991 UBC formula: $T = C_t \cdot (h_n)^{3/4}$, where T = building's fundamental period (s), C_t = structural coefficient = 0.020 for a typical building, and h_n = height of the building (ft). A rough estimate of a level site's fundamental period can be calculated by the formula $T_s = 4D/V_s$, where T_s = the site's fundamental period, D = the soil thickness, and V_s = the soil's average **shear wave velocity**. Computer programs such as SHAKE91 can calculate the site's fundamental period as well as calculate horizontal acceleration and shear stress time histories throughout the soil profile.

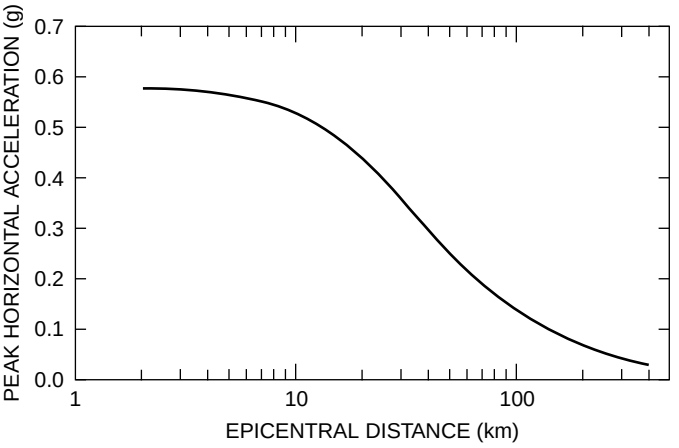

FIGURE 25.5 MHA attenuation relationship proposed by Nuttli and Herrmann [1984] for $m_B = 7.5$ earthquake in the central U.S.

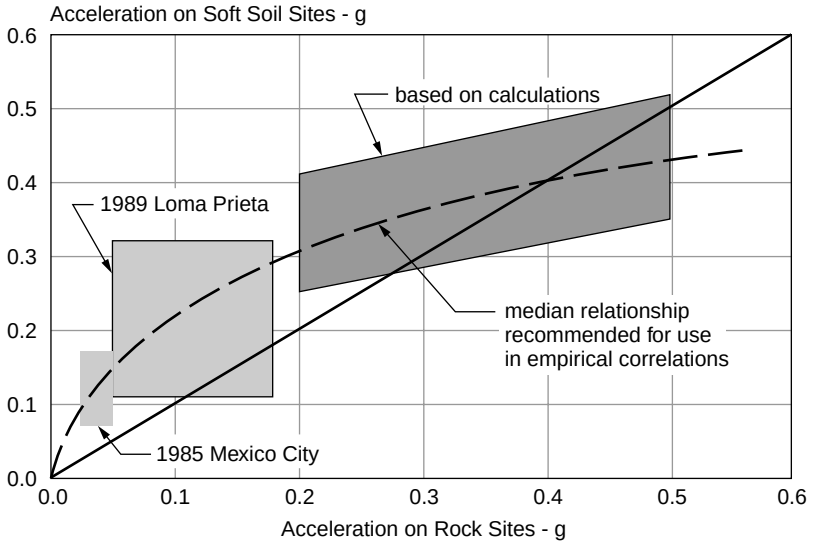

FIGURE 25.6 Variations of peak horizontal accelerations (MHA) at soft soil sites with accelerations at rock sites (after Idriss, I. M. 1991. Earthquake Ground Motions at Soft Soil Sites. *Proceedings, Second International Conference on Recent Advances in Geotechnical Engineering and Soil Dynamics,* March 11–15, St. Louis, pp. 2265–2272).

Assuming a story height of 13 feet (4 m), the eight-story building would be 104 feet (32 m) high, and $T = 0.020 \cdot (104 \text{ ft})^{3/4} = 0.65$ s. The soil deposit's average initial shear wave velocity is estimated to be $V_s = [(150 \text{ m/s})(6 \text{ m}) + (130 \text{ m/s})(6 \text{ m}) + (180 \text{ m/s})(6 \text{ m}) + (250 \text{ m/s})(9 \text{ m}) + (330 \text{ m/s})(12 \text{ m}) + (480 \text{ m/s})(15 \text{ m})]/54 \text{ m} = 300$ m/s. The site's fundamental period at low levels of shaking is then approximately $T_s = 4 \cdot (54 \text{ m})/300 \text{ m/s} = 0.72$ s. As a check, SHAKE91 analyses calculate the site's fundamental period to be 0.71 seconds, which is in close agreement with the first estimate ($T_s = 0.72$ s).

Since the building's fundamental period ($T = 0.65$ s) is close to that of the site ($T_s = 0.72$ s), an earthquake with a concentration of energy around 0.6 to 0.7 s would have the potential to produce heavy damage to this structure. In fact, SHAKE91 results indicate a maximum spectral acceleration amplification factor of almost 15 at a period around 0.7 s. In comparison, this site would be classified as an S_3 site with a site coefficient (or site amplification factor) of 1.5, and the design base shear would be

multiplied by an amplification factor of $C = 2.5$ for this site (see Table 25.1). Alternatively, using the normalized response spectrum for deep stiff clay soils in the UBC (Fig. 25.3), the spectral response at $T = 0.7$ s would be twice the MHA value of $0.2g$.

25.4 Soil Liquefaction

Unlike many other construction materials, cohesionless soils such as sand possess negligible strength without effective confinement. The overall strength of an uncemented sand depends on particle interaction (interparticle friction and particle rearrangement), and these particle interaction forces depend on the effective confining stresses. Soil **liquefaction** is a phenomenon resulting when the pore water pressure (the water pressure in the pores between the soil grains) increases, thereby reducing the effective confining stress and hence the strength of the soil. Seed and Idriss [1982] present this qualitative explanation of soil liquefaction:

If a saturated sand is subjected to ground vibrations, it tends to compact and decrease in volume; if drainage is unable to occur, the tendency to decrease in volume results in an increase in pore water pressure, and if the pore water pressure builds up to the point at which it is equal to the overburden pressure, the effective stress becomes zero, the sand loses its strength completely, and it develops a liquefied state.

If the strength of the ground underlying a structure reduces below that required to support the overlying structure, excessive structural movements can occur and damage the structure. The pore water pressure in the liquefied soil may be sufficient to cause the liquefied soil to flow up through the overlying material to the ground surface producing sand boils, lateral spreading, and ground breakage. This dramatic seismic response of a saturated, loose sand deposit can pose obvious hazards to constructed facilities, and the potential for soil liquefaction should be assessed in seismic regions where such soil deposits exist.

An example of the structural damage that can result from soil liquefaction is shown in Fig. 25.7. The Marine Research Facility at Moss Landing, California was a group of modern one-and two-story structures founded on concrete slabs. This facility was destroyed beyond repair by foundation displacements as a result of liquefaction of the foundation soils during the 1989 Loma Prieta earthquake [Seed et al., 1990]. The facility settled a meter or two and lateral spreading of the structure "floating" on the liquefied soil below the slab foundation stretched the facility by 2 m, literally pulling it apart.

Engineering procedures for evaluating liquefaction potential have developed rapidly in the past twenty years, and a well-accepted approach is the Seed and Idriss [1982] simplified procedure for evaluating soil liquefaction potential. The average cyclic shear stress imparted by the earthquake in the upper 12 m of a soil deposit can be estimated using the equation developed by Seed and Idriss [1982]:

$$(\tau/\sigma_0')_d \approx 0.65 \cdot \mathrm{MHA}/g \cdot \sigma_0/\sigma_0' \cdot r_d \tag{25.2}$$

where

$(\tau/\sigma_0')_d$ = average cyclic stress ratio developed during the earthquake
MHA = maximum horizontal acceleration at the ground surface
g = acceleration of gravity
σ_0 = total stress at depth of interest
σ_0' = effective stress (total stress minus pore water pressure) at depth
r_d = reduction in acceleration with depth ($r_d \approx 1 - 0.008 \cdot$ depth, m)

For a magnitude (M_s) 7.5 event at a level ground site, the cyclic stress ratio required to induce liquefaction, $(\tau/\sigma_0')_l$, of the saturated sand deposit can be estimated using the empirically based standard penetration test (SPT) correlations developed by Seed et al. [1985]. The SPT blowcount (the number of hammer blows required to drive a standard sampling device 1 foot into the soil deposit) provides an index of the *in situ* state of a sand deposit, and especially of its relative density. Field measured SPT

FIGURE 25.7 Liquefaction-induced damage of the Marina Research Facility at Moss Landing, California, caused by the 1989 Loma Prieta earthquake (after Seed, R. B., Dickenson, S. E., Riemer, M. F., Bray, J. D., Sitar, N., Mitchell, J. K., Idriss, I. M., Kayen, R. E., Kropp, A., Harder, L. F., and Power, M. S. 1990. Preliminary Report on the Principal Geotechnical Aspects of the October 17, 1989 Loma Prieta Earthquake. Earthquake Engineering Research Center, Report No. UCB/EERC-90/05, University of California).

blowcount numbers are corrected to account for overburden pressure, hammer efficiency, saturated silt, and other factors. A loose sand deposit will generally have low SPT blowcount numbers (4–10) and a dense sand deposit will generally have high SPT blowcount numbers (30–50). Moreover, changes in factors that tend to increase the cyclic loading resistance of a deposit similarly increase the SPT blowcount. Hence, the cyclic stress required to induce soil liquefaction can be related to the soil deposit's penetration resistance. Well-documented sites where soil deposits did or did not liquefy during earthquake strong shaking were used to develop the correlation shown in Fig. 25.8. Correction factors can be applied to the $(\tau/\sigma_0')_l$ versus SPT correlation presented in Fig. 25.8 to account for earthquake magnitude, greater depths, and sloping ground [see Seed and Harder, 1990].

Finally, the liquefaction susceptibility of a saturated sand deposit can be assessed by comparing the cyclic stress ratio required to induce liquefaction, $(\tau/\sigma_0')_l$, with the average cyclic stress ratio developed during the earthquake, $(\tau/\sigma_0')_d$. A reasonably conservative factor of safety should be employed (≈ 1.5) because of the severe consequences of soil liquefaction.

Illustrative Soil Liquefaction Problem

Problem 25.2

Evaluate the liquefaction susceptibility of the soil deposit shown in Fig. 25.4.

Soil Liquefaction

At this site, MHA $\approx 0.2g$ (see Problem 25.1). At a depth of 5 m, $\sigma_0 = \rho_t \cdot g \cdot z = (2.0\ \text{Mg/m}^3)(9.81\ \text{m/s}^2)(5\ \text{m}) = 98$ kPa; $\sigma_0' = \sigma_0 - \gamma_w \cdot z_w = 98\ \text{kPa} - (1\ \text{Mg/m}^3)(9.81\ \text{m/s}^2)(3\ \text{m}) = 68$ kPa; and $r_d \approx 1.0 - 0.008(5m) = 0.96$. Hence, using Eq. (25.2), the average cyclic stress ratio developed during the earthquake is

$$(\tau/\sigma_0')_d \approx 0.65 \cdot (0.2g/g) \cdot \frac{98\ \text{kPa}}{68\ \text{kPa}} \cdot 0.96 = 0.18 \tag{25.3}$$

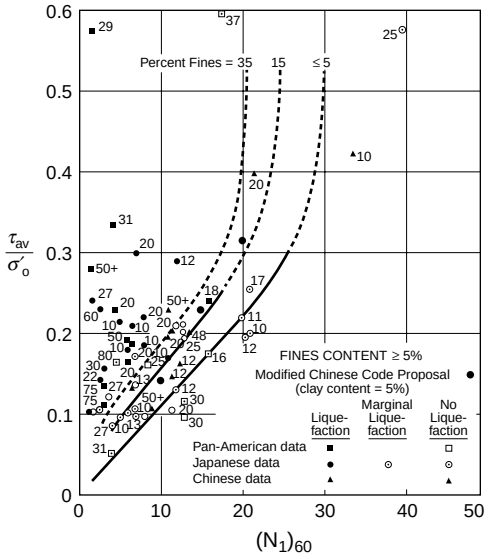

FIGURE 25.8 Relationship between stress ratios causing liquefaction and $(N_1)_{60}$-values for silty sands for $M_s = 7½$ earthquakes (after Seed, H. B., Tokimatsu, K., Harder, L. F., and Chung, R. M. 1985. Influence of SPT Procedures in Soil Liquefaction Resistance Evaluations. *Journal of the Geotechnical Engineering Division,* ASCE. (111) 12:1425–1445).

The corrected penetration resistance of the sand at a depth of 5 m is around 10, and using Fig. 25.8, for a clean sand with less than 5% fines, $(\tau/\sigma'_0)_l \approx 0.11$.

The factor of safety (FS) against liquefaction is then

$$\text{FS} = (\tau/\sigma'_0)_l/(\tau/\sigma'_0)_d = 0.11/0.18 = 0.6 \tag{25.4}$$

Since the factor of safety against liquefaction is less than 1.0, the potential for soil liquefaction at the site is judged to be high. Modern ground improvement techniques (e.g., dynamic compaction) may be used to densify a particular soil deposit to increase its liquefaction resistance and obtain satisfactory performance of the building's foundation material during earthquake strong shaking.

25.5 Seismic Slope Stability

Considerable attention has been focused over the last few decades on developing procedures to analyze the seismic performance of earth embankments [e.g., Newmark, 1965; Seed, 1979; Marcuson et al., 1992]. The first issue that must be addressed is an evaluation of the potential of the materials comprising the earth structure to lose significant strength under cyclic earthquake loading. Saturated cohesionless materials (gravels, sands, and nonplastic silts) that are in a loose state are prime candidates for liquefaction and hence significant strength loss. Experience has shown that cohesionless materials placed by the hydraulic fill method are especially vulnerable to severe strength loss as a result of strong shaking. A modified version of the Seed and Idriss [1982] simplified method has been employed to evaluate the liquefaction potential of cohesionless soils in earth slopes and dams [see Seed and Harder, 1990]. Certain types of clayey materials have also been shown to lose significant strength as a result of cyclic loading. If clayey materials have a small percentage of clay-sized particles, low liquid limits, and high water contents, the material's cyclic loading characteristics should be determined by cyclic laboratory testing [Seed and Idriss, 1982].

The potentially catastrophic consequences of an earth embankment material that undergoes severe strength loss during earthquake shaking is demonstrated by the near failure of the Lower San Fernando

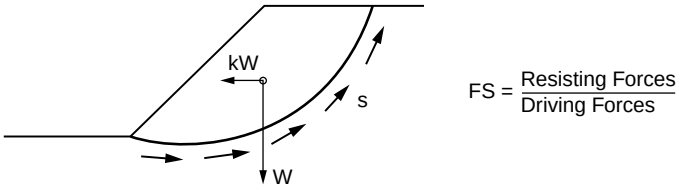

FIGURE 25.9 Pseudostatic slope stability analysis.

dam as a result of the 1971 San Fernando earthquake [Seed et al., 1975]. The center and upstream sections of the dam slid into the reservoir because a large section within the dam liquefied. The slide movement left only 1.5 m of earth fill above the reservoir level. Fortunately, the reservoir level was 11 m below the original crest at the time of the earthquake. Still, because of the precarious condition of the dam after the main shock, 80,000 people living downstream of the dam were ordered to evacuate until the reservoir could be lowered to a safe elevation.

Surveys of earth dam performance during earthquakes suggest that embankments constructed of materials that are not vulnerable to severe strength loss as a result of earthquake shaking (most well-compacted clayey materials, unsaturated cohesionless materials, and some dense saturated sands, gravels, and silts) generally perform well during earthquakes [Seed et al., 1978]. The embankment, however, may undergo some level of permanent deformation as a result of the earthquake shaking. With well-built earth embankments experiencing moderate earthquakes, the magnitude of permanent seismic deformations should be small, but marginally stable earth embankments experiencing major earthquakes may undergo large deformations that may jeopardize the structure's integrity. Simplified procedures have been developed to evaluate the potential for seismic instability and seismically induced permanent deformations [e.g., Seed, 1979; Makdisi and Seed, 1978], and these procedures can be used to evaluate the seismic performance of earthen structures and natural slopes.

In pseudostatic slope stability analyses, a factor of safety against failure is computed using a static limit equilibrium stability procedure in which a pseudostatic, horizontal inertial force, which represents the destabilizing effects of the earthquake, is applied to the potential sliding mass. The horizontal inertial force is expressed as the product of a seismic coefficient, k, and the weight, W, of the potential sliding mass (Fig. 25.9). If the factor of safety approaches unity, the embankment is considered unsafe. Since the seismic coefficient designates the horizontal force to be used in the stability analysis, its selection is crucial. The selection of the seismic coefficient must be coordinated with the selection of the dynamic material strengths and minimum factor of safety, however, as these parameters work together to achieve a satisfactory design. For earth embankments, case histories are available which have guided the selection of these parameters. For example, Seed [1979] recommends using appropriate dynamic material strengths, a seismic coefficient of 0.15, and a minimum factor of safety of 1.15 to ensure that an embankment composed of materials that do not undergo severe strength loss performs satisfactorily during a major earthquake.

A significant limitation of the pseudostatic approach is that the horizontal force, representing the effects of an earthquake, is constant and acts in only one direction. With dynamically applied loads, the force may be applied for only a few tenths of a second before the direction of motion is reversed. The result of these transient forces will be a series of displacement pulses rather than complete failure of the slope. Normally, a certain amount of limiting displacement during an earthquake event is considered tolerable. Hence, if conservative strength properties are selected and the seismic coefficient represents the maximum disturbing force (i.e., maximum shear stress induced by the earthquake on the potential sliding surface; see Seed and Martin, 1966), a factor of safety of one is likely to ensure adequate seismic performance. Other conservative combinations of these parameters could be developed, but their use must be evaluated in the context that their use in analysis ensures a design that performs well during earthquakes (i.e., tolerable deformations).

Seismically induced permanent deformations are generally calculated using a Newmark-type procedure. The Newmark [1965] analysis assumes that relative slope movements would be initiated when the inertial force on a potential sliding mass was large enough to overcome the yield resistance along the slip surface, and these movements would stop when the inertial force decreased below the yield resistance and the velocities of the ground and sliding mass coincided. The yield acceleration is defined as the average acceleration producing a horizontal inertial force on a potential sliding mass which gives a factor of safety of one and can be calculated as the seismic coefficient in pseudostatic slope stability analyses that produces a safety factor of one. By integrating the equivalent average acceleration [see Bray et al., 1993] acting on the sliding surface in excess of this yield acceleration as a function of time, the displacement of the slide mass can be estimated. A commonly used procedure for calculating seismically induced permanent deformations has been developed by Franklin and Chang [1977] and computer programs are available [e.g., Pyke and Beikae, 1991]. Simplified chart solutions have been developed by Makdisi and Seed [1978] for earth embankments.

An emerging area of concern in many regions of the world is the seismic performance of waste fills. For example, recent U.S. federal regulations (40 CFR 258-USEPA 1991: Subtitle D) require that municipal solid waste landfills located in seismic impact zones be designed to resist earthquake hazards. Since these designated seismic impact zones encompass nearly half of the continental U.S., these regulations are having a pronounced impact on the design of new landfills and the lateral expansion of existing landfills. The results of a comprehensive study of the effects of the characteristics of the waste fill, subsurface soils, and earthquake ground motions are presented in Bray et al. [1993]. The investigators found that the seismic loading strongly depends on the dynamic properties and height of the waste fill. General design considerations regarding the seismic stability of solid waste landfills are discussed in Repetto et al. [1993].

25.6 Summary

Geotechnical earthquake engineering phenomena such as site-specific amplification, soil liquefaction, and seismic slope stability are important aspects of earthquake engineering, and these aspects must be adequately addressed in the development of sound earthquake-resistant designs. Seismic risk assessments of a facility, community, or region must incorporate engineering analyses that properly evaluate the potential hazards resulting from these phenomena. Deep soil deposits can amplify the underlying bedrock ground motions and produce intense levels of shaking at significant distances from the earthquake's epicenter. Under sufficient cyclic loading, loose, saturated sand deposits may suddenly liquefy, undergo severe strength loss, and fail as a foundation or dam material. Seismically induced permanent deformations of a landfill's liner system can jeopardize the integrity of the system and potentially release pollutants into the environment. Simplified empirical procedures employed to evaluate these hazards have been presented and they provide a starting point. The field of earthquake engineering is quite complex, however, and there are many opportunities for future research.

Defining Terms

Attenuation relationship — Provides the value of an engineering parameter versus distance from the zone of energy release of an earthquake.

Damping ratio — An indication of the ability of a material to dissipate vibrational energy.

Duration of strong shaking — Duration of the earthquake record in which the intensity is sufficiently high to be of engineering importance (i.e., MHA $\geq 0.05g$).

Fundamental period — Period at which a structure tends to vibrate when allowed to vibrate freely without any external excitation.

Liquefaction — Phenomenon resulting when the pore-water pressure within saturated particulate material increases dramatically, resulting in a severe loss of strength.

Magnitude — Measure of the amount of energy released during an earthquake. Several magnitude scales exist (e.g., local magnitude, M_L, and moment magnitude, M_w).

Maximum horizontal ground acceleration (MHA) — Highest horizontal ground acceleration recorded at a free-field site (i.e., not in a structure) during an earthquake.

Predominant period (Tp) — Period at which most of the seismic energy is concentrated, often defined as the period at which the maximum spectral acceleration occurs.

Response spectrum — Displays maximum response induced by ground motions in damped single-degree-of-freedom structures of different fundamental periods.

Shear wave velocity (Vs) — Speed that shear waves travel through a medium. An indication of the dynamic stiffness of a material. Note that $G = \rho V_s^2$, where G = shear modulus and ρ = mass density.

26.1 Introduction

The objective of this chapter is to present the main applications of geotechnical engineering to environmental projects. There are numerous examples of these applications, among which the most frequent are waste disposal projects, environmental compliance projects, and environmental remediation projects.

Although some projects could be classified under more than one category, in this introduction they are separated depending on whether the project is (1) to be designed prior to the disposal of waste; (2) the objective of the project is to control **releases** to the environment caused by current activities or to bring a facility into compliance with current environmental or health and safety regulations; or (3) the objective is to remediate a site impacted by previous releases and/or control releases from contaminants or wastes accumulated at a site. Although there is not uniformity in these definitions, generally the term *environmental compliance* is applied to active facilities, whereas *environmental remediation* is applied to closed facilities.

The main objective of the three categories of projects mentioned above is to reduce or minimize impacts to the environment. Releases that impact the environment may occur through the disposal or spreading of **solid wastes** or **liquid wastes**, the infiltration or runoff of liquids that have been in contact with wastes, or through gaseous emissions. These releases may, in turn, impact different media. They may carry contaminants into soils located in upland areas or into sediments within water bodies, transport liquids or dissolved contaminants through groundwater or surface water bodies, or be released to the atmosphere.

The geo-environmental structures used to reduce or minimize the propagation of contaminants through the different media are called containment systems. The most commonly used containment systems are **liner** systems, cover systems (or caps), and slurry wall cut-offs. The use of liner systems is generally limited to new projects or expansions, while cover systems and slurry walls are used with all categories of projects.

This chapter presents a brief description of the main categories of environmental projects mentioned above, followed by a detailed discussion of liner and cover systems, including materials used for their construction and some construction-related aspects.

Waste Disposal Projects

As indicated above, the first category of environmental projects comprises those projects designed and constructed to contain waste materials prior to the disposal of waste. This includes projects such as

landfills, **lagoons**, and tailings impoundments. Although tailings impoundments are basically landfills, their design and operation, requiring simultaneous management of liquids and solids, differs substantially from typical landfills, in which mostly solids are managed, and therefore it is justified to consider them as a different type of project.

A brief discussion of landfill projects is presented below as an introduction to the use of containment systems in environmental projects. For brevity, a discussion of tailings impoundments and lagoons is omitted. However, the reader should keep in mind that several of the elements of landfill projects have similar application for tailings impoundments and lagoons.

Modern landfills are complex structures that include a number of systems to prevent undue releases to the environment. The main systems are:

- Bottom liner system
- Final cover system
- Surface water management system
- **Leachate** management system (leachate collection, removal, and disposal systems)
- Gas management system
- Environmental monitoring system

Although all these systems are important to prevent undue releases to the environment, only the bottom liner and the final cover systems will be discussed, since the other systems are beyond the scope of this chapter. The function of the liner system is to contain leachate and prevent it from migrating downward into the subsoil or groundwater. The function of the final cover is to control infiltration of precipitation into the waste, to prevent contact of runoff with the waste, to prevent the displacement or **washout** of wastes to surrounding areas, to reduce the potential for disease **vectors** (birds, insects, rodents, etc.), and to control the emission of gases.

Landfills may be classified in accordance with several criteria. The most common criteria used to classify landfills are type of waste, type of liner system, and geometrical configuration. Based on current federal regulations, landfills are classified with respect to the type of waste as **municipal solid waste** (MSW), **hazardous waste**, and other types of solid waste. Federal regulations regarding these three types of landfills are published in Sections 258, 264, and 257, respectively, of the Code of Federal Regulations. State regulations are, however, frequently more stringent than federal regulations. State regulations frequently include specific regulations for landfills where other types of waste will be disposed, such as **industrial waste**, **construction demolition debris**, and residual waste.

With respect to the liner system, landfills are classified as single or double lined. Liner systems comprising only one (primary) liner are called single-liner systems. Liner systems comprising a primary and a secondary liner, with an intermediate leachate detection system, are called double liner systems. Each of the liners (primary or secondary) may consist of only one layer [clay, geomembrane, or geosynthetic clay liner (GCL)] or adjacent layers of two of these materials, in which case it is called a composite liner. A detailed discussion of liner systems is presented later in this chapter.

The geometrical configuration of a landfill is the result of a number of factors that have to be considered during the design. It is generally intended to design the subgrade excavation as deep as possible, so that airspace is maximized and soils are made available for daily, intermediate, and final covers, structural fill, soil liners, perimeter and intercell berms, sedimentation basin berms, and access roads. However, the footprint shape and extent, cell layout, excavation depth, and subbase grading are strongly influenced by the following factors:

- Depth to the water table or uppermost aquifer. Some regulations require a minimum separation from the water table. Even if regulations do not require separation from the water table, excavation dewatering has a significant cost impact.
- Depth to bedrock. The cost of hard-rock excavation negatively impacts the economic feasibility of a project. Additionally, excavated rock generally has little use in landfill projects.

- Stability of the foundation. Weak foundation soils, as well as areas previously mined or susceptible to sinkhole development, may cause instability problems.
- Site topography and stability of natural and cut slopes. In flat areas only fill embankments and cut slopes need to be considered, whereas excavations close to natural slopes may affect their stability and need to be considered in selecting the landfill footprint.
- Stability of cut slopes. The stability of cut slopes is a function of their height, inclination, groundwater conditions, and the strength and unit weight of the *in situ* soils. The inclination and height of the cut slopes affects the landfill airspace and the volume of soils to be excavated.
- Soils balance. The soils balance refers to the types and volumes of soils available and needed. An adequate soils balance allows a sufficient volume of soils to be available from on-site excavations and, at the same time, avoids excessive excavation that would have to be stockpiled on-site or disposed off-site.
- Permeability of natural soils. In some cases a natural clay liner may be acceptable, which would eliminate the need for low-permeability borrow for an engineered liner.
- Required airspace and available area. A minimum airspace may be required to make the landfill project economically feasible.
- Waste stream. The waste rate is directly related to the life of each cell. Normally cells are dimensioned so that they do not remain empty for an extended period of time.
- Filling sequence. One of the design goals is to avoid excessive stockpiling of excavated soils and to minimize leachate production by placing the final cover as soon as possible.
- Grading of the landfill floor. A minimum slope is required for the leachate collection system.

Finally, from the point of view of geometrical configuration, the most common landfill types are:

- Area fill. Landfilling progresses with little or no excavation (Fig. 26.1). Normally used in relatively flat areas with shallow water table.
- Above-ground and below-ground fill. The landfill consists of a two-dimensional arrangement of large cells that are excavated one at a time. Once two adjacent cells are filled, the area between them is also filled (Fig. 26.2). Normally used in relatively flat areas without a shallow water table.
- Valley fill. The area to be filled is located between natural slopes (Fig. 26.3). It may include some below-ground excavation.
- Trench fill. This method is similar to the above-ground and below-ground configuration, except that the cells are narrow and parallel (Fig. 26.4). It is generally used only for small waste streams.

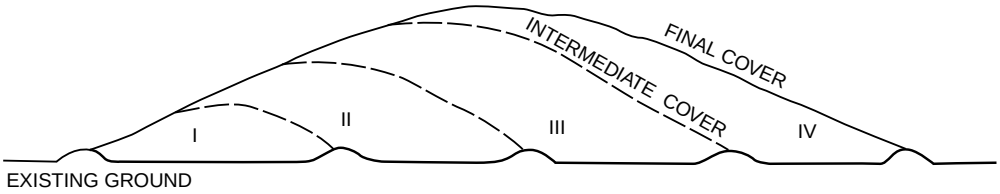

FIGURE 26.1 Area fill.

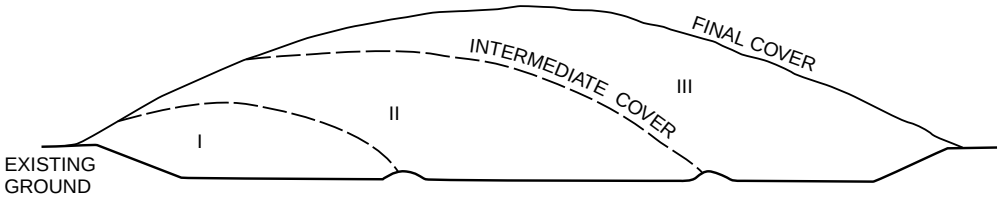

FIGURE 26.2 Above-ground and below-ground fill.

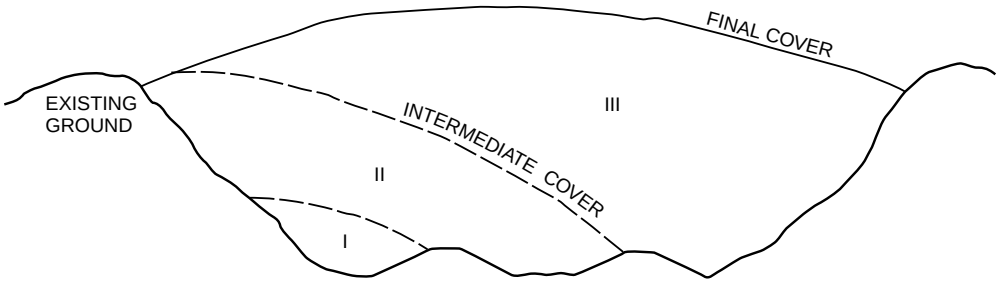

FIGURE 26.3 Valley fill.

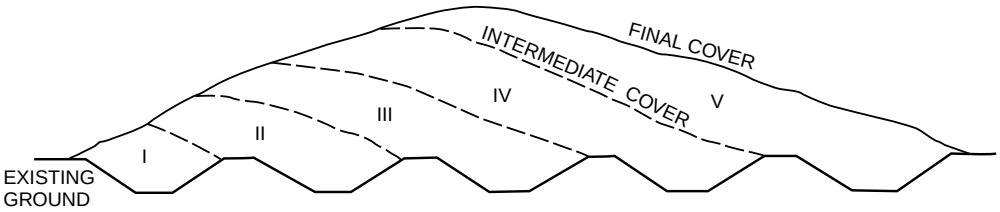

FIGURE 26.4 Trench fill.

Environmental Compliance Projects

The second category comprises a very broad range of projects, in which the aim is to bring a facility into compliance with current regulations (including health and safety) and/or to control releases to the environment caused from current site activities. As mentioned above, these releases may occur through solid, liquid, or gaseous discharges, and may affect soils, sediments, water bodies, or the atmosphere. The type of facility involved may be of any kind: landfill, tailings impoundment, lagoon, or any industrial facility.

The actions for controlling releases from active facilities are multiple and can be classified into three major groups:

- Modifications to the operations or processes in the facility itself, with the objective of avoiding or reducing the release of contaminants
- Treatment of discharges, so that contaminants are removed before the discharges take place
- Containment of contaminants (as discussed previously, the main containment systems are liner systems, cover systems, and slurry wall cut-offs)

The first two groups of actions listed above are beyond the scope of this chapter. Containment systems are discussed later in this chapter.

Environmental Remediation Projects

This category comprises projects in which the aim is to control releases to the environment from wastes or contaminants accumulated at a site and/or to remediate areas whose environmental functions have been impaired by previous site activities. As discussed previously, this category of projects generally applies to sites where activities have ceased. As in the case of environmental compliance projects, the types of activities that took place at the site can be of any kind.

The actions used to control releases from closed facilities can be classified into four major groups:

- Removal of the wastes or contaminated materials, and disposal at an appropriate facility
- Fixation or removal of the contaminants in place, so that releases are prevented

- Interception and treatment of contaminated releases
- Isolation of the wastes or contaminated materials by means of containment systems, so that releases are prevented

Of these four groups, only the use of containment systems is within the scope of this chapter and is discussed next.

26.2 Geo-Environmental Containment Systems

Liners

Liner systems are containment elements constructed under the waste to control infiltration of contaminated liquids into the subsoil or groundwater. The contaminated liquid, or leachate, may be part of the waste itself or may originate from water that has infiltrated into the waste.

Liner systems consist of multiple layers which fulfill specific functions. The description presented below refers specifically to landfill liner systems. However, the main characteristics of liner systems are similar for other applications. Landfill liner systems may consist, from top to bottom, of the following functional layers:

- *Protective layer.* This is a layer of soil, or other appropriate material, that separates the **refuse** from the rest of the liner to prevent damage from large objects.
- *Leachate collection layer.* This is a high-permeability layer, whose function is to collect leachate from the refuse and to convey it to sumps from where it is removed. Frequently the functions of the protective layer and the leachate collection layer are integrated in one single layer of coarse granular soil.
- *Primary liner.* This is a low-permeability layer (or layers of two different low-permeability materials in direct contact with each other). Its function is to control the movement of leachate into the subsoil.
- *Secondary leachate collection layer, or leakage detection layer.* This is a high-permeability (or high-transmissivity, if geosynthetic) layer designed to detect and collect any leachate seeping through the primary liner. This layer is used only in conjunction with a secondary liner.
- *Secondary liner.* This is a second (or backup) low-permeability layer (or layers of two different low-permeability materials in direct contact with each other). Not all liner systems include a secondary liner.
- *Drainage layer.* In cases where the liner system is close or below the water table, a high-permeability (or high-transmissivity, if geosynthetic) blanket drainage layer is generally placed under the liner system to control migration of moisture from the foundation to the liner system.
- *Subbase.* This layer is generally of intermediate permeability. Its function is to separate the liner system from the natural subgrade or structural fill.

These layers are normally separated by geotextiles to prevent migration of particles between layers, or to provide cushioning or protection of geomembranes.

As indicated above, liner systems may have a primary liner only or may include primary and secondary liners. In the first case it is called a *single-liner* system, and if it has a primary and a secondary liner it is called a *double-liner* system. Further, each of the liners (primary or secondary) may consist of one layer only (low-permeability soil, geomembrane, or GCL) or adjacent layers of two of these materials, in which case it is called a *composite* liner. There are multiple combinations of these names, some of which are given below as examples (obviously there are many more combinations):

- Single synthetic liner: primary liner only, consisting of a geomembrane.
- Single soil liner: primary liner only, consisting of a low-permeability soil layer.

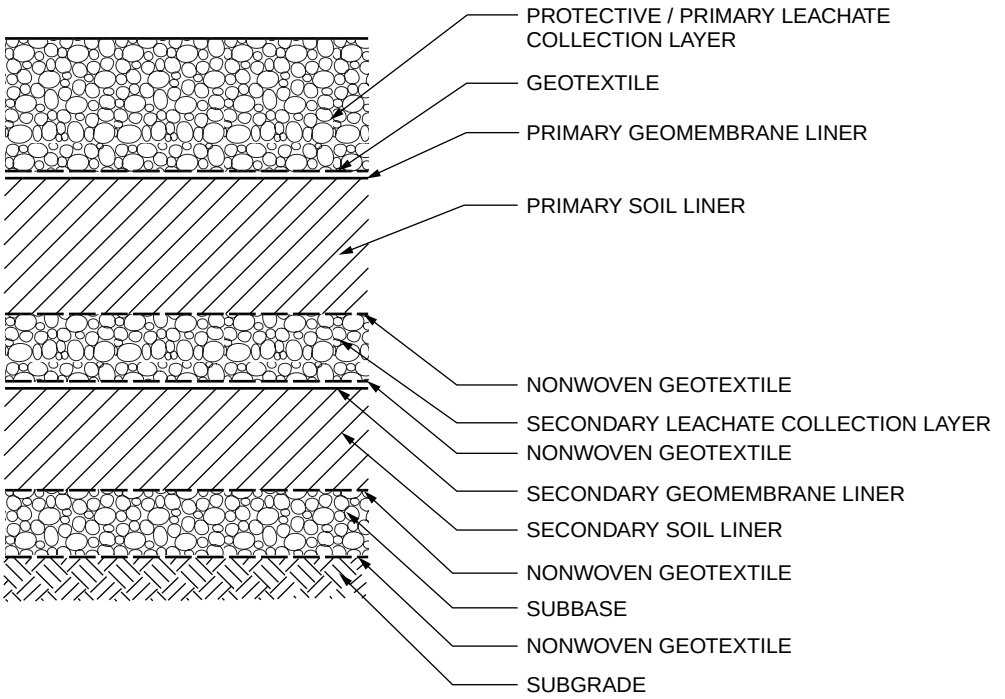

FIGURE 26.5 Double composite liner system.

- Double synthetic liner: primary and secondary liners, each consisting of a geomembrane, separated by a secondary leachate collection layer.
- Single composite liner: primary liner only, consisting of a geomembrane in direct contact with a low-permeability soil layer. (This is the design standard specified in Subtitle D regulations of the Resource Conservation and Recovery Act for **municipal solid waste landfill units**).
- Double composite liner: primary and secondary liners, each consisting of a geomembrane in direct contact with a low-permeability soil layer, separated by a secondary leachate collection layer (see Fig. 26.5).

Low-Permeability Covers

A low-permeability cover is a containment system constructed on top of the waste, primarily to control the infiltration of precipitation. Cover systems control infiltration in two ways: (1) by providing a low-permeability barrier and (2) by promoting runoff with adequate grading of the final surface. Other functions of cover systems are to prevent contact of runoff with waste, to prevent spreading or washout of wastes, to reduce disease vectors, and to control the emission of gases.

Cover systems also consist of multiple layers with specific functions related to the management of surface water. Of the precipitation that falls on a cover, part becomes surface water runoff, a portion infiltrates into the cover, and the remainder is lost through evapotranspiration. A low-permeability cover may include, from top to bottom, the following functional layers (see Fig. 26.6):

- *Erosion (vegetative) layer.* This is a layer of soil capable of supporting vegetation (typically grass) and with good resistance to erosion due to surface water runoff.
- *Infiltration layer.* The functions of this layer, also frequently called **cover material**, are to protect the barrier layer from frost penetration and to separate the precipitation that does not evaporate into runoff and infiltration. Each of these two components of the flow has to be controlled

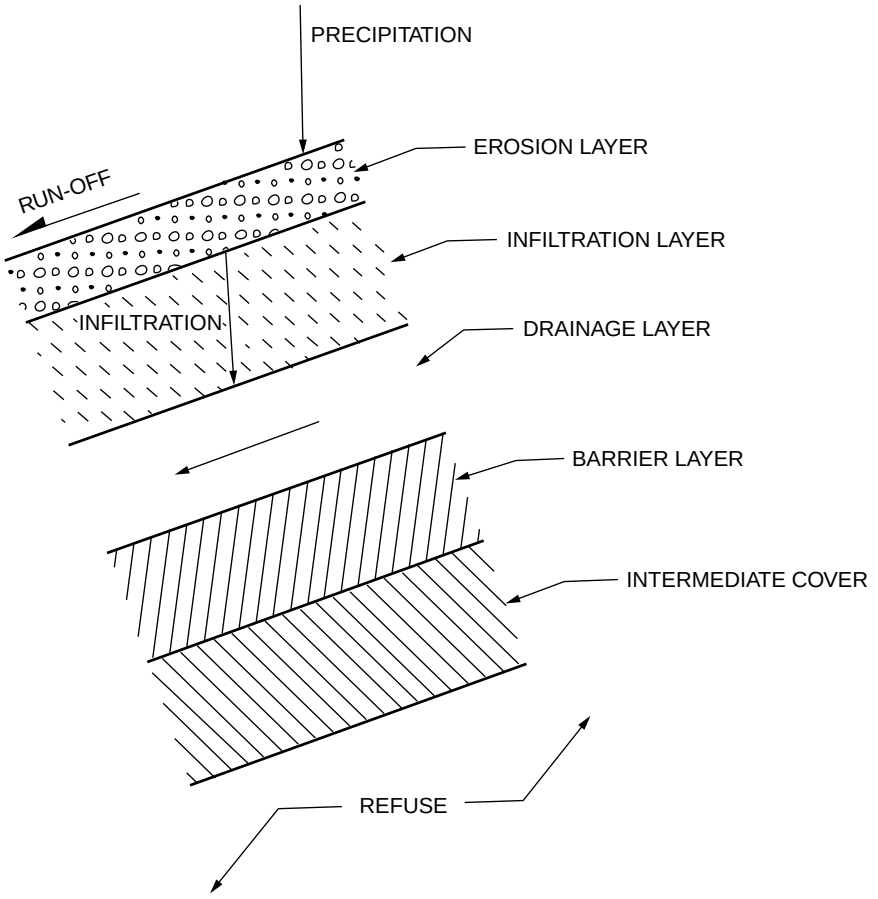

FIGURE 26.6 Cover functional layers.

separately: the runoff through adequate erosion resistance of the erosion layer and the infiltration through adequate hydraulic capacity of the underlying drainage layer.

- *Drainage layer*. This is a permeable layer whose function is to convey the water that infiltrates into the cover system. A cover without a drainage layer is susceptible to damage by pop-outs.
- *Barrier layer*. This is a low-permeability layer (or layers of two different low-permeability materials in direct contact with each other) whose function is to control infiltration into the waste.

The erosion and the infiltration layers are normally constructed of soils, since they must support vegetation and provide frost protection. The drainage layer can be constructed of a permeable soil, a geonet, or a geocomposite. The barrier layer can be constructed of a low-permeability soil, a geomembrane, a GCL, or adjacent layers of two of these materials, in which case it is called a *composite* barrier layer. Some of these layers are also generally separated by geotextiles.

Slurry Walls

Slurry walls are a type of cut-off wall whose function in environmental projects is to control the horizontal movement of contaminated liquids. The single most important characteristic of slurry walls is that the stability of the trench walls during excavation is maintained without any bracing or shoring by keeping the trench filled with a slurry.

During excavation, stability of the trench walls is achieved by maintaining a pressure differential between the slurry inside the trench and the active soil and groundwater pressures acting from outside

of the trench. In permeable soils there is initially some loss of slurry, due to the infiltration of slurry from the trench into the surrounding soils. After a short period of time, a low-permeability crust, called *cake*, forms on the trench walls; it provides a hydraulic barrier between the slurry and the groundwater. If the length of trench that is open at any given time is short relative to the height of the trench, the stability is improved by arching effect.

After some length of trench has been excavated, the slurry is displaced and replaced by a permanent backfill mix, consisting either of a soil–bentonite admixture or a bentonite–cement admixture. The backfill mix needs to have low permeability, but at the same time adequate shear strength and low compressibility. The low permeability is achieved by incorporating bentonite into the backfill mix, and the shear strength and low compressibility by including some granular soil or cement as part of the backfill mix.

The most important aspects related to the design and construction of slurry walls are:

- *Keying of the wall bottom*. The intent of slurry walls is to control the lateral flow of liquids. In order to achieve this objective, it is necessary to have the bottom of the trench keyed into a low-permeability stratum, so that flow under the slurry wall is not significant. Therefore, continuity of the low-permeability stratum requires careful consideration.
- *Hydrogeologic effects*. Slurry walls restrict the horizontal flow of groundwater. The effects of introducing this containment system in the hydrogeologic regime, such as mounding upgradient of the wall and drawdown downgradient of the wall, need to be evaluated by means of groundwater modeling.
- *Stability of the trench during excavation*. As indicated above, achieving stability of the trench walls during excavation requires a slurry pressure inside the trench that exceeds the active soil and groundwater pressures acting outside the trench. Calculation of the active soil pressure acting outside the trench must include the effects of adjacent slopes, surcharges, and any other effects that would increase the active soil pressure. Similarly, the groundwater pressure must take into account the effects of upward gradient, confined aquifers, horizontal flow, and any other characteristic of the hydrogeological regime that would affect groundwater pressures.
- *Backfill mix composition*. The backfill mix requires low permeability, adequate shear strength, and low compressibility. Ideally, this is achieved by selecting a backfill mix consisting of granular soil, cohesive soil, and bentonite. The granular soil provides shear strength and reduces compressibility, whereas the cohesive soil reduces the amount of bentonite required to achieve low permeability.

26.3 Liners and Covers

Although the functions of liners and covers are quite different, they use similar materials and are subjected to similar construction considerations. Therefore, for simplicity, the materials used for liners and covers are presented together in this section.

Materials used for the construction of liners and covers can be classified with respect to their origin and function. With respect to their origin they are classified into two major groups: natural soils and geosynthetic materials. With respect to their function the classification is more complex and includes the following:

- *Barrier layers*. These are low-permeability layers of natural soils (clay, soil–bentonite admixtures) or geosynthetic materials (geomembranes, GCLs).
- *Drainage layers*. These are high-permeability (if soil) or high-transmissivity (if geosynthetic) layers. In the first case they consist of granular soils and in the latter of geonets or geocomposites.
- *Fill*. The uses of fill include applications such as grading, intercell berms, perimeter berms, and sedimentation basin berms. Obviously this category is limited to natural soils.
- *Vegetative layer*. Vegetative layers are used as the uppermost layer of final covers, or as erosion protection for permanent or temporary slopes. This category is also limited to natural soils.

- *Filtration/protection/cushion layers*. Liners and covers consist of functional layers of soils of very different gradations, or geosynthetic materials that require special protection to prevent damage during installation or operation. Separation and protection are generally provided by geotextiles placed between functional layers. Geotextiles are placed as filters between soil layers of different gradations to prevent migration of soil particles, as cushion below geomembranes to be installed on granular soils, or as protection on top of geomembranes placed below granular soils.
- *Tensile reinforcement*. In cases where large deformations can be expected in liners or covers, geogrids or geotextiles are used as tensile reinforcement to avoid excessive tensile strains in other elements of the liner or cover system. Additionally, sliding is a potential failure mode in steep cover slopes. In this case geogrids or geotextiles are installed embedded within the layer susceptible to sliding to provide a stabilizing tensile force.

Soils

Barrier Layers

Barrier layers constructed of natural soils may consist of clay or a soil–bentonite admixture. In the case of admixtures, the required bentonite content is selected based on laboratory permeability tests performed with different bentonite percentages.

The typical requirement of most regulations for barrier layers is to have a permeability not exceeding 10^{-7} cm/s. However, since most regulations do not specify under what conditions this value is to be determined, the project specifications must address those conditions. The main factors that influence the permeability of a given soil or soil–bentonite admixture are discussed below:

- *Compaction dry density*. All other factors being constant, the higher the compaction dry density of a soil, the lower its permeability. However, at the same compaction dry density, the permeability also varies as a function of the compaction moisture content and the compaction procedure. The compaction dry density is normally specified as a percentage of the standard or modified Proctor test maximum dry density.
- *Compaction moisture content*. All other factors maintained constant, the permeability of a given soil increases with increasing compaction moisture content. It should be noted, however, that as the moisture content approaches saturation, it becomes more difficult to achieve a target dry density, and other properties of the compacted soil, such as compressibility or shear strength, may become critical.
- *Compaction procedure*. It has been observed that specimens compacted to identical dry densities and moisture contents may exhibit different permeabilities if compacted following different procedures. Therefore, if laboratory test results are close to the required permeability, the compaction procedure used for preparation of laboratory specimens should be similar to the field compaction procedures.
- *Consolidation pressure*. In geo-environmental applications, barrier layers may be subjected to high permanent loads while in service, as is the case in landfill liner systems. In these cases there is an increase in dry density due to consolidation under the service loads. On the other hand, permanent loads are minimal on cover systems and an increase in dry density with time should not be expected. Therefore, permeability tests should be performed using a consolidation pressure consistent with the expected loads.

The combination of compaction dry densities and moisture contents that yields a permeability not exceeding a specified value can be determined by means of a permeability window. A permeability window is constructed by performing permeability tests on a series of specimens compacted at different dry densities and moisture contents, covering the ranges of dry density and moisture content of interest. The specimens should be prepared using a compaction procedure consistent with the field procedure (generally Proctor compaction) and the tests should be performed at a consolidation pressure similar to those to be produced by the expected loads.

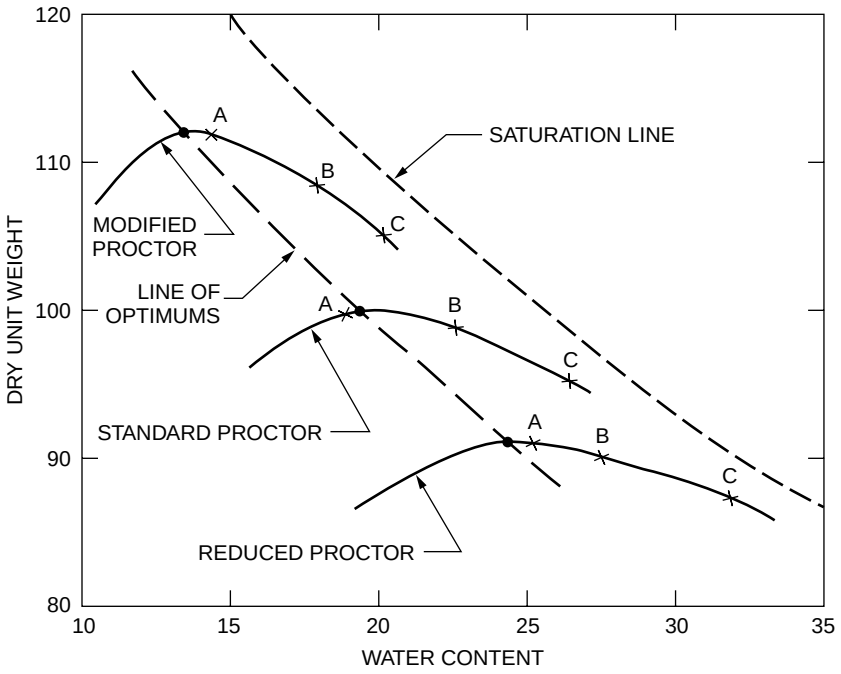

FIGURE 26.7 Dry density–moisture graph.

A practical way of determining a permeability window is described below:

- A large sample of the soil, sufficient to perform three Proctor tests and to prepare nine permeability specimens, should be carefully homogenized, so that differences due to individual specimens are avoided.
- Specific gravity of the soil is determined and the saturation line is plotted in a dry density–moisture graph (see Fig. 26.7).
- Three Proctor tests are performed (modified, standard, and reduced) and plotted in the dry density–moisture graph (Fig. 26.7). The reduced Proctor is a test performed with the same hammer as the standard Proctor, but using a reduced number of blows per layer. Assuming a four-inch mold is used, generally the reduced Proctor is performed using 10 or 15 blows per layer.
- For each of the three Proctor tests, the maximum density and the optimum moisture content are determined, and a line of optimums connecting the three curves is drawn (Fig. 26.7).
- For each of the Proctor curves, three moisture contents are selected corresponding to points on the Proctor curve. The moisture contents typically range from the optimum moisture content to about 95% saturation (points *A*, *B*, and *C* in Fig. 26.7).
- Specimens for permeability testing are prepared at each of the three moisture contents selected above, compacted with the same energy and procedure of the Proctor curve used to select the moisture contents.
- The same procedure is followed for the other two Proctor curves, thus obtaining a total of nine permeability specimens.
- Flexible wall permeability tests are performed on the nine specimens, using a consolidation pressure consistent with the expected loads. Typically the consolidation pressure is selected equal to K_0 times the vertical stress.
- The results of the permeability tests are plotted on the dry density–moisture graph and isopermeability lines are drawn by interpolating between the nine test points (Fig. 26.8). If needed, additional test points may be selected to improve accuracy or to verify questionable points.

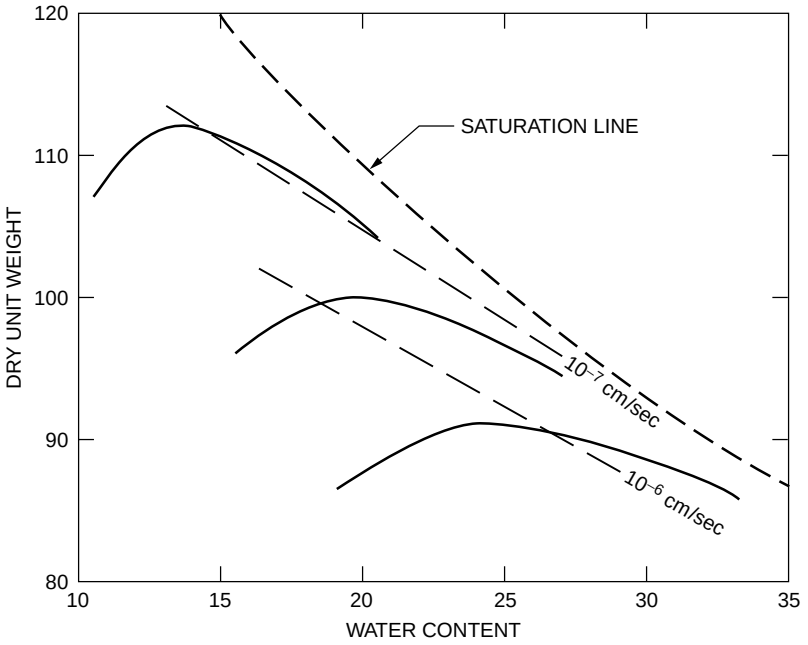

FIGURE 26.8 Permeability window.

- Finally, the permeability window is selected as the area bound by the isopermeability line corresponding to the required permeability and the saturation line. Additionally, the permeability window is generally truncated by moisture content lower and upper bounds. The line of optimums is generally selected as the moisture content lower bound, because cohesive soils compacted dry of optimum are too rigid and may easily crack. The moisture content upper bound is selected based on unconfined strength and compressibility, depending on the specific application.

It should be noted that selecting moisture contents on the Proctor curves and compacting the specimens following the Proctor procedure does not provide points on a grid. However, this procedure is preferred because the compaction procedure is uniform and considered to be more representative of the field procedures. Some laboratories prefer to prepare the specimens following a rectangular grid on the dry density–moisture graph, compacting the specimens within a mold using a jack. In these cases the procedure is less representative of the field conditions and some differences can be expected with respect to tests performed on specimens prepared using Proctor procedures.

The discussion presented above refers, in general, to tests in which the permeant is clean water. However, in geo-environmental applications, the permeant is leachate in the case of liners. The flow of leachate through cohesive soils may produce changes in the cations, which in turn may affect the permeability of the soil. In order to evaluate these changes, leachate compatibility permeability tests are performed as described below.

Leachate compatibility permeability tests are long-duration permeability tests, in which distilled water is used initially as the permeant and then leachate from the facility (or a similar leachate) is used as the permeant. These tests are continued until several pore volumes (typically three or four) of leachate have circulated through the specimen. During this period changes in the permeability of the soil are monitored. A leachate compatibility permeability test of a low-permeability soil generally lasts several months.

Drainage Layers

Drainage layers constructed of natural soils consist of sands or gravels, and may be used in liners or covers. Drainage layers are designed to have a hydraulic capacity adequate to convey the design flow rate without significant head buildup. The hydraulic capacity of a drainage layer is a function of its permeability,

thickness, and slope. Frequently the transmissivity, defined as the product of the permeability by the thickness, is used. The main considerations regarding drainage layers are listed below:

The gradation of the granular soil to be used for a drainage layer is selected based on the required permeability. In general, there are no strict gradation requirements, since the requirements for filtration between adjacent soil layers are satisfied by means of a geotextile acting as a filter. Frequently, gradation requirements, are driven mostly by availability (i.e., aggregates commercially available).

Drainage layers in liner systems must resist the attack of leachate, which is generally acidic. Therefore calcareous granular soils must be avoided.

Drainage layers are frequently adjacent to geomembranes, which are susceptible to puncture. Geotextiles are used to protect geomembranes from granular soils. However, if gravel-size soil is used, geotextiles may not provide sufficient protection from angular gravel. Therefore, the maximum angularity of gravels is generally limited to subangular.

The minimum drainage layer thickness that can be practically constructed is approximately six inches. However, if the drainage layer has to be placed on a geomembrane, driving construction equipment on the drainage layer may seriously damage the geomembrane. In these cases placement considerations control the minimum layer thickness and must be carefully evaluated.

Fill

The requirements for fills are, in general, similar to those for other types of engineering projects. The following types of fills are frequent in geo-environmental projects:

- *Grading fill*. There are no strict requirements for grading fills in which fill slopes are not constructed. Depending on the thickness of the fill and the loads to be applied on them, compressibility may be an important consideration. When grading fill is used to form fill slopes, coarse granular soil is used to provide adequate shear strength.
- *Structural fill*. This category comprises fill used for elements such as intercell berms and perimeter berms in landfills, or perimeter berms for leachate ponds. When these elements will be subjected to significant lateral pressures, these berms are constructed of coarse granular soils. These berms are generally lined, so permeability is not an issue.
- *Water-containment berms fill*. Berms containing water-retaining structures, such as sedimentation and detention basin berms, require a combination of low permeability and high shear strength. These two conditions are difficult to satisfy simultaneously, since soils of low permeability are weak, and vice versa. In these cases the type of fill generally used consists of a granular soil with significant fines content, which provides intermediate permeability and shear strength. Alternatively, lined berms may be constructed.

Vegetative Layer

As explained previously, the vegetative layer is the uppermost layer of a cover system. Vegetative layers must be adequate to support vegetation, generally grass, and must have adequate resistance to erosion.

In order to support vegetation, the soil must contain sufficient nutrients. Nutrients can also be supplied by adding limestone or other fertilizers. For information about this topic, consult the state erosion and sediment control manual or the country Soil Conservation District, since the requirements vary as a function of climate.

The erosion that a vegetative layer may suffer is a function of the soil type and the slope inclination and length. The soil loss is estimated by means of the Universal Soil Loss Equation, published by the U.S. Department of Agriculture. The maximum soil loss recommended by the U.S. Environmental Protection Agency for landfill covers is 2 tons/acre/year.

It should be noted that specifications frequently refer to vegetative layers as "topsoil." The term *topsoil* has a specific meaning from an agricultural point of view and is generally more expensive than other soils that can also support vegetation with adequate fertilization. For these reasons, it is recommended to use the term *topsoil* only when that type of soil is specifically required.

Geosynthetics

A large number of geosynthetic materials are used in environmental applications and there are many different tests to characterize their properties. This prevents a detailed presentation within the space allocated in this section. Therefore this section presents a brief summary of the most common types of geosynthetic materials generally used in environmental applications and their properties. For a detailed discussion on the applications and testing of geosynthetic materials, product data, and manufacturers, Koerner [1994], GRI and ASTM test methods and standards, and the Specifier's Guide of the Geotechnical Fabrics Report [Industrial Fabrics Association International, 1993] are recommended.

In general, two types of test are included in geosynthetic specifications: conformance tests and performance tests. Conformance tests are performed prior to installing the geosynthetics, to demonstrate compliance of the materials with the project specifications; some of the conformance tests are frequently provided by the manufacturer. Performance testing is done during the construction activities, to ensure compliance of the installed materials and the installation procedures with the project specifications.

Barrier Layers

Geosynthetic barrier layers may consist of geomembranes, also called flexible membrane liners (FMLs), or geosynthetic clay liners (GCLs).

As discussed previously, geomembranes are used as barrier layers for landfill liner and cover systems. They are also used as canal liner, surface impoundment liner and cover, tunnel liner, dam liner, and leach pad liner. In general, geomembranes are classified with respect to the polymer that they are made of and their surficial roughness. These two classifications are discussed below.

The most common polymers used for geomembranes are high density polyethylene (HDPE), very low density polyethylene (VLDPE), polypropylene, and PVC. Selection of the polymer is based primarily on chemical resistance to the substances to be contained. The polymer most widely used for landfill liner systems is HDPE, since it has been shown to adequately resist most landfill leachates. In the case of cover system barrier layers, flexibility is frequently an important selection factor, since landfill covers are subjected to significant settlements. VLDPE geomembranes are generally more flexible than HDPE and therefore are frequently used for cover systems.

The chemical resistance of geomembranes and other geosynthetic materials is evaluated by means of the EPA 9090 Compatibility Test. In this test, the initial physical and mechanical properties of a geosynthetic are determined (baseline testing) prior to any contact with the chemicals to be contained (leachate in the case of landfills). Then, geosynthetic specimens are immersed in tanks containing those chemicals, at 23 and 50°C. Specimens are removed from the tanks after 30, 60, 90, and 120 days of immersion and tested to determine their physical and mechanical properties. Comparison of these properties with the results of the baseline testing serves as an indicator of the effect of the chemicals on that specific geosynthetic material.

With respect to surface roughness, geomembranes are classified as smooth or textured. Smooth geomembranes are less expensive and easier to install than textured geomembranes, but exhibit a low interface friction angle (as low as 6 to 8 degrees) with other geosynthetics and with cohesive soils. Textured geomembranes provide a higher interface friction angle. The reader is warned that interface friction angles are not fixed values and must be evaluated on a case-specific basis, since they vary with parameters such as relative displacement (peak versus residual strength), normal stress, moisture conditions, backing used in the test (soil or rigid plates), and so on.

The main physical and mechanical properties generally used to characterize geomembranes and the test procedures to measure those properties are as follows:

Thickness	ASTM D751 and D1593
Density	ASTM D1505
Tensile properties	ASTM D638
Yield strength	
Break strength	
Elongation at yield	
Elongation at break	

Puncture resistance	FTMS 101C method 2065
Tear resistance	ASTM D1004
Low-temperature brittleness	ASTM D746
Carbon black content	ASTM D1603
Environmental stress crack resistance	ASTM D5397

Seaming of geomembranes is performed by bonding together two sheets. The main methods for seaming geomembranes are:

- *Extrusion welding*. A ribbon of molten polymer is extruded on the edge of one of the sheets or in between the two sheets. This method is applicable only to polyethylene and polypropylene geomembranes.
- *Thermal fusion*. Portions of the two sheets are melted using a hot wedge or hot air. This method is applicable to all types of geomembranes.
- *Solvent or adhesive processes*. These methods are not applicable to polyethylene and polypropylene geomembranes.

Seam strength (shear and peel) of geomembranes is controlled during installation by means of performance (destructive) testing performed in accordance with ASTM D4437 procedures.

GCLs consist of a thin layer of bentonite sandwiched between two geotextiles or bonded to a geomembrane. GCLs are currently available under the following registered names: Gundseal, Claymax, Shear-Pro, Bentofix, Bentomat, and NaBento. Gundseal is manufactured with a geomembrane on one side only, while the other products have geotextiles on both sides. The geomembrane and geotextiles are fixed to the bentonite layer by means of adhesives, needle-punched fibers, or stitches. The types of geotextiles used include several combinations of woven and nonwoven geotextiles.

The main physical and mechanical properties generally used to characterize GCLs and the test procedures to perform those tests are as follows:

Bentonite mass per unit area	ASTM D3776
GCL permeability	ASTM D5084
Base bentonite properties	
Moisture content	ASTM D4643
Swell index	USP-NF-XVII
Fluid loss	API 13B
Geotextiles	
Weight	ASTM D3776
Thickness	ASTM D1593
GCL tensile strength	ASTM D4632
Percent elongation	ASTM D463

Evaluation of the strength of a GCL must take into account its internal shear strength and the interface strength between the GCL and adjacent materials. The reader is warned that both the internal and interface shear strengths are not fixed values and must be evaluated on a case-specific basis, since they vary with parameters such as relative displacement (peak versus residual strength), normal stress, hydration of the bentonite, backing used in the test, and so on. Special attention must be given to the effects of long-term shear (creep) on needle-punched fibers and stitches, and to the squeezing of hydrated bentonite through the geotextiles. Seaming of GCLs is performed by overlapping adjacent sheets.

Drainage Layers

Geosynthetic drainage layers used as part of liner and cover systems may consist of geonets or geocomposites. Geocomposites consist of a geonet with factory-welded geotextile on one side or on both sides.

Polymers used for geonets are polyethylene (PE), HDPE, and medium density polyethylene (MDPE). The EPA 9090 Compatibility Test is also used to evaluate the chemical resistance of geonets and geocomposites. Geotextiles of various types and weights are attached to geonets to manufacture geocomposites, the most common type being nonwoven.

The main physical, mechanical, and hydraulic properties generally used to characterize geonets and geocomposites, and the test procedures to measure those properties, are thickness (ASTM D5199), compressive strength at yield (ASTM D1621), and in-plane flow rate [transmissivity (ASTM D4716)]. The most important property of geonets and geocomposites, in relation to their performance as drainage layers, is the transmissivity. The reader is warned that the results of laboratory transmissivity tests on geonets and geocomposites vary with several parameters, including normal stress, gradient, the type and weight of geotextiles attached, and the backing used in the tests. Furthermore, transmissivity values determined in short-term laboratory tests must be decreased, applying several correction factors to calculate long-term performance values. These correction factors account for elastic deformation of the adjacent geotextiles into the geocomposite core space, creep under normal load, chemical clogging and/or precipitation of chemicals, and biological clogging. A complete discussion of the correction factors recommended for various applications is presented by Koerner [1990].

In addition to the properties of the geonet or geocomposite, the properties of the geotextiles attached to the geonet are generally specified separately as discussed below. Seaming of geonets and geocomposites is generally performed using plastic ties, which are not intended to transfer stresses.

Geotextiles

Geotextiles may be used to perform several different functions. The most important are:

- *Separation*. Consists of providing separation between two different soils to prevent mixing. A typical application is placement of a granular fill on a soft subgrade.
- *Reinforcement*. Applications of geotextiles for reinforcement are identical to those of geogrids, discussed in the next section.
- *Filtration*. The geotextile is designed as a filter to prevent migration of soil particles across its plane. Several aspects need to be considered associated with this function: filtration (opening size relative to the soil particles), permittivity (flow rate perpendicular to the geotextile), and clogging potential.
- *Drainage*. In-plane capacity to convey flow or transmissivity.
- *Cushioning/protection*. The geotextile serves to separate a geomembrane from a granular soil, to protect the geomembrane from damage.

Geotextiles are classified with respect to the polymer that they are made of and their structure. The polymers most commonly used to manufacture geotextiles are polypropylene and polyester. With respect to their structure geotextiles are classified primarily as woven or nonwoven. Each of these types of structure is in turn subdivided, depending on the manufacturing process, as follows: woven (monofilament, multifilament, slit-film monofilament, slit-film multifilament); or nonwoven (continuous-filament heat bonded, continuous-filament needle punched, staple needle punched, spun bonded, or resin bonded).

The main physical, mechanical, and hydraulic properties generally used to characterize geotextiles and the test procedures to measure those properties are:

Specific gravity	ASTM D792 or D1505
Mass per unit area	ASTM D5261
Percent open area (wovens only)	CWO-22125
Apparent opening size	ASTM D4751
Permittivity	ASTM D4491
Transmissivity	ASTM D4716
Puncture strength	ASTM D4833
Burst strength	ASTM D3786
Trapezoid tear strength	ASTM D4533
Grab tensile/elongation	ASTM D4632
Wide-width tensile/elongation	ASTM D4595
UV resistance	ASTM D4355

Seaming of geotextiles is performed by sewing. Seam strength is tested following ASTM D4884.

Most geotextiles are susceptible to degradation under ultraviolet light. Therefore, appropriate protection is required during transport, storage, and immediately after installation.

Geogrids

Geogrids are used to provide tensile reinforcement. Typical applications include:

- *Reinforcement of slopes and embankments*. Potential failure surfaces would have to cut across layers of geogrid. The resisting forces on the potential failure surface would be comprised of the shear strength of the soil and the tensile strength of the geogrid.
- *Reinforcement of retaining walls*. In this application, some of the soil pressure that would act against the retaining wall is transferred by friction to the part of the reinforcing geogrid layer adjacent to the wall, while the rest of the geogrid (away from the wall) provides passive anchorage.
- *Unpaved roads*. The stiffness of the geogrid allows distribution of loads on a larger area and prevents excessive rutting.
- *Reinforcement of cover systems*. A potential mode of failure of relative steep covers is sliding of a soil layer on the underlying layer (veneer-type sliding). To control this type of failure, a geogrid layer is embedded within the unstable soil layer to provide a stabilizing tensile force. The opposite side of the geogrid must be anchored or must develop sufficient passive resistance to restrain its displacement.
- *Bridging of potential voids under liner systems*. When liner systems are constructed on existing waste (vertical expansions) or in areas where sinkholes may develop, geogrids are used within the liner system to allow bridging of voids.

Geogrids are made of polyester, polyethylene, and polypropylene. If exposed to waste or leachate, selection of the polymer is based on chemical resistance, as in the case of geomembranes. Depending on the direction of greater strength and stiffness, geogrids are classified as uniaxial or biaxial.

The main physical and mechanical properties generally used to characterize geogrids and the test procedures to measure those properties are mass per unit area (ASTM D5261), aperture size, wide-width tensile strength (ASTM D4595), and long-term design strength (GRI GG4).

Defining Terms

The definitions presented in this section have been extracted from the Code of Federal Regulations (CFR), 40 CFR 258, "EPA Criteria for Municipal Solid Waste Landfills," and 40 CFR 261, "Identification and Listing of Hazardous Waste." Definitions not available in the federal regulations were obtained from the Virginia Solid Waste Management Regulations.

Agricultural waste — All solid waste produced from farming operations, or related commercial preparation of farm products for marketing.

Commercial solid waste — All types of solid waste generated by stores, offices, restaurants, warehouses, and other nonmanufacturing activities, excluding residential and industrial wastes.

Construction/demolition/debris landfill — A land burial facility engineered, constructed, and operated to contain and isolate construction waste, demolition waste, debris waste, inert waste, or combinations of the above solid wastes.

Construction waste — Solid waste which is produced or generated during construction, remodeling, or repair of pavements, houses, commercial buildings, and other structures. Construction wastes include, but are not limited to, lumber, wire, sheetrock, broken brick, shingles, glass, pipes, concrete, paving materials, and metal and plastics if the metal or plastics are part of the materials of construction or empty containers for such materials. Paints, coatings, solvents, asbestos, any liquid, compressed gases or semiliquids, and garbage are not construction wastes.

Cover material — Compactable soil or other approved material which is used to blanket solid waste in a landfill.

Debris waste — Wastes resulting from land-clearing operations. Debris wastes include, but are not limited to, stumps, wood, brush, leaves, soil, and road spoils.

Demolition waste — That solid waste which is produced by the destruction of structures and their foundations and includes the same materials as construction wastes.

Garbage — Readily putrescible discarded materials composed of animal, vegetal, or other organic matter.

Hazardous waste — The definition of hazardous waste is fairly complex and is provided in 40 CFR Part 261, "Identification and Listing of Hazardous Waste." The reader is referred to this regulation for a complete definition of hazardous waste. A solid waste is classified as hazardous waste if it is not excluded from regulations as a hazardous waste; it exhibits characteristics of ignitability, corrosivity, reactivity, or toxicity as specified in the regulations; or it is listed in the regulations (the regulations include two types of hazardous wastes: from nonspecific sources and from specific sources).

Household waste — Any solid waste (including garbage, trash, and sanitary waste in septic tanks) derived from households (including single and multiple residences, hotels and motels, bunkhouses, ranger stations, crew quarters, campgrounds, picnic grounds, and day-use recreation areas).

Industrial solid waste — Solid waste generated by a manufacturing or industrial process that is not a hazardous waste regulated under Subtitle C of RCRA. Such waste may include, but is not limited to, waste resulting from the following manufacturing processes: electric power generation; fertilizer/agricultural chemicals; food and related products/by-products; inorganic chemicals; iron and steel manufacturing; leather and leather products; nonferrous metals manufacturing/foundries; organic chemicals; plastics and resins manufacturing; pulp and paper industry; rubber and miscellaneous plastic products; stone, glass, clay, and concrete products; textile manufacturing; transportation equipment; and water treatment. This term does not include mining waste or oil and gas waste.

Industrial waste landfill — A solid waste landfill used primarily for the disposal of a specific industrial waste or a waste which is a by-product of a production process.

Inert waste — Solid waste which is physically, chemically, and biologically stable from further degradation and considered to be nonreactive. Inert wastes include rubble, concrete, broken bricks, bricks, and blocks.

Infectious waste — Solid wastes defined to be infectious by the appropriate regulations.

Institutional waste — All solid waste emanating from institutions such as, but not limited to, hospitals, nursing homes, orphanages, and public or private schools. It can include infectious waste from health care facilities and research facilities that must be managed as an infectious waste.

Lagoon — A body of water or surface impoundment designed to manage or treat wastewater.

Leachate — A liquid that has passed through or emerged from solid waste and contains soluble, suspended, or miscible materials removed from such waste.

Liner — A continuous layer of natural or synthetic materials beneath or on the sides of a storage or treatment device, surface impoundment, landfill, or landfill cell that severely restricts or prevents the downward or lateral escape of hazardous waste constituents, or leachate.

Liquid waste — Any waste material that is determined to contain free liquids.

Litter — Any solid waste that is discarded or scattered about a solid waste management facility outside the immediate working area.

Monitoring — All methods, procedures, and techniques used to systematically analyze, inspect, and collect data on operational parameters of the facility or on the quality of air, groundwater, surface water, and soils.

Municipal solid waste — Waste which is normally composed of residential, commercial, and institutional solid waste.

Municipal solid waste landfill unit — A discrete area of land or an excavation that receives household waste, and that is not a land application unit, surface impoundment, injection well, or waste pile. A municipal solid waste landfill unit also may receive other types of RCRA Subtitle D wastes, such as commercial solid waste, nonhazardous sludge, small quantity generator waste, and industrial solid waste. Such a landfill may be publicly or privately owned.

Putrescible waste — Solid waste which contains organic material capable of being decomposed by microorganisms and causing odors.

Refuse — All solid waste products having the character of solids rather than liquids and which are composed wholly or partially of materials such as garbage, trash, rubbish, litter, residues from cleanup of spills or contamination, or other discarded materials.

Release — Any spilling, leaking, pumping, pouring, emitting, emptying, discharging, injection, escaping, leaching, dumping, or disposing into the environment solid wastes or hazardous constituents of solid wastes (including the abandonment or discarding of barrels, containers, and other closed receptacles containing solid waste). This definition does not include any release which results in exposure to persons solely within a workplace; release of source, by-product, or special nuclear material from a nuclear incident, as those terms are defined by the Atomic Energy Act of 1954; and normal application of fertilizer.

Rubbish — Combustible or slowly putrescible discarded materials which include but are not limited to trees, wood, leaves, trimmings from shrubs or trees, printed matter, plastic and paper products, grass, rags, and other combustible or slowly putrescible materials not included under the term *garbage*.

Sanitary landfill — An engineered land burial facility for the disposal of household waste which is located, designed, constructed, and operated to contain and isolate the waste so that it does not pose a substantial present or potential hazard to human health or the environment. A sanitary landfill also may receive other types of solid wastes, such as commercial solid waste, nonhazardous sludge, hazardous waste from conditionally exempt small-quantity generators, and nonhazardous industrial solid waste.

Sludge — Any solid, semisolid, or liquid waste generated from a municipal, commercial, or industrial wastewater treatment plant, water supply treatment plant, or air pollution control facility exclusive of treated effluent from a wastewater treatment plant.

Solid waste — Any garbage (refuse), sludge from a wastewater treatment plant, water supply treatment plant, or air pollution control facility, and other discarded material, including solid, liquid, semisolid, or contained gaseous material resulting from industrial, commercial, mining, and agricultural operations and from community activities. Does not include solid or dissolved materials in domestic sewage, or solid or dissolved materials in irrigation return flows or industrial discharges that are point sources subject to permit under 33 U.S.C. 1342, or source, special nuclear, or by-product material as defined by the Atomic Energy Act of 1954, as amended.

Special wastes — Solid wastes that are difficult to handle, require special precautions because of hazardous properties, or the nature of the waste creates management problems in normal operations.

Trash — Combustible and noncombustible discarded materials. Used interchangeably with the term *rubbish*.

Vector — A living animal, insect, or other arthropod which transmits an infectious disease from one organism to another.

Washout — Carrying away of solid waste by waters of the base flood.

Yard waste — That fraction of municipal solid waste that consists of grass clippings, leaves, brush, and tree prunings arising from general landscape maintenance.

Test Pits • Conventional Drilling And Sampling • Penetration Testing • Geophysical Testing • Other Testing Techniques
27.4 Shipping and Storage of Samples

27.1 Introduction

The *in situ* **subsurface** characterization section of a civil engineering handbook published 20 years ago would have been dominated by details of the standard penetration test with perhaps no more than a passing reference to some other test methods. As a result of significant technological advances in the past two decades and, perhaps equally important, increased recognition that there is a direct relationship between the efficiency of a design and the quality of the parameters on which this design is based, discussion of a much broader range of test methods is now appropriate in a text such as this. **Invasive** and **noninvasive** test methods using a variety of penetrometers and wave propagation techniques (e.g., cone **penetration testing**, seismic reflection/refraction testing, dilatometer testing, and pressuremeter testing) are now routinely used in many instances in preference to, or at least as a complement to, the standard penetration test. A listing of the more common techniques is given in Table 27.1.

27.2 Subsurface Characterization Methodology

The process of characterizing a site begins long before the first boring or sounding is advanced. In most cases, there will be information available either at the immediate site or at least in the general vicinity such that some initial impressions can be synthesized with respect to the subsurface conditions and the types of potential problems which may be encountered during the proposed development at the site. Example sources and types of information which may be available are summarized in Table 27.2.

When this available data has been synthesized, the engineer can then develop a site investigation strategy to supplement/complement the existing information and help achieve the objectives of the exploration program, including:

- Determine the subsurface stratigraphy (geologic profile), including the interface between fill and natural materials and the depth to bearing strata (e.g., bedrock) if appropriate.
- Investigate the groundwater conditions, including the location of water-bearing seams as well as perched aquifer and permanent groundwater table elevations.

TABLE 27.1 Summary of Common *In Situ* Subsurface Characterization Techniques

Test	Invasive/ Noninvasive	Sample Recovered	Usage
Standard penetration test	Invasive	Yes	Extensive
Cone penetration test	Invasive	No	Extensive
Pressuremeter test	Invasive	No	Moderate
Dilatometer	Invasive	No	Moderate
Vane shear test	Invasive	No	Moderate
Becker density test	Invasive	Yes	Limited
Borehole seismic test	Invasive	No	Extensive
Surface seismic test	Noninvasive	No	Extensive

TABLE 27.2 Sources and Types of Background Information

Data Source	Information Available
Topographic maps	Maps published by the U.S. Geological Survey showing site terrain, dams, surface water conditions, rock quarries
Previous geologic studies	Soil types, current and previous river and lake locations, floodplains, groundwater conditions, rock profiles
Soil survey data	Maps published by the Department of Agriculture profiling the upper 6 to 10 feet of soil
Previous engineering reports	Site geological description, record of fills or cuts, groundwater information, floodplains, wetlands, previous construction activity
Aerial photogrammetry	Macroscopic identification of topography, surface water drainage/erosion patterns, vegetation
State/municipal well logs	Groundwater table information, pumping rates, water table drawdown
Seismic potential	Maps published by the U.S. Geological Survey delineating seismicity zones in the U.S.
Personal reconnaissance	Identification of geological features through the examination of road cuts, vegetation, slopes, rivers, previously constructed buildings

- Obtain samples of subsurface materials for additional laboratory testing as appropriate.
- Install any instrumentation as required to permit additional assessment of the subsurface environment at subsequent time intervals (e.g., piezometers, inclinometers, thermistors).

27.3 Subsurface Characterization Techniques

As noted above, the range of test methods available today for subsurface characterization programs has increased significantly over the past few decades. For discussion purposes, they are considered herein under the following broad categories:

- Test pits
- Conventional drilling and sampling
- Penetration testing
- **Geophysical testing**
- Other testing techniques

Additional details of these categories are given below.

Test Pits

Test pits are a valuable technique for investigating near-surface conditions under a variety of scenarios. Typical depths of 15 to 20 feet are readily excavated with backhoe equipment of the type generally available on most construction sites. Excavations to greater depths are possible with long-boom equipment or if

a multiple-layer excavation is made. The method becomes less efficient with deeper test pits since the area of the excavation typically increases for deeper holes as the sides are sloped to facilitate excavation and personnel access and safety. Among the advantages of test pits are that the engineer can clearly document and photograph the subsurface stratigraphy, and the recovery of bulk samples for laboratory compaction and other tests requiring large samples is easy. Near-surface groundwater and cohesionless soils can combine to make excavation difficult as soil caving undermines the edges of the test pit. Although, unfortunately, less frequently used nowadays than the authors consider appropriate, block sampling techniques are easily conducted in the base or side of a test pit.

Conventional Drilling and Sampling

Depending on the anticipated subsurface conditions and the specific objectives of the investigation program, a number of conventional drilling and sampling techniques are available. An example field borehole log is shown in Fig. 27.1. Typical boring techniques used include auger drilling, rotary drilling, cable tool drilling, and percussion drilling. Factors ranging from the anticipated stratigraphy (sequence and soil type) to depth requirements can influence the method chosen. A summary of the main advantages and disadvantages for the various methods is given in Table 27.3.

Samples of soil and rock for subsequent analysis and testing can be obtained using a variety of techniques. These may range from chunk samples (taken from flights of augers) to split spoon samples (disturbed samples), which are typically obtained by driving a split barrel sampler as in the standard penetration test [ASTM D1586], to thin-walled tube samples (**undisturbed samples**), which can be obtained using one of a variety of mechanical or hydraulic insertion devices [ASTM D1587]. A summary of the factors pertinent to the selection of a specific sampling technique is listed in Table 27.4.

Penetration Testing

The term *penetration testing* is being used herein to describe a variety of test procedures which involve the performance of a controlled application and recording of loads and/or deformations as a tool is being advanced into the subsurface. For the purposes of this text, this includes pressuremeter tests [ASTM D4719] performed in predrilled holes (although obviously this is strictly not a penetration-type test as defined above). In some cases, the loads and/or deformations are recorded continuously as the device is being inserted into the ground, while in other cases measurements are made when the insertion process is halted at predetermined intervals. An assessment of *in situ* testing is given in Table 27.5. Brief descriptions of the most common methods follow.

Standard Penetration Testing

Standard penetration testing refers to a test procedure wherein a split tube sampler is driven into the ground with a known force and the number of blows required to drive the sampler 12 inches is recorded as an N value [de Mello, 1971]. The standard test procedure [ASTM D1586] refers to sampler devices which have an outside diameter of 5.1 cm, an inside diameter of 3.5 cm, and a length somewhere in the range of 50 to 80 cm to retain the soil sample. The sampler is driven into the ground with a drive weight of 63.5 kg dropping 76 cm. A variety of different hammer types are available. These range from donut and safety hammers, which are manually operated through the use of a rope and cathead, to automatic trip hammers. There is little question that this is still probably the most widely used penetration test device in the U.S. although there is clearly more widespread recognition of the many limitations of the test device resulting from equipment and operator error sources. The principal advantages and disadvantages of standard penetration testing are summarized in Table 27.6.

Cone Penetration Testing

Cone penetration testing refers to a test procedure wherein a conical-shaped probe is pushed into the ground and the penetration resistance is recorded [Robertson and Campanella, 1983]. The standard test procedure [ASTM D3441] refers to test devices which have a cone with a 60° point angle and a base

diameter of 3.57 cm that results in a projected cross-sectional area of 10 cm^2. While original cones operated with an incremental mechanical system, most new cones are electronic and are pushed continuously at a rate of 2 cm/sec. Other frequent additions to a penetrometer include a friction sleeve with an area of 150 cm^2 and a porous element which permits the pore water pressure to be recorded by a pressure transducer. A typical cone penetration test system along with details of an electronic piezo-friction cone are illustrated in Fig. 27.2. Simultaneous continuous measurements of tip resistance, q_c, side friction, f_s, and pore pressure, u, are recorded. Appropriate corrections are required to account for

TABLE 27.3 Comparison of Various Drilling Methods

Drilling Method		Advantages	Disadvantages
Auger drilling	Hollow stem	• Rapid • Inexpensive • Visual recognition of changes in strata • Hole easily cased to prevent caving • Soil/water samples easily recovered, although disturbed • No drilling fluid required	• Depth limited to approximately 80–100 ft • Cannot drill through rock • Can have heave in sands • Limited casing diameter
	Solid stem	• Rapid • Inexpensive • Small borehole required	• Sampling difficulty • Borehole collapse on removal
Rotary drilling	Direct	• Rapid • Used in soil or rock • Casing not required • Wells easily constructed • Soil disturbance below borehole minimal • Easily advances borehole through dense layers	• Drilling fluid required • No water table information during drilling • Difficult to identify particular strata • Sampling not possible during boring • Slow in coarse gravels
	Air	• Rapid • Used in soil or rock • Capable of deep drilling • No water-based drilling fluid required	• Casing required in soft heaving soils • Relatively expensive
Cable tool		• Inexpensive • Small quantities of drilling fluid required • Used in soil or rock • Water levels easily determined	• Minimum casing diameter 4 in. • Steel casing required • Slow • Screen required to take water sample • Depth limited to approximately 50–60 ft • Difficult to detect thin layers
Percussion drilling (Becker density test)		• Measure penetration resistance of gravelly soils • Relatively operator independent • Estimate pile drivability • Continuous profiling • Designed for gravels and cobbles	• Equipment strongly influences test results • Based on empirical correlations

TABLE 27.4 Selection of Sampling Technique

Sample Type	Sample Quality	Suitability for Testing
Block sample	Excellent	Classification, water content, density, consolidation, shear strength
Thin-walled tube, piston	Very good	Classification, water content, density, consolidation, shear strength
Thin-walled tube	Good	Classification, water content, density, consolidation, shear strength
Split spoon	Poor	Classification, water content
Auger/wash cuttings	Very poor	Soil identification

unequal end areas behind the tip of the penetrometer. An example cone sounding record is shown in Fig. 27.3. The principal advantages and disadvantages of cone penetration testing are summarized in Table 27.7. Cone penetrometers are being used for an increasing number of applications as new sensors are being developed and incorporated into penetration devices for a variety of geotechnical and geo-environmental applications, as summarized in Table 27.8.

TABLE 27.5 Assessment of *In Situ* Testing

Advantages	Disadvantages
Rapid	No sample recovered (except SPT)
Inexpensive	Indirect measurement related through calibration
Difficult deposits can be tested	Complex data reduction
In situ stress, pore fluid, temperature conditions	Relies heavily on empirical correlations
Real-time measurements	Unknown boundary conditions
Reproducible results	Unknown drainage conditions
Large volume of soil tested	Strain-rate effects
Continuous or semicontinuous profiling	Nonuniform strains applied
	Specialized equipment and skilled operators often required

TABLE 27.6 Assessment of Standard Penetration Testing

Advantages	Disadvantages
Commonly available	Based on empirical correlations
Applicable to most soils	Significant operator/equipment influences (See Navfac DM7.1)
Sample (disturbed) recovered	Not useful in gravels, cobbles
Rapid/inexpensive	Not useful in sensitive clays

Dilatometer Testing

The flat plate dilatometer test [Marchetti, 1980; Schmertmann, 1986] was originally introduced to provide an easy method for determining the horizontal soil pressures acting on laterally loaded piles. The present design of the dilatometer blade consists of a flat blade 1.5 cm thick by 9.6 cm wide with a 6.0 cm diameter membrane on one face, as shown in Fig. 27.4. The test is performed by advancing the blade by quasi-static push at a rate of 2 cm/s. At regular intervals, typically every 20 cm, two or three pressure readings are obtained. The A pressure reading is a membrane liftoff pressure and is obtained just as the membrane begins to move. The B pressure reading is the pressure required to cause the center of the membrane to move 1.1 mm into the soil mass. If desired, a C pressure reading may be obtained by controlling the rate of deflation of the membrane and finding the pressure at which the membrane once again comes in contact with its seat. The A and B pressure readings, corrected for membrane stiffness to P_1 and P_0, respectively, are used to define a number of dilatometer indices:

$$\text{Dilatometer index, } E_D = 34.7(P_1 - P_0)$$

$$\text{Horizontal stress index, } K_D = (P_1 - U_0) \S(s,¢)$$

$$\text{Material index, } I_D = (P_1 - P_0) \S(P_0 - U_0)$$

The C pressure reading, corrected for membrane stiffness, is thought to provide an upper bound to the induced pore pressures.

Using these dilatometer indices and numerous correlations which have been developed, a large number of soil parameters can be estimated. The principal advantages and disadvantages of dilatometer testing are summarized in Table 27.9.

Pressuremeter Testing

The pressuremeter test [Baguelin et al., 1978] typically consists of placing an inflatable cylindrical probe in a predrilled borehole and recording the changes in pressure and volume as the probe is inflated. The standard test procedure (ASTM D4719) uses probes with typical diameters ranging between 4.4 and

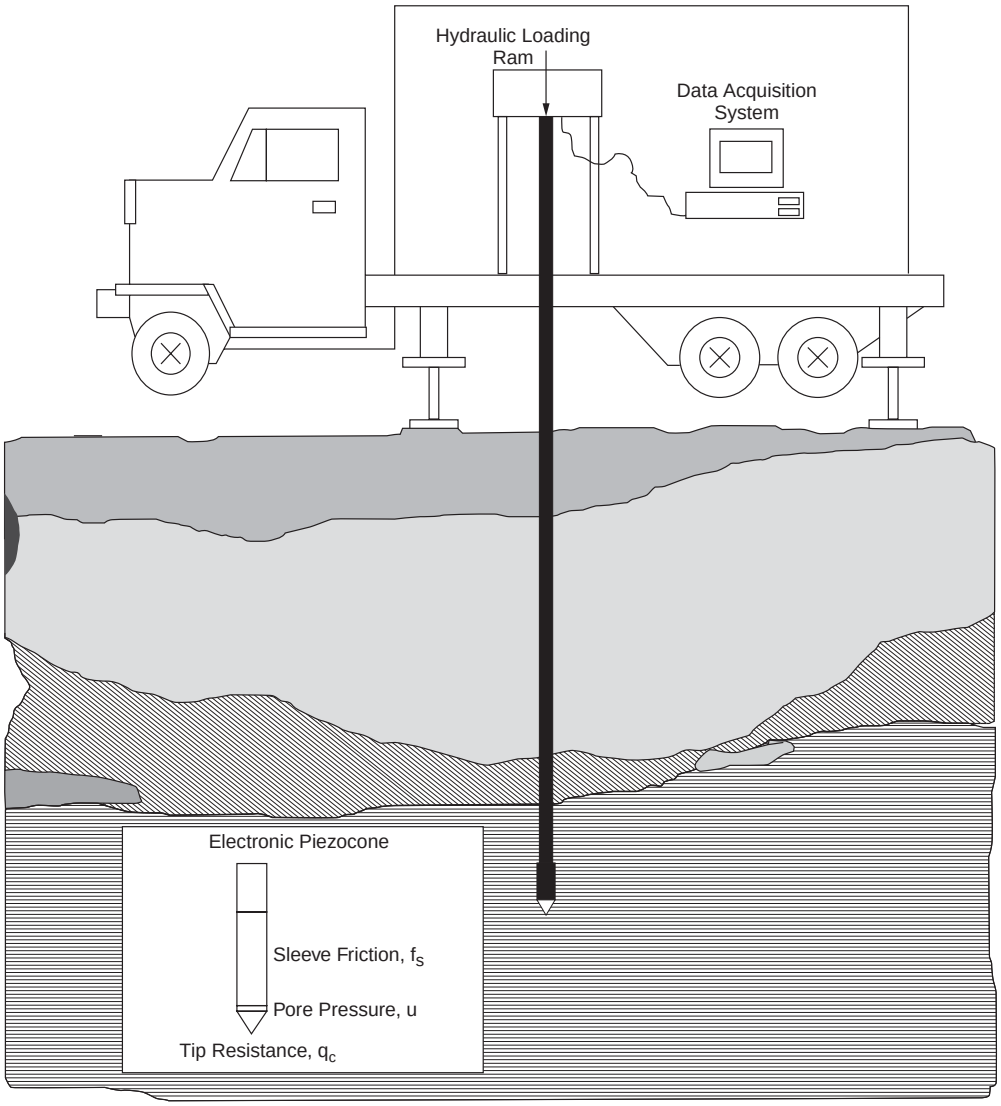

FIGURE 27.2 Cone penetration test system.

7.4 cm while the length of the inflatable portion of the probe on which the soil response is based varies between about 30 and 60 cm depending on whether the unit is a single-cell type or has guard cells at either end of the measuring cell. The probe can be expanded using equal pressure increments or equal volume increments. A schematic of a typical test arrangement is shown in Fig. 27.5. Pressuremeter soundings consist of tests performed at 1 m intervals, although clearly this is a function of the site geology and the purpose of the investigation. The test results, appropriately corrected for membrane stiffness and hydrostatic pressure between the control unit and the probe, are plotted as shown in Fig. 27.6, from which the pressuremeter modulus, E_{PM}, and the limit pressure, P_L, are determined. Using these pressuremeter indices and numerous correlations which have been developed, a large number of soil parameters can be estimated. The principal advantages and disadvantages of pressuremeter testing are summarized in Table 27.10.

One of the key factors which affects the results of the pressuremeter test is the amount of stress relief which occurs before the probe is expanded. To minimize this problem, guidelines for borehole sizes and

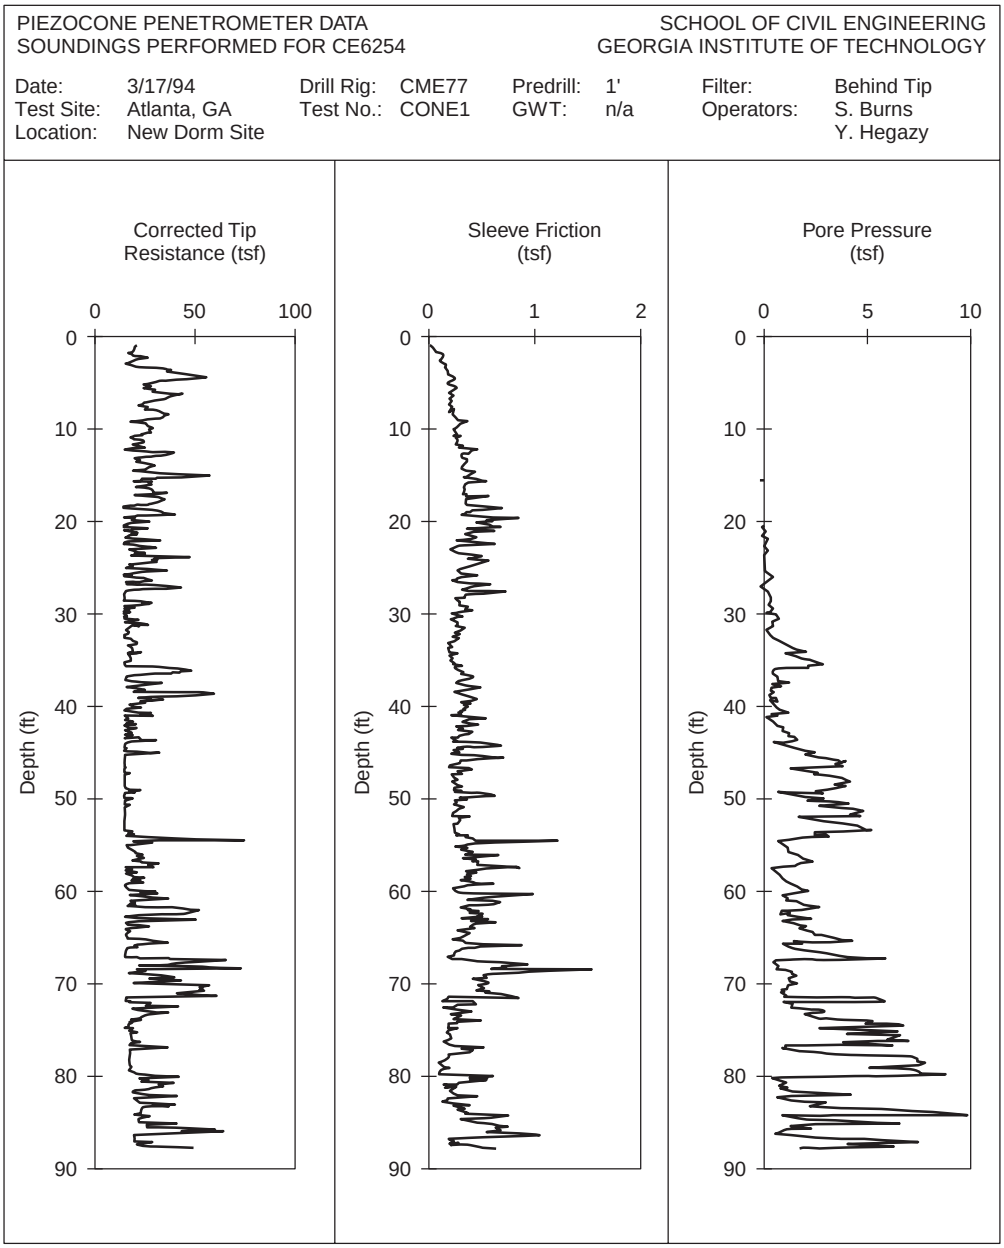

FIGURE 27.3 Typical cone penetrometer record.

the test sequence are given in ASTM D4719 for probes requiring a predrilled borehole. Alternatively, self-boring devices can be used to reduce the impact of stress relief.

Vane Shear Test

The vane shear test consists of placing a four-bladed vane in the undisturbed soil at the bottom of a boring and determining the torsional force required to cause a cylindrical surface to be sheared by the vane [Becker et al., 1987]. The test is applicable for cohesive soils. The standard test procedure [ASTM D2573] uses vanes with typical diameters ranging between 3.8 and 9.2 cm and lengths of 7.6 to 18.4 cm, as shown in Fig. 27.7. Selection of the vane size depends on the soil type with larger vanes used in softer

TABLE 27.7 Assessment of Cone Penetration Testing

Advantages	Disadvantages
Rapid/inexpensive	No sample recovered
Reproducible results	Penetration depth limited to 150–200 ft
Continuous tip resistance, sleeve friction, and pore pressure (piezocone) profile	Normally cannot push through gravel
Accurate, detailed subsurface stratigraphy/identification of problem soils	Requires special equipment and skilled operators
Real-time measurements	Most analysis based on correlations
Pore pressure dissipation tests allow prediction of permeability and C_h	
Models available to predict strength, stress history, compressibility	

TABLE 27.8 Specialized Cone Penetrometers

Sensor	Application
Accelerometer	Measurement of seismic wave velocity
Nuclear moisture content sensors	Measurement of soil moisture content
Resistivity electrodes	Identification of pore characteristics and fluids
Laser-induced fluorescence	Hydrocarbon detection
Temperature	Measurement of cone body temperature
Hydrocarbon sensors	Detection of BTEX chemicals in pore fluid and vadose zone

clays so as to provide measured torque values of a reasonable magnitude. The torque is applied at a relatively slow rate of the order of 0.1°/s which results in times to failure of 2 to 10 minutes depending on soil type. The shear strength of the soil is calculated as the product of the torque applied and a constant depending on the geometry of the vane. The principal advantages and disadvantages of vane shear testing are summarized in Table 27.11.

Geophysical Testing

Geophysical testing techniques [Woods, 1978] for investigating subsurface conditions have become a frequently used tool by engineers. They offer a number of advantages over other investigation techniques, including the noninvasive nature of the methods and the volume of soil for which properties are determined. The most common methods are seismic reflection and seismic refraction. The basis of these methods is that the time for seismic waves to travel between a source and receiver can be used to interpret information about the material through which it travels. Depending on the arrangement of the source and receivers, the subsurface environment can thus be characterized. In general, the methods require a subsurface profile where the layer stiffnesses and hence wave velocities increase with depth. Advantages and disadvantages of geophysical test methods are given in Table 27.12.

Seismic Reflection

Seismic reflection is used to describe methods where the time for the reflection of a seismic wave induced at the surface is recorded. A typical test configuration is shown in Fig. 27.8. This method involves study of complete wave trains from multiple receivers to characterize the subsurface; thus, interpretation of the test results can be subjective.

Seismic Refraction

Seismic refraction is used to describe methods where the time for seismic waves which are refracted when they encounter a stiffer material in the subsurface are recorded. A typical test configuration is shown in Fig. 27.9. Unlike reflection methods, refraction methods only rely on the time for first arrivals; thus, interpretation of the results can be more straightforward.

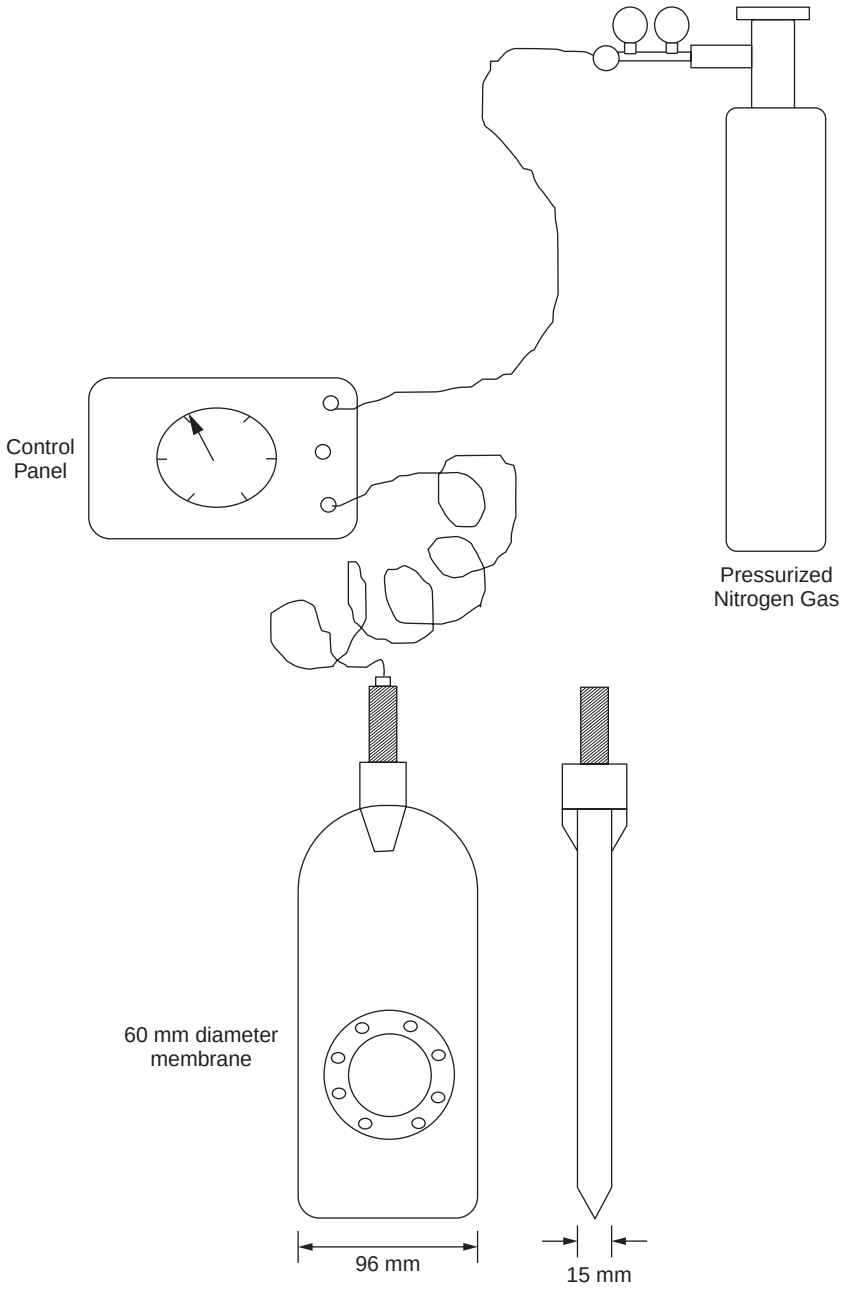

FIGURE 27.4 Dilatometer test system.

TABLE 27.9 Assessment of Dilatometer Testing

Advantages	Disadvantages
Rapid/inexpensive	Not applicable in gravels
Does not require skilled operators	No sample recovered
Semicontinuous profile	Based on empirical correlations
Estimates of horizontal stress and OCR	
Rapid data reduction	

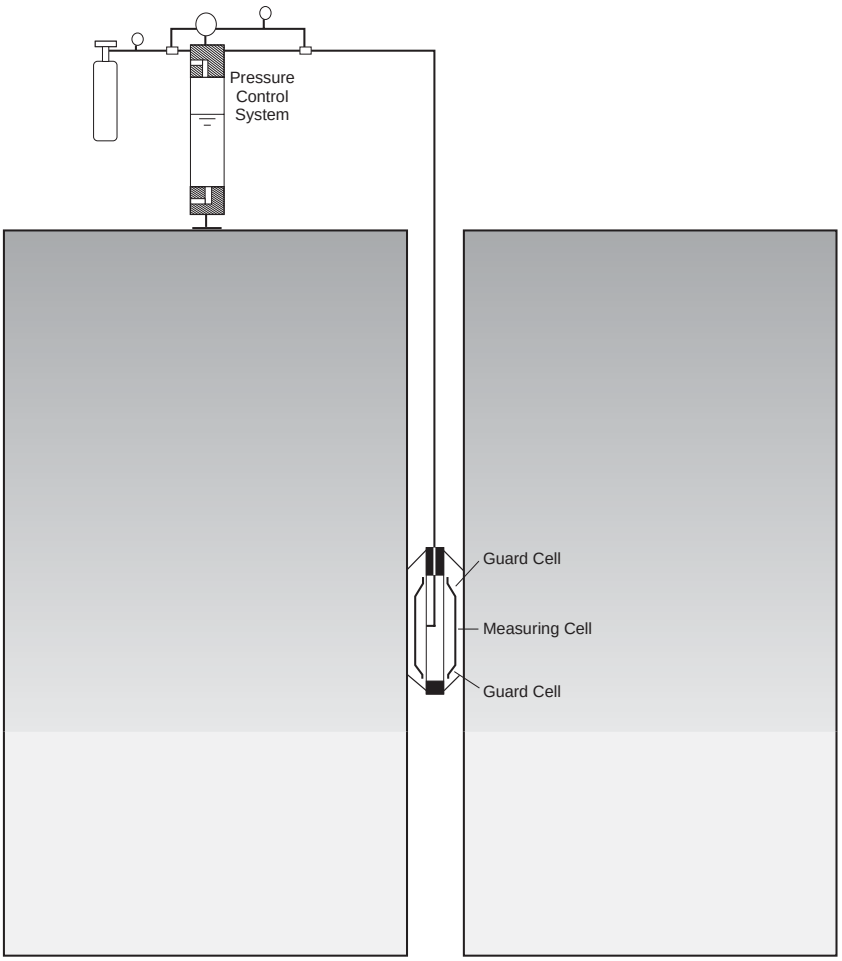

FIGURE 27.5 Pressuremeter test system.

Crosshole Testing

Crosshole seismic testing differs from the methods described above in that the source and receiver are located at the same depth in adjacent boreholes and the time for seismic waves to travel between these instruments is recorded. The standard test procedure for crosshole testing [ASTM D4428] involves drilling a minimum of three boreholes in line spaced about 3 m apart. A PVC casing is then grouted in place to ensure a good couple between the source/receiver and the PVC casing and between the PVC casing and the surrounding soil. A typical configuration is shown in Fig. 27.10.

Other Testing Techniques

While the specific test methods described above represent those that are most frequently used, there are a large number of other devices and methods that are available and should be considered by the engineer designing a site investigation program. A number of these methods are used extensively in geo-environmental site characterization programs while others are still in development or are available only for use on a limited basis. Nevertheless, since the efficiency and quality of any foundation design is directly dependent on the quality of the subsurface information available, the engineer should be aware of all possible investigation tools available and select those which can best suit the project at hand. Recognition

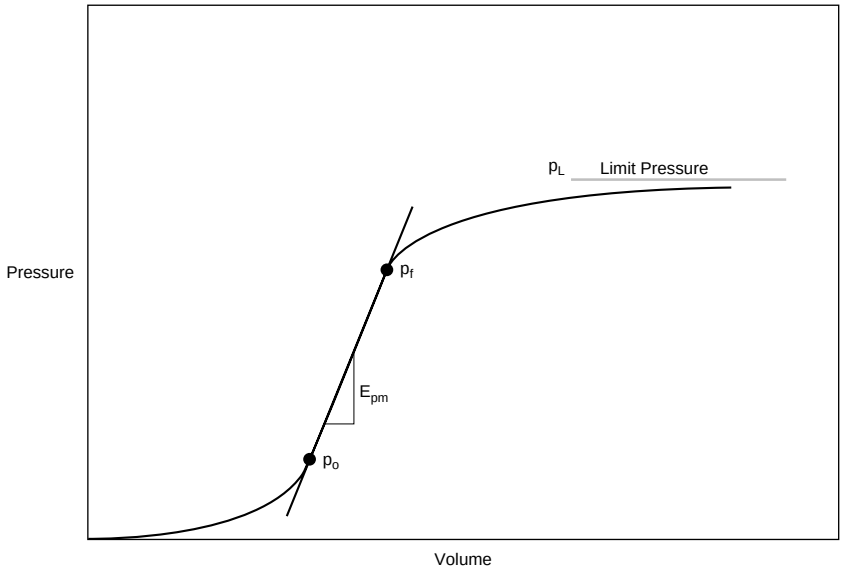

FIGURE 27.6 Typical pressuremeter test result.

TABLE 27.10 Assessment of Pressuremeter Testing

Advantages	Disadvantages
Applicable in most soils	Expensive
In situ measurements of horizontal stresses, deformability, strength	Specialized equipment and skilled operators required
Prediction of modulus	Delicate equipment
	Independent soil characterization required
	Prebored hole may be required

of the simple fact that the expenditure of an additional few thousand dollars at the site investigation stage could result in the savings of many thousands or even millions of dollars as a result of an inefficient design or, worse, a failed foundation system, is important. Accordingly, Table 27.13 contains a listing of several other testing techniques which should be considered.

27.4 Shipping and Storage of Samples

Use of the best available techniques for drilling and sampling can be negated if appropriate procedures are not used for shipping and storing samples. Accordingly, an integral part of the planning of any site investigation program should be the identification of procedures required for shipping samples to a laboratory and for their subsequent storage prior to testing. Typical details of procedures and containers appropriate for maintaining subsurface samples in a condition as close as possible to their undisturbed state are available [for example, ASTM D3213, ASTM D4220, ASTM D5079].

Defining Terms

Geophysical testing — Test procedures which involve the application and recording of the travel of relatively low frequency, high amplitude waves in the subsurface.

Invasive — Test procedure which involves physical insertion of a test instrument into the subsurface.

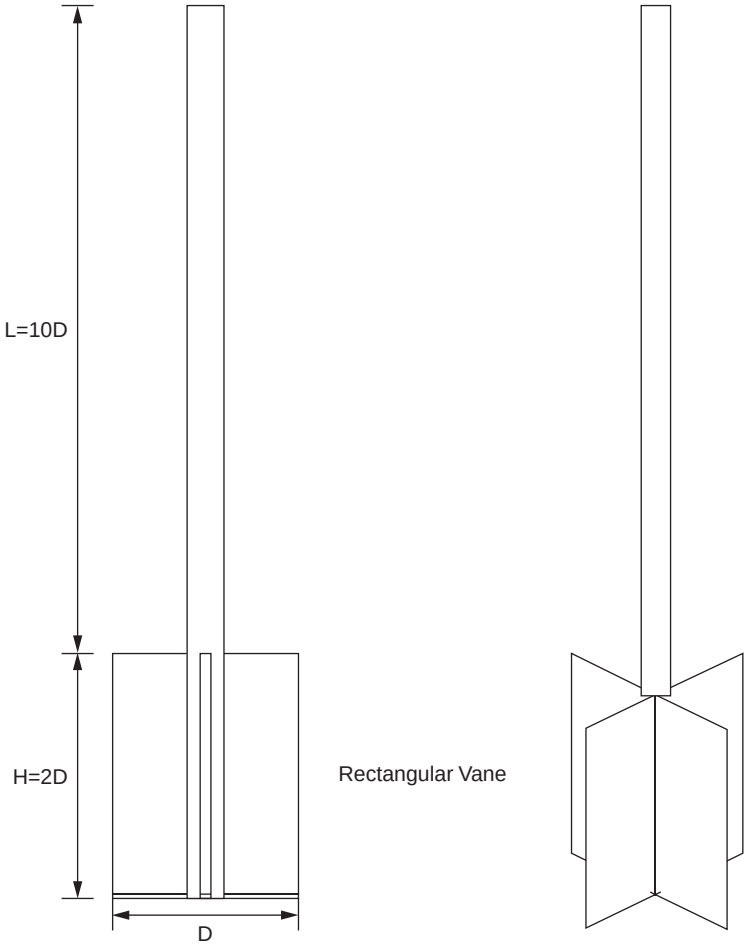

FIGURE 27.7 Vane shear test system.

TABLE 27.11 Assessment of Vane Shear Testing

Advantages	Disadvantages
Rapid/inexpensive	Only applicable in soft clays
Applicable to sensitive clays	Point measurement
Theoretical basis	Generally only undrained shear strength measurements
Measurement of shear strength, remolded shear strength, and sensitivity	No sample recovered
	Prebored hole may be required
	Independent soil characterization required

Noninvasive — Test procedure which does not involve physical insertion of a test instrument into the subsurface.

Penetration testing — Test procedures which involve the performance of a controlled application and recording of loads and/or deformations as a device is being advanced into the subsurface.

Subsurface — Matrix of soil, rock, groundwater, and pores from which earth structures will be made and on which buildings will be supported.

Undisturbed sampling — Retrieval of samples from subsurface for subsequent laboratory evaluation and testing with minimum of disturbance.

TABLE 27.12 Assessment of Geophysical Testing

Method	Advantages	Disadvantages
Downhole	Only one borehole required	Attenuation with depth
	Relatively inexpensive	Invasive
	Measurement of seismic soil properties	No sample recovered
		Limited by depth of borehole
Crosshole	Minimum of two boreholes required	Expensive
	No attenuation with depth	Invasive
	Measurement of seismic soil properties	Possible refraction interference
		No sample recovered
		Limited by depth of borehole
Surface	Noninvasive	Complex data analysis
	Inexpensive	Special equipment and skilled operators required
	Measurement of seismic soil properties	
	No boreholes required	No sample recovered
	Environmental applications due to limited contaminant exposure	Attenuation with depth
		Refraction method applicable only when velocities increase with depth
		Possible refraction interference

For Further Information

There is a very extensive bibliography describing the numerous test devices and methods introduced in this chapter. There have been a number of important conferences, symposia, and workshops over the past two decades. The interested reader is encouraged to review the proceedings of such meetings for additional information. The principal proceedings include the following:

- Proceedings of ASCE Specialty Conference on *In Situ* Measurement of Soil Properties, Raleigh, USA, 1975.
- Proceedings of ASCE Specialty Session on Cone Penetration Testing and Experience, St. Louis, USA, 1981.

28.1 Introduction

In all geotechnical engineering problems, performance prediction requires determination of the properties of the soil or rock mass under consideration, and their appropriate use employing soil mechanics theories. For the determination of the soil properties to be used in design, geotechnical engineers can follow two, often complementary, approaches: obtain soil samples from the field and subsequently perform laboratory tests on these samples, or make use of ***in situ* tests**.

Laboratory tests are performed under well-defined and controlled boundary and testing conditions (e.g., drainage, stress path, strain rate) and have the benefits of isolating specific engineering properties. However, their use is limited by the variable and often not completely understood effects of sample disturbance and by generally long testing times and high costs. In addition, because testing involves relatively small specimens, extrapolation of the measured properties to the entire site is often challenging.

In contrast, *in situ* tests, which represent the focus of the first part of this chapter, provide the response of a much larger soil mass under natural, *in situ* conditions (e.g., stresses, void ratio, saturation, temperature) often through approximately continuous records. Thus, they not only provide more economical and rapid estimates of some properties, especially when sampling is difficult, but also are excellent means for soil profiling, furnishing information on the stratigraphy of the site and on trends in engineering properties. In this capacity, they are often used in conjunction with laboratory testing to obtain information on the spatial variation of properties measured in the laboratory.

In situ tests also have limitations, namely poorly defined boundary conditions, non-uniform and high strain rates imposed during testing, inability to control drainage conditions, and effects of installation that are hard to quantify (in the case of some tests). For these reasons, most *in situ* tests do not provide a way to measure directly the fundamental properties of the soil. Instead, the measurements must be related to the quantities of interest in most instances by means of empirical correlations.

The second class of field instruments that are discussed in this chapter are those used for monitoring field conditions before, during, and after construction. Deep foundations, braced excavations, mining excavations, natural or excavated slopes, bridges, embankments on compressible ground, and dams are

just some of the structures that may be monitored during construction or operation. In this process, quantities (such as pore-water pressures, total stresses, loads or stresses in structural elements, deformation and displacements) whose values were assumed, computed, or specified during design are measured and recorded. The analysis of these data provides the means to modify the design or the construction procedures to reduce costs or avoid catastrophic failure, in accordance with the observational method (Peck, 1969). In addition, some monitoring instruments may also be used before design and construction, such as piezometers, which are routinely used during site investigation to obtain information about the groundwater conditions at a site.

The goal of this chapter is to present the devices most commonly used for *in situ* testing and monitoring, and discuss their use and the interpretation of the measurements.

28.2 *In Situ* Tests

The Role of *In situ* Testing in a Site Investigation Program

Geotechnical design requires an assessment of the properties of the soil or rock at the site where construction activity will take place. Information gathered during this process, referred to as the *site investigation phase*, generally includes:

1. The groundwater regime at the site
2. The nature of soil and rock found at different depths as far down as thought to be of consequence. For soils, key characteristics include particle size distribution, water content, Atterberg limits, and unit weight. For rocks, geologic origin, degree of weathering, frequency, thickness, length and spatial orientation of discontinuities are some of the most relevant parameters.
3. The engineering properties of relevance for the particular problem under investigation (e.g., shear strength, compressibility, hydraulic conductivity)
4. Any particular geologic characteristic, such as an underground cavity or a fault

In the site investigation phase of a project, *in situ* tests play an important role, and at least one form of *in situ* test is always performed. The most common tests in the U.S. are the standard penetration test (SPT) and the cone penetration test (CPT). Other *in situ* tests include the pressuremeter test (PMT), the dilatometer test (DMT), and the field vane test (FVT). Table 28.1 summarizes the properties that can be estimated using these devices.

Standard Penetration Test

The SPT is performed by advancing a split spoon sampler into the base of a borehole by blows from a hammer with a standard weight of 140 pounds falling from a height of 30 inches. The number of blows N required to advance the sampler a distance of 1 foot into the soil is recorded and indicates the soil's density and confining stress. In addition, a sample, on which classification tests can be performed, is obtained when the split spoon sampler is extracted. The approach to SPT interpretation is usually based on correlations to the blow count. For example, a number of widely used relationships exist between N and properties such as the relative density and the friction angle of cohesionless soils. In addition, the SPT is used commonly for the evaluation of liquefaction susceptibility of a deposit.

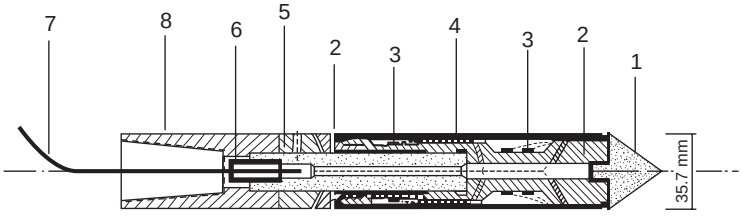
Unfortunately, SPT blow counts also depend on the equipment and procedure used to perform the test. The following have all been found to affect the test results: procedure used to raise and drop the hammer, hammer type, string length, presence of a liner inside the sampler, sampler condition, borehole condition, and drilling method. Attempts to standardize the test have been made (Seed et al., 1985; Skempton, 1986). These authors recommend how to correct N for a variety of factors, so that the N value becomes more representative of the soil density and stress state and less representative of equipment and procedural factors. Although these corrections are not perfect, they make it possible to use the test with some effectiveness. That, associated with the familiarity engineers have with the test, is responsible for the continuing importance and wide use of the SPT in geotechnical field testing.

The following are references on the interpretation of SPT results: estimation of friction angle in sands (Skempton, 1986); estimation of undrained shear strength in clays (Stroud, 1975); estimation of liquefaction resistance in sands (Seed et al., 1985; Seed and Harder, 1990); estimation of the settlement of shallow foundations in sand (Burland and Burbidge, 1985); estimation of pile capacity in all soils (Bandini and Salgado, 1998).

Cone Penetration Test

In the CPT (ASTM D3441 and D5778), a cylindrical penetrometer (Fig. 28.1) with a conical tip (10 cm^2 in cross section, with apex angle of 60 degrees) is pushed vertically down into the soil at a rate of 2 cm/sec while the vertical force acting on the tip during penetration is measured. The ratio of this force to the projected area of the tip provides the cone penetration resistance, q_c, which is the most important parameter through which estimates of engineering properties are determined. The frictional resistance, f_s, along a lateral sleeve located immediately behind the cone is also routinely measured.

The most important use of cone resistance values is the estimation of shear strength in both clays and sands. In sands, this is done by first estimating relative density and lateral effective stress using charts of



1. conic point
2. load cell
3. strain gages
4. friction sleeve
5. adjustment ring
6. waterproof bushing
7. cable
8. connection with rods

FIGURE 28.1 The standard electrical cone penetrometer. (From De Ruiter, J. 1971. Electric penetrometer for site investigation, *J. Soil Mech. Found. Div. ASCE*, vol. 97, no. SM2, February. With permission.)

cone resistance as a function of these two quantities, such as those presented by Salgado et al. (1997a). The most common procedure is to first calculate the vertical effective stress at the point of interest from the known soil profile. Then an estimate of K_0 is made. This often is possible based on knowledge of the site geology. If the sand is known to be normally consolidated, K_0 ranges from 0.4 for dense to 0.5 for loose sand. Finally, one enters a suitable chart with the value of K_0 and the measured value of q_c to obtain the relative density.

In clays, the undrained shear strength, s_u, is obtained directly from the cone resistance q_c through

$$s_u = \frac{q_c - \sigma_v}{N_k} \tag{28.1}$$

where σ_v = vertical total stress
N_k = cone factor, which is approximately equal to 10 for fully undrained penetration (e.g., see Yu et al. 2000).

Penetration is fully undrained when vd_c/C_v is less than approximately 1, where v = penetration rate, d_c = cone diameter, and C_v = coefficient of consolidation (Bandini and Salgado, 2002). If the clay contains large percentages of either silt or sand, C_v becomes too small and the ratio vd_c/C_v, larger than 1. In these cases, penetration is not fully undrained for the standard penetration rate of 2 cm/sec. Consequently, either the penetration rate must be increased or a higher value of N_k must be used in Eq. (28.1).

Another important use of the CPT is in the assessment of the liquefaction potential of cohesionless soils. Correlations have been developed between the tip resistance (appropriately corrected and normalized) and the cyclic resistance ratio (Robertson and Campanella, 1985), and today the CPT is the preferred tool for determining liquefaction resistance.

One important and widely used variation of the CPT is the piezocone (CPTU – e.g., Baligh et al., 1981), which contains a pressure transducer for measurement of the pore pressure generated during penetration in a porous element located at the face of the conical tip or immediately behind it. The CPTU represents an excellent means for soil profiling, allowing accurate detection of thin lenses of different soils and delineation of drainage boundaries. It can also be used to determine the horizontal coefficient of consolidation of the soil by performing dissipation tests (Baligh and Levadoux, 1980).

Various soil identification and classification charts based on tip resistance, friction ratio, and excess pore water pressure (in the case of the CPTU) have been proposed (e.g., Robertson, 1990). The use of these charts is recommended only when experience with similar soil conditions exists.

The advantages of cone penetrometers over other field testing devices are numerous, including the limited influence of the operator and hardware on the values of the measured quantities, and the fact that they provide continuous records. In addition, these devices are very versatile and many different **sensors** can be incorporated into the cone, facilitating measurement of additional quantities, such as the shear wave velocity V_s along the penetration path (Robertson et al., 1986), and a number of properties of interest in geoenvironmental projects, including temperature, electrical resistivity, organic content in the pore fluid, and other pore fluid chemistry parameters (e.g., Mitchell, 1988; Sinfield and Santagata, 1999). Finally, various analytical models describing the advancement of the cone penetrometer through soil have been developed, allowing a more rational interpretation of the data (e.g., Salgado et al., 1997a, b; Salgado and Randolph, 2001; Yu and Mitchell, 1998).

Jamiolkowski et al. (1985) discuss many details of both performance and interpretation of the CPT. Additional references, focusing on interpretation of CPT results include the following: theoretical relationships for cone resistance (Salgado et al., 1997b; Yu and Mitchell, 1998; Yu et al., 2000; Salgado and Randolph, 2001); estimation of friction angle in sands (Salgado et al., 1997b), using the Bolton (1986) relationship for friction angle in terms of relative density and stress state; estimation of undrained shear strength in clays (Yu and Mitchell, 1998); estimation of liquefaction resistance in sands (Robertson and

Campanella, 1986; Mitchell and Tseng, 1989; Stark and Olson, 1995; Bandini and Salgado, 2002; Mitchell and Brandon, 1998); estimation of the settlement of shallow foundations in sand (Schmertmann, 1970; Schmertmann et al., 1978; Lee and Salgado, 2002); estimation of the load capacity of drilled shafts and driven piles in sand (Lee and Salgado, 1999); load capacity of both closed and open-ended pipe piles in sand (Lehane and Randolph, 2002; Paik et al., 2002); summary of methods to estimate capacity of all types of piles in all types of soils (Bandini and Salgado, 1998).

Pressuremeter Test

The PMT is performed by expanding a cylindrical membrane (Fig. 28.2) in the soil while simultaneously measuring the pressure (p) inside the membrane and the displacement of the membrane. From these data, the expansion curve (usually expressed in terms of p versus the hoop strain) is obtained. There are essentially two methods for installation of the pressuremeter: in one, a borehole is prebored and the pressuremeter is lowered into it (this is known as the Menard pressuremeter); in the other, the pressuremeter has a drilling tool at its lower end that is used to install it at the desired depth (this is the so-called self-boring pressuremeter). Apart from any disturbance due to drilling (and unloading in the case of the Menard pressuremeter), the expansion curve obtained in a PMT, as well as any unloading-reloading

FIGURE 28.2 A pressuremeter. (Picture courtesy of A. Bernal and A. Karim, Bechtel Geotechnical Laboratory, Purdue University.)

loops, can be related to the stress-strain relationship of the soil. In addition, the limit pressure extrapolated from the pressuremeter curve provides an indication of the shear strength of the material. In practice, the pressuremeter is most commonly used to determine the friction angle of cohesionless soils and the modulus degradation behavior. The pressuremeter is also the only device that can provide a direct measurement of the horizontal effective stress, σ'_h. While the use of the PMT for this purpose is considered somewhat reliable in soft clays, its reliability and accuracy in the case of stiffer soils, such as sands, remains questionable (e.g., Fahey, 1998).

The main problems with the use of the pressuremeter are related to assessing the degree of disturbance due to installation and the effect of the length-to-diameter (L/D) ratio of the membrane. While interpretation methods are generally based on the assumption that the expansion of the membrane can be approximated by a cylindrical cavity expansion, for typical values of the L/D ratio this assumption deviates from reality, and correction for L/D effects are needed.

References on pressuremeter test performance and interpretation include: ASTM D 4719–87, Baguelin et al. (1978), Clark (1995), Hughes et al. (1977), Mair and Wood (1987), Manassero (1992), and Yu (1990).

Dilatometer Test

The DMT is performed by pushing down into the soil the blade shown in Fig. 28.3. Penetration is halted at preselected depths, and the circular membrane on one of the sides of the dilatometer is expanded and the pressures at deflections of zero and 1.1 mm are recorded and corrected for membrane stiffness. Based on these two fundamental parameters, a number of empirical relationships have been proposed for soil parameters of interest in design (Marchetti, 1980; Schmertmann, 1986; Fretti et al., 1992).

A shortcoming of the DMT is that the membrane expansion is accomplished against soil that has been considerably disturbed by penetration of the device. This obscures, more than for other *in situ* tests, the relationship between measurement and undisturbed soil properties, reducing the reliability of correlations proposed for this test.

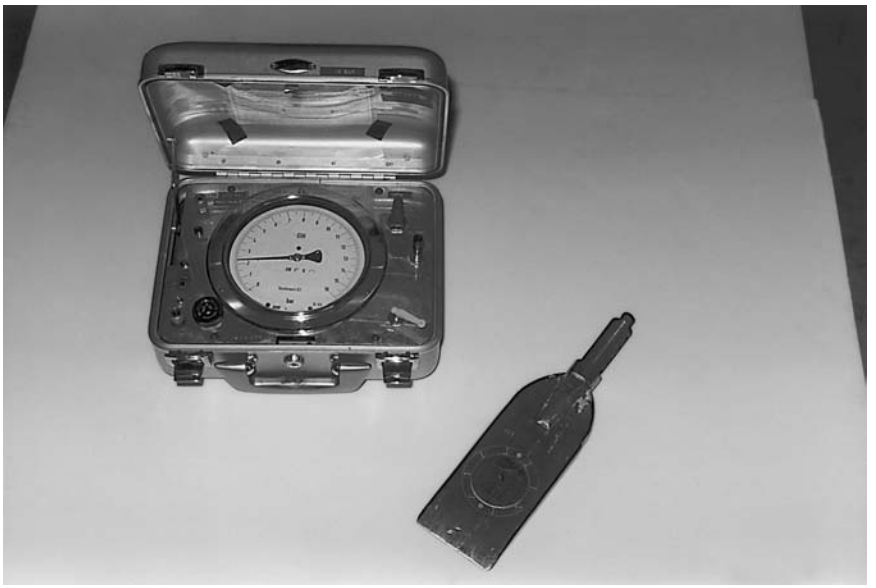


FIGURE 28.3 A dilatometer. (Picture courtesy of A. Bernal and A. Karim, Bechtel Geotechnical Laboratory, Purdue University.)

Field Vane Test

The FVT involves pushing a four-bladed vane having a height-to-diameter ratio of two into the soil and then rotating the blade at a rate of 0.1 degrees/sec (ASTM 2573). This test provides a simple and inexpensive means of estimating the undrained strength of cohesive soils, which is derived from the maximum torque measured during rotation of the blade, assuming full and uniform mobilization of the shear strength along the cylindrical surface created by the rotating vane. The use of this test is advocated particularly in the case of relatively homogeneous clay deposits, in absence of shells, granular layers, varves and fibers (Ladd, 1990). A correction (Bjerrum, 1972, 1973), based on the plasticity index of the soil, is generally applied to the shear strength measured with the FVT, to obtain a "field" value of the strength to be used in design. A correction for end effects that are associated with the mobilization of shear strength on the top and bottom of the cylindrical volume of soil sheared by the vane is also necessary. Despite the simplicity of the test, a number of procedural aspects (e.g., rate of rotation of the blade, delay between vane insertion and testing); influence the test results (Ladd et al., 1977), and adherence to standard practice and equipment is essential.

28.3 Instrumentation for Monitoring Performance

Planning of an Instrumentation Program

There are multiple reasons to use **instrumentation.** It may be that a project design has enough flexibility to be changed if measurements made during early stages of construction indicate that changes are required or could be beneficial. Alternatively, the facility under construction may be so important and its loss may lead to so much damage or danger that instrumentation must be used to detect any deviations from the assumed or predicted behavior of the facility, to allow timely implementation of previously planned actions to either correct the deviation or minimize losses. In other cases, the construction procedure (e.g., staged construction) may rely on indications of changes in the *in situ* conditions for proper execution of the construction plan. Finally, when a new construction concept is used, instrumentation is sometimes used to show or ascertain that the concept indeed works. Whatever the reason, detailed planning is essential for a successful instrumentation project.

Design of the instrumentation program must rely on a clear definition of the geotechnical problem that is being addressed and on the fundamental understanding of the mechanisms that control the behavior. Once the objectives of the monitoring program are identified, its implementation requires selection of the following: type and number of instruments to be used, specific locations where measurements are to be made, installation procedures, and data acquisition system, methods for analyzing and interpreting the data. Figure 28.4 illustrates the main steps in the planning and implementation of an instrumentation program.

Ultimate selection of the instruments depends on the quantities to be measured and estimates of the magnitudes of changes in these quantities resulting from construction or operation of the facility. The maximum expected change of the parameter to be measured will define the range for the instrument selected to measure it. The minimum expected change defines the sensitivity or resolution of the instrument. Such predictions are also required in defining criteria for remedial action, if the purpose of the instrumentation is to ensure proper and safe operation of the facility.

When selecting instruments, several characteristics must be evaluated carefully:

1. Conformance: the instrument should conform to the surrounding soil or rock in such a way that it does not alter the values of the properties it is intended to measure.
2. Accuracy: the measure should be as close as possible to the true value.
3. Repeatability: under identical conditions, an instrument must measure the same value for the quantity it is intended to measure whenever a measurement is taken.

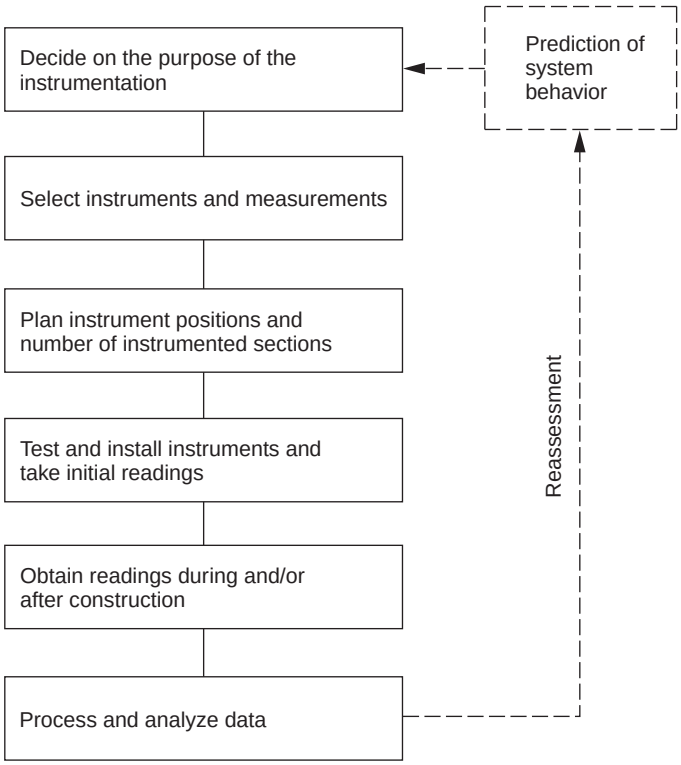

FIGURE 28.4 Planning of an instrumentation program. (From Ortigão, J.A.R. and Almeida, M.S.S. 1988. Stability and deformation of embankments on soft clay, in *Handbook of Civil Engineering Practice*, P.N. Chereminisoff, N.P. Chereminisoff and S.L. Cheng, eds., Technomic Publishing Co., New Jersey, vol. III, 267–336, With permission.)

4. Resolution: the smallest division of the instrument read-out scale must be compatible with the minimum expected change in the quantity being measured.
5. Sensitivity: the change in output per unit change in the input should be as large as possible to optimize data acquisition and limit the effects of noise.
6. Linearity: the relationship between input and output should be as linear as possible for the range in which the input is to be measured to facilitate data reduction.
7. Hysteresis: it is undesirable that a different value for the quantity of interest be measured depending on whether the quantity is increasing or decreasing; this difference should be kept to a minimum, particularly if cyclic measurements are needed.
8. Noise: random variations in the measurement should be limited.
9. Environmental compatibility: the instruments' readings should not be affected by changes in environmental conditions (e.g., temperature, relative humidity).

There are two approaches for selecting instrument location. Instruments can be installed in "trouble spots," such as points where it is expected there will be large stress concentrations or large pore pressure increases, or where difficult soil conditions exist. Alternatively, they can be placed at a number of representative points or zones. In either case, the designer should make every effort to ensure that the instrument locations are consistent with the expected behavior of the facility and with the data required for the analysis. It is also important that there is some redundancy in the instrumentation to filter anomalies in measured quantities and ensure that the required information is obtained.

Testing and installation of the instrumentation is the next major step. All instruments should be properly calibrated and tested before placement. Installation is one of the most critical steps in the entire monitoring program because minor variations in the process can have significant effects on the performance

of the devices and the reliability of the data. In many cases, hiring instrumentation specialists might be justified.

During installation, steps should be taken to ensure the protection of the instrument (e.g., protection from impact, water-tightness if required) and the instrument should be installed to minimize disturbance of the medium under investigation.

Once installed, initial readings should be obtained and verified to ensure that changes from the time of installation are represented accurately.

Data acquisition, processing, and analysis must be carried out in a systematic, organized way. Careful recordkeeping is crucial and should include documentation of all construction activities and any significant events that may later be correlated with unanticipated or significant changes in the quantities measured. Techniques and schedule for data acquisition depend on specific instruments and on the requirements of the particular project. While many instruments still require on-site personnel, there is increased availability of systems providing automated data acquisition and storage.

Instruments

In general, three primary quantities are measured in monitoring programs for traditional geotechnical projects: loads and stresses, deformations, and pore pressures.

Instruments for Measurement of Loads and Stresses

In geotechnical engineering applications, load measurements are often required for load testing of deep foundations, load testing and performance monitoring of tiebacks and rock bolts, and monitoring of loads in strutting systems for deep excavations.

In most instances, such measurements are made with **load cells**. When accuracy is not a great concern, a calibrated hydraulic jack can also be used. Based on the operating principle, there is a variety of different types of load cells, including hydraulic, mechanical, electrical resistance, and vibrating wire cells.

Hydraulic cells consist of a chamber filled with fluid and connected to a pressure sensor. Load is applied to a flat element that is in contact with the fluid and is free to move with respect to the rest of the cell. The pressure generated in the fluid is measured by a pressure sensor, which can be a Bourdon gage, which requires access to the cell for reading, or an electrical or pneumatic transducer for remote reading.

Mechanical and electrical resistance and vibrating wire cells function by measuring the deformation of a load-bearing member and are based on the existence of a direct and unique relationship between deformation and load.

In the case of a mechanical load cell, the deformation of either a torsion lever system or an elastic cup spring is measured by dial gages. In electrical and vibrating wire load cells, the load-bearing member is usually a steel or aluminum cylinder, the deformation of which is measured by **electrical resistance strain gages** or vibrating wire transducers mounted at mid-height on its surface. Some of the gages (or transducers) are oriented for measuring axial strain, others for measuring tangential strains. The arrangement and the connections are designed to minimize errors associated with load eccentricity.

Strain gages can be used effectively for measurement of loads or stresses in a structural member, provided that the stress-strain relationship of the material on which they are mounted is known with some accuracy. Their main advantages are that they can be placed almost anywhere in a structure, and that, due to their limited cost, measurements can be performed at a number of different locations. A distinction is generally made between surface-mounted strain gages, which are applied to an exposed surface (for example, to the surface of a steel strut) and embedment strain gages, which are placed inside a mass, for example, a concrete tunnel lining.

Pressure cells are used to measure total stresses behind retaining walls or underneath shallow foundations, as well as within soil masses, such as fills. They are circular (Fig. 28.5) or rectangular pads with metallic walls, and are of two types: hydraulic and diaphragm cells. In hydraulic cells, a fluid, such as oil, is contained between the metallic walls. A pressure transducer positioned at the end of a rigid tube connected to the inside of the cell measures the pressure in the fluid, which corresponds to the stress

FIGURE 28.5 Pressure cells for measurement of stresses in soil masses or contact stresses between soil masses and concrete or steel surfaces. (Picture courtesy of A. Bernal and A. Karim, Bechtel Geotechnical Laboratory, Purdue University.)

acting on the face of the cell. In diaphragm cells, the pressure acting on the cell correlates with the deflection of the face, which is measured through strain gages or vibrating wire transducers mounted on the inside of the cell. Many factors, including characteristics of the cell, such as size, thickness, and stiffness, affect the measurements performed. The accuracy with which total stresses are measured is limited by conformance problems between the cell and soil arising from the difference in stiffness, the effects of the installation procedures, and difficulties in calibrating the cell to represent field conditions (Dunnicliff, 1988). When pressure cells are embedded for measurement of stresses inside a fill, arching of stresses around the cell is often the source of considerable error in the measurements.

Instruments for Measurement of Deformations

A reliable way of measuring displacements of the ground surface or parts of structures that can be observed above the ground surface is by surveying techniques.

The measurement of absolute motions requires that reference points be established. The reference for the measurement of a vertical displacement is called a **benchmark**; for horizontal displacement measurements, a **reference monument** is used. Reference stations should be motionless. If no permanent structure, known to be stable and free of deformation, exists, a reference station (benchmark or monument) must be installed. A benchmark may consist of a rod or pipe extending all the way down to a relatively incompressible layer, isolated from the surrounding soils to avoid deformation. This can be accomplished by placing the rod inside a pipe without allowing any contact between the rod and the pipe.

Points where deformations are to be determined are called **measuring points** and should satisfy three requirements: first, that they are well marked so measurements are consistent; second, that they are placed at the actual seat of movement; and third, that they last for the time during which measurements will be needed. For measurements on structures, the first requirement can be satisfied by the use of bolts embedded into wall surfaces. Sometimes a grid, scale, or bullseye may be used for improved readings.

If ground surface displacement measurements are desired and a pavement exists, particularly if it is a structural pavement, it is important to place the measuring point below the pavement, in the ground, to get an accurate measurement of the displacement. It is also important to go beyond the freeze-and-thaw depth, and any layer of expansive or collapsible soil, unless it is desired to know the motions related to these phenomena.

In addition to techniques that rely on direct visual observations, a number of other instruments are used for measurement of deformations. The most common instruments include tiltmeters, inclinometers, extensometers, settlement plates, and telltales.

Tiltmeters are instruments used for measuring the rotational component of motion of points on a structure or in the ground, usually inside a borehole. They rely on a servo-accelerometer, an electrolytic tilt sensor, or another gravity sensing device for the measurement. More common applications are for measuring the rotation of retaining walls and concrete dams, and for monitoring landslides.

Inclinometers are devices used to measure the inclination with respect to the vertical. Their applications include monitoring of landslides, measurement of horizontal displacements of embankments on soft ground and of motion of retaining structures, evaluation of deformations produced around a deep excavation, and assessment of the location of a possible failure surface. In addition, inclinometers can also be placed horizontally; for example, to determine the settlement or heave profile under an embankment or a foundation.

An inclinometer system typically consists of a casing, a probe, and a readout unit. The casing, which is generally formed by sections of grooved plastic pipe, may be installed in a borehole, embedded in a fill or in concrete, or attached to a structure. Measurements are obtained by periodically lowering the probe inside the casing all the way to a depth where no motion is expected. Grooves in the casing act as guides for the inclinometer probe, maintaining its orientation. The probe consists of a tube with two sets of hinged wheels 0.50 m apart (Fig. 28.6), and typically contains two sensors: one aligned in the

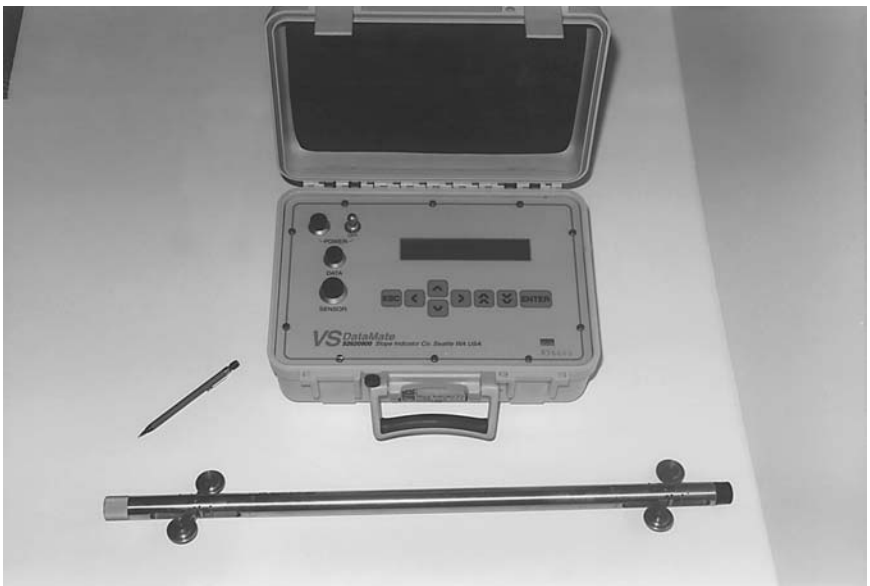

FIGURE 28.6 Inclinometer and read-out unit. (Picture courtesy of A. Bernal and A. Karim, Bechtel Geotechnical Laboratory, Purdue University.)

plane of the wheels and the other at 90 degrees. While various types of inclinometers are available, the most common are based on servo-accelerometers, vibrating wire strain gauge transducers, and magneto-restrictive sensors. Two sets of readings are typically obtained by rotating the probe 180 degrees to check for errors in the data produced by faulty equipment or poor technique.

From the readings of the two sensors, which measure the angle of inclination to the vertical, the two components of horizontal movement can be determined. Using as reference the initial profile of the casing determined from the first set of measurements, the evolution of the entire borehole profile can be assessed. Because errors in the use of inclinometers are often associated with spiraling of the casing, particularly in the case of deep installations, a spiral sensor that allows correction of the inclinometer data may be used.

In addition to the portable inclinometer probe, which is the most standard device used in practice, in-place inclinometers may be used in critical applications requiring real time observations such as for construction control and safety monitoring. These devices consist of a string of inclinometer sensors connected in sequence through pivot points.

Extensometers are instruments for measuring the relative displacement between two points. Depending on how they are deployed in the field, these instruments can be classified as surface or borehole extensometers. **Surface extensometers** include devices such as jointmeters and strainmeters used to monitor cracks in structures, rock, or behind slopes, as well as gages used for monitoring convergence within tunnels and braced excavations. All these devices function in a similar manner, by measuring the relative movement of two pins or anchors fixed to the soil or rock with techniques as simple as a tape measure or a dial gage or as sophisticated as **vibrating wire transducers**, **LVDTs**, and optical sensors.

Borehole extensometers are used to monitor the change in distance between two or more points along the axis of a borehole, and are used for a variety of purposes including monitoring of settlement or heave in excavations, foundations, dams and embankments, and monitoring of compression of piles.

Measurements are typically obtained by lowering a probe inside a casing and measuring the position of reference points, typically rings or magnets, relative to a fixed point at the surface or at the bottom of the borehole. Settlement and heave are determined comparing the initial and current values of these measurements. Borehole extensometers are often used in conjunction with inclinometers and may share the same casing.

In addition to the probe-based systems previously described, other devices permanently installed in a borehole can be used to monitor changes in vertical position at one or more points. These instruments typically consist of one or more anchors connected to rods, which extend to the surface. Movement at depth is detected from the change in distance between the top end of each rod and a reference point.

Settlement plates carry out the same function for monitoring of deformations underneath embankments constructed on soft clays. A 1- to 1.2-m square steel plate is embedded under the embankment and connected to a 25- to 50-mm diameter coupled pipe, which extends all the way to the surface and is isolated from the soil by a casing. The displacement of the plate is determined by measuring the elevation of the top of the pipe.

The principle is also essentially the same for **telltales**, which are rods extending from a point inside a structural element, such as a drilled shaft, and isolated from the surrounding concrete (or other material) by means of a casing. Measurement of the displacement of the tip of the rod with respect to a reference provides a measure of the displacement at the inaccessible point in the structure.

Instruments for Measurement of Pore Water Pressure

Piezometers are used to measure groundwater pressure. This is an essential parameter in all geotechnical engineering projects, required for computation of effective stresses and earth pressures exerted on retaining systems. Calculation of pore pressures may be straightforward if the depth to the groundwater table is known and hydrostatic conditions are known to exist, but there are many situations where there is enough uncertainty about pore pressure values to warrant the use of piezometers.

Piezometers are commonly used for monitoring groundwater draw-down around excavations; for evaluating rates of consolidation during embankment construction on soft soils so that the fill may be

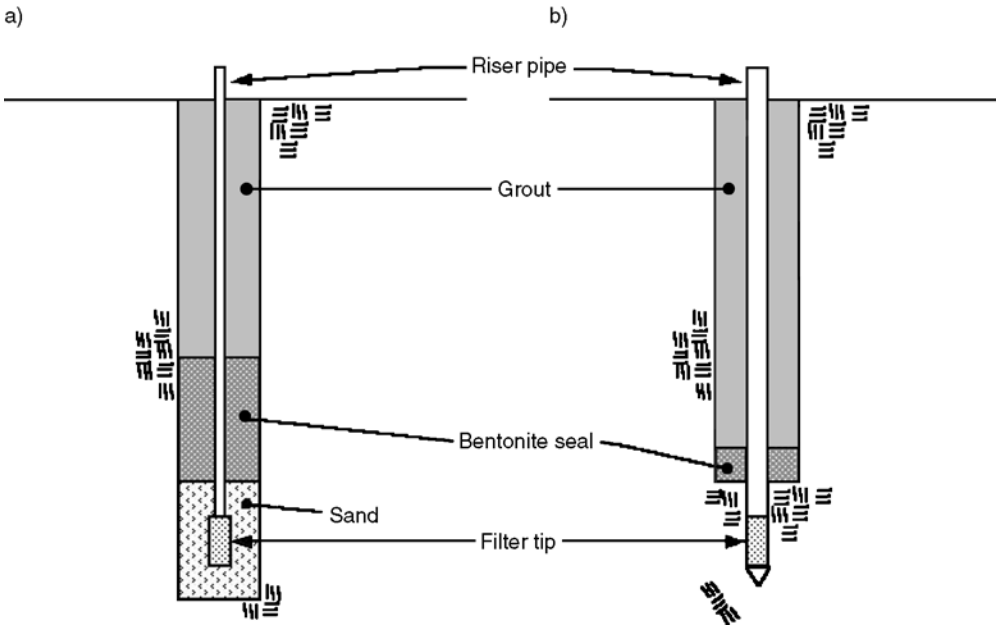

FIGURE 28.7 Schematic of standpipe piezometer (a) installed at bottom of a borehole and (b) pushed into base of borehole.

placed without risks of failure; for verification of pore pressure dissipation around a pile after driving to determine the right time to start a static load test; and for monitoring of pore pressure build-ups produced by ineffective drainage in earth dams.

Piezometers can be classified in five main groups: open standpipe, hydraulic, pneumatic, electrical, and vibrating-wire.

Open standpipe (or Casagrande) piezometers consist of a porous tip installed at the point where the pore pressure readings are to be made. These piezometers are usually installed at the base of a borehole with a diameter of 50 to 100 mm. They can be placed on the base of the borehole, which is then backfilled with sand that will completely surround the porous tip, and sealed to prevent vertical migration of water (Fig. 28.7(a)). Alternatively, they can be pushed into the base, so they are surrounded by natural material (Fig. 28.7(b)). A single pipe (10–50 mm in diameter) is connected to the porous tip, which extends to the ground surface and is generally open to the atmosphere. The level to which the water rises in the tube is measured with a water level indicator and reflects the pore pressure at the porous tip.

In a hydraulic piezometer, twin tubing filled with de-aired water connects the porous tip to remote pressure-reading devices, which may be mercury **manometers**, electrical pressure transducers, or **Bourdon gages**. The double-tube system allows verification that there is no entrapped air, as well as flushing of the system. The use of this type of device is advocated for long-term monitoring of pore water pressures in embankment dams (Dunnicliff, 1988).

Pneumatic, electrical resistance and vibrating-wire piezometers, all contain a pressure diaphragm. Water pressure acts on one side of this diaphragm, via a filter, and the difference between the piezometers resides in the mechanism on the other side of the diaphragm used to measure the pressure.

In a pneumatic piezometer (Fig. 28.8(a)), a pneumatic indicator is connected to the diaphragm through twin tubes. Measurement of the pressure at the diaphragm is performed by increasing the pressure of a gas inside one of the tubes until it exceeds the water pressure, resulting in flow of the gas back up to the indicator through the second tube.

In vibrating-wire piezometers (Fig. 28.8(b)) and electrical resistance (Fig. 28.8(c)), the diaphragm is the sensing element of a pressure transducer contained in the same housing that holds the filter. The transducers function by measuring the deflection of the pressure-sensitive diaphragm through a resistance

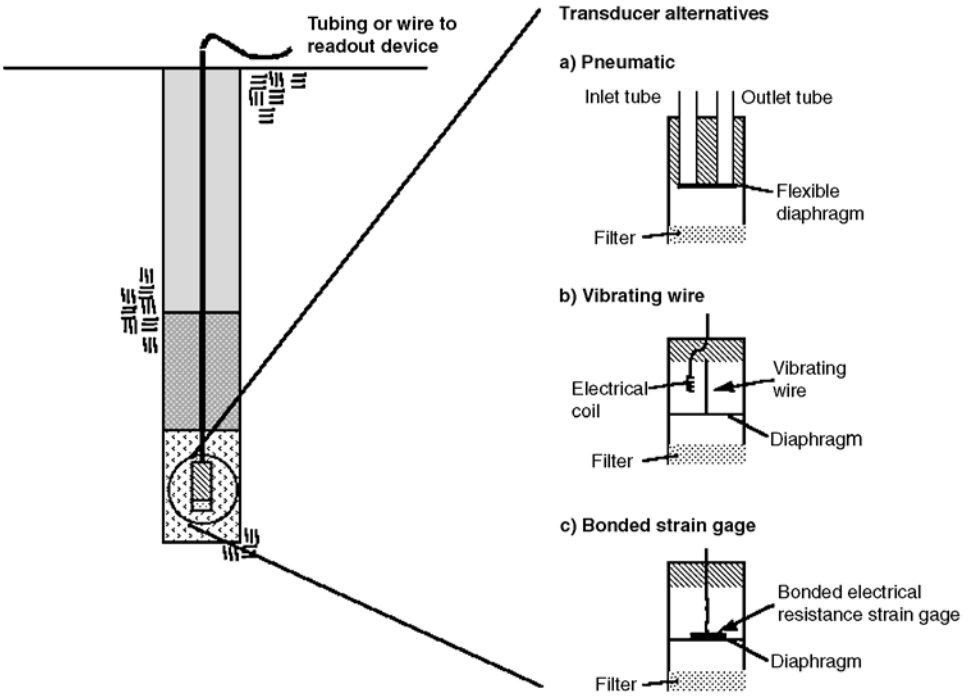

FIGURE 28.8 Schematic of (a) pneumatic, (b) vibrating wire piezometer, and (c) bonded strain gage electrical resistance.

strain gage bridge (two configurations are available: unbonded and bonded strain gages) mounted on the diaphragm, or through measurement of the resonant frequency of a tensioned wire connected to the diaphragm.

In addition to being installed in boreholes as shown in Fig. 28.8, pneumatic, electrical resistance, and vibrating wire piezometers are all available also as push-in instruments. Dunnicliff (1988) points out that while push-in piezometers are installed more easily and at less cost than in a borehole, problems arise due to the potential for inadequate seal and for smearing and clogging. Selection of the appropriate piezometer is a function of the purpose and the duration of the measurements, and is based on considerations of accuracy, ease of installation, reliability, and durability of the instruments. In addition, an important characteristic is the hydrodynamic lag time of the piezometer, which is the time required for equalization of the pore pressure. Because it depends on the time necessary for water to flow in or out of the porous tip, the lag time depends on the type of piezometer and on the permeability of the soil in which it is installed. For example, Ortigão and Almeida (1988) show that in a soil with a hydraulic conductivity of 10^{-10} m/sec, the lag time corresponding to 95% pressure equalization can vary from approximately 1000 hours for a typical Casagrande piezometer to approximately 10 seconds for a vibrating-wire piezometer.

For pore pressure measurements in unsaturated soils, any of the piezometers previously described can be used depending on the specific application, provided that they are equipped with a fine, high bubble pressure filter.

Table 28.2 summarizes some of the advantages and disadvantages of the described piezometers.

Examples of Applications of Field Instrumentation

Construction of Embankments on Soft Ground

Construction of embankments on soft soils presents risks associated with both short-term stability and excessive long-term settlements arising from both primary and secondary consolidation. In these projects, the use of the observational method is often valuable to ensure that construction proceeds safely and in

TABLE 28.2 Advantages and Disadvantages of Different Types of Piezometers

Piezometer	Advantages	Disadvantages
Open standpipe	• Highly reliable • Low cost • Simple to install • Easy to read • Can perform permeability tests • Can obtain groundwater samples	• Long time lag especially in low permeability soils • Interference with construction when used in embankments on soft soils • Susceptible to damage by construction equipment
Hydraulic twin tubing	• Reliable for long term monitoring • Flushing possible to remove air • Can perform permeability tests • Can measure negative pore pressure	• Complex installation • Very difficult and costly to implement automated data acquisition • Periodic flushing required • Limitation on elevation above piezometric head at which measurement is made • Freezing problems
Pneumatic	• Short time lag (provided tubing not excessively long) • No freezing problems • Can be used in corrosive environments	• Very difficult and costly to implement automated data acquisition • Reading time increases with length of tubing
Electrical resistance	• Simple to install • Short time lag • Simple to read • Easy to implement automated data acquisition • Some types can be used for dynamic measurements • Can measure negative pore pressure • No freezing problems	• Moderate to high cost • Susceptible to damage by lightning • Susceptible to damage by moisture • Low electrical output
Vibrating wire	• Simple to install • Short time lag • Very accurate • Simple to read • Easy to implement automated data acquisition • Can measure negative pore pressure • No freezing problems	• Moderate to high cost • Susceptible to damage by lightning

the most cost-effective manner; thus, monitoring of field performance plays an important role. This is true particularly when more complex construction designs and procedures are used, as in the case of staged construction, in which loading is applied in a controlled manner in different stages, relying on the increase in shear strength due to consolidation for stability.

In the case of construction of embankments on soft soils, the goals of the field monitoring program, which normally involves measurement of pore pressures as well as of vertical and horizontal deformations, are generally the following:

1. Evaluate the progress of the consolidation process. Knowledge of the rate of consolidation is essential so that construction schedules (e.g., placement of the pavement or structure, which would be damaged by excessive settlements; timing of subsequent loading stages in the case of staged construction; removal of surcharge in the case of preloading) can be safely and economically carried out. When vertical drains are used, information might also be gathered on the effectiveness of the drains.
2. Assess at all times the *stability* of the embankment so that, in case of incipient failure, remedial actions (such as the construction of a temporary berm, the reduction in the design fill elevation, or the removal of part of the fill) may be implemented.
3. Obtain data that will allow improvement of the prediction of behavior during subsequent construction phases, or even after construction. For example, if the project involves a preloading phase, data gathered during construction may allow modification of the thickness of the surcharge layer, based on revised estimates of soil compressibility.

As indicated by Ladd (1990) determination of the *in situ* rates of consolidation typically relies on measurements of pore pressures and vertical settlements performed under the centerline of the embankment with piezometers and extensometers, respectively. These data are also used to determine the *in situ* compression curve. Measurement of the boundary pore pressures is also in general necessary.

Additional piezometers are typically installed under the slope and, when applicable, under the berm(s) of the embankment. These instruments complement the data on rates of pore pressure dissipation, allowing, in the case of staged construction, definition of the current effective stress profile from which the updated undrained shear strength values to be used in the stability analysis can be estimated. In the use of vertical drains, Ladd (1990) suggests that care should be placed in positioning the piezometers near the midpoint of the drains and that part of the instrumentation be in place before the drains to measure excess pore pressures generated by their installation.

In addition to the measurements performed under the centerline of the embankment, vertical deformations of the soft soil layer may also be measured at other locations. This can be done, for example, by using settlement platforms to define the embankment profile.

Pore pressure field data are also used to assess the conditions of stability of the embankment; however, Ladd (1990) suggests that, as dramatic pore pressure increases often occur before or during actual failures, pore pressures may not provide timely warning of impending failure. Field measurement of vertical and especially horizontal displacements (which reflect deformations caused by undrained shear and are less affected by consolidation) better serve this purpose. In this context, data obtained from inclinometers installed at the toe of the embankment, which can be supplemented by monitoring of surface deformations with surveying techniques, provide the most unambiguous proof of foundation instability.

A thorough discussion on the use of field instrumentation in monitoring the performance of embankments constructed on soft soils, with emphasis on the role of the stress-strain characteristics of the foundation soil and on the interpretation of field data for stability analysis is provided by Ladd (1990). An extensive list of case histories of instrumented embankments on soft ground is presented by Dunnicliff (1988).

Static Load Tests on Deep Foundations

The main purpose of a standard **static load test** on a pile or drilled shaft is to obtain the relationship between the load and the displacement at the head of the pile. Instrumented load tests aim to obtain the load carried by the pile in each cross section, and, in particular, to separate the load carried by the pile base from the load carried by the pile shaft. These data are used to verify that the pile or shaft can carry the design load with an appropriate factor of safety, there are no major differences in behavior between piles, and the piles have been appropriately installed or constructed. Load tests may be performed in the design phase or during construction.

A typical arrangement for load-testing a pile is shown in Fig. 28.9 (ASTM D 1143). The figure refers to the most common load test performed, which involves the application of an axial compressive load using a hydraulic jack. (Testing under different loading conditions, such as tension or lateral loading, is also possible.) Load is applied in increments that are generally a constant fraction of the maximum applied load, which is either an estimate of the limit or plunging load or the design load multiplied by an appropriate factor of safety. The maximum load is maintained for a long time, following which the pile is completely unloaded in increments. Alternative loading protocols, in which loads are maintained for shorter times, are also possible, but do not provide the best estimates of long-term pile capacity.

Reaction is usually provided by two piles, which are installed on each side of the test pile, at a sufficient distance that they do not interfere (at least 5 to 8 pile diameters, according to Poulos and Davis [1990]). Alternatively, a weighted platform can also be used for reaction. The hydraulic jack or a load cell is used to measure the load applied at the pile head. A major concern is that the load is applied uniformly and with no eccentricity. For these purposes, steel plates of appropriate thickness are positioned on the pile cap and between the jack and the test beam and special care must be placed in centering the plates and the jack. For the same reason, spherical bearings particularly when a load cell is used should be used.

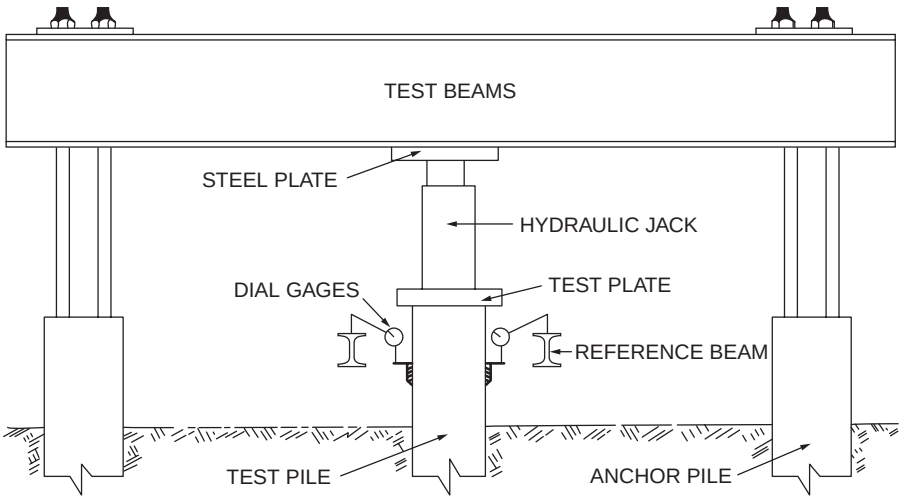

FIGURE 28.9 Set-up for pile static load test. (From ASTM D 1143 - 81 (Reapproved 1987). Standard method for piles under static compressive load. With permission.)

At least three dial gages or other devices for measurement of displacements (e.g., LVDTs) should be used to measure the displacement at the pile head with time, following the application of each load increment. Each sensor is affixed to a reference beam that should be protected from sunlight and temperature changes, and whose supports must be placed sufficiently far from the test and anchor piles so it does not move during the test. Measurements of the horizontal displacement of the pile cap are also recommended to verify that the load is properly applied.

Instrumented static load tests have the general objective of establishing the distribution of the load along the pile or drilled shaft, and determining what fraction of the applied load is carried by side friction and what fraction by base resistance for any given displacement of the pile head. To obtain the load distribution along the pile shaft, the axial strain at different depths is determined and then the axial stress and load are calculated with the appropriate modulus for concrete or steel based on the type of pile. The load carried by side friction between the surface and any depth is equal to the difference between the total load at the pile head and the normal load at the section of the pile at that depth. Measurement of the pile deformation can be accomplished by using telltales (Fig. 28.10), strain gages, or **Mustran cells** (Fig. 28.11) (Crowther, 1988). Telltales are particularly convenient for use in drilled shafts, in which they are installed inside polyvinyl chloride (PVC) tubes that isolate them from the surrounding concrete. This ensures that they will move freely and the displacement measured at the pile head with a dial gage (or other displacement sensor) will be equal to the displacement at the tip of the telltale. Dunnicliff (1988) raises a number of concerns regarding the use of telltales and suggests that they should not be used as the primary measurement system, but rather be used in combination with strain gages. Surface mounted strain gages are the most common solution for deformation measurement in the case of steel piles, while embedment strain gages are used for both concrete-driven piles and drilled shafts. The strain gages in these cases are attached directly to a rebar at appropriate intervals. A Mustran (multiplying strain transducer) cell consists of a short bar with a number of electrical resistance strain gages attached that are protected by a plastic sheath filled with an inert gas to avoid moisture intrusion. Mustran cells are occasionally used in instrumented tests of drilled shafts. Figure 28.12 shows how a Mustran cell or a telltale can be connected to a rebar before concrete placement. Note that strain gages and Mustran cells directly provide the strain at the location where they are mounted. In the case of telltales, an average strain between two telltale tips is computed from the ratio in the difference in displacements to the difference in depths.

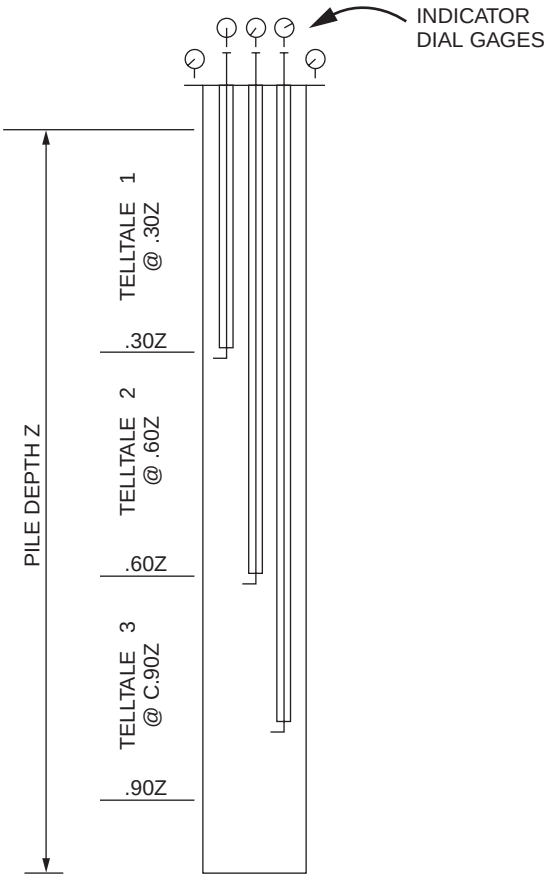

FIGURE 28.10 Possible arrangement of telltales to determine load distribution along shaft of a drilled shaft. (From Crowther, C.L. 1988. *Load Testing of Deep Foundations*. John Wiley & Sons, New York. With permission.)

For open-ended pipe piles, base capacity is due to both annulus and plug resistances, and in large projects, with a large number of piles, it may be attractive to accurately separate the two. Paik et al. (2002) describe in detail how this can be accomplished though the use of logically placed strain gauges.

Defining Terms

Benchmark — reference for measurement of vertical displacements using surveying methods.

Borehole extensometer — a device used to monitor the change in distance between two or more points along the axis of a borehole.

Bourdon pressure gage — a gage for measuring hydraulic pressure, consisting of a curved tube that, when pressurized, uncoils by an amount directly related to the pressure.

Electrical resistance strain gage — a conductor whose electrical resistance changes as it is deformed.

Extensometer — a device that gives the distance between two points (see also surface extensometer and borehole extensometer).

Inclinometer — device used for measuring lateral displacement that runs down inside a cased borehole.

***In-situ* tests —** tests performed to determine soil properties in the field.

Instrumentation — the collection of devices and the way they are arranged and linked to measure quantities deemed of interest in a particular project.

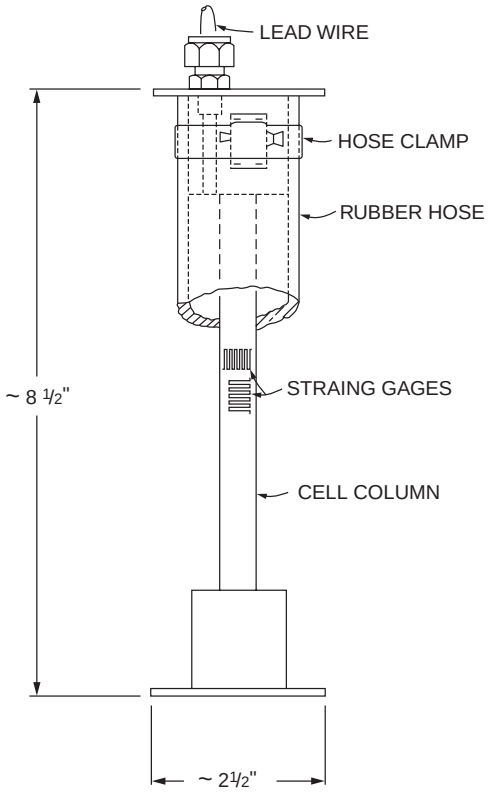

FIGURE 28.11 Mustran cell. (From Crowther, C.L. 1988. *Load Testing of Deep Foundations*. John Wiley & Sons, New York. With permission.)

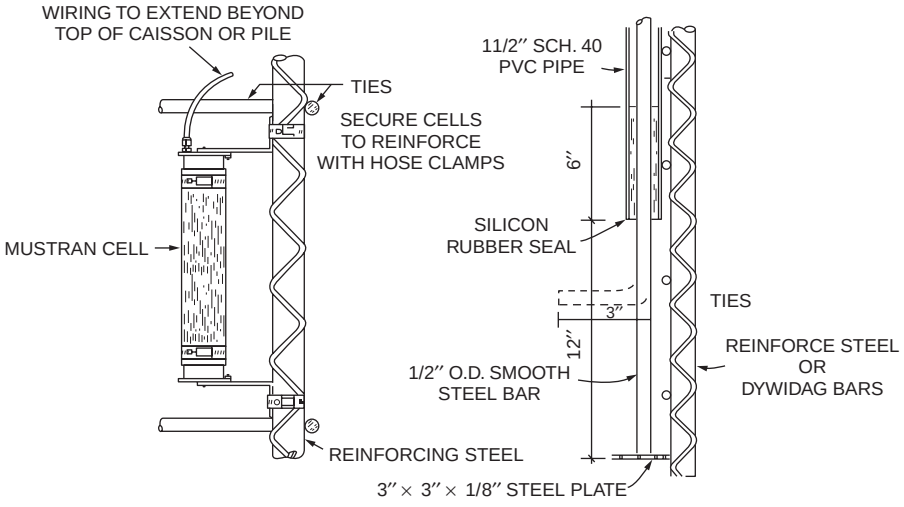

FIGURE 28.12 Attachment of Mustran cell or telltale to rebars in a drilled shaft. (From Crowther, C.L. 1988. *Load Testing of Deep Foundations*. John Wiley & Sons, New York. With permission.)

Instrumented static load tests — when said of a deep foundation, the measurement of displacements or strains at different levels in the deep foundation element as load is applied at the pile head (see also static load tests).

Load cells — devices used to measure load.

LVDT — the linear variable differential transformer, a device consisting of a central magnetic core and two coils used to measure displacements.

Manometer — a U-tube filled with two fluids, used to measure the pressure at their interface.

Measuring points — points where measurements are to be taken using surveying techniques.

Mustran cells — multiple strain transducers cells, devices consisting of a bar with strain transducers attached, used to obtain strain measurements inside drilled shafts or concrete piles.

Piezometer — device used to measure hydraulic pressure.

Pressure cell — cell used to measure total stresses inside a soil mass or at soil-concrete or soil-steel interface.

Reference monument — a reference for horizontal displacement measurements.

Sensor — a device that allows the measurement of a certain quantity at a point.

Settlement plate — plate that is embedded in a soil mass at a depth where the vertical displacements are to be determined.

Static load test — when said of a deep foundation, the measurement of the displacement at the pile head corresponding to a sequence of loads applied also at the pile head.

Strain gage — a gage used to measure strain (term is often used to refer to an electrical resistance strain gage – see definition above).

Surface extensometer — a device used to monitor the change in distance between two points located on the surface of the ground or of a structure.

Telltale — a steel rod or bar placed inside a structure, whose purpose is to determine the displacement at the location where its tip is located.

Tiltmeter — a device to measure the rotational component of a displacement.

Transducer — a device that transforms one energy type (such as mechanical) into another (such as electrical or pneumatic).

Vibrating wire transducer — a transducer that relies on measuring the natural frequency of a tensioned wire to determine a strain.

Further Information

Books

The books by Dunnicliff, Hanna, and Hunt are excellent references to devices and procedures of field instrumentation. Pile load tests are better addressed in more specific publications, such as Crowther's book. For instrumentation of dynamic or vibratory problems, a good starting point is Richart et al. There has been much recent research on the interpretation of *in situ* tests, so it is best to review recent journal papers if that is the specific interest.

ASTM has standards for the use of many of the devices discussed in this chapter. A volume is published every year with standards for geotechnical engineering.

Journals

Geotechnical engineering journals are a good source for new improvements in the instruments and techniques, as well as for case histories where instrumentation has been used. Journals in English include the *Journal of Geotechnical and Geoenvironmental Engineering* of ASCE, *Géotechnique* of the Institute of Civil Engineers of Great Britain, *The Canadian Geotechnical Journal*, the *Journal of Soil Testing* of ASTM, and *Soils and Foundations* of Japan. Some foreign journals publish papers both in the native language of the country where the journal is published and in English. The *Rivista Italiana di Geotecnica* of Italy and *Solos e Rochas* of Brazil often carry interesting papers on *in situ* tests and field instrumentation.

Catalogs and Other Publications by Manufacturers

Catalogs and other publicity material of companies manufacturing instruments, as well as reference manuals for the instruments, are a good source of information, general and specific. Some companies manufacturing instrumentation devices include the Slope Indicator Company (Sinco) of Seattle, Washington; Durham Geo of Stone Mountain, Georgia; Geokon of Lebanon, New Hampshire; Geotest of Evanston, Illinois; Omega of Stamford, Connecticut; Phoenix Geometrix of Mountlake Terrace, Washington; and Dresser Industries of Newtown, Connecticut.

Also of interest are periodicals such as Experimental Stress Analysis Notebook of the Measurements Group, Inc., of Raleigh, North Carolina. They carry current information on transducers and other devices, as well as articles on the general subject of instrumentation and materials testing.

IV.1 Introduction

Global freshwater resources comprise 1 million cubic miles. Most of this water is in groundwater, less than 1/2 mile deep within the earth. Of this resource, only 30,300 cubic miles reside in freshwater lakes and streams. However, all of this water is in a continuous movement known as the "hydrologic cycle." The dynamic nature of this movement is quite variable. The response time of urban runoff is minutes to hours and the average residence time of atmospheric moisture is a little more than 9 days, while the global average residence time of freshwater in streams is approximately 10 days, and that of groundwater is 2 weeks to 10,000 years.

As the field of hydraulic engineering enters the third millennium, more noticeable water resources impacts on society are expected. These impacts result from increasing world population, political and economic instabilities, and possibly anthropogenic-driven climatic changes.

Because of the diversity of the amounts of water involved, the variability of the response times, and the myriad of water uses, civil engineers must deal with a multitude of physical and management water problems. Some of these problems are water supply for cities, industries, and agriculture; drainage of urban areas; and the collection of used water. Other problems deal with flows in rivers, channels, and estuaries; and flood protection; while others are concerned with oceans and lakes, hydropower generation, water transportation, etc. Although the emphasis of this section is on water quantity, some aspects of water quality are considered.

Because of the multitude of different types of problems, hydraulic engineering is subdivided into a number of specialties, many of which are the object of separate chapters in this section. These specialties all have fluid mechanics as a common basis. Because the concern is with water, there is little interest in gases, and the fundamental science is hydraulics, which is the science of motion of incompressible fluids.

The chapter on *Fundamentals of Hydraulics* presents properties of fluids, hydrostatics, kinematics, and dynamics of liquids. A separate chapter is devoted to *Open Channel Hydraulics* because of the importance of free surface flows in civil engineering applications. Erosion, deposition, and transport of sediments are important in the design of stable channels and stable structures. Sediment resuspension has important implications for water quality. These problems are treated in the chapter on *Sediment Transport in Open Channels*.

The flow of water in the natural environment such as rainfall and subsequent infiltration, evaporation, flow in rills and streams, etc., is the purview of *Surface Water Hydrology*. Because of the uncertainty of natural events, the analysis of hydrologic data requires the use of statistics such as frequency analysis. *Urban Drainage* is the object of a separate chapter. Because of the importance of the problems associated with urban runoff quality and with the deleterious effects of combined sewer overflows, a new chapter has been added on *Quality of Urban Runoff*.

Hydrology is generally separated into surface water hydrology and subsurface hydrology, depending on whether the emphasis is on surface water or on groundwater. The chapter on *Groundwater Engineering* is concerned with hydraulics of wells, land subsidence due to excessive pumping, contaminant transport, site remediation, and landfills.

Many *Hydraulic Structures* have been developed for the storage, conveyance, and control of natural flows. These structures include dams, spillways, pipes, open channels, outlet works, energy-dissipating structures, turbines, pumps, etc. The interface between land and ocean and lakes is part of *Coastal*

Engineering. The chapter on Coastal Engineering also contains a discussion of the mechanics of ocean waves and their transformation in shallow water and resultant coastal circulation. It also includes a discussion of coastal processes and their influence on coastal structures.

Many forms of software and software packages are available to facilitate the design and analysis tasks. Several of these were originally developed by government agencies and later improved by private companies, which add preprocessors and postprocessors that greatly facilitate the input of data and the plotting of output results. Many of these models, such as SWMM and the HEC series, have well-defined graphical and expert system interfaces associated with model building, calibration, and presentation of results. Several of the public domain packages are listed in the chapter on *Simulation in Hydraulics and Hydrology* and detailed examples of application to urban drainage are also given.

It is not sufficient for civil engineers to deal only with the physical problems associated with water resources. They are also concerned with planning and management of these resources. Conceptualization and implementation of strategies for delivering water of sufficient quantity and quality to meet societal needs in a cost-effective manner are presented in the chapter on *Water Resources Planning and Management*.

As are most engineering sciences, hydraulic engineering is a rapidly moving field. The computer, which was a means of making computations, is now becoming a knowledge processor. The electronic encapsulation of knowledge and information in the form of software, databases, expert systems, and geographical information systems has produced a "Copernican revolution in Hydraulics" (Abbott 1994). The Europeans have coined the word "Hydroinformatics" to designate the association of computational hydraulic modeling and information systems. Thus hydraulic and hydrologic models become part of larger computer-based systems that generate information for the different interests of the water resources managers. For example, the linkage of storm sewer design and analysis packages with databases, geographical information systems, and computer-aided design systems is now becoming routine. Similarly, decision support systems have integrated combinations of water resources simulations and optimization models, databases, geographic information systems, expert- and knowledge-based systems, multiobjective decision tools, and graphical user-friendly interfaces (Watkins et al. 1994). The emphasis has passed from *numerics* to *semiotics* (Abbott et al. 2001).

Hydroinformatics also introduces new methods to encapsulate existing knowledge often with the goal of accelerating the rate of access to this knowledge. Some of these are data mining, genetic programming, and artificial neural networks (Abbot et al. 2001). For example, artificial neural networks have been used in the real time control of urban drainage systems.

One of the early issues of hydraulic modeling known as *model calibrations* is still an uncertainty, although perhaps less apparent in this new paradigm. For example, if the roughness coefficient is used to fit calculated flows to measured discharges, unrealistic values of Mannings roughness coefficient could hide unknown information or physical phenomena not represented in the model. In that case, the model would not be predictive, even with an excellent calibration (Abbott et al. 2001). However, in some cases, the laws governing roughness coefficients are not complete and new interpretations are needed. For example, in the case of wetlands, as vegetation is deflected to one side and eventually flattened, the values of the roughness coefficient departs markedly from the traditional Manning formulation (Kutija and Hong 1999).

The 1993 extreme floods in the Mississippi and Missouri basins indicated the importance of hydrologic forecasting of the design of flood protection structures and of water management at the basin scale while taking into account the environmental, ecological, and economic impacts. According to Starosolski (1991), the old approach of first designing the engineering project and then considering the ecological effects should be replaced by a systems approach in which the hydraulic, environmental, and ecological aspects are all included in the planning, execution, and operation of water resources projects.

Progress in a topic of hydraulic engineering is presented in the Hunter Rouse Lecture at the annual meeting of the Environmental and Water Resources Institute of the American Society of Civil Engineers and is subsequently published in the *Journal of Hydraulic Engineering*. The proceedings of the Congresses of the International Association of Hydraulic Research, held every 4 years, summarize the advances in the field, primarily in the keynote papers.

Both in surface water and groundwater hydrology, recent researchers have been inspired by the improved ability to observe and model the many heterogeneities of surface and material properties and of transport processes (van Genuchten 1991). Remote sensing now makes it possible to model land surface hydrologic processes at the global scale. Then these processes can be included in general circulation models of the atmosphere (Wood 1991). The research accomplishments in surface water and groundwater hydrology are summarized every 4 years in reports from several countries to the International Union of Geodesy and Geophysics. The U.S. quadrennial report is prepared by the American Geophysical Union and is published in *Reviews of Geophysics.*

Similarly, in coastal engineering, recent mathematical models make it possible to simulate large-scale coastal behavior that is at scales larger than tens of kilometers and time scales of decades. These models include waves, currents, and sediment transport. Models capable of describing the interaction with the bottom topography are under development at least for short-term coastal behavior (De Vriend 1991, Holman 1994). The new techniques mentioned in the previous paragraphs are still in the research stage and are beyond the scope of this handbook, but the references at the end of this introduction provide entry points into several research fields.

29.1 Introduction

Engineering hydraulics is concerned broadly with civil engineering problems in which the flow or management of fluids, primarily water, plays a role. Solutions to this wide range of problems require an understanding of the fundamental principles of fluid mechanics in general and hydraulics in particular, and these are summarized in this section.

29.2 Properties of Fluids

The material properties of a fluid, which may vary, sometimes sensitively, with temperature, pressure, and composition (if the fluid is a mixture), determine its mechanical behavior. The physical properties of water and other common fluids are given in Tables 29.1 to 29.7 at the end of this chapter.

Fluid Density and Related Quantities

The density of a fluid, denoted as ρ, is defined as its mass per unit volume with units kg/m^3 or slug/ft.^{3} The *specific gravity*, denoted as s, refers to the dimensionless ratio of the density of a given material to the density of pure water, ρ_{ref}, at a reference temperature and pressure (often taken to be 4°C and 1 standard atmosphere): $s \equiv \rho/\rho_{ref}$. The *specific weight*, denoted as γ, is the weight per unit volume, or the product of ρ and g, the gravitational acceleration: $\gamma \equiv \rho g$.

Fluid Viscosity and Related Concepts

Fluids are *Newtonian* if their strain rate is linearly proportional to the applied shear stress, and is zero when the latter is zero. The strain rate can be related to gradients of fluid velocity. The proportionality constant is the *dynamic viscosity*, denoted by μ, with units N s/m^2 or lb s/ft.^{2} Frequently μ arises in combination with ρ, so that a *kinematic viscosity*, defined as $\nu \equiv \mu/\rho$, with units m^2/s or ft^2/s, is defined. Some materials, e.g., mud, may, under certain circumstances, behave as fluids but may not exhibit such a relationship between shear stress and the strain rate. These are termed *non-Newtonian fluids*. The most common fluids, air and water, are Newtonian. Because the values of μ for common fluids are relatively small, the concept of an *ideal fluid*, for which $\mu = 0$, is useful; effects of fluid friction (shear) are thereby neglected. This approximation is not valid in the vicinity of a solid boundary, where the *no-slip condition* must be satisfied, i.e., at the fluid-solid interface, the velocity of the fluid must be equal to the velocity of the solid surface.

The Vapor Pressure

The *vapor pressure* of a pure liquid, denoted as p_v, with units Pa abs or lb/ft^2 abs (abs refers to the absolute pressure scale, see Section 29.3), is the pressure exerted by its vapor in a state of vapor-liquid equilibrium at a given temperature. It derives its importance from the phenomenon of *cavitation*, the term applied to the genesis, growth, and eventual collapse of vapor bubbles (cavities) in the interior of a flowing liquid when the fluid pressure at some point in the flow is reduced below the vapor pressure. This leads to reduced performance and possibly damage to pumping and piping systems and spillways.

The Bulk Modulus and the Speed of Sound

The *bulk modulus of elasticity*, denoted by E_v, is the ratio of the change in pressure, p (see Section 29.3) to the relative change in density: $E_v = \rho\, \partial p/\partial \rho$, with units Pa or lb/ft,^{2} and measures the compressibility of a material. Common fluids such as water and air may generally be treated as *incompressible*, i.e., $E_v \to \infty$. Compressibility effects become important, however, where large changes in pressure occur suddenly, as in *waterhammer* problems resulting from fast closing valves, or where high speeds are involved as in supersonic flow. The kinematic quantity, the speed of sound, defined by $c = \sqrt{E_v/\rho}$, may be more convenient than E_v to use.

Surface Tension and Capillary Effects

The interface between immiscible fluids acts like an infinitely thin membrane that supports a tensile force. The magnitude of this force per unit length of a line on this surface is termed the *coefficient of surface tension*, denoted as σ, with units N/m or lb/ft. Effects of surface tension are usually important

only for problems involving highly curved interfaces and small length scales, such as in small-scale laboratory models. *Capillary* effects refer to the rise or depression of fluid in small-diameter tubes or in porous media due to surface tension. The value of σ varies with the fluids forming the interface, and is affected by chemically active agents (surfactants) at the interface.

29.3 Fluid Pressure and Hydrostatics

Pressure in a fluid is a normal compressive stress. It is considered positive even though compressive, and its magnitude does *not* depend on the orientation of the surface on which it acts. In most practical applications, pressure differences rather than absolute pressures are important because only the former induce net forces and drive flows. Absolute pressures are relevant however in problems involving cavitation, since the vapor pressure (see Section 29.2) must be considered. A convenient pressure scale, the *gage pressure scale*, can be defined with zero corresponding to atmospheric pressure, p_{atm}, rather than an *absolute pressure scale* with zero corresponding to the pressure in an ideal vacuum. The two scales are related by $p_{gage} = p_{abs} - p_{atm}$. At the free surface of a water body (Fig. 29.1) that is exposed to the atmosphere, $p_{gage} = 0$, since $p_{abs} = p_{atm}$. Unless otherwise specified, the gage pressure scale is always used in the following.

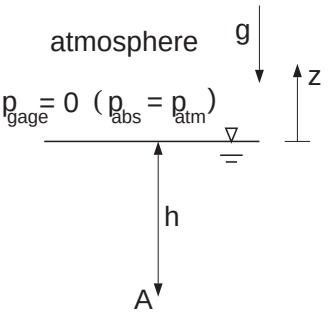

FIGURE 29.1 Pressure scales and coordinate system for Eq. (29.1).

Hydrostatics

Hydrostatics is concerned with fluids that are stagnant or in uniform motion. Relative motion (shear forces) and acceleration (inertial forces) are excluded; only pressure and gravitational forces are assumed to act. A balance of these forces yields

$$\frac{dp}{dz} = -\rho(z)g = -\gamma(z), \tag{29.1}$$

which describes the rate of change of p with elevation z, and where the chosen coordinate system is such that gravity acts in a direction opposite to that of increasing z (Fig. 29.1). In Eq. (29.1), ρ or γ may vary in the z-direction, as is often the case in the thermally stratified atmosphere or lake. Where ρ or γ is constant over a certain region, Eq. (29.1) may be integrated to give

$$p(z) - p(z_0) = -\gamma(z - z_0) \tag{29.2}$$

which indicates that pressure increases *linearly* with depth.

Only differences in pressure and differences in elevation are of consequence, so that a pressure datum or elevation datum can be arbitrarily chosen. In Fig. 29.1, if the elevation datum is chosen to coincide with the free surface, and the gage pressure scale is used, then the pressure at a point, A, located at a depth, h, below the free surface (at $z = -h$), is given by $p_A = \gamma h$. If $\gamma \approx 0$, as in the case of gases, and elevation differences are not large, then $p \approx$ constant. Eq. (29.2) can also be rearranged to give

$$\frac{p(z)}{\gamma} + z = \frac{p(z_0)}{\gamma} + z_0 \tag{29.3}$$

The *piezometric head* with dimensions of length is defined as the sum of the pressure head, p/γ, and the elevation head, z. Equation (29.3) states that the piezometric head is constant everywhere in a constant-density fluid where hydrostatic conditions prevail.

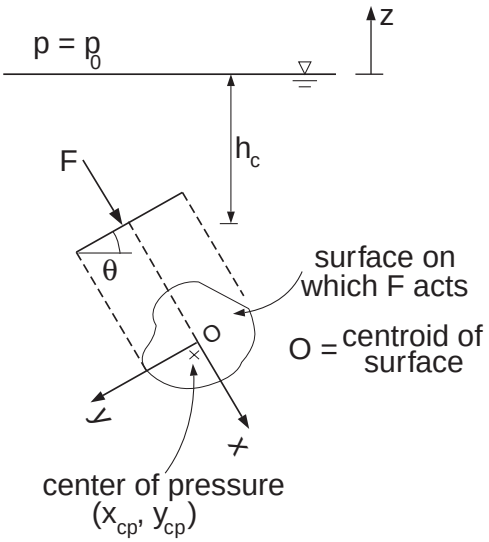

FIGURE 29.2 Hydrostatic force on a plane surface.

Forces on Plane Surfaces

The force on a surface, *S*, due to hydrostatic pressure is obtained by integration over the surface. If the surface is plane, a single resultant point force can always be found that is mechanically equivalent to the distributed pressure load (Fig. 29.2). For the case of constant-density fluid, the magnitude of this resultant force, *F*, may be determined from

$$F = \int_s p\, dS = p_c A \tag{29.4}$$

where $p_c = p_0 + \gamma h_c$ is the pressure at the centroid of the surface, situated at a depth, h_c, and A is the area of the surface. Because $p_c = F/A$, it is interpreted as the average pressure on the surface.

This resultant point force acts compressively, normal to the surface, through a point termed the center of pressure. If the surface is inclined at an angle, θ, to the horizontal, the coordinates of the *center of pressure*, (x_{cp}, y_{cp}), in a coordinate system in the plane of the surface, with origin at the centroid of the surface, are

$$\left(x_{cp}, y_{cp}\right) = \left[\frac{\left(\gamma \sin\theta\right) I_{xy}}{F}, \frac{\left(\gamma \sin\theta\right) I_{xx}}{F}\right] \tag{29.5}$$

where I_{xx} is the area moment of inertia, I_{xy} the product of inertia of the plane surface, both with respect to the centroid of the surface, and y is positive in the direction below the centroid.

The properties of common plane surfaces, such as centroids and moments of inertia, are discussed in the section on mechanics of materials. The surface is often symmetrically loaded, so that $I_{xy} = 0$, and hence, $x_{cp} = 0$, or the center of pressure is located directly below the centroid on the line of symmetry. If the surface is horizontal, the center of pressure coincides with the centroid. Further, as the surface becomes more deeply submerged, the center of pressure approaches the centroid, $(x_{cp}, y_{cp}) \rightarrow (0,0)$, because the numerators of Eq. (29.5) remain constant while the denominator increases (p_c increases).

For plane surfaces that can be decomposed into simpler elementary surfaces, the magnitude of the resultant force can be computed as the vector sum of the forces on the elementary surfaces. The coordinates of the center of pressure of the entire surface are then determined by requiring a balance of moments.

Forces on Curved Surfaces

For general curved surfaces, it may no longer be possible to determine a single resultant force equivalent to the hydrostatic load; three mutually orthogonal forces equivalent to the hydrostatic load can however be found. The horizontal forces are treated differently from the vertical force. The horizontal forces acting on the plane projected surfaces are equal in magnitude and have the same line of action as the horizontal forces acting on the curved surface. For the curved surface ABC in Fig. 29.3, the plane projected surface is represented as A′C′. The results of Section 29.3 can thus be applied to find the horizontal forces on A′C′, and hence on ABC.

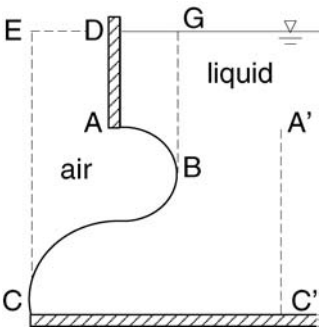

FIGURE 29.3 Hydrostatic forces on a curved surface.

A systematic procedure to deal with the vertical forces distinguishes between those surfaces exposed to the hydrostatic load from above, like the surface AB in Fig. 29.3, and those surfaces exposed to a hydrostatic load from below, like the surface BC. The vertical force on each of these subsurfaces is equal in magnitude to the weight of the volume of (possibly imaginary) fluid lying above the curved surface to a level where the pressure is zero, usually to a water surface level. It acts through the center of gravity of that fluid volume. The vertical force acting on AB equals in magnitude the weight of fluid in the volume, ABGDA, while the vertical force acting on BC equals in magnitude the weight of the imaginary fluid in the volume BGDECB. If the load acts from above, as on AB, the direction of the force is downwards, and if the load acts from below, as on BC, the direction of the force is upwards. The net vertical force on a surface is the algebraic sum of upward and downward components. If the net vertical force is upward, it is often termed the buoyant force. The line of action is again found by a balance of moments. A simple geometric argument can often be applied to determine the net vertical force. For example, in Fig. 29.3, the net vertical force is upwards, with a magnitude equal to the weight of the liquid in the volume DECBAD, and its line of action is the center of gravity of this volume.

In the special case of a curved surface that is a segment of a circle or a sphere, a single resultant force can be obtained, because pressure acts *normal* to the surface, and all normals intersect at the center. The magnitudes and direction of the components in the vertical and horizontal directions can be determined according to the procedure outlined in the previous paragraph, but these components must act through the center, and it is not necessary to determine individually the lines of action of the horizontal and vertical components. The analysis for curved surfaces can also be applied to plane surfaces. In some problems, it may even be simpler to deal with horizontal and vertical components, rather than the seemingly more direct formulae for plane surfaces.

Application 1: Force on a Vertical Dam Face

What are the magnitude and direction of the force on the vertical rectangular dam (Fig. 29.4) of height H and width, W, due to hydrostatic loads, and at what elevation is the center of pressure? Equation (29.4) is applied and, using Eq. (29.2), $p_c = \gamma h_c$, where $h_c = H/2$ is the depth at which the centroid of the dam is located. Because the area is $H \times W$, the magnitude of the force, $F = \gamma WH^2/2$. The center of pressure is found from Eq.(29.5), using $\theta = 90°$, $I_{xx} = WH^3/12$, and $I_{xy} = 0$. Thus, $x_{cp} = 0$, and $y_{cp} = [\gamma(1)(WH^3/12]/[\gamma WH^2/2] = H/6$. The center of pressure is therefore located at a distance $H/6$ directly below the centroid of the dam, or a distance of $2H/3$ below the water surface. The direction of the force is normal and compressive to the dam face as shown.

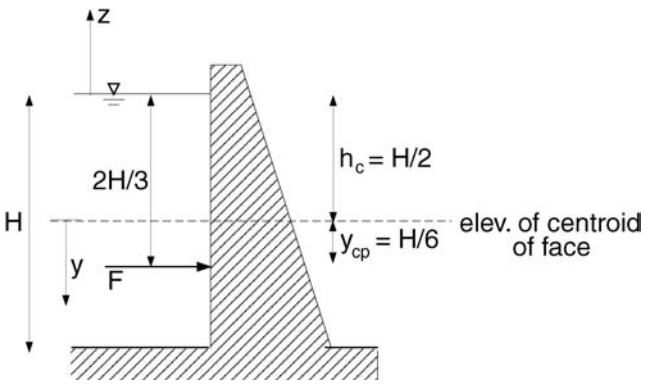

FIGURE 29.4 Hydrostatic forces on a vertical dam face.

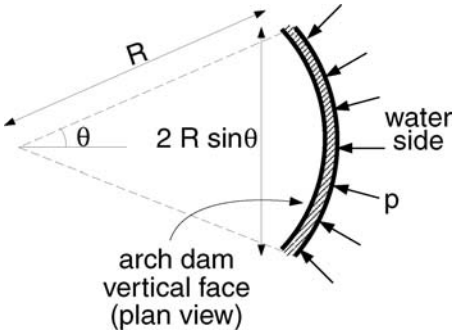

FIGURE 29.5 Hydrostatic forces on the face of a vertical arch dam.

Application 2: Force on an Arch Dam

Consider a constant radius arch-dam with a vertical upstream face (Fig. 29.5). What is the net horizontal force acting on the dam face due to hydrostatic forces? The projected area is $A_p = (2R \sin\theta) \times H$, while the pressure at the centroid of the projected surface is $p_c = \gamma H/2$. The magnitude of the horizontal force is thus $\gamma RH^2 \sin\theta$, and the center of pressure lies (as in App. 1) $2H/3$ below the water surface on the line of symmetry of the dam face. Because the face is assumed vertical, the vertical force on the dam is zero.

Application 3: Force on a Tainter Gate

Consider a radial (Tainter) gate of radius R with angle θ and width W (Fig. 29.6). What are the horizontal and vertical forces acting on the gate? For the horizontal force computation, the area of the projected surface is $A_p = (2R \sin\theta) \times W$, and the pressure at the centroid of the projected surface is $p_c = \gamma(2R \sin\theta)/2$, because the centroid is located at a depth of $(2R \sin\theta)/2$. Hence, the magnitude of the horizontal force is $2\gamma(R \sin\theta)W$, and it acts at a distance $2(2R \sin\theta)/3$ below the water surface. The vertical force is the sum of a downward force equal in magnitude to the weight of the fluid in the volume AB′BA, and an upward force equal in magnitude to the weight of the fluid in the volume, AB′BCA. This equals in magnitude the weight of the fluid in the volume, ABCA, namely, $gWR^2(\theta - \sin\theta \cos\theta)$, and acts upwards through the center of gravity of this volume. Alternatively, because the gate is an arc of a circle, the horizontal and vertical forces act through the center, O, and no net moment is created by the fluid forces.

Application 4: Archimedes′ Law of Buoyancy

Consider an arbitrarily shaped body of density, ρ_s, submerged in a fluid of density, ρ (Fig. 29.7). What is the net vertical force on the body due to hydrostatic forces? The net horizontal force is necessarily zero

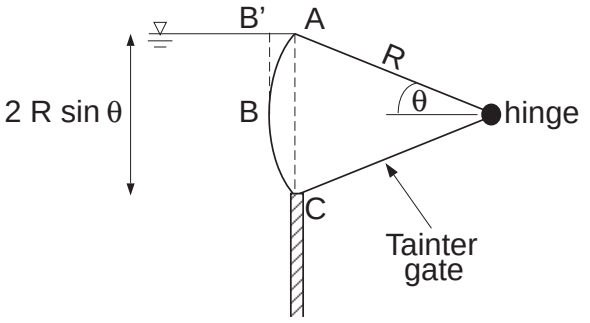

FIGURE 29.6 Hyrdrostatic forces on a radial (Tainter) gate.

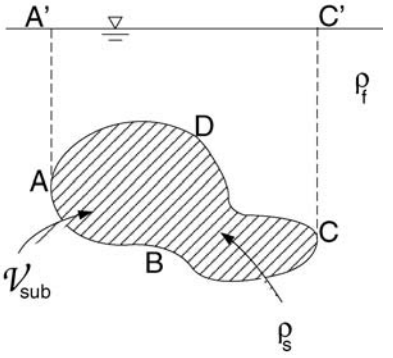

FIGURE 29.7 Hydrostatic forces on a general submerged body.

since the horizontal forces on projected surfaces are equal and opposite. The surface in contact with the fluid and therefore exposed to the hydrostatic load is divided into an upper surface, marked by curve ADC, and a lower surface, marked by curve ABC. The vertical force on ADC equals in magnitude the weight of the fluid in the volume, ADCC′A′A, and acts downward since the vertical component of the hydrostatic forces on this surface acts downward. The vertical force on ABC equals in magnitude the weight of the fluid in the volume, ABCC′A′A, but this acts upward since the vertical component of the hydrostatic forces on this surface acts upward. The vector sum, F_b, of these vertical forces acts upward through the center of gravity of the submerged volume, and equals in magnitude the weight of the fluid volume displaced by the body, $F_b = \rho g \mathbf{V}_{sub}$, where $\mathbf{V}_{sub}$ is the submerged volume of the body. This result is known as *Archimedes' principle*. The effective weight of the body in the fluid is $W_{eff} = (\rho_s - \rho)\, g\, \mathbf{V}_{sub}$.

29.4 Fluids in Non-Uniform Motion

Description of Fluid Flow

A flow is described by the velocity vector, $\mathbf{u}(x, y, z, t) = (u, v, w)$, at a point in space, (x, y, z), and at a given instant in time t. It is one-, two-, or three-dimensional if it varies only in one, two or three coordinate directions. If flow characteristics do not vary in a given direction, the flow is said to be uniform in that direction. Similarly, if flow characteristics at a point (or in a region of interest) do not vary with time, it is termed steady; otherwise, it is unsteady. Although a flow may strictly speaking be unsteady and three-dimensional, it can often for practical purposes be approximated or modeled as a steady one-dimensional flow.

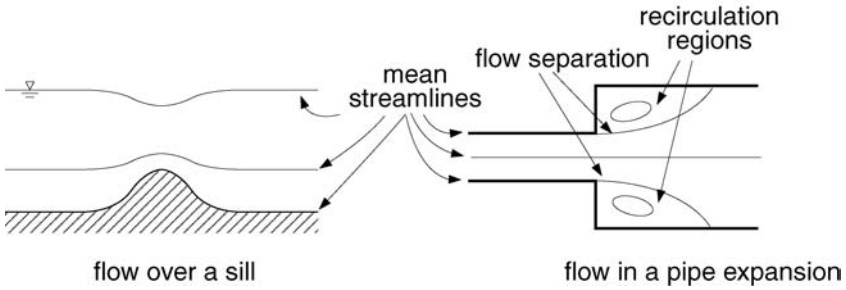

FIGURE 29.8 Examples of mean streamlines and flow separation

A *streamline* is a line to which the velocity vectors are tangent, and thus indicates the instantaneous direction of flow at each point on the streamline (see Fig. 29.8 for examples of streamlines). As such, there can be no flow across streamlines; flow boundaries, such as a solid impervious boundary or the free water surface, must therefore coincide with streamlines (actually stream surfaces). If an unsteady flow is approximated as being steady, the concept of time-averaged streamlines corresponding to the time-averaged velocity field is useful. A collection of streamlines can be used to give a picture of the overall flow pattern. Streamlines should however be distinguished from *streaklines*. The latter are formed when dye or particles are injected at a point into the flow, as is often done in flow visualization. While streaklines and streamlines coincide in a strictly steady flow, they differ in an unsteady flow.

Qualitative Flow Features and Flow Classification

Broad classes of qualitatively similar flow phenomena may be distinguished. *Laminar flows* are characterized by gradual and regular variations over time and space, with relatively little mixing occurring between individual fluid elements. In contrast, *turbulent flows* are unsteady, with rapid and seemingly random instantaneous variations in flow variables such as velocity or pressure over time and space. A high degree of bulk mixing accompanies these fluctuations, with implications for transport of momentum (fluid friction) and contaminants. In dealing with predominantly turbulent flows in practice, the hydraulic engineer is concerned primarily with time-averaged characteristics.

Flow separation occurs when a streamline begins at a solid boundary (at the separation point) and enters the region of flow (Fig. 29.8). This may happen when the solid boundary diverges sufficiently sharply in the streamwise direction, and is associated with downstream recirculating regions (regions with closed streamlines). The latter are sometimes termed dead-water zones, and their presence may have important implications for mixing efficiency. In flows around bodies, flow separation creates a low-pressure region immediately downstream of the body, termed the *wake*. The difference in pressure upstream and downstream of the body may therefore contribute significantly to flow resistance (see Section 29.8).

The Bernoulli Theorem

In the case of an ideal constant-density fluid moving in a gravitational field, a balance along a streamline between inertial (acceleration), pressure and gravitational forces yields the *Bernoulli theorem*. This states that, on a streamline,

$$\int \frac{\partial u_s}{\partial t}\, ds + \left(\frac{p}{\rho} + gz + \frac{u_s^2}{2} \right) = \text{constant} \tag{29.6}$$

where the integration is performed along the streamline, and u_s is the *magnitude* of the velocity at any point on the streamline. Equation (29.6) applies on a given streamline, and the 'constant' will in general vary for different streamlines. The Bernoulli equation for steady flows ($\partial/\partial t = 0$) is usually expressed as

$$\left(\frac{p}{\gamma}+z+\frac{u_s^2}{2g}\right)_A=\left(\frac{p}{\gamma}+z+\frac{u_s^2}{2g}\right)_B \tag{29.7}$$

where the subscripts A and B indicate two points on the same streamline along which the Bernoulli theorem is applied (Fig. 29.9). The quantity, $(p/\gamma)+z+(u_s^2/2g)$, is termed the Bernoulli constant. For steady uniform flows, $(u_s^2/2g)_A=(u_s^2/2g)_B$, and Eq. (29.7) reduces to the equality of piezometric heads as found before for hydrostatic conditions. The Bernoulli theorem thus generalizes the hydrostatic result to account for the non-uniformity or acceleration of the flow field by including a possibly changing velocity head. The quantity, $\rho u_s^2/2$ is sometimes termed the *dynamic pressure* (as distinct from the static pressure, p, in Eq. [29.7]), and the sum, $p+\rho u_s^2/2$, is termed the total or *stagnation pressure* (stagnation, as this would be the pressure if the fluid particle were brought to a stop).

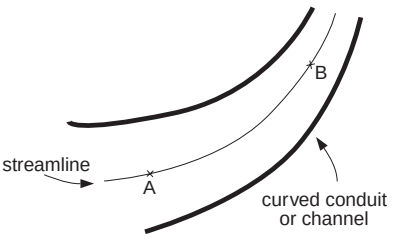

FIGURE 29.9 Flow streamline along which the Bernoulli theorem is applied.

The Bernoulli theorem provides information about variations along the streamline direction; in the direction normal to the streamline, a similar force balance shows that the *piezometric head is constant in the direction normal to the streamline provided the flow is steady and parallel or nearly parallel.* In other words, hydrostatic conditions prevail at a flow cross-section in a direction normal to the nearly parallel streamlines. This is implicitly assumed in much of hydraulics.

Application 5: An Orifice Flow

An orifice is a closed contour opening in a wall of a tank or in a plate at a pipe cross-section. A simple example of flow through an orifice from a large tank discharging into the atmosphere is shown in Fig. 29.10. What is the exit velocity at (or near) the orifice? The Bernoulli theorem is applied on a streamline between a point A on the free surface and a point B at the *vena contracta* of the orifice, the section at which the jet area is a minimum. At the *vena contracta*, the streamlines are straight, such that hydrostatic conditions prevail, and the piezometric head in the fluid must be the same throughout that section. For the situation shown, the elevation is the same over the section, which implies that the pressure must be constant over the entire section. Because the pressure on the surface of the jet is zero, the pressure, $p_B=0$. Because the tank is open to the atmosphere, $p_A=0$, and the tank is large, the velocity head in the tank, $(u_s^2/2g)_A$, is negligible. Hence, $(u_s^2/2g)_B=z_A-z_B=H$, where H is the elevation difference between the tank free surface and the *vena contracta* section. The exit velocity at the *vena contracta* is given by $u_s=\sqrt{2gH}$, a result also known as Torricelli's theorem. The related result that the discharge (see the definition in Section 29.5), $Q\propto A\sqrt{2gH}$, where A is the area of the orifice, arises also in discussions of culverts flowing full and other hydraulic structures.

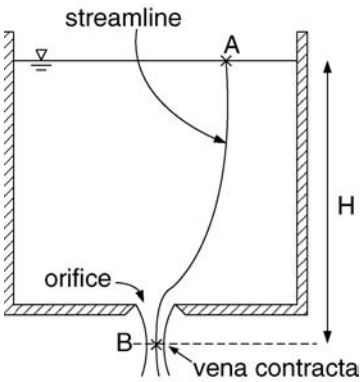

FIGURE 29.10 Flow through an orifice in the bottom of a large tank.

29.5 Fundamental Conservation Laws

The analysis of flow problems is based on three main conservation laws, namely, the conservation of mass, momentum, and energy. For most hydraulic problems, it suffices to formulate these laws in integral form for one-dimensional flows to which the following is restricted. A systematic approach is based on the analysis of a control volume, which is an imaginary volume bounded by control surfaces through which

mass, momentum, and energy may pass. The *control volume* plays the role of the free body in statics as a device to organize and systematize the accounting of fluxes and forces. In the following, the fluid is assumed to be of constant density, ρ, and the control volume is assumed fixed in space and non-deforming.

Fluxes and Correction Coefficients

The *flux* of a quantity, such as mass or momentum, across a control surface, *S*, is defined as the amount that is transported across *S* per unit time. The *mass flux*, $\dot{m}$, is defined as an integral over the surface,

$$\dot{m} \equiv \int_S \rho u \, dS = \rho V A \tag{29.8}$$

where the velocity, *u*, may vary over the control surface, the discharge or volume flow rate is $Q = \int_S u \, dS$, and *V* is the average velocity over the area *A*.

The *momentum flux* can similarly be expressed as

$$\dot{m}\beta \mathbf{V} = \int_S \rho \mathbf{u} \, u dS \tag{29.9}$$

The *momentum correction factor*, β, accounts for the variation of *u* over *S*, and is defined by Eq. (29.9). If **u** is constant over *S*, then β = 1. The momentum flux, unlike the mass flux, is a vector quantity, and is therefore associated with a direction as well as a magnitude. The *mechanical energy flux* can be expressed as

$$\dot{m}g\left(z + \alpha \frac{V^2}{2g}\right) = \int_S \gamma \left(z + \frac{u^2}{2g}\right) u dS \tag{29.10}$$

The *kinetic energy correction factor*, α, accounts for variations in *u* across the control surface, and is defined as

$$\alpha = \frac{1}{A} \int_S \left(\frac{u}{V}\right)^3 dS \tag{29.11}$$

For fully developed turbulent flows in pipes and rectangular channels, β and α are generally close to unity, but may deviate significantly from unity in a channel with a complicated cross-sectional geometry or in separated flows.

The Conservation Equations

The law of *conservation of mass*, also termed *mass balance* or *continuity*, states that the change in time of fluid mass in a control volume, *cv*, must be balanced by the sum of all mass fluxes crossing all control surfaces:

$$\frac{d}{dt} \int_{cv} \rho \, dV = \sum \dot{m}_{in} - \sum \dot{m}_{out} \tag{29.12}$$

where the integral is taken over the control volume, and the subscripts, in and out, refer to fluxes into and out of the control volume.

For steady flow with one inlet and one outlet, Eq. (29.12) simplifies to $\dot{m}_{in} = \dot{m}_{out}$, and

$$Q = V_{in} A_{in} = V_{out} A_{out} \tag{29. 13}$$

The law of *conservation of momentum*, based on Newton's second law, states that the change in time of fluid momentum in the control volume is equal to the sum of all momentum fluxes across all control surfaces plus all forces, ***F***, acting on the control volume:

$$\frac{d}{dt}\int_{cv} \rho \mathbf{u}\, d\mathbf{V} = \sum (\dot{m}\beta\mathbf{V})_{in} - \sum (\dot{m}\beta\mathbf{V})_{out} + \sum \mathbf{F} \tag{29.14}$$

For steady flow with one inlet and one outlet, Eq. (29.14) simplifies to

$$\dot{m}\left[(\beta V)_{out} - (\beta V)_{in}\right] = \sum \boldsymbol{F} \tag{29.15}$$

since $\dot{m} = \dot{m}_{in} = \dot{m}_{out}$ because of mass conservation. In contrast to the mass conservation equation, the momentum balance equation is a vector equation. Care must therefore be taken in considering different components, and accounting for the directions of the individual terms. The analysis is identical to free-body analysis of statics except that fluxes of momentum must also be considered in the force balance.

The law of *conservation of energy*, based on the first law of thermodynamics, states that the change in time of the total energy of a system is equal to the rate of heat input minus the rate at which work is being done by the system. For problems with negligible heat transfer, this can be usefully expressed in terms of 'fluxes' of total head as:

$$\frac{d}{dt}\int_{cv} \rho\left(\frac{u^2}{2} + gz\right) d\mathbf{V} = \sum (\dot{m}gH)_{in} - \sum (\dot{m}gH)_{out} - \sum \dot{W}_s - \sum \dot{m}gh_L, \tag{29.16}$$

where the *total head*, H, is defined as

$$H \equiv \frac{p}{\gamma} + z + \alpha\frac{V^2}{2g} \tag{29.17}$$

which is the sum of the piezometric head, $(p/\gamma) + z$, and the velocity head, $\alpha V^2/2g$. While z and $\alpha V^2/2g$ are readily identified as energy components, arising from gravitational potential energy and kinetic energy respectively, the pressure-work or flow-work term, p/γ, measures the (reversible) work done by pressure forces. $\dot{W}_s$ represents the shaft work, as in pumps and turbines, done *by* the system. The *head loss*, $h_L \geq 0$, represents the conversion of useful mechanical energy per unit weight of fluid into unrecoverable internal or thermal energy. For the frequent case of a steady flow with a single inlet and a single outlet, Eq. (29.16) becomes

$$H_{in} + H_p = H_{out} + H_t + h_L \tag{29.18a}$$

where $\dot{W}_s = -\dot{W}_p + \dot{W}_t$, the rate of work done by the system on the pump is $-\dot{W}_p = -\dot{m}gH_p$, and the rate of work done by the system on the turbine is $\dot{W}_t = \dot{m}gH_t$, H_p and H_t represent respectively the head per unit weight of liquid delivered by a pump or lost to a turbine. In expanded form, this is often expressed as

$$\left(\frac{p}{\gamma} + z + \alpha\frac{V^2}{2g}\right)_{in} + H_p = \left(\frac{p}{\gamma} + z + \alpha\frac{V^2}{2g}\right)_{out} + H_t + h_L, \tag{29.18b}$$

Because of its similarity to Eq. (29.7), the energy equation, Eq. (29.18), is often also termed loosely the (generalized) Bernoulli equation.

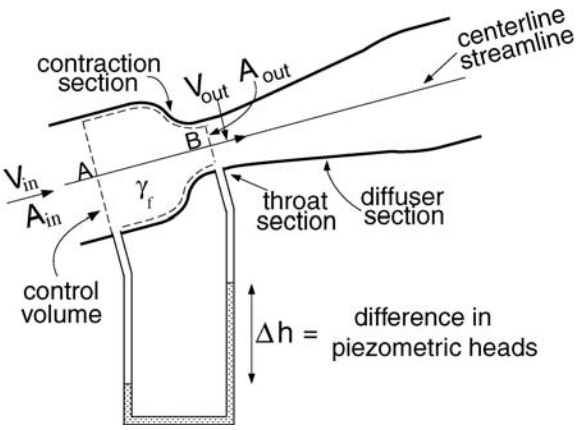

FIGURE 29.11 Flow through a Venturi tube.

Energy and Hydraulic Grade Lines

For the typical steady one-dimensional nearly horizontal flows, *hydraulic and energy grade lines* (HGL and EGL, respectively) are useful as graphical representation of the piezometric and the total head respectively. For flows in which frictional effects are neglected, the EGL is simply a horizontal line, since the total head must remain constant. If frictional effects are considered, the EGL slopes downward in the direction of flow because the total head, H, is reduced by frictional losses. The slope is termed the friction or energy slope, denoted by $S_f = h_f/L$, where h_f is the *continuous* head loss over a conduit of length, L, due to boundary friction along pipe or channel boundaries. In pipe flows, S_f is *not* related to the pipe slope (in open-channel flows, however, for the special case of uniform flow, S_f is equal to the slope of the channel). The EGL rises only in the case of energy input, such as by a pump. For flows that are uniform in the streamwise direction, the HGL runs parallel to the EGL because the velocity head is constant. The HGL excludes the velocity head, and so lies at an elevation exactly $\alpha V^2/2g$ *below* the EGL; it coincides with the EGL only where the velocity head is negligible, such as in a reservoir or large tank. Even without energy input or output, the HGL may rise or fall, due to a decrease or increase in flow area leading to an increase or decrease in velocity head. The elevation of the HGL above the pipe centerline is equal to the pressure head; if the HGL crosses or lies below the pipe centerline, this implies that the pressure head is zero or negative, i.e., the static pressure is equal to or below atmospheric pressure, which may have implications for cavitation. Since the pressure at the free surface of an open-channel flow is necessarily zero, the HGL for an open channel flow coincides with the free surface, except in flows with highly curved streamlines.

Application 6: The Venturi Tube

Many devices for measuring discharges depend on reducing the flow area, thus increasing the velocity, and measuring the resulting difference in piezometric head or pressure across the device. An example is the Venturi tube (Fig. 29.11), which consists of a short contraction section, a throat section of constant diameter, and a long gradual diffuser (expansion) section. Static pressure taps, where the static pressures are measured, are located upstream of the contraction and at the throat, since the streamlines can be considered straight at these sections, thus justifying the use of the hydrostatic assumption. The analysis begins with the choice of control volume as shown with inlet and outlet control surfaces at the pressure tap locations. The Bernoulli theorem is applied on a streamline between points A and B with $V = Q/A$ to give

$$\Delta h = \left(\frac{p}{\gamma} + z\right)_A - \left(\frac{p}{\gamma} + z\right)_B = \frac{(Q/A)_A^2}{2g} - \frac{(Q/A)_B^2}{2g} = \frac{Q^2}{2g}\left(\frac{1}{A_A^2} - \frac{1}{A_B^2}\right)$$

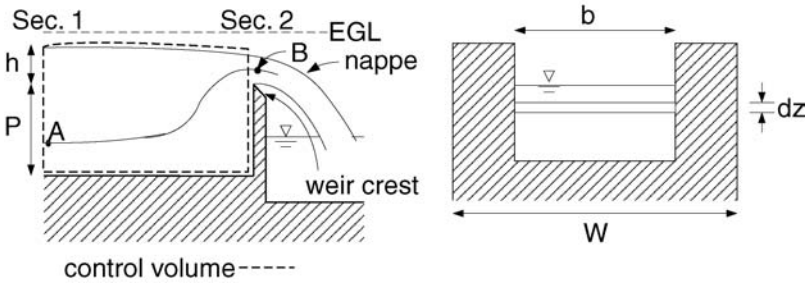

FIGURE 29.12 Flow over a sharp-crested rectangular weir.

Thus, the flow rate, Q, can be directly related to the change in piezometric head, Δh, which can be simply measured by means of *piezometers* (open tubes in which the flowing liquid can rise freely without overflowing). The level to which the liquid rises in a piezometer coincides with the HGL since it is a free surface. The discharge, Q, can therefore be expressed as

$$Q = \frac{C_d A_{\text{out}}}{\sqrt{1-\left(A_{\text{out}}/A_{\text{in}}\right)^2}}\sqrt{2g\Delta h},$$

where the discharge coefficient, C_d, is an empirical coefficient introduced to account for various approximations in the analysis (see Section 29.9 for further discussion of C_d for Venturi tubes).

Application 7: The Rectangular Sharp-Crested Weir

The *sharp-crested weir* (Fig. 29.12) is commonly used to measure discharges in open channels by a simple measurement of water level upstream of the weir. It consists of a thin plate at the end of an open channel over which the flow discharges freely into the atmosphere. The crest of the weir is the top of the plate. The jet flow or *nappe* just beyond the crest should be completely aerated, i.e., at atmospheric pressure. The discharge, Q, is to be related to the weir head, h, the elevation of the upstream free surface above the weir crest. With the control volume as shown, mass conservation implies $Q = V_1 A_1 = V_2 A_2$. Sec. 1 is chosen so that the flow is nearly parallel, and hence hydrostatic conditions prevail. As such, the piezometric head at Sec. 1 is constant, $[(p/\gamma) + z] = h + P$, with the channel bottom as datum. The Bernoulli equation is applied on the streamline shown between points A and B at Sec. 1 and at Sec. 2, with the result that

$$h + P = \left(\frac{p}{\gamma} + z\right)_{\text{B}} + \frac{u_{\text{B}}^2}{2g}$$

For an aerated nappe, $p \approx 0$ at any *point* at Sec. 2, from which is obtained $u_{\text{B}} = \sqrt{2g(h + P - z)}$. The similarity between this and the result on orifice flow should be noted. The discharge is obtained, with the further assumption that the velocity is constant across the weir crest, as

$$Q = \int_S u_B(z)\, dA = \int_P^{h+P} \sqrt{2g\left(h+P-z\right)}\,\left(b\, dz\right)$$

The upper limit of integration assumes that there is no *drawdown* at the weir, i.e., no depression of the free surface below the undisturbed upstream level. The final result is that

$$Q = C_d\left(\frac{2}{3} b\sqrt{2gh^3}\right)$$

where a discharge coefficient, C_d, has been introduced to account for any approximations that have been made.

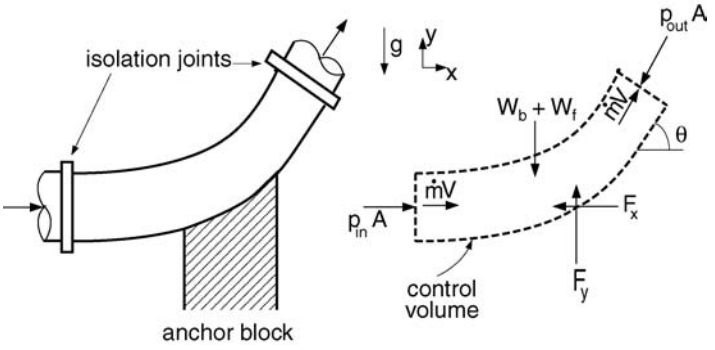

FIGURE 29.13 Forces on an anchor block supporting a pipe bend.

A more complete discussion of C_d for weirs is given in Section 29.9. The 'weir' discharge relation, $Q \propto bh^{3/2}$, also arises in other applications, such as flows over spillways or other structures..

Application 8: Forces On a Pipe Bend Anchor Block

A vertical pipe bend is to be anchored by a block (Fig. 29.13). The average pressures at the inlet and outlet are p_{in} and p_{out}, the steady discharge is $Q = VA$, and the pipe cross-sectional area is A. The weight of the bend is W_{bend}, and the weight of the fluid in the bend is W_f. The entire load is assumed to be carried by the anchor block, and so a control volume is considered as shown with force components on the pipe bend due to the anchor block, F_x and F_y. The coordinate system is chosen so that velocities and forces are positive upwards or to the right. The velocity vectors are $\mathbf{V}_{in} = (V,0)$, and $\mathbf{V}_{out} = (V\cos\theta, V\sin\theta)$, and the pressure force at the inlet is $(p_{in}A, 0)$, and at the outlet, $(-p_{out}A\cos\theta, -p_{out}A\sin\theta)$. The signs in the latter are negative because the compressive pressure force components act in the negative x- and y-directions. With $\beta_{in} \approx \beta_{out} \approx 1$, the two components of the momentum conservation equation can be written as:

$$\dot{m}(V\cos\theta - V) = p_{in}A - p_{out}A\cos\theta - F_x \qquad (x\text{-momentum})$$

$$\dot{m}(V\sin\theta - 0) = 0 - p_{out}A\sin\theta + F_y - W_{bend} - W_f \qquad (y\text{-momentum})$$

Here, the signs of F_x and F_y follow from the (arbitrarily) assumed directions shown in Fig. 29.13; as in elementary statics problems, if the solution for F_x or F_y is found to be negative, then the originally assumed direction of the relevant force is incorrect. If the other quantities are known, then the forces, F_x and F_y, can be computed. The forces on the block due to the pipe must be equal in magnitude and opposite in direction.

Application 9: Energy Equation in a Pipe System with Pump

Fluid is pumped from a large pressurized tank or reservoir at pressure, p_{in}, through a pipe of uniform diameter discharging into the atmosphere (Fig. 29.14). The difference in elevation between the fluid level in the tank and the pipe end is H. If the head loss in the pipe is known to be h_L, and the head delivered by the pump is H_p, what is the discharge, Q? Equation (29.18b) is applied to the control volume with inlet and outlet as shown and yields:

$$\left(\alpha\frac{V^2}{2g}\right)_{out} = \left(\frac{p}{\gamma}\right)_{in} + H_p - h_L - H,$$

where the velocity head in the tank has been neglected, and the pressure at the outlet is zero because the pipe discharges into the atmosphere. The discharge is calculated as $Q = VA$, where A is the pipe cross-sectional area.

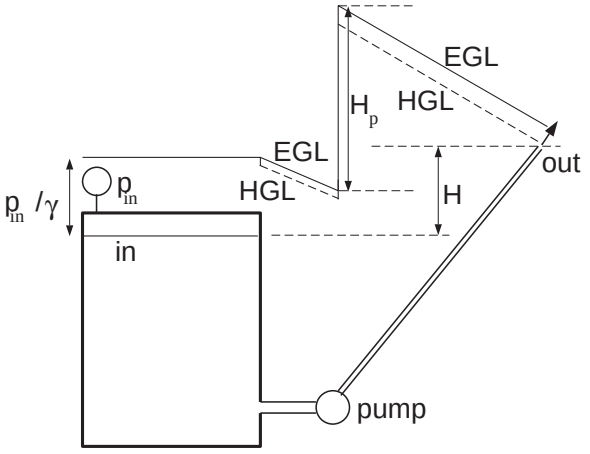

FIGURE 29.14 Energy analysis and associated hydraulic and energy grade lines of a pipe-pump system.

The EGL (solid line) and HGL (dashed line) begin at a level p_{in}/γ above the liquid level in the tank because the tank is pressurized, and coincide because the velocity head in the tank is negligible. In the pipe flow region, they both slope downward in the direction of flow, the HGL always running parallel but below the EGL, because the constant pipe diameter implies a constant difference due to the constant velocity head. At the pump, energy is added to the system, so both the EGL and the HGL rise abruptly, with the magnitude of the rise equaling the head delivered by the pump, H_p. For a smaller pipe diameter (say from the pump to the outlet), the vertical distance between the EGL and the HGL will be larger, due to the larger velocity head, and for the same pipe material, the slope of the grade lines will be larger because the friction slope, S_f, increases with velocity. At the outlet, the HGL intersects the pipe centerline because the pressure head there is zero (discharge into the atmosphere).

29.6 Dimensional Analysis and Similitude

Analysis based purely on conservation equations (including the Bernoulli theorem) is generally not sufficient for the solution of engineering problems. It must be complemented by empirical correlations or results from scale model tests. Dimensional analysis guides the organization of empirical data and the design of scale models.

The Buckingham-Pi Theorem and Dimensionless Groups

Dimensions are associated with basic physical quantities, as distinct from *units* which are conventional measures of physical quantities. In hydraulics, the basic dimensions are those of mass [M], length [L], and time, [T], though that of force [F] may sometimes be more conveniently substituted for [M]. In this section, square brackets indicate dimensions. A physically sound equation describing a physical phenomenon must be *dimensionally homogeneous* in that all terms in the equation must have the same dimensions. The basic theoretical result is the *Buckingham-Pi theorem*, which states that, for a problem involving N independent physical variables and M basic dimensions, $N - M$ independent dimensionless groups (of variables) can be formed. The design of empirical correlations and scale models needs therefore consider only the $N - M$ dimensionless groups rather than the original N variables in order to describe completely the flow phenomena. Further, a relationship among the dimensionless groups relevant to a problem is automatically dimensionally homogeneous, and as such satisfies a requirement for a physically sound description.

The two most useful dimensionless groups in hydraulics are the *Reynolds number*, $Re \equiv \rho UL/\mu$, and the *Froude number*, $Fr \equiv U/\sqrt{gL}$, where U and L are velocity and length scales characteristic of a given problem. The former is interpreted as measuring the relative importance of inertial forces ($ma \sim \rho U^2L^2$)

to viscous forces ($\tau A \sim \mu(U/L)L^2$), where m is a mass, a an acceleration, τ a shear stress, and A an area on which the shear stress acts. At sufficiently high Re (for pipe flows, $Re = \rho VD/\mu \approx 2000$, where D is the pipe diameter, for open-channel flows, $Re = \rho VD/\mu \approx 500$, where h is a flow depth), flows become turbulent. Similarly, for given boundary geometry, high Re flows are more likely than low Re flows to separate. The Froude number may be similarly interpreted as measuring the relative importance of inertial to gravitational forces ($\sim \rho g L^3$). It plays an essential role in flow phenomena involving a free surface in a gravitational field, and is discussed at length in the section on open channel flows.

An argument that can often be applied arises in the asymptotic case where a dimensionless group becomes very large or very small, such that the effect of this group can be neglected. An example of this argument is that used in the case of high Re flows, where flow characteristics become essentially independent of Re (see the discussion in Section 29.7 of the Moody diagram).

Similitude and Hydraulic Modelling

Similitude between hydraulic scale model and prototype is required if predictions based on the former are to be applicable to the latter. Three levels of similarity are *geometric, kinematic, and dynamic*, and follow from the basic dimensions. Geometric similarity implies that all length scale ratios in both model and prototype are the same. Kinematic similarity requires, in addition to geometric similarity, that all time scale ratios be the same. This implies that streamline patterns in model and prototype must be geometrically similar. Finally, dynamic similarity requires, in addition to kinematic similarity, that all mass or force scale ratios be the same. This implies that all force scale ratios at corresponding points in model and prototype flows must be the same. Equivalently, similitude requires that all but one relevant independent dimensionless groups be the same in model and prototype flows. Typically, dynamic similarity is formulated in terms of dimensionless groups representing force ratios, e.g., $Re_p = Re_m$, or $Fr_p = Fr_m$, where the subscripts, p and m, refer to prototype and model quantities respectively.

Practical hydraulic scale modeling is complicated because strict similitude is generally not feasible, and it must be decided which dimensionless groups can be neglected, with the possible need to correct results a posteriori. In many hydraulic models involving open-channel flows, the effects of Re are neglected, based on an implicit assumption of high Re similarity, and only Fr scaling is satisfied, since it is argued that free-surface gravitational effects are more important than viscous effects. Flow resistance, which may still be dependent on viscous effects, may therefore be incorrectly modeled, and so empirical corrections to the model results for flow resistance may be necessary before they can be applied to the prototype situation. Similarly, geometric similarity is often not achieved in large-scale models of river sytems or tidal basins, because this would imply excessively small flow depths, with extraneous viscous and surface-tension effects playing an erroneously important role. Distorted modeling with different vertical and horizontal length scales is therefore often applied. These deviations from strict similitude are discussed in more detail in Yalin (1971) and Sharpe (1981) specifically for problems arising in hydraulic modeling.

Application 10: Pump Performance Parameters

The power required by a pump, $\dot{W}_p$ [ML^2/T^3], varies with the impeller diameter, D [L], the pump rotation speed, n [1/T], the discharge, Q [L^3/T], and the fluid density, ρ [M/L^3]. How can this relationship be expressed in terms of dimensionless groups? It follows from the Buckingham-Pi theorem that only two independent dimensionless groups may be formed since five variables ($\dot{W}_p$, D, n, Q, and ρ) and three dimensions ([M], [L], [T]) are involved. The dimensionless groups are not unique, and different groups may be appropriate for different problems. Three basic variables involving the basic dimensions are chosen, e.g., n, D, and ρ. Mass (m), length (l), and time (t) scales are formed from these basic variables, e.g., ρD^3, $l = D$, $t = 1/n$. The remaining variables are then made dimensionless by these scales, e.g., $\dot{W}/(ml^2/t^3) = \dot{W}/[(\rho D^3)D^2n^3]$, and $Q/(l^3/t) = Q/(nD^3)$. These are the power and the flow-rate (or discharge) coefficients respectively of a pump. A relationship between these dimensionless groups can be written as $\dot{W}/[(\rho D^3)D^2n^3] = \mathbf{F}\,[Q/(nD^3)]$ which can be used to characterize the performance of a series of similar pumps.

Application 11: Spillway model

A dam spillway is to be modeled in the laboratory. Strict similitude requires $Re_p = Re_m$ and $Fr_p = Fr_m$, or, $\rho_p U_p L_p/\mu_p = \rho_m U_m L_m/\mu_m$ and $U_p/\sqrt{g_p L_p} = U_m/\sqrt{g_m L_m}$. For practical purposes, $g_p = g_m$, which implies that $(\mu_m/\rho_m)/(\mu_p/\rho_p) = (L_m/L_p)^{3/2}$. For practical scale ratios, this restriction is not feasible because no common fluid has such a small $\nu_m = (\mu_m/\rho_m)$. The test is therefore conducted using Froude scaling, $Fr_p = Fr_m$, with the only condition on Re_m being that it must be sufficiently high (say $Re_m > 5000$) such that the flow is turbulent and Reynolds number effects can be assumed negligible. $Fr_m = Fr_p$ requires that $U_m/U_p = (L_m/L_p)^{1/2}$, which in turn implies that $Q_m/Q_p = (U_m L_m^2)/(U_p L_p^2) = (L_m/L_p)^{5/2}$. Thus, if Q_m is measured in the scale model, then the corresponding discharge in the prototype is expected to be $Q_p = Q_m\,(L_p/L_m)^{5/2}$.

29.7 Velocity Profiles and Flow Resistance in Pipes and Open Channels

Flow Resistance in Fully Developed Flows

A *fully developed* steady flow in a conduit (pipe or open channel) is defined as a flow in which velocity characteristics do not change in the streamwise direction. This occurs in straight pipe or channel sections of constant geometry far from any transitions such as entrances or exits. Under these conditions, application of momentum and energy conservation equations yields a balance between shear forces on the conduit boundary and gravitational and/or pressure forces, or

$$\tau_w = \gamma\left(\frac{A}{P}\right)\left(\frac{h_f}{L}\right) \tag{29.19}$$

where τ_w is the average shear stress on the conduit boundary, A is the cross-sectional flow area, P is the *wetted perimeter*, h_f is the head loss due to boundary friction over a conduit section of length, L. The wetted perimeter is the length of perimeter of the conduit which is in contact with the fluid; for a circular pipe flowing full (Fig. 29.15), the wetted perimeter is the pipe circumference, or $P = \pi D$.

Equation (29.18) is also frequently written as $\tau_w = \gamma R_h S_f$, where $R_h \equiv A/P$ is called the hydraulic radius, and $S_f = h_f/L$, the energy or friction slope. For a circular pipe flowing full, $R_h = A/P = D/4$. A *shear velocity*, u_*, can be defined such that $u_*^2 = \tau_w/\rho$, from which it follows that

$$u_*^2 = gR_hS_f \tag{29.20}$$

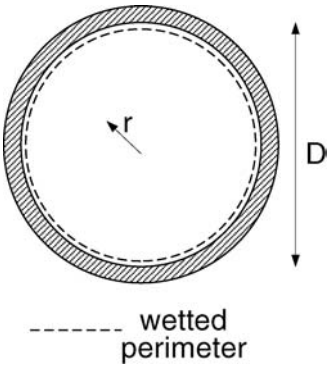

FIGURE 29.15 Coordinate system for pipe flow velocity profile, and the wetted perimeter for a pipe flowing full.

These expressions hold for both laminar and turbulent flows. The frictional head loss, h_f, increases linearly with the length, L, of the conduit, and so may be conveniently expressed in terms of the *Darcy-Weisbach friction factor, f*, as

$$h_f = f\frac{L}{4R_h}\frac{V^2}{2g} \tag{29.21}$$

or $(u_*/V)^2 = f/8$.

Laminar Velocity Profiles

Velocity profiles for steady fully developed laminar flows in a circular pipe and in an infinitely wide open channel can be theoretically obtained. For a circular pipe, it can be shown that

$$\frac{u(r)}{u_*} = \frac{1}{4}\frac{u_*}{V}Re\left[1-\left(\frac{2r}{D}\right)^2\right] \tag{29.22}$$

where $u(r)$ is the point velocity at a radial distance, r, measured from the centerline (Fig. 29.15), and the pipe Reynolds number, $Re = \rho VD/\mu$. For an infinitely wide open channel,

$$\frac{u(y)}{u_*} = \frac{1}{8}\frac{u_*}{V}Re\left(\frac{y}{h}\right)\left(2-\frac{y}{h}\right) \tag{29.23}$$

where $u(y)$ is the velocity at a vertical distance y measured from the channel bottom (Fig. 29.16), h the flow depth, and the channel Reynolds number, $Re = V(4R_h)/\nu$. Note that $R_h = h$ for an infinitely wide channel. Both profiles exhibit a quadratic dependence on r or y.

Friction Relationships for Laminar Flows

A simple relation between f and Re can be obtained by integrating Eqs. (29.21) or (29.22) over the cross section of the flow. For a circular pipe,

$$f = \frac{64}{\mathrm{Re}} \quad \text{and} \quad h_f = \frac{32\nu L}{gD^2}V \tag{29.24}$$

while for an infinitely wide channel,

$$f = \frac{96}{\mathrm{Re}} \quad \text{and} \quad h_f = \frac{3\nu L}{gh^2}V \tag{29.25}$$

where the appropriate definition of the Reynolds number must be used.

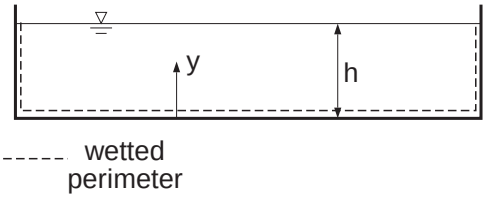

FIGURE 29.16 Coordinate system for open-channel flow velocity profile, and the corresponding wetted perimeter.

Turbulent Velocity Profiles

Because a complete theory for turbulent pipe or channel flows is lacking, a greater reliance on empirical results is necessary in discussing turbulent velocity profiles. Two types of profiles are the *log-law profile* and the *power-law profile*. The log-law profile is more physically sound, but a detailed discussion becomes complicated. A useful approximate form may be given as

$$\frac{u(\xi)}{u_*} = \frac{V}{u_*} + \frac{1}{\kappa}\ln\frac{\xi}{\Delta} + B \tag{29.26}$$

where ξ is the coordinate measured from the wall, $\kappa \approx 0.4$ is the von Kármán constant, Δ is the depth in the case of open-channel flow, and the radius in the case of pipe flow, and B is a constant with value ≈2.5 for flow in a wide open channel, and ≈3.7 for pipe flows. This profile is not valid very near the boundary ($\xi \to 0$). Near the centerline or free surface, ($\xi \to \Delta$), it also deviates from observations, though for practical purposes, the deviation can generally be considered negligible in pipes and channels. In some problems, the power-law profile may be more convenient; it is expressed as

$$\frac{u(\xi)}{u_{\max}} = \left(\frac{\xi}{\Delta}\right)^{1/m} \tag{29.27}$$

where $u_{\max}$ is the maximum velocity attained in the flow (at $\xi = \Delta$), and m increases slowly with increasing Re from $m = 6$ at $Re = 5000$ to $m = 10$ for $Re > 2 \times 10^6$. In real open-channel flows, the maximum velocity may not occur at the free surface due to the effects of secondary currents, and Eq. (29.27) must be accordingly interpreted.

Effects of Roughness

The effects of the small-scale roughness of solid boundaries on flow resistance are negligible for laminar flows, but become important for turbulent flows. Wall roughness for a given conduit material is characterized by a typical *roughness height*, k_s, of roughness elements. The wall is said to be *hydrodynamically smooth* if $k_s < \delta_v$, where the thickness of the viscous sublayer, $\delta_v \approx 5\nu/u_*$. Similarly, the wall is said to be *fully rough* if $k_s \gg \delta_v$. Precise information regarding k_s is usually available only for new pipes, and with age, k_s is likely to increase. For natural open-channel flows, such as in rivers, a roughness height may also be used to characterize flow resistance, though the wide variety of roughness elements makes difficult a precise practical definition of k_s. A range of values of k_s is given on the Moody diagram at the end of this chapter.

Friction Relationships for Turbulent Flows in Conduits

The turbulent velocity profiles can be integrated to give friction relationships for steady fully developed turbulent flows. The well-known *Colebrook-White formula*,

$$\frac{1}{\sqrt{f}} = -0.86\ln\left(\frac{k_s}{3.7D} + \frac{2.51}{Re\sqrt{f}}\right) \tag{29.28}$$

is based on a log-law profile. Given Re and k_s/D, then f can be determined. This formula is implicit and transcendental for f, and its graphical form (the *Moody diagram,* Fig. 29.22, at the end of this chapter) is useful for understanding the qualitative behavior of f in response to changes in Re and k_s/D. On log-log coordinates, curves of f vs Re at constant k_s/D are plotted. To the left of the Moody diagram, the laminar-flow solution for f (Eq. [29.24]) appears as a straight line of slope –1 (since $f \propto Re^{-1}$) for $Re <$ 2000. For given k_s/D, the curves of f vs Re become horizontal for sufficiently high Re, which is an example of the high Re similarity mentioned in Section 29.6. In this 'fully rough' regime, f is practically independent of Re and depends only on k_s/D, such that for given k_s/D, the head loss, $h_f \propto Q^2$, or $h_f \propto V^2$ (or $h_f \propto S_f^{1/2}$) which is characteristic of high Re turbulent flows, and contrasts with laminar flows (see Eqs. 29.24 through

29.25). With commonly available software tools, such as spreadsheets, Eq. (29.28) can be readily solved for one variable if the remaining two variables are known. The Moody diagram also permits a graphical solution. If *Re* and k_s/D are known, the curve corresponding to the given k_s/D is found, and the value of *f* corresponding to the given *Re* on that curve can be immediately read.

For non-circular conduits or open-channel flows, Eq. (29.28) (or the Moody diagram) can be used as an approximation by substituting an effective diameter, $D_{\text{eff}} = 4R_h$ for *D*, in determining the relative roughness and the Reynolds number. In some problems, k_s/D and/or *Re* may not be directly available, because the discharge, *Q*, or the pipe diameter, *D*, is to be determined. For such problems, an iterative solution is required, which can either be graphical using the Moody diagram or be accomplished via software.

Other traditional formulae describing flow resistance in conduits, intended for use with water only, are encountered in practice. The *Chezy-Manning* equation is used frequently in open-channel flows and is discussed more fully in that chapter. The *Hazen-Williams* equation is frequently used in the waterworks industry, and is discussed in the chapter on hydraulic structures. These equations, while convenient, approximate the more generally applicable Colebrook-White-type formulae only over a restricted range of *Re* and k_s/D. In practice, this may be compensated by judiciously adjusting the relevant empirical coefficients to particular situations.

Minor Losses

Head losses that are caused by localized disturbances to a flow, such as by valves or pipe fittings or in open-channel transitions, are traditionally termed minor losses, and will be denoted by h_m as distinct from continuous head losses denoted previously by h_f. Because they are not necessarily negligible, a more precise term would be transition or local losses, because they occur at transitions from one fully developed flow to another. Being due to localized disturbances, they do not vary with the conduit length, but are instead described by an overall head loss coefficient, K_m. The greater the flow disturbance, the larger the value of K_m; for example, as a valve is gradually closed, the associated value of K_m for the valve increases. Similarly, K_m for different pipe fittings will vary somewhat with pipe size, decreasing with increasing pipe size, since fittings may not be geometrically similar for different pipe sizes. Values of K_m for various types of transitions are tabulated at the end of this chapter. An alternative treatment of minor losses replaces the sources of the minor losses by equivalent lengths of pipes, which are often tabulated. In this way, the problem is converted to one with entirely continuous losses, which may be computationally convenient. The total head loss, h_L, of Eq. (29.18) consists of contributions from both friction and transition losses:

$$h_L = h_f + h_m = \sum_j \left(\frac{fL}{D}\right)_j \frac{V_j^2}{2g} + \sum_i \left(K_m\right)_i \frac{V_i^2}{2g} \tag{29.29}$$

In some problems with long pipe sections and few instances of minor losses, such that $fL/D \ll K_m$, minor losses may be indeed minor and therefore negligible.

Application 12: A Piping System with Minor Losses

Consider a flow between two reservoirs through the pipe system shown in Fig. 29.17. If the difference in elevation between the two reservoirs is *H*, what is the discharge, *Q*? The energy equation between the two free surfaces yields $h_L = H$, since pressure and velocity heads are zero at the reservoir (control) surfaces. The total head loss consists of friction losses in pipe 1 and pipe 2, as well as minor losses at the entrance, the valve, the contraction, and the submerged exit:

$$h_L = H = \frac{Q^2}{2g}\left[\left(\frac{f_1 L_1}{D_1}\right)\frac{1}{A_1^2} + \left(\frac{f_2 L_2}{D_2}\right)\frac{1}{A_2^2} + \left\{\left(K_m\right)_{\text{entrance}} + \left(K_m\right)_{\text{valve}}\right\}\frac{1}{A_1^2} + \left\{\left(K_m\right)_{\text{contraction}} + \left(K_m\right)_{\text{exit}}\right\}\frac{1}{A_2^2}\right]$$

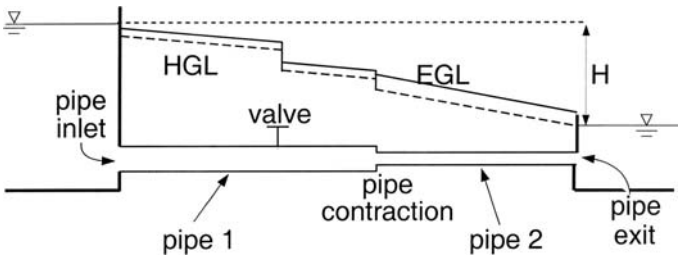

FIGURE 29.17 A pipe system with minor (transitional) losses.

where the subscripts refer to pipes 1 and 2. The minor loss coefficients are obtained from tabulated values, e.g., from Table 29.8 at the end of this chapter, $(K_m)_{\text{entrance}} = 0.5$. The friction factors, f_1 and f_2, may differ since Re and k_s/D may differ in the two pipes. Because Q is not known, neither Re_1 nor Re_2 can be computed, and hence neither f_1 nor f_2 can be directly determined from the Moody diagram: an iterative solution is necessary if the Moody diagram is used. With an algebraic relationship for the friction factors, such as Eq. (29.28), a simultaneous solution of the resulting nonlinear system of equations can be performed to obtain Q. If an iterative graphical solution with the Moody diagram is undertaken, initial guesses of f_1 and f_2 would be made, which would permit the evaluation of Q, and hence Re_1 and Re_2 could be estimated. The friction factors corresponding to the thus estimated values of Re_1 and Re_2 are then checked for consistency with the initial guesses for f_1 and f_2; if they are in reasonable agreement, then a solution has been found, otherwise the iterative procedure continues with additional guesses for f_1 and f_2 until consistency is achieved. The HGL and EGL run parallel to each other in the two pipes; the distance between them is however larger in pipe 2 because of the larger velocity head (due to the smaller pipe diameter). The energy slope is constant for each pipe section, but will generally differ in the two pipe sections, with the slope being larger in the case of the pipe with the smaller pipe due to larger velocity ($S_f \propto V^2$). The losses at transitions, shown as abrupt drops in the grade lines, are exaggerated for visual purposes.

29.8 Hydrodynamic Forces on Submerged Bodies

Bodies moving in fluids or stationary bodies in a moving fluid experience *hydrodynamic* forces in addition to the hydrostatic forces discussed in Section 29.3. A net force in the direction of mean flow is termed a *drag* force, while a net force in the direction normal to the mean flow is termed a *lift* force. These are described in terms of dimensionless coefficients of drag or lift, defined as $C_D = F_D/[(\rho U^2/2)A_p]$ and $C_L = F_L/[(\rho U^2/2)A_p]$, where the drag force, F_D, and the lift force, F_L, have been made dimensionless by the product of the dynamic pressure, $\rho U^2/2$, where U is the approach velocity (assumed constant) of the fluid, and the projected area, A_p, of the body. In hydraulics, the drag force is usually of greater interest, as in the determination of the terminal velocity of sediment or of gas bubbles in the water column, or loads on structures. The contribution due to *skin friction drag*, because of shear stresses on the body surface, is distinguished from that due to *form drag* (also termed pressure drag), stemming from normal stresses (pressure) on the body surface. At low Re (based on the relative velocity of body and fluid) or in flows around streamlined bodies, skin friction drag will dominate, while in high Re flows around bluff bodies, flow separation will occur and, with the formation of the low-pressure wake region, form drag will dominate.

The Standard Drag Curve

Theoretical results are available only for low Re flows around bodies with simple geometrical shapes. For steady flow around solid spheres in a fluid of infinite extent and $Re \to 0$, then $C_D = 24/Re$, where $Re \equiv UD/\nu$, where U is the relative velocity of body in a fluid with kinematic viscosity, ν, and D is the diameter of the sphere. In this so-called Stokes flow regime, where $Re < 1$, the *terminal velocity* of a solid sphere, w_T,

i.e., the steady velocity it attains when falling under gravity in a stagnant fluid of infinite extent, is given by $w_T = g(s_s - s_f)D^2/(18\nu)$, where s_s and s_f are respectively the specific gravities of the body and the fluid. For larger *Re* and for more complicated geometries, empirical correlations for C_D as a function of *Re* and other factors such as relative roughness must be used. A standard drag curve (such as Fig. 29.23 at the end of this chapter), which plots C_D vs *Re* is available for common geometries, such as spheres or infinitely long circular cylinders. In these cases, C_D exhibits a form of limited high *Re* similarity (see Sections 29.6 and 29.7) in the range, $10^3 < Re < 10,^5$ where it attains an approximately constant value: $C_D \approx 0.5$ for smooth spheres, and $C_D \approx 1$ for smooth infinitely long circular cylinders. For high *Re* flows around bluff bodies without sharp edges to fix the separation point, C_D undergoes an abrupt decrease at a critical value of *Re* because the separation point on the body moves downstream, resulting in a narrower low-pressure wake region, and hence lower drag and smaller C_D. For a smooth sphere or a smooth infinitely long cylinder, the critical value is observed to be $\approx 2 \times 10,^5$ but surface roughness will decrease this critical value.

Application 13: Terminal Velocity of a Solid Sphere

Consider a metal sphere (density, ρ_s, and diameter, D), falling under gravity in a fluid (density, ρ, and kinematic viscosity, ν). When the sphere attains its terminal velocity, w_T, its effective weight (including hydrostatic buoyancy effects), $g(\rho_s - \rho)(\pi D^3/6)$, is balanced by the drag force, $F_D = C_D(\rho w_T^2/2)A_p$, where the projected area is taken to be $A_p = \pi D^2/4$, so that $w_T = \sqrt{4g[(\rho_s/\rho) - 1]D/(3C_D)}$. Since C_D varies with $Re \equiv w_T D/\nu$, and w_T is unknown, the standard drag curve (in its graphical form) cannot be used directly, and an iterative procedure is necessary to determine w_T. As usual, the iterative solution might begin with an initial guess for C_D, from which a w_T and a *Re* can be computed. A solution is obtained when the computed *Re* is consistent with the guessed C_D in agreeing with the standard drag curve.

29.9 Discharge Measurements

Discharge measurements are made for monitoring and control purposes. Measurement methods may be divided into those for pipe and those for open-channel flows. The following summarizes some results for both types.

Pipe Flow Measurements

Traditional methods for measurements of discharge, Q, in a pipe of diameter, D, and cross-sectional area, A, have depended on the production of a pressure difference, Δp, across a device constricting the flow. Foremost among such devices are various types of orifice and Venturi meters, the basic theory of which has been outlined in Appendixes 5 and 6.

In general, Q is related to the difference in piezometric head across the device, Δh, by

$$Q = \frac{C_d}{\sqrt{1-\beta^4}} A_o \sqrt{2g(\Delta h)} \tag{29.30}$$

where A_o is cross-sectional area of the contraction, and $\beta = d/D$, d being the diameter of the contracted section. The discharge coefficient, C_d, may vary according to the device, the exact location of the pressure taps where the measurements are made, β and *Re*. The head loss across the device, h_m, is given as fraction of measured differential pressure head.

The common *thin-plate orifice meter* is square-edged and concentric with the pipe (Fig. 29.18a). It is used for clean fluids and is inexpensive, but is associated with relatively high head loss. Miller (1989) gives a correlation for C_d for an orifice with corner taps:

$$C_d = 0.5959 + 0.0312\beta^{2.1} - 0.184\beta^8 + \frac{91.71\beta^{2.5}}{Re^{0.75}} \tag{29.31}$$

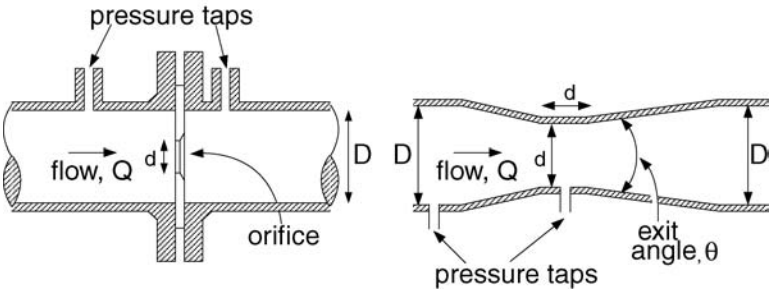

FIGURE 29.18 Pipe flow-measuring devices. (a) Thin-plate orifice with corner pressure taps. (b) Venturi tube.

and a correlation for h_m as

$$\frac{h_m}{\Delta h} = 1 - 0.24\beta - 0.52\beta^2 - 0.16\beta^3 \tag{29.32}$$

These correlations are valid for $0.2 < \beta < 0.75$ and $10^4 < Re < 10^7$.

In comparison to orifice meters, the *Venturi meter* (Fig. 29.18b) incurs low head losses, is suitable for flows with suspended solids, and exhibits less variation in performance characteristics. Disadvantages include higher initial cost and the length and weight of the device. C_D for a Venturi meter ranges from 0.975 to 0.995 (for $Re > 5 \times 10^4$), while $h_m/\Delta h$ varies with the exit cone angle as (Miller, 1989)

$$\begin{aligned} \frac{h_m}{\Delta h} &= 0.436 - 0.83\beta + 0.59\beta^2 \qquad \theta = 15^\circ \\ &= 0.218 - 0.42\beta + 0.38\beta^2 \qquad \theta = 7^\circ \end{aligned} \tag{29.33}$$

Various other flow meters are in use, and only a few are noted here. Elbow meters are based on the pressure differential between the inner and the outer radius of the elbow. Attractive because of their low cost, they tend to be less accurate than orifice or Venturi meters, because of a relatively small pressure differential. *Rotameters* or variable-area meters are based on the balance between the upward fluid drag on a float located in an upwardly diverging tube and the weight of the float. By the choice of float and tube divergence, the equilibrium position of the float can be made linearly proportional to the flow rate. More recently developed non-mechanical devices include the electromagnetic flow meter and the ultrasonic flow meter. In the former, a voltage is induced between two electrodes that are located in the pipe walls but in contact with the fluid. The fluid must be conductive, but can be multiphase. The output is linearly proportional to Q, independent of Re, and insensitive to velocity profile variations. Ultrasonic flow meters are based on the transmission and reception of acoustic signals, which can be related to the flow velocity. An attractive feature of some ultrasonic meters is that they can be clamped on to a pipe, rather than being installed in place as is the case of most other devices.

Open-Channel Flow Measurements

Open-channel flow measurements are typically based on measurements of flow depth, which are then correlated with discharge in head-discharge curves. The most common measurement structures may be divided into weirs and critical-depth (Venturi) flumes. Weirs are raised obstructions in a channel, with the top of the obstruction being termed the crest. The streamwise extent of the weir may be short or long, corresponding to sharp-crested and broad-crested weirs respectively. A critical-depth flume is a constriction built in an open channel, which causes the flow to become critical ($Fr = 1$, see the discussion

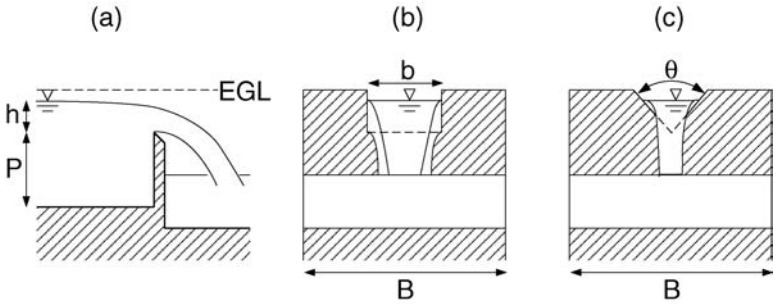

FIGURE 29.19 Open-channel discharge measurement structures. (a) Side view of a sharp-crested weir. (b) Front view of a rectangular weir. (c) Front view of a triangular (V-notch) weir.

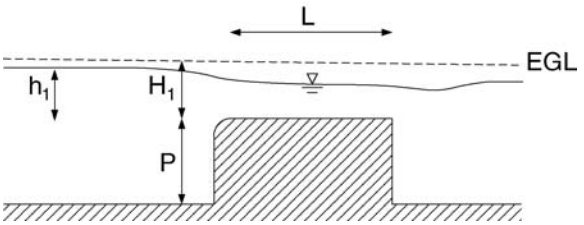

FIGURE 29.20 Broad-crested weir.

of critical flows in the section on open-channel flows) in, or near, the throat of the flume. As shown in Fig. 29.20a, the width of the channel will be denoted by B, the height of the weir crest above the channel bottom is P, and the upstream elevation of the free surface relative to the weir crest is h. The fluid is assumed to be water, and viscous and surface tension effects are assumed negligible.

For a *rectangular sharp-crested weir* (Fig. 29.19b, see also Application 7), the head-discharge formula may be expressed as

$$Q = C_d\left(\frac{2}{3}\sqrt{2g}\right)bh^{3/2} \tag{29.34}$$

where b is the width of the weir opening, and C_d is a discharge coefficient that varies with b/B and h/P as (Bos, 1989)

$$\begin{aligned} C_d &= 0.602 + 0.075(h/P), \qquad b/B = 1 \\ &= 0.593 + 0.018(h/P), \qquad b/B = 0.6 \\ &= 0.588 - 0.002(h/P), \qquad b/B = 0.1 \end{aligned} \tag{29.35}$$

Equation (29.35) should give good results if $h > 0.03$ m, $h/P < 2$, $P > 0.1$ m, $b > 0.15$ m, and the water surface level downstream of the weir should be at least 0.05 m below the crest. For contracted weirs ($b/B < 1$), an alternative treatment of the effect of b/B uses an effective weir width, b_{eff}, that is reduced relative to the actual width, b. Further, the weir formula, Eq. (29.34), is often expressed as $Q = C_{\text{weir}}\, b_{\text{eff}}\, h^{3/2}$, where C_{weir} is a weir coefficient that varies with the system of units.

The *triangular or V-notch weir* (Fig. 29.19c) is often chosen when a wide range of discharges is expected, since it is able to remain fully aerated at low discharges. The head-discharge formula for a triangular opening with an included angle, θ, may be expressed as

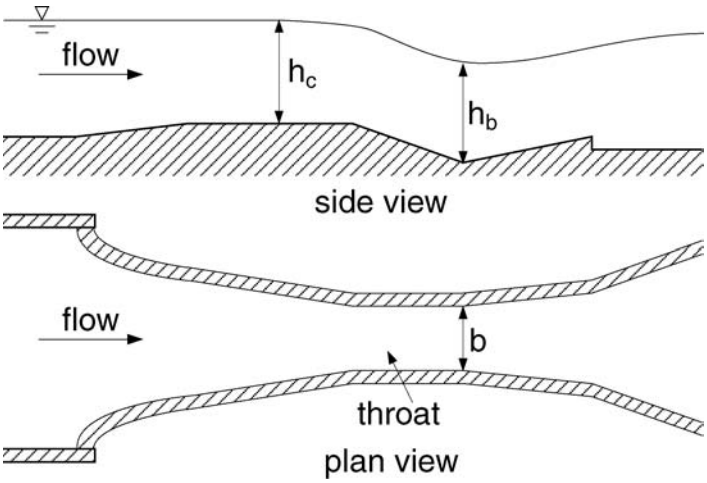

FIGURE 29.21 Critical-depth or Venturi flume (Parshall type).

$$Q = C_{dV}\left(\frac{8}{15}\sqrt{2g}\right)h^{5/2}\tan\theta \tag{29.36}$$

If $h/P \le 0.4$ and $(h/B)\tan(\theta/2) \le 0.2$, then the discharge coefficient, C_{dV} varies only slightly with θ, $C_{dV} = 0.58 \pm 0.01$ for $25° < \theta < 90°$ (Bos, 1989). It is also recommended that $h > 0.05$ m, $P > 0.45$ m, and $B > 0.9$ m.

Under field conditions, where sharp-crested weirs may present maintenance problems, the *broad-crested weir* (Fig. 29.20) provides a more robust structure. It relies on the establishment of critical flow (see the chapter of open-channel flows for a discussion of critical flows) over the weir crest. In order to justify the neglect of frictional effects and the assumption of hydrostatic conditions over the weir, the length of the weir, L, should satisfy $0.07 \le H_1/L \le 0.5$, where H_1 is the upstream total head referred to elevation of the weir crest. The head-discharge formula may be expressed as

$$Q = C_{dB}C_V\left(\frac{2}{3}\sqrt{\frac{2g}{3}}\right)bh^{3/2} \tag{29.37}$$

where C_{dB} is a discharge coefficient, and C_V is a coefficient to account for a non-negligible upstream velocity head ($C_V \ge 1$, and $C_V = 1$ if the approach velocity is neglected in which case $H_1 = h$; a graphical correlation for C_V is given in Bos, 1989). Bos (1989) recommends that $C_{dB} = 0.93 + 0.10(H_1/L)$.

In situations where deposition of silt or other debris may pose a problem, a *critical-depth flume* may be more appropriate than a weir. Since it too is based on the establishment of critical flow in the throat of the flume, its approximate theoretical analysis is essentially the same. The most common example is the *Parshall flume* (Fig. 29.21), which resembles a Venturi tube in having a converging section with a level bottom, a throat section with a downward sloping bottom, and a diverging section with an upward sloping bottom. The dimensioning of the Parshall flume is standardized; as such the calibration curve for each size (e.g., defined by the throat width) is different, since the different sizes are *not* geometrically similar. The head-discharge relation is typically expressed in terms of a piezometric head, h_c, at a prescribed location in the converging section, which is different for each size. This relationship is given by $Q = Kh_c^m$, where the exponent, m, ranges from 1.52 to 1.6, and the *dimensional* coefficient, K, varies with the size of the throat width, b_c, with K ranging from 0.060 for $b_c = 1$ in to 35.4 for $b_c = 50$ ft. More detailed information concerning K can be found in Bos (1989).

Open channel hydraulics, a subject of great importance to civil engineers, deals with flows having a free surface in channels constructed for water supply, irrigation, drainage, and hydroelectric power generation; in sewers, culverts, and tunnels flowing partially full; and in natural streams and rivers. Open channel hydraulics includes steady flows that are unchanging in time, varied flows that have changes in depth and velocity along the channel, and transient flows that are time dependent. This chapter deals only with rigid-boundary channels without sediment deposition or erosion. In addition, this chapter assumes that wind and surface tension stresses exerted on the free surface are negligible, and that velocities are low enough that air is not entrained. The emphasis is on the one-dimensional treatment of uniform and nonuniform flows which are common in civil engineering practice. Design aspects of structures involving free surface flows are discussed in Chapter 35. Sediment transport in open channels is covered in Chapter 33.

30.1 Definitions and Principles

Open channel flow is the flow of a single phase liquid with a free surface in a gravitational field when the effects of surface tension and of the overlying gas can be neglected. Because laminar open channel flows

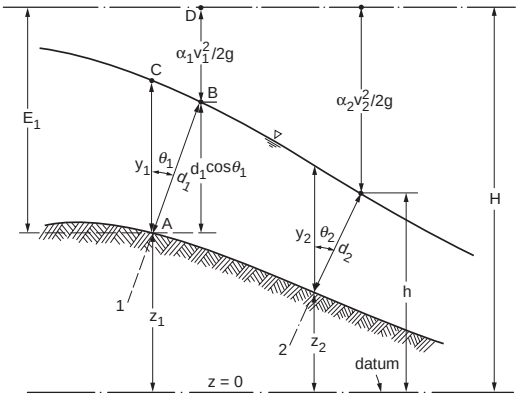

FIGURE 30.1 Definitions: *y*, depth of stream; *d*, thickness of stream; z, bottom elevation; θ, angle between channel bottom and horizontal; *E,* specific energy; *h,* piezometric head and water surface elevation; *H,* total head; $\alpha V^2/2g$, velocity head. Subscripts denote flow area.

are seldom encountered in civil engineering practice, only turbulent flows will be considered in this chapter. The analysis of open channel flows is largely based on the approximation that the mean streamlines are nearly parallel. As shown below, this implies that the piezometric head is nearly constant on planes normal to the flow, and allows a one-dimensional analysis. Regions of nonparallel streamlines are considered by using control volume arguments. In some cases, these assumptions are inadequate, and a much more complicated two- or three-dimensional analysis must be used.

For any given cross section, the following terminology and notation are used:

- The region of the cross section occupied by the liquid is called the *flow area*, *A*.
- The part of the cross section perimeter which is below the water surface is called the *wetted perimeter*, *P*.
- The length of the free surface is called the *top width*, *T*. This is normally assumed to be horizontal.
- The hydraulic depth is $D = A/T$.
- The hydraulic radius is $R = A/P$.
- The *water surface elevation, h*, is the vertical distance of the free surface above a reference elevation or datum. In Fig. 30.1, *h* is the water surface elevation at cross section 2.
- The *invert* is the lowest point of the cross section.
- The vertical distance to the free surface from the lowest point of the cross section is called the *depth of flow, y*, or *depth*. Referring to Fig. 30.1, y_1 is the depth corresponding to the invert at point A.
- The perpendicular distance from the invert to the free surface is called the *thickness of the stream*, *d*. Referring to Fig. 30.1, d_1 is the thickness of the stream at cross section 1. If the free surface is nearly parallel to the bottom of the channel, $d = y \cos\theta$, where θ is the angle between the bottom of the channel and the horizontal. For the small slopes normally encountered in rivers and canals $d \cong y$. The pressure head on the channel bottom is $y \cos^2\theta = d \cos\theta$. For $\theta < 5°$ the error in approximating the pressure head by *y* is less than 1%.
- The width of a rectangular channel is its *breadth*, *b*.

Special importance attaches to *prismatic channels*: those that have a constant cross sectional shape, longitudinal slope, and alignment. The generators of prismatic channels are parallel straight lines. The most common prismatic channel cross sections are trapezoids, rectangles, and partially full circles. Constructed channels often consist of long prismatic reaches connected by short transition sections. Natural channels are never prismatic, although the assumption that they are is sometimes tolerable.

The direction of flow is indicated by the spatial variable *x*; the two coordinates orthogonal to each other and to *x* are called *y′* and *z′*. For a parallel flow, the total volume of water flowing per unit time across an orthogonal flow area, is the *flowrate* or *discharge*, *Q*, given by

$$Q(x,t) = \iint_A v(x, y', z', t)dy'dz' = V(x,t)A(x,t) \tag{30.1}$$

where $v(x, y', z', t)$ is the local x-velocity at coordinates x, y', z' and time t.

The integral extends across the whole flow area, and V is the *mean velocity*.

Classification of Flows

Steady flows are time invariant and *unsteady flows* are time dependent. Because open channel flows are typically turbulent, and thus inherently unsteady in detail, these terms are understood to apply to the time-averaged components of the flow variables. *Uniform* or *normal flow* is the important special case of constant thickness flow in a prismatic channel. More common is *gradually varied flow* in which streamwise changes in the flow area are sufficiently gradual that the time-averaged streamlines can be assumed parallel. When the deviation of the time-averaged streamlines from being parallel cannot be neglected, the flow is termed *rapidly varied*. If the flowrate changes along the direction of flow (due to addition or withdrawal of liquid) it is a *spatially varied flow*.

Flow Regimes

Since free surface flows are affected by gravitational, viscous, and surface tension forces, the relevant dimensionless parameters are the Froude number, the Reynolds number, and the Weber number. The most important of these is the Froude number, $Fr = V/c$ where c, the celerity, is the velocity of propagation of a small amplitude, shallow water gravity wave. For an arbitrary cross section $c = (g\ D)^{1/2}$. For a rectangular cross section this reduces to $c = (g\ y)^{1/2}$. The Froude number compares the speed of the liquid to the speed at which small disturbances of the free surface propagate relative to the liquid. When $Fr < 1$, small disturbances can propagate upstream as well as downstream, and the flow regime is called *subcritical, tranquil,* or *streaming*. When $Fr > 1$, small disturbances are too slow to propagate upstream. This regime is called *supercritical, rapid*, or *shooting.* This distinction is of great practical importance because if the flow at a given cross section is supercritical, downstream events cannot influence the flow unless they are large enough to force the flow to change to subcritical. The rare case of $Fr = 1$ is called *critical flow.* The Froude number can also be interpreted as being proportional to the square root of the ratio of the inertial forces to the gravitational forces. Some authors define the Froude number as the square of the present definition.

The Reynolds number may be defined for open channel flow as $Re = 4\rho eRV/\mu$, where ρ is the *mass density* and μ is the *dynamic viscosity* of the liquid. (Many authors omit the factor of 4.) The Reynolds number is proportional to the ratio of inertial forces to viscous forces. For $Re < 2000$, open channel flow is laminar. When Re exceeds about 8000, it is turbulent. At intermediate values the flow is transitional. In hydraulic engineering practice, laminar and transitional flows are rare, occurring mostly in shallow sheet storm runoff from roofs and pavements.

The Weber number for open channel flow is defined as $We = \rho eDV^2/\sigma$, where σ is the surface tension coefficient. The Weber number is a measure of the ratio of inertial forces to surface tension forces. Although threshold values have not been determined, the high values typical of hydraulic engineering applications indicate that surface tension effects may be neglected.

30.2 Balance and Conservation Principles

As shown in Chapter 28, the fundamental principles of nature may be written in a balance form for an arbitrarily specified region called a *control volume*. In this chapter we consider a control volume which contains all of the liquid between an upstream flow area (A_1) and a downstream flow area (A_2). The lateral boundaries coincide with the wetted channel lining and the free surface.

Conservation of Mass

The principle of conservation of mass states that the time rate of change of mass inside a control volume is equal to the balance between the inflowing and outflowing mass through the control surfaces. For liquids of constant density, conservation of mass implies conservation of volume. In the case of steady flow in a control volume which contains all of the liquid between an upstream flow area and a downstream flow area, we have $Q_{in} = Q_{out} = Q$ or

$$Q = A_1 V_1 = A_2 V_2 \tag{30.2}$$

This is known as the *continuity equation*. For a rectangular channel of constant breadth

$$q = V_1 d_1 = V_2 d_2 \tag{30.3}$$

where $q = Q/b$ is the specific flowrate or flowrate per unit breadth.

Conservation of Momentum

The principle of conservation of momentum states that the time rate of change of the momentum inside a control volume is equal to the sum of all the forces acting on the control volume plus the difference between the incoming and outgoing momentum flowrates. Note that it is a vector equation. For steady flow with constant density along a straight channel, the streamwise component of the momentum equation for a control volume that contains all of the liquid between an upstream flow area and a downstream flow area becomes

$$\sum F' = \rho Q\left(\beta_2 V_2 - \beta_1 V_1\right) \tag{30.4}$$

where $\Sigma F'$ is the sum of the streamwise forces on the control volume.

These forces typically include the hydrostatic pressure forces on the flow areas, the streamwise component of the weight of liquid within the control volume, and the streamwise force exerted by the wetted surface of the channel. β is called the *momentum correction factor* and accounts for the fact that the velocity is not constant across the flow areas:

$$\beta = \frac{1}{V^2 A}\int_A v^2 dA \tag{30.5}$$

The value of β is 1.0 for a flat velocity profile, but its value increases as the irregularity of the velocity distribution increases.

Piezometric Head

As a first application of the momentum equation, consider the control volume shown in Fig. 30.2 having sides AB and DC of length Δx parallel to the streamlines, sides AD and BC of length $\Delta y'$, and breadth $\Delta z'$ normal to the page. Since the momentum fluxes and shears along the faces AB and DC have no normal component, the net pressure force in the y'-direction $(\partial p/\partial y')\,\Delta y'\Delta x\Delta z'$, must be balanced by the normal component of the weight of the liquid in the control volume $\rho\, g\Delta x\Delta y'\Delta z'\cos\theta = \rho\, g\Delta x\Delta y'\Delta z'(\partial z/\partial y')$, thus $\partial/\partial y'[z + p/(\rho\, g)] = 0$.

Integration gives

$$z + \frac{p}{\gamma} = h \tag{30.6}$$

where $\gamma = \rho\, g$ is the *specific weight* of the liquid
h = the elevation of the free surface

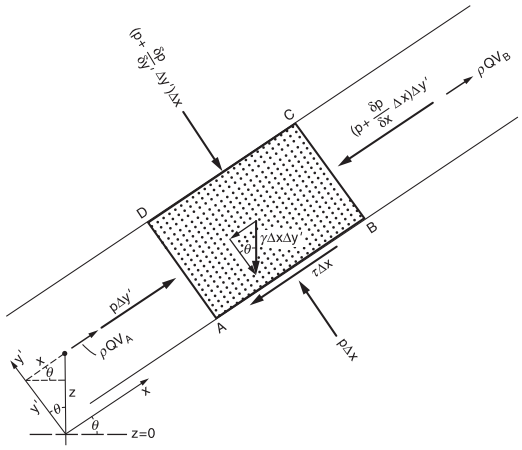

FIGURE 30.2 Forces and momentum flowrate on a fluid element.

The sum of the elevation head and the pressure head, called the *piezometric head*, has the same value at all the points of the same cross section of a parallel flow. This value is the elevation of the free surface for that cross section. This result is of fundamental importance for open channel hydraulics and suggests two corollaries: the pressure distribution within a given cross section of a parallel flow is hydrostatic, and the free surface profile of a parallel flow may be defined as its *piezometric head line* or *hydraulic grade line*.

Boundary Shear

Apply the streamwise momentum Eq. (30.4) to a control volume that contains all of the liquid contained between an upstream flow area and a downstream flow area in a prismatic channel. For uniform flow the momentum flowrates and the pressure forces on the entry and exit faces of the control volume cancel. Therefore the streamwise component of the weight of the fluid in the control volume must be balanced by the shear force acting on the wetted perimeter. Thus, if τ is the average shear stress on the channel lining, $\gamma A \Delta x \sin\theta = \tau P \Delta x$, or

$$\tau = \gamma R \sin\theta = \gamma R S \tag{30.7}$$

where $S = \sin\theta$ is the bottom slope of the channel.

Because the flow is uniform, S is also the slope of the piezometric head line and the total head line. When Eq. (30.7) is applied to gradually varied flow, S is interpreted as the slope of the total head line and is usually called the friction slope.

Total Thrust and Specific Force

Consider a control volume containing all of the liquid between upstream flow area A_1 and downstream flow area A_2 in a prismatic channel. In this case the flow depth may vary in the streamwise direction. The forces in the streamwise momentum Eq. (30.4) are the hydrostatic forces on the end surfaces and the component of the weight of the liquid in the flow direction. Friction forces are neglected. The momentum equation in the flow direction is thus

$$\gamma\delta_1 A_1 - \gamma\delta_2 A_2 + W\sin\theta = \beta_2\rho Q^2/A_2 - \beta_1\rho Q^2/A_1 \tag{30.8}$$

where δ_1 represents the vertical depth of the centroid of flow area A_1 below the free surface of A_1, and W is the weight of the liquid in the control volume.

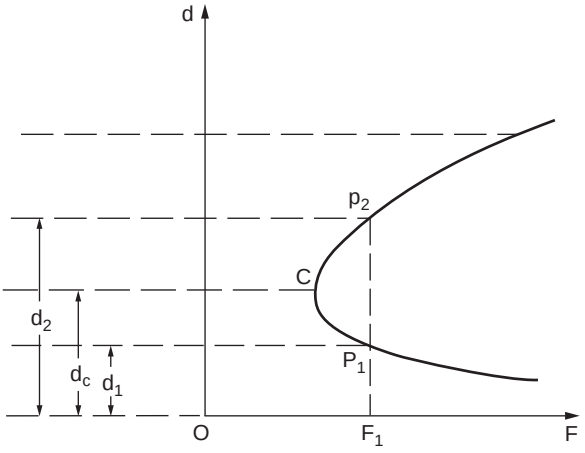

FIGURE 30.3 Total thrust curve.

This can be rearranged as

$$\left(\gamma\delta_1 A_1 + \beta_1\rho Q^2/A_1\right) = \left(\gamma\delta_2 A_2 + \beta_2\rho Q^2/A_2\right) - W\sin\theta \tag{30.9}$$

where the expression in parentheses is called the *total thrust, F.*

$$F = \gamma\delta A + \beta\rho Q^2/A \tag{30.10}$$

The total thrust is the sum of the *hydrostatic thrust* $\gamma\delta A$, which increases with flow thickness, and the *momentum flowrate* $\beta\rho Q^2/A$, which decreases with flow thickness if Q and β are assumed constant. Therefore the total thrust reaches a minimum at the *critical stream thickness*, d_c, as illustrated in Fig. 30.3. This value can be found by setting the derivative of F with respect to d equal to zero with the result that

$$\left(A^3/T\right)_{d_c} = \beta Q^2/\left(g\cos\theta\right) \tag{30.11}$$

For most cross sections, Eq. (30.11) must be solved numerically. The function F/γ is known variously as the *specific force*, *momentum function*, or *thrust function*.

Balance of Mechanical Energy

The mechanical energy of a body of mass m is the sum of its gravitational potential energy mgz and of its kinetic energy $mv^2/2$, where z is the elevation of the mass m above a reference datum. The principle of conservation of mechanical energy states that the time rate of change of the mechanical energy in a control volume is equal to the net flowrate of mechanical energy at the inlet and outlet sections, plus the work done by the pressure forces at the inlet and outlet sections, plus the loss of mechanical energy in the control region. For the steady flow of an incompressible liquid through a control volume where the flow is parallel and normal to a single plane inflow area and a single plane outflow area, the mechanical energy equation in terms of head becomes

$$z_1 + \frac{p_1}{\gamma} + \alpha_1\frac{V_1^2}{2g} = z_2 + \frac{p_2}{\gamma} + \alpha_2\frac{V_2^2}{2g} + h_L \tag{30.12}$$

where h_L is the *head loss* and α is the *kinetic energy correction factor* that accounts for the nonuniformity of the velocity across the flow area.

$$\alpha = \frac{1}{V^3 A}\int_A v^3 dA \tag{30.13}$$

The value of α is 1.0 for a flat velocity profile, but increases as the velocity profile becomes more irregular.

The total head H is defined as the sum of the elevation head, pressure head, and velocity head, or as the sum of the piezometric head and the velocity head.

$$H = z + \frac{p}{\gamma} + \alpha\frac{V^2}{2g} = h + \alpha\frac{V^2}{2g} \tag{30.14}$$

Therefore Eq. (30.12) states that the total head at cross section 1 exceeds that at cross section 2 by the head loss between the sections. In terms of the variables shown in Fig. 30.1, Eq. (30.12) can be written as

$$z_1 + d_1\cos\theta_1 + \alpha_1 V_1^2/(2g) = z_2 + d_2\cos\theta_2 + \alpha_2 V_2^2/(2g) + h_L \tag{30.15}$$

Specific Energy

Bakhmeteff (1932) first emphasized the importance of the quantity E, where

$$E = d\cos\theta + \alpha V^2/(2g) = d\cos\theta + \alpha Q^2/(2gA^2) \tag{30.16}$$

which he called the *specific energy*. (Because of its dimensions, E is more properly called *specific head*.) In terms of the specific energy, Eq. (30.12) becomes

$$z_1 + E_1 = z_2 + E_2 + h_L \tag{30.17}$$

which shows that the specific energy is conserved when $h_L = z_1 - z_2$, i.e., in uniform flow. It is this property that gives the specific energy its importance.

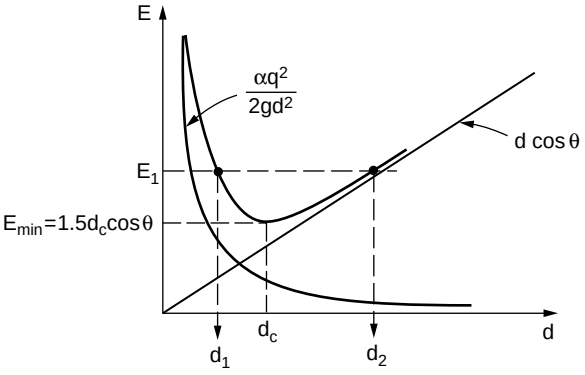
Equations (30.16) and (30.17) are the foundations for the calculation of gradually varied water surface profiles. Given Q, θ, α_1, d_1, and the geometry of cross-section 1, E_1 can be evaluated using Eq. (30.16). Then Eq. (30.17) can be solved for E_2, if an estimate of the head losses h_L is possible. Once E_2 is known, Eq. (30.16) can be solved for d_2.

Equation (30.16) shows that E is the sum of two terms. Assuming that α and Q are constant, the first term increases and the second decreases as d increases. Hence there is a *critical thickness*, d_c, for which E is a minimum. By differentiating Eq. (30.16) with respect to d and equating the derivative to zero, the following condition for critical flow is obtained.

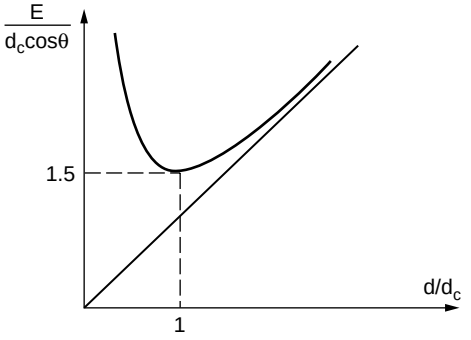
$$\left(A^3/T\right)_{d_c} = \alpha Q^2/(g\cos\theta) \tag{30.18}$$

The expression A^3/T is called the *section factor for critical flow*. For most cross sections, Eq. (30.18) must be solved numerically. Note that the critical depth is independent of the channel slope and roughness. It is interesting to recognize that the critical thickness which satisfies Eq. (30.18) differs from that which satisfies Eq. (30.11) unless $\alpha = \beta$, which is true only for a flat velocity profile. In practice, the difference is usually negligible; and Eq. (30.18) is used in the calculation. The velocity corresponding to d_c, called the critical velocity, V_c, is given by

$$V_c = \left(g\cos\theta\, D/\alpha\right)^{1/2} \tag{30.19}$$



a. Specific Energy Diagram



b. The Non-Dimensional Specific Energy Diagram

FIGURE 30.4 (a) Specific energy diagram for rectangular channel; (b) Dimensionless specific energy diagram for rectangular channel.

If the slope is small and the velocity profile is flat, this reduces to the previous expression for the wave celerity.

The behavior of the specific energy function can be clarified by considering the rectangular channel, for which Eq. (30.16) becomes

$$E = d\cos\theta + \alpha q^2 / \left(2gd^2\right) \tag{30.20}$$

The variation of E with d for a rectangular channel assuming constant α and q is shown in Fig. 30.4(a). For any value of $E > E_{min}$ there are two possible flow thicknesses, $d_R < d_c$ corresponding to supercritical flow and $d_T > d_c$ for subcritical flow. These are called *alternate thicknesses* (or *alternate depths* in the small slope case). For $E = E_{min}$ only one thickness is possible. It is impossible to transmit the specified flowrate for $E < E_{min}$. Eq. (30.20) can also be presented in dimensionless form as shown in Fig. 30.4(b) and in Table 30.1. In a rectangular channel, Eq. (30.18) can be solved explicitly for the critical thickness.

$$d_c = \left[\alpha q^2 / \left(g\cos\theta\right)\right]^{1/3} \tag{30.21}$$

and the corresponding minimum of specific energy for a rectangular channel is

$$E_{min} = 1.5 d_c \cos\theta \tag{30.22}$$

In reality, α always varies with d. When the variation is appreciable, as in the case of a river and its flood plain, there may be multiple local extrema in the specific energy vs. thickness curve and hence

multiple critical depths. Discussion of this recently recognized phenomenon is found in Chaudhry (1993), Sturm (2000), and Jain (2001). Channels having a single critical depth are called *regular*.

Hydraulic Jump

A *hydraulic jump* is a sudden increase in depth that occurs when the flow changes from supercritical to subcritical as a result of a rapid deceleration. For a stationary hydraulic jump in a horizontal rectangular channel, the depth before the jump, y_1, and the depth after the jump, y_2, are related by the expression

$$y_2 = y_1\left[\left(1+8Fr_1^2\right)^{1/2} - 1\right]\Big/2 \tag{30.23}$$

where $Fr_1 = V_1/(gy_1)^{1/2}$ is the Froude number of the flow before the jump.

The depths y_1 and y_2 are called *conjugate depths* (they are *not* alternate depths). The formula obtained by interchanging the subscripts is also valid. The head loss in this hydraulic jump, h_J, is given by

$$h_J = E_1 - E_2 = \left(y_2 - y_1\right)^3 \Big/ \left(4y_1y_2\right) \tag{30.24}$$

The length of the jump is approximately $6y_2$ for $Fr_1 > 4.5$. The hydraulic jump is an effective means of dissipating excess kinetic energy in supercritical flows.

Example 30.1 Subcritical Flow on a Step

Consider the subcritical flow in the rectangular horizontal channel shown in Fig. 30.5, which presents an upward step of height s with respect to the direction of the current. The specific energy upstream of

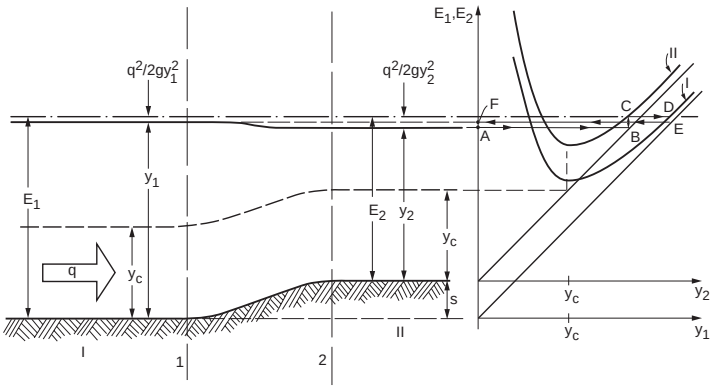

FIGURE 30.5 Subcritical stream on upward step.

the step is larger than the minimum $(3y_c/2)$ and the flow is subcritical. The water surface elevation at section 1 is higher than at section 2. Given $q = 10$ m^2/s, $y_2 = 3.92$ m, and $s = 0.5$ m, find y_1, assuming no losses.

1. Find $y_c = (q^2/g)^{1/3} = 2.17$ m
2. Find $E_2 = y_2 + q^2/(2gy_2^2) = 4.25$ m
3. Find $E_1 = E_2 + s = 4.75$ m
4. Enter Table 30.1 with $E_1/y_c = 2.19$
5. Find $y_1/y_c = 2.07$. Thus $y_1 = 4.49$ m.

This result can also be obtained by solving Eq. (30.20). If the bottom of the upward step increases very gradually, one can find intermediate points along the step as shown in Fig. 30.5. It is useful to draw the critical depth line in order to visualize the relative distance of the free surface profile from it. Fig. 30.5 also illustrates a graphical technique based on the curve $E(y)$. Follow the path A, B, C, D, E, F. The limit case is where the specific energy on the upper part of the step is a minimum, i.e., where the depth is critical.

Example 30.2 Supercritical Flow on a Step

Consider the supercritical flow in the rectangular horizontal channel shown in Fig. 30.6, which presents an upward step of height s with respect to the direction of the current. The specific energy upstream of the step is larger than the minimum specific energy $(3y_c/2)$ and the flow is supercritical. The water depth at cross section 2 is larger than at section 1 due to the decreased kinetic energy of the stream. Given $q = 10$ m^2/s, $y_1 = 1.2$ m, $s = 0.5$ m, find y_2, assuming no losses.

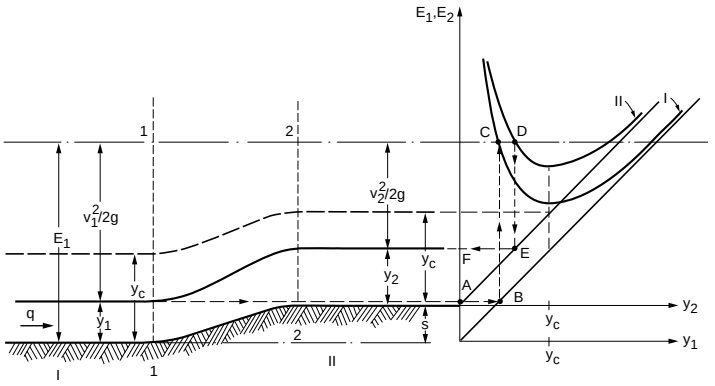

FIGURE 30.6 Supercritical stream on upward step.

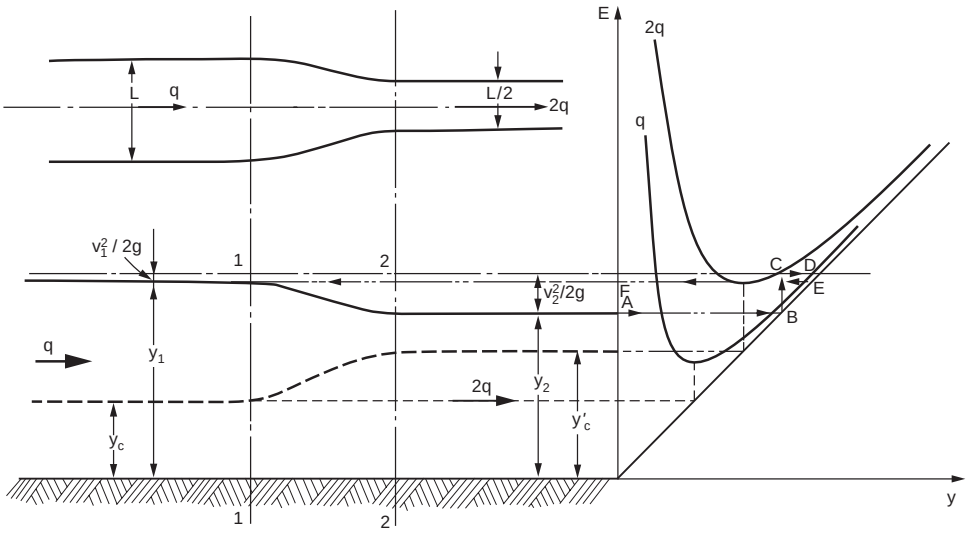

FIGURE 30.7 Subcritical stream in a channel contraction.

1. Find $y_c = (q^2/g)^{1/3} = 2.17$ m
2. Find $E_1 = y_1 + q^2/(2gy_1^2) = 4.74$ m
3. Find $E_2 = E_1 - s = 4.24$ m
4. Enter Table 30.1 with $E_2/y_c = 1.95$
5. Find $y_2/y_c = 0.612$, thus $y_2 = 1.33$ m.

This result can also be obtained from Eq. (30.20). Fig. 30.6 shows a graphical technique based on the curve $E(y)$. Follow the path A, B, C, D, E, F. The limit case occurs where the specific energy on the upper part of the step is a minimum, i.e., where the depth is critical.

Example 30.3 Contraction in a Subcritical Stream

Consider the horizontal rectangular channel of Fig. 30.7 with a lateral contraction in the direction of the current. The width of the contracted channel is half that of the upstream channel. The specific energy upstream of the contraction is larger than $E_{min} = 3y_c/2$. The water depth at section 2 is shallower than at section 1 as the kinetic energy of the stream increases. Given $q = 10$ m^2/s, $y_2 = 5.46$ m, find y_1, assuming no losses.

1. Find $y_{c1} = (q_1^2/g)^{1/3} = 2.17$ m and $y_{c2} = [(2q_1)^2/g]^{1/3} = 3.44$ m
2. Find $E_1 = E_2 = y_2 + (2q_1)^2/2gy_2^2 = 6.14$ m
3. Enter Table 30.1 with $E_1/y_{c1} = 2.83$.
4. Find $y_1/y_{c1} = 2.76$, thus $y_1 = 5.99$ m.

It is seen that $E_2 > 1.5y_{c2} = 5.16$ m, thus the flow is subcritical in the contraction. Fig. 30.7 shows a graphical technique based on the curve $E(y)$. Follow the path A, B, C, D, E, F. The limiting case occurs when $y_2 = y_{c2}$. Further information on sills, contractions, and expansions for subcritical and supercritical flows can be found in Ippen (1950).

30.3 Uniform Flow

When a steady flowrate is maintained in a prismatic channel, a constant depth flow will be reached somewhere in the channel if it is long enough. Such a flow is called *uniform flow* or *normal flow*. In uniform flow there is a perfect balance between the component of fluid weight in the direction of flow

TABLE 30.2 Manning Roughness Coefficient (Giorgini, 1987)

Nature of Surface	n_{min}	n_{max}
Neat cement surface	0.010	0.013

Very weedy	0.075	0.150

and the resistance to flow exerted by the channel lining. Assuming that the average shear stress τ given by Eq. (30.7) is proportional to the square of the average velocity gives

$$V = C\sqrt{RS} \tag{30.25}$$

Equation (30.25) is called the *Chezy equation* and C is the *Chezy C*, a dimensional factor which characterizes the resistance to flow. The Chezy C may depend on the channel shape, size, and roughness and on the Reynolds number. Equation (30.25) and the equations derived from it are often applied to gradually varied flows. In these cases, S is interpreted as the slope of the total head line, called the *friction slope*. Numerous equations have been suggested for the evaluation of C. The most popular was proposed independently by several engineers including Manning for high Reynolds numbers where the flow is independent of Reynolds number (fully rough flow). This is

$$C = BR^{1/6}/n \tag{30.26}$$

where B is a dimensional constant equal to 1 $m^{1/3}$/sec in the International System (SI) or 1.486 $ft^{1/3}$/sec in the U. S. Customary System, and n is a dimensionless number characterizing the roughness of a surface.

Table 30. 2 lists typical values of n; a much more comprehensive table is given by Chow (1959). Many investigators have proposed equations relating n to a typical particle size in particle lined streams. As an example, Subramanya (1982) proposed

$$n = 0.047 d_{50}^{1/6} \tag{30.27}$$

where d_{50} is the diameter in meters chosen so that 50% of the particles by weight are smaller.

Substituting Eq. (30.26) in Eq. (30.25) gives

$$V = \frac{B}{n} R^{2/3} S^{1/2} \tag{30.28}$$

Multiplying this by the flow area A yields

$$Q = \frac{B}{n} AR^{2/3} S^{1/2} = KS^{1/2} \tag{30.29}$$

Equations (30.28) and (30.29) are both called the *Manning equation*. The multiplier of $S^{1/2}$ in Eq. (30.29) is called the *conveyance of the cross-section, K*.

Because Eq. (30.26) is valid only for fully rough flow, the Manning equation is likewise limited. Henderson (1966) proposed that for water at ordinary temperatures, the Manning equation is valid if

$$n^{12}RS \geq 1.100 \times 10^{-26}\,\mathrm{m} = 3.61 \times 10^{-26}\,\mathrm{ft} \tag{30.30}$$

In the event that the *Henderson criterion* is violated, but the flow is nonetheless turbulent ($Re > 8000$), C can be calculated iteratively from a transformation of the Colebrook equation of pipe flow.

$$\frac{C}{\sqrt{8g}} = -2.0\log_{10}\left[\frac{\varepsilon}{14.8R} + \frac{2.51\,C}{Re\sqrt{8g}}\right] \tag{30.31}$$

Here, ε is the equivalent sand grain roughness (Henderson, 1966, Table 4.1, p. 95).

The thickness of a uniform flow is called the *normal thickness*, d_o. Assuming that the Manning equation is valid, the normal thickness for a general cross section is found by solving Eq. (30.29) for d_o. This is facilitated by writing the Manning equation so that the factors which depend on d are on the left side.

$$\left(AR^{2/3}\right)_{d_O} = nQ\Big/\left(BS^{1/2}\right) \tag{30.32}$$

The expression $AR^{2/3}$ is called the *section factor for uniform flow*. For most cross sections, Eq. (30.32) must be solved numerically, but for a wide rectangular channel d_o can be calculated directly from

$$d_o = \left[nq\Big/\left(BS^{1/2}\right)\right]^{3/5} \tag{30.33}$$

For open top cross sections, d_o is unique; but when the channel has a gradually closing top, such as a circular pipe, there will be two normal depths for some flowrates. For the case of an open top section, if $d_o > d_c$ the normal flow is subcritical and the channel slope is *mild*; if $d_o < d_c$ the normal flow is supercritical and the channel slope is *steep*. The *critical slope*, S_c, for which uniform flow is also critical flow, can be found for a wide rectangular channel by equating the thicknesses given by Eqs (30.21) and (30.33) and solving for S_c.

$$S_c = \left(n/B\right)^2\left(g\cos\theta/\alpha\right)^{10/9} q^{-2/9} \tag{30.34}$$

A channel whose bottom slope is less then S_c is called *mild* and a channel whose bottom slope is larger than S_c is called *steep*. For a wide rectangular channel, Eq. (30.34) can be solved for the *critical discharge*, q_c, when S, n, and α are fixed, or the *critical Manning coefficient*, n_c, when S, α, and q are fixed.

30.4 Composite Cross-Sections

Consider the determination of the discharge, global Manning n, normal depth, and critical depth of a composite section as shown in Fig. 30.8(a) having a small slope. The three parts of the global channel are assumed to behave as three different channels in parallel with the same slope and the same water surface elevation. The wetted perimeters of the subsections include only the portions of the solid boundary belonging to that subsection. According to the Manning equation, the total discharge is

$$Q = B\left(\frac{1}{n_l}\frac{A_l^{5/3}}{P_l^{2/3}} + \frac{1}{n_m}\frac{A_m^{5/3}}{P_m^{2/3}} + \frac{1}{n_r}\frac{A_r^{5/3}}{P_r^{2/3}}\right)S^{1/2} \tag{30.35}$$

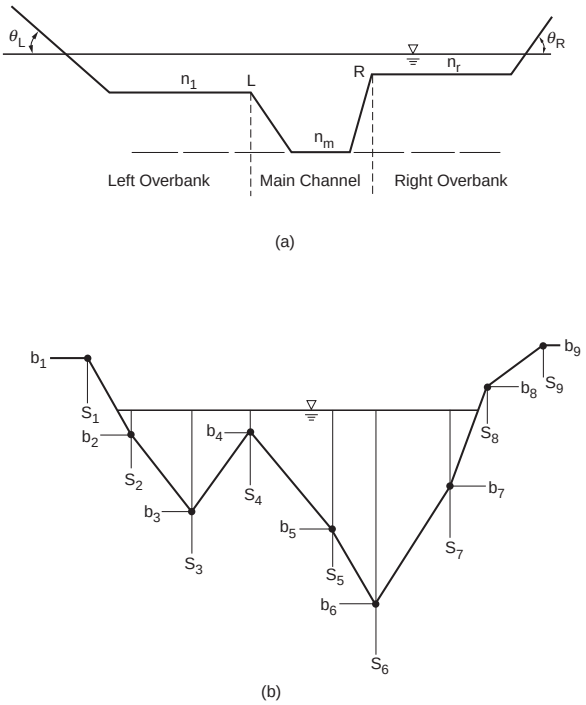

FIGURE 30.8 Composite cross-sections.

where the subscripts *l, m, r* refer to the left overbank, the main channel, and the right overbank.

From Eq. (30.35) with A representing the total cross sectional area and P the total wetted perimeter, the global value of n is

$$\frac{1}{n} = \sum_{l}^{r} \frac{1}{n_i} \frac{\left(A_i/A\right)^{5/3}}{\left(P_i/P\right)^{2/3}} \tag{30.36}$$

Given the quantities Q, S, n_1, n_m, and n_r, and given the functions $A_1(y)$, $A_m(y)$, $A_r(y)$, $P_1(y)$, $P_m(y)$, and $P_r(y)$, the *normal depth* is the root y_o of Eq. (30.35). Then y_o can be substituted to find the actual values of the areas and wetted perimeters of the subsections to obtain Q_1, Q_m, and Q_r.

To find the critical depth it is necessary to obtain an estimate of the kinetic energy correction factor. For an irregular cross section, α defined in Eq. (30.13) becomes

$$\alpha = \frac{1}{A}\sum_{l}^{r}\left(\frac{V_i}{V}\right)^3 A_i = \sum_{l}^{r}\left(\frac{Q_i}{Q}\right)^3\left(\frac{A}{A_i}\right)^2 = \frac{B^3A^2S^{3/2}}{Q^3}\sum_{l}^{r}\frac{1}{n_i^3}\frac{A_i^3}{P_i^2} \tag{30.37}$$

Substituting Eq. (30.37) into Eq. (30.18) (for small slopes) yields

$$\frac{gQ}{B^3S^{3/2}} = \left(\frac{T}{A}\sum_{l}^{r}\frac{1}{n_i^3}\frac{A_i^3}{P_i^2}\right)_{y_c} \tag{30.38}$$

The *critical depth* is obtained by solving Eq. (30.38) for $y = y_c$. Numerical techniques are generally needed to obtain the root(s).

Usually river cross sections are given as sequences of station abscissas, s_i, and bottom elevations, b_i, and a general cross section is approximated as shown in Fig. 30.8(b). With z_i as the water surface elevation, the flowrate Q_i in trapezoidal element i is

$$Q_i = \frac{B}{n_i}\frac{A_i^{5/3}}{P_i^{2/3}}S^{1/2} = \frac{B}{n_i}\frac{\left(s_{i+1}-s_i\right)^{5/3}\left\{z_i - \left[\left(b_{i+1}+b_i\right)/2\right]\right\}^{5/3}}{\left[\left(s_{i+1}-s_i\right)^2 + \left(b_{i+1}-b_i\right)^2\right]^{1/3}}S^{1/2} \tag{30.39}$$

30.5 Gradually Varied Flow

In gradually varied flow, the depth changes in the flow direction slowly enough that the piezometric head can be assumed constant on every cross section. The channel need not be prismatic, but it cannot change abruptly in the streamwise direction. In contrast to uniform flow, the slope of the channel bottom, S_o, the slope of the water surface, S_w, and the slope of the total head line (the friction slope), S_f, must be distinguished. Consider the development of an expression for the rate of change of the depth along the channel, called the *gradually varied flow equation*. In the interest of simplicity, consider only the special case of a regular open top prismatic channel of small bottom slope in which the velocity profile is flat ($\alpha = 1$) and Q does not change with x. For such a channel, there is one normal depth and one critical depth.

From Fig. 30.1, the total head H for an open channel flow of small slope with $\alpha = 1$ is

$$H = z + y + V^2/(2g) \tag{30.40}$$

Differentiate Eq. (30.40) with respect to x; recognize that $dH/dx = -S_f$, $dz/dx = -S_o$, and $dA/dy = T$; and solve for dy/dx to obtain

$$\frac{dy}{dx} = \frac{S_o - S_f}{1 + \dfrac{d}{dy}\left(\dfrac{V^2}{2g}\right)} = S_o\frac{1-\left(S_f/S_o\right)}{1-\dfrac{Q^2T}{gA^3}} = S_o\frac{1-\left(S_f/S_o\right)}{1-\dfrac{V^2}{gD}} \tag{30.41}$$

Recalling the definition of the Froude number, the gradually varied flow equation for a prismatic channel may also be written as

$$\frac{dy}{dx} = \frac{S_o - S_f}{1 - Fr^2} = \frac{\mathcal{N}(y)}{\mathcal{D}(y)} \tag{30.42}$$

where $\mathcal{N}$ is the numerator and $\mathcal{D}$ is the denominator of the right side of Eq. (30.42). Eqs. (30.41) and (30.42) are forms of the differential equation for the water surface profile $y(x)$ in a prismatic channel. They are some of the ways of writing the *gradually varied flow equation* for regular open top prismatic channels. Note that dy/dx is the slope of the water surface with respect to the bottom of the channel, not necessarily with respect to the horizontal. Eq. (30.42) is a separable first order ordinary differential equation, whose formal solution is

$$x = x_1 + \int_{y_1}^{y}\frac{\mathcal{D}(\xi)}{\mathcal{N}(\xi)}d\xi \tag{30.43}$$

where y_1 is the boundary condition at x_1 and ξ is a dummy variable.

Because of the physical restrictions on the direction of surface wave propagation discussed in Section 30.1, the boundary condition for a given reach is usually given at the downstream boundary if the type of flow in the reach is subcritical, and at the upstream boundary if the flow in the reach is supercritical.

As Eq. (30.43) is integrable in closed form only under very particular conditions of channel geometry and of resistance law, some general observations, valid for any regular open top prismatic channel and for the Manning resistance law, will be made here. In Eq. (30.42), $\mathcal{N} \to S_o$ as y $\to \infty$ because $S_f \to 0$. As $y \to y_o$, $\mathcal{N} \to 0$. Thus the derivative of y with respect to x is zero when either the curve coincides with the y_o line (normal flow) or as the curve approaches the y_o line asymptotically. As $y \to 0$, $S_f \to \infty$, so $\mathcal{N} \to -\infty$.

As $y \to \infty$, $Fr \to 0$ and $\mathcal{D} \to 1$. As $y \to y_c$, $Fr \to 1$, so $\mathcal{D} \to 0$ which implies that if a free surface profile approaches the y_c line, it must do so with infinite slope. But in such an event, the assumption of quasi-parallel flow becomes invalid; and Eq. (30.42) no longer represents the physics of the flow. This means that where the mathematical water surface profiles cut the y_c line, they do not represent accurately what happens in nature. Fortunately this phenomenon is of limited extent. In reality, the water surface approaches the y_c line at an angle which is large, but less than 90°. A similar discrepancy occurs as $y \to 0$: namely Fr $\to \infty$, so $\mathcal{D} \to -\infty$. This makes dy/dx indeterminate, but it can be shown that $dy/dx \to \infty$ as $y \to 0$. Observe that, for any reach of given constant slope S_o, the lines $y = y_c$, $y = y_o$ (if it exists), and the bottom line $y = 0$, divide the x,y plane into three regions if $y_o \neq y_c$, or two regions if $y_o = y_c$. With these observations in mind, a brief presentation of all possible types of water surface profiles is made in the next section.

30.6 Water Surface Profile Analysis

Once again consider only the special case of a regular open top prismatic channel of small bottom slope in which the velocity profile is flat ($\alpha = 1$) and Q does not change with x. Figure 30.9 illustrates the different classes of profiles which can be distinguished according to the relative magnitude of the critical depth, y_c, calculated from Eq. (30.18) and the normal depth, y_o, calculated from Eq. (30.32). The sign of dy/dx is determined by considering the gradually varied flow equation Eq. (30.42).

The Mild Slope Profiles ($y_c < y_o$)

The M_1 Profile ($y_o < y$)

With the actual depth y exceeding the normal depth y_o, the friction slope S_f is less than the bottom slope S_o so that $\mathcal{N}$ is positive. The actual depth y also exceeds the critical depth y_c so that the flow is subcritical and $\mathcal{D}$ is also positive. Thus dy/dx is always positive, and y grows as the stream proceeds downstream. As the depth increases, $S_f \to 0$ and $Fr \to 0$, so $\mathcal{D} \to 1$ and $\mathcal{N} \to S_o$. Thus dy/dx asymptotically approaches S_o. Since the slope is with respect to the channel bottom, the water surface becomes horizontal. The water surface asymptotically approaches the normal depth line in the upstream direction for reasons given previously. Since the M_1 profile is subcritical, it is drawn from downstream to upstream, starting from a known depth such as P_6. The M_1 profile is called a *backwater profile*.

The M_2 Profile ($y_c < y < y_o$)

Because the actual depth is less than the normal depth, the friction slope must exceed the bottom slope so that $\mathcal{N} < 0$. With the actual depth greater than the critical depth, the flow is subcritical so that $\mathcal{D} > 0$. Consequently dy/dx is always negative and the depth decreases from upstream, where the surface profile is asymptotic to the y_o line, to downstream, where it approaches the y_c line vertically. Since the stream is subcritical it is drawn from downstream to upstream, starting from a known depth such as P_7. The M_2 profile is a *drawdown profile.*

The M_3 Profile ($0 < y < y_c$)

In this case $\mathcal{N} < 0$ and $\mathcal{D} < 0$, therefore $dy/dx > 0$. Since dy/dx tends to infinity as y approaches either zero or y_c, the profile has an inverted S shape. It can be shown that the tangent to the profile at the

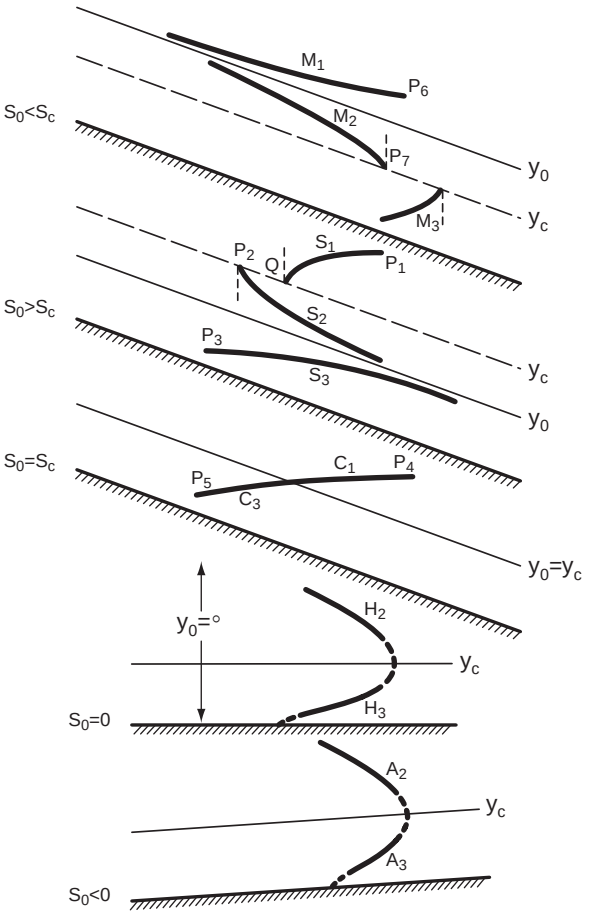

FIGURE 30.9 Gradually varied flow water surface curves.

inflection point is slightly larger than S_o, which means that the profile has always a slope above the horizontal line.

The Steep Slope Profiles ($y_o < y_c$)

The S_1 Profile ($y_c < y$)

In this case $\mathcal{N} > 0$, and $\mathcal{D} > 0$, so dy/dx is always positive; and y grows as x increases from a starting datum. If this datum coincides with the critical depth y_c, then the profile grows from it with infinite slope. The slope decreases very rapidly to become S_o for large values of x (where the values of y are large). This means that the S_1 profile has a horizontal asymptote for $x \to \infty$. Since S_1 is a subcritical profile, it is drawn from downstream to upstream, always below a horizontal line through the known control point P_1. It cuts the y_c line vertically at Q.

The S_2 Profile ($y_o < y < y_c$)

Since in this case $\mathcal{N} > 0$ and $\mathcal{D} < 0$, dy/dx is always negative; and y decreases as x increases from the starting datum. If this datum coincides with the critical depth y_c, then the profile decreases from an initial infinite slope to approach y_o asymptotically. Since S_2 is a supercritical profile, it is drawn from upstream to downstream through a control point such as P_2.

The S_3 Profile ($0 < y < y_o$)

In this case $\mathcal{N} < 0$ and $\mathcal{D} < 0$, therefore dy/dx is always positive; and the water surface profile tends to the y_o line asymptotically downstream. Moving upstream, the depth approaches zero vertically. The S_3 profile is drawn from upstream to downstream because it is supercritical.

The Critical Slope Profiles ($y_o = y_c$)

Critical slope profiles rarely occur in practice because equality of the critical and normal depths is highly unlikely.

The C_1 Profile ($y_c = y_o < y$)

In this case $\mathcal{N} > 0$ and $\mathcal{D} > 0$, so $dy/dx > 0$. Eq. (30.42) is indeterminate at y_c but it can be shown that the slope has a finite value there that decreases asymptotically to S_o as x increases. Since the stream is subcritical, it is drawn from downstream to upstream, starting from a known datum point such as P_4.

The C_2 Profile ($y = y_c = y_o$)

Region 2 degenerates to the $y_o = y_c$ line. In reality this profile is unstable and a wavy surface occurs.

The C_3 Profile ($0 < y < y_c = y_o$)

In this case $\mathcal{N} < 0$ and $\mathcal{D} < 0$, so $dy/dx > 0$. According to the mathematical model, the profile rises vertically from the channel bottom and decreases in slope until it intersects the $y_c = y_o$ with a finite slope. Because the stream is supercritical, it is drawn from upstream to downstream, starting from a known depth such as P_5.

The Horizontal Slope Profiles ($y_c < y_o \rightarrow \infty$)

As the slope of a channel is reduced, the depth of a uniform flow of magnitude Q tends to infinity. Therefore region 1 does not exist for a horizontal channel. Because $S_o = 0$, $\mathcal{N} = -S_f < 0$.

The H_2 Profile ($y_c < y$)

The flow is subcritical, so $\mathcal{D} > 0$. This implies that $dy/dx < 0$. As x increases, y decreases toward the y_c line, which it approaches vertically.

The H_3 Profile ($y < y_c$)

The flow is supercritical so $\mathcal{D} < 0$. This implies that $dy/dx > 0$. As x increases, y increases from the channel bottom toward the y_c line, which it approaches vertically.

The Adverse Slope Profiles ($S_o < 0$)

It is impossible to have uniform flow in a channel of negative bottom slope because both gravity and friction oppose the motion. As a consequence, the normal depth does not exist. In all adverse slope cases, $\mathcal{N} < 0$.

The A_2 Profile ($y_c < y$)

The flow is subcritical so $\mathcal{D} > 0$. This implies that $dy/dx < 0$. As x increases, y decreases toward the y_c line, which it approaches vertically.

The A_3 Profile ($y < y_c$)

The flow is supercritical so $\mathcal{D} < 0$. This implies that $dy/dx > 0$. As x increases, y increases from the channel bottom toward the y_c line, which it approaches vertically. Persons who believe that "water always flows downhill" are often astounded by the A_3 profile.

30.7 Qualitative Solution of Flow Profiles

The steady water surface profile in a series of regular open top prismatic channels connected by short transition sections will consist of the elementary solutions discussed above, connected by short reaches of gradually or rapidly varied flow in the transition sections. In addition, hydraulic jumps may occur in the prismatic reaches. Among the possible transition sections are upward steps, downward steps, channel contractions, channel expansions, weirs, gates, spillways, and culverts. If the flowrate is given, the first step in deducing the form of the profile is to draw the channel bottom and the normal and critical depth lines in each reach. This determines the slope family (M, S, C, H, or A) to which the profile in each prismatic reach belongs.

As the gradually varied flow equation is a first order differential equation, it needs only one boundary condition to define the elementary water surface profile in a given reach. In some cases, this condition is fixed by the requirement of continuity with the water surface elevation in the upstream or downstream reach. But there will always be one or more features which provide a definite relationship between flowrate and depth. Such features are usually called *controls* in open channel hydraulics. The second step in sketching the profile is the determination of the control points. By fixing the zone (1, 2, or 3) through which the profile must pass, the shape of the profile in that reach can be determined. Fig. 30.10 shows a long mild channel flowing into a long steep channel. In any long channel, the flow must tend toward y_o far away from a disturbance. Therefore, the only possible profiles in the mild channel are M_1 and M_2. If the M_1 profile occurred, the profile in the steep reach would be an S_1, which could not approach y_o. The same problem happens if the mild channel contains an M_2 profile unless it crosses the y_c line at the break in grade. In that case, the flow in the steep section follows an S_2 profile that does approach y_o. In obtaining the numerical solution, it is important to start the process of integration for both reaches at the known depth y_c because the normal depth is approached, but not equaled, in both reaches. Thus the control in this example is at the break in grade. In general, the correct solution is deduced by the process of elimination; however there may be several possible alternatives in more complicated situations.

Figure 30.11 illustrates a complex channel system in which each prismatic reach is a wide rectangular cross section of small slope. As is usual, the vertical scale is drawn much larger than the horizontal scale for clarity. The prismatic reaches *AB, CD, DE, FG, HI,* and *JK* are intermingled with shorter transition sections: *BC*, a downward step; *EF*, a sluice gate; *GH*, an upward step; and *IJ*, a contraction. Discharges, slopes and roughness coefficients are shown on the figure. The channel terminates at *K* in a free overfall. The solution process can be divided in three phases as follows:

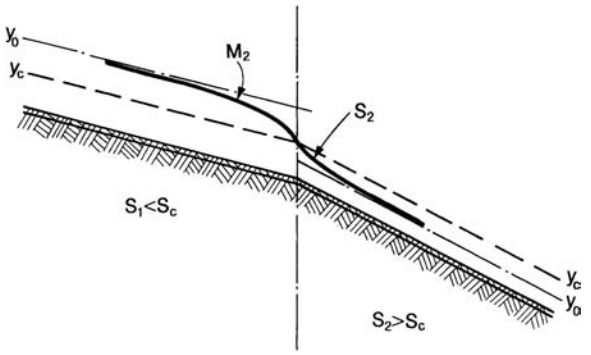

FIGURE 30.10 Channel with abrupt change of slope from mild to steep.

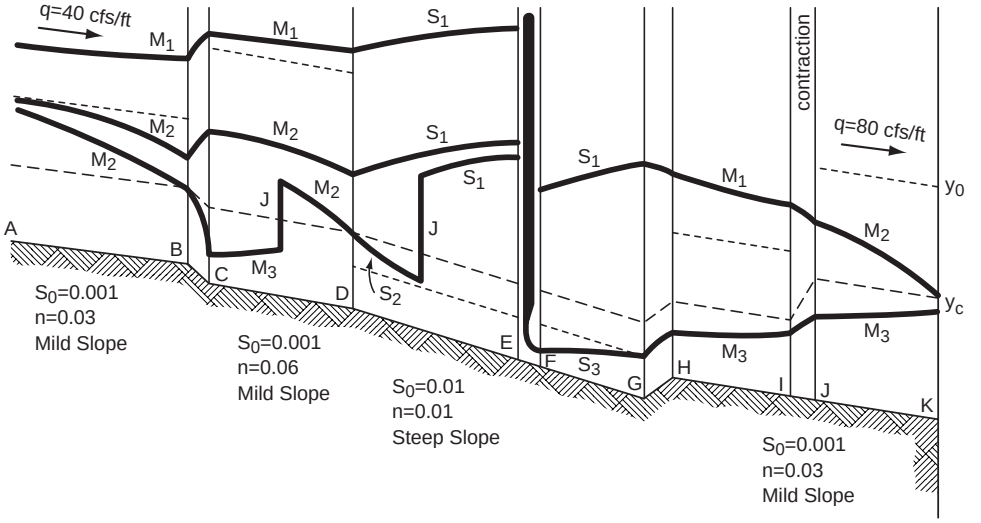

FIGURE 30.11 Complex open channel system with some possible water surface profiles. Profiles U1, U7, U12, D1, and D3 are shown. Refer to Tables 30.3 and 30.4 for details.

Phase I — Determination of Critical Depths and Normal Depths

Calculate the values of y_c and of y_o throughout the channel length:

From Eq. (30.21) $y_c = (q^2/g)^{1/3} = 3.68$ ft from *A* to *I*. Similarly, $y_c = 5.84$ ft from *J* to *K*.
From Eq. (30.33) $y_o = [nq/(1.486\, S_o^{1/2})]^{3/5} = 6.99$ ft on *AB*. Similarly, $y_o = 10.59$ ft on *CD*, 1.81 ft on *DE* and *FG*, 6.99 ft on *HI*, and 10.59 ft on *JK*.

The y_c and y_o lines are then sketched as shown in Fig. 30.11. Reaches *AB*, *CD*, *HI*, and *JK* are mild; reaches *DE* and *FG* are steep.

Phase II — Virtual Control Section (VCS) Determination

The adjective "virtual" indicates the uncertainty that these cross sections are actually "controlling" the water surface profile. Only at the end of the solution process will it be determined whether a virtual control section actually does control the flow. Recall that subcritical streams are controlled from downstream and supercritical streams are controlled from upstream.

Start the search process by inquiring whether the cross section *A* is a VCS. No indication of this is given by the sketch of Fig. 30.11. It is permissible to assume that *AB* is long enough to allow the depth at *A* to approach y_o.

Next consider the downward step *BC* as a possible site for a control section. It is obvious that if any cross section between *B* on *C* is a control section, it should be *B*, because if no loss of energy occurs between *B* and *C*, *B* is the point of lowest specific energy. This would make cross section *B* a *natural control*, that is a section that controls both upstream and downstream.

As seen in Fig. 30.11, there is the possibility of another natural control at *D*. Moving downstream, consider the segment *EF* where a sluice gate is situated. The flow from *E* to *F* is a strongly curved rapidly varied flow. If the efflux from the sluice gate is not submerged, then the water surface elevation at *F*, the vena contracta of the efflux, is known to be $C_c a$ where C_c is a contraction coefficient and *a* is the gate opening. Notice that the water depth at the cross section through *E* can then be found as the alternate of the depth at *F*, assuming negligible loss of energy occurs between *E* and *F*.

Go now to the upward step *GH*. If any cross section between *G* and *H* is a control section, it is *H* because, with no energy loss, *H* has the lowest specific energy. It could possibly be a natural control if

the water surface profile would cut the cross section through *H* at the critical depth, but this is not possible because *HI* is a mild reach and no mild elementary solution starts at critical depth and moves away from it.

The same argument is valid for the contraction *IJ*: neither *I* nor *J* nor any cross section in between can be a control. The only section left is *K*, which is a virtual control. If *K* is a control the water depth is critical there.

Phase III — Profile Sketching

The action of the sluice gate allows the profile analysis of the channel to be divided into two parts. Fig. 30.11 shows the opening of the sluice gate to be in zone 3, implying that the flow at the vena contracta *F* is supercritical, unless a drowned hydraulic jump occurs. Assuming no loss of energy between *E* and *F* allows the depth at *E* to be determined, providing the relationship between the profiles upstream and downstream of the sluice gate. The depth upstream of the gate at *E* is the subcritical alternate depth corresponding to $E_E = E_F = y_F + q^2/(2gC_c^2a^2)$. Here y_F is the actual water depth, whether or not a submerged hydraulic jump occurs.

Table 30.3 lists 15 possible profiles upstream of the sluice gate. Fig. 30.11 illustrates U1, U7, and U12. Solutions U1 through U7 are entirely subcritical and are controlled from *E*. Solutions U8 through U12, U14, and U15 contain one or two hydraulic jumps. For a hydraulic jump to occur, the depths before and after the jump must be conjugate, i.e., they must have the same value of specific force. Solution U13 passes from subcritical to supercritical at *B* and from supercritical back to subcritical at *D* without a hydraulic jump. In the transcritical cases, the subcritical segments are controlled from downstream, and the supercritical parts are controlled from upstream.

Table 30.4 lists the eight possible water surface profiles downstream of the sluice gate. Fig. 30.11 shows solutions D1 and D3. Solutions D1 and D2, being entirely subcritical, are controlled from *K*. Solution D3 is completely supercritical and has its control at *F*. Solutions D4 through D8 have a supercritical portion controlled from *F* followed by a subcritical portion controlled at *K*.

Each of the 15 upstream solutions could be followed by any of the eight downstream solutions so that there are 120 possible qualitatively distinct water surface profiles for this problem. Only a detailed numerical calculation, based on the lengths of each prismatic reach and the dimensions of each transition, can determine which would actually occur.

30.8 Methods of Calculation of Flow Profiles

The integration of the gradually varied flow Eq. (30.42) can be performed by either direct or numerical integration. The *direct integration method* is based on tables for the evaluation of the integral in Eq. (30.43). This integral cannot be evaluated in terms of elementary functions except for some simplified cases such as an infinitely wide rectangular channel, but a much wider class of channels can be treated by the introduction of special tabulated functions. This requires the definitions of the *hydraulic exponent for critical flow* (Chow, 1959, p. 66) and of the *hydraulic exponent for uniform flow* (Chow, 1959, p. 131). The *varied flow function* for regular open top prismatic channels was developed and tabulated by Bakhmeteff (1932) and extended by Chow (1959, p. 254–261, tables p. 641–655). Keifer and Chu applied the method of direct integration to circular pipes (Chow, 1959, p. 261–262, Tables p. 657–661). With the widespread availability of computers, the various methods of *numerical integration* are the most widely used methods of solving the gradually varied flow equation. We shall consider only two: the *direct step method*, a non-iterative method suitable only for prismatic channels, and the *standard step method*, an iterative method which can be used for both prismatic and nonprismatic channels. Either can be readily adapted for computer solution using a programming language such as Fortran or a spreadsheet program. To establish the equations for the direct step method, a new form of the gradually varied flow equation is derived by differentiating the specific energy E with respect to streamwise distance x.

$$\frac{dE}{dx} = \frac{d(H-z)}{dx} = -S_f + S_o \tag{30.44}$$

Multiplying by dx and integrating from station 1 to station 2 gives

$$E_2 - E_1 = S_o(x_2 - x_1) - \int_{x_1}^{x_2} S_f dx = \left(S_o - \langle S_f \rangle\right)(x_2 - x_1) \tag{30.45}$$

Here $\langle S_f \rangle$, is the average friction slope over the reach from 1 to 2. It can be approximated by the arithmetic average of the friction slopes calculated at 1 and 2 using the Manning equation to find S_f.

$$\langle S_f \rangle = \left(S_{f_1} + S_{f_2}\right)/2 = 0.5\left[\left(\frac{nQ}{BAR^{2/3}}\right)_1^2 + \left(\frac{nQ}{BAR^{2/3}}\right)_2^2\right] \tag{30.46}$$

Solving Eq. (30.45) for x_2 gives the equation for the direct step method.

$$x_2 = x_1 + \left(E_2 - E_1\right)/\left(S_o - \langle S_f \rangle\right) \tag{30.47}$$

In a prismatic channel, knowing y permits the calculation of A, $V = Q/A$, $E = y + \alpha V^2/2g$, and S_f. The calculation starts at x_1 where y_1 is known. By specifying y_2, Eq. (30.47) can be solved for the corresponding x_2. (The restriction to prismatic channels occurs because of the need to calculate $A(y_2)$ at an unknown x_2.) After y_2 is found, station 2 becomes the new station 1 and the process is repeated for the next reach. The computation should proceed upstream if the flow is subcritical and downstream otherwise. The accuracy of the solution is improved by using smaller y increments. Care must be taken to specify depths that lie within the zone of the solution, i.e., which do not cross the normal or critical depths.

Example 30.4 Direct Step Method

A trapezoidal channel having a bottom width b = 10 ft, side slopes 2 horizontal on 1 vertical, n = 0.02 and S_o = 0.0016 carries a discharge of 160 cfs. Assume α = 1.0. A dam creates a depth of 4.5 ft. Calculate the backwater profile.

1. Find y_o = 2.47 ft by iteration from Eq. (30.32):

$$y_o\left(10+2y_o\right)\left[\frac{y_o\left(10+2y_o\right)}{\left(10+2\sqrt{5y_o}\right)}\right]^{2/3}=\frac{0.02(160)}{1.486\sqrt{0.0016}}$$

2. Find y_c = 1.76 ft by iteration from Eq. (30.18):

$$\left[y_c\left(10+2y_c\right)\right]^3/\left[10+2(2)y_c\right]=1(160)^2/32.2$$

3. Find profile type: since y_1 = 4.5 ft > y_o > y_c the solution is an M_1 curve.
4. The direct step method is illustrated in Table 30.5 using only two steps for brevity. For an accurate solution, much shorter steps should be used.

In contrast to the direct step method, the standard step method solves for the depth at specified values of x. This method is especially suited for natural rivers for which cross-sections have been surveyed only at specific stations. The calculation begins at x_1 where the depth y_1 and the total head H_1 are known. The standard step method uses two equations to calculate the unknown total head at x_2. The first is simply the definition of total head in a channel of small slope.

$$H_2' = z_2 + y_2 + \alpha_2 V_2^2/(2g) \tag{30.48}$$

The second equation is the mechanical energy Eq. (30.12) written in terms of the total head

$$H_2'' = H_1 - h_L = H_1 - \langle S_f \rangle (x_2 - x_1) - h_E \tag{30.49}$$

where h_E is a minor loss term to account for local expansions, contractions, or other localized irregularities.

The standard step method proceeds by choosing x_2, guessing a trial value for y_2, estimating α_2, finding A_2 and V_2, and calculating H_2' from Eq. (30.48). Then h_L is calculated based on the assumed y_2 and Eq. (30.49) is used to get H_2''. If the correct y_2 has been used, $H_2' = H_2''$. If the difference between the estimates is too

large, a new y_2 is chosen and the process is repeated. After the calculation has converged, station 2 becomes the new station 1 and the process is repeated for the next reach. The computation should proceed upstream if the flow is subcritical and downstream otherwise. The accuracy of the solution is improved by using smaller x increments. Care must be taken to specify depths that lie within the zone of the solution.

Example 30.5 Standard Step Method

Although this method is generally used for nonprismatic channels, this example repeats the flow of Example 30.4, specifying in Table 30.6 the same x values calculated in Table 30.5. In Table 30.6 the y values are guessed and adjusted until H' and H'' are nearly equal. It can be seen that the agreement between the two methods is excellent. Table 6 contains only two steps for brevity. For an accurate solution, much smaller steps should be used.

30.9 Unsteady Flows

Applying the conservation of mass and conservation of streamwise momentum principles to unsteady flow in a prismatic open channel control volume of infinitesimal length which contains all of the liquid between an upstream flow area and a downstream flow area yields the *St. Venant equations*:

$$\frac{\partial y}{\partial t} + V\frac{\partial y}{\partial x} + D\frac{\partial V}{\partial x} = 0 \tag{30.50}$$

$$\frac{\partial V}{\partial t} + V\frac{\partial V}{\partial x} + g\frac{\partial y}{\partial x} - gS_o + gS_f = 0 \tag{30.51}$$

This is one non-conservative form of the St. Venant equations; several other forms are also common.

The St. Venant equations are nonlinear hyperbolic partial differential equations that can be solved by the *method of characteristics*. This means that there are two families of special lines in x,t space called *characteristics* along which Eqs. (30.50) and (30.51) can be replaced by ordinary differential equations. The characteristics, along which information propagates, are themselves defined by the solution of the following ordinary differential equations:

$$\frac{dx}{dt} = V \pm (gD)^{1/2} = V \pm c \tag{30.52, 30.53}$$

The characteristics defined by these equations are known as the C^+ and C^- families. Excluding singularities, one characteristic of each family passes through each point in the computational domain, a subregion of the x,t plane. If a flow is subcritical, $V < c$ and the C^+ characteristics will have a positive slope in the computational domain while the C^- characteristics have a negative slope. In supercritical regions, $V > c$ so both families have positive slopes.

Because the St. Venant equations are partial differential equations with x and t as independent variables, both initial and boundary conditions must be specified. A typical initial condition would be the specification of y and V at every point of the channel at $t = 0$. To understand how the boundary conditions are specified, it is useful to consider the characteristic equations. One boundary condition must be specified for each characteristic where it enters the computational domain. For a subcritical flow, one condition must be specified at the upstream boundary and the second must be at the downstream

boundary. For a supercritical flow, both conditions are specified at the upstream boundary; none can be given on the downstream boundary.

The method of characteristics can be solved by hand in some simplified cases, yielding important insights; but for more realistic applications two variants have evolved for computer solution: the *characteristic grid method* and the *method of specified intervals*. The programming of these methods is rather complex, and most recent work has used the *finite difference* or *finite element methods* in which the St. Venant differential equations themselves are discretized and solved numerically.

30.10 Software

Numerous software packages have been developed to solve problems of open channel hydraulics under the approximation of one-dimensional flow. Perhaps the most powerful program presently available is the U. S. Army Corps of Engineers Hydrologic Engineering Center River Analysis System (HEC-RAS). This Windows-based program can solve both steady and unsteady flows in single channels, dendritic systems, or complex networks. It can handle mixed subcritical and supercritical flows with hydraulic jumps, and can model the effects of obstructions such as bridge piers, culverts, and weirs. HEC-RAS has superceded the U. S. Army Corps of Engineers' HEC-2 (formerly the industry standard) and the Natural Resources Conservation Service's WSP-2, both of which are limited to steady state simulations. Another commonly used steady state program is WSPRO, developed by the U. S. Geological Survey (USGS) for the Federal Highway Administration. The USGS has developed several programs for unsteady open channel hydraulics including FEQ, BRANCH, and FOURPT. All of the programs mentioned in this section are in the public domain. Those that have not been superceded can be downloaded from the Websites of the appropriate agencies.

Defining Terms

Alternate depths — The subcritical or tranquil depth, y_T, and the supercritical or rapid depth y_R for a given specific energy and flowrate.

Conjugate depths — The depths before and after a hydraulic jump corresponding to a given total thrust (or specific force) and flowrate.

Control section — A section in a nonuniform flow at which the depth is known *a priori* and which serves as a boundary condition for the calculation of a water surface profile. Often the flow goes through critical depth at the control section. In general, a control is any feature which determines a relationship between depth and flowrate.

Critical depth — The depth of flow corresponding to an extremum (usually a minimum) of specific energy. The Froude number is unity at critical depth.

Critical slope — The slope of the bottom of a channel in which the normal depth and the critical depth coincide.

Critical velocity — The velocity occurring at critical depth. It is equal to the celerity or speed of propagation of an infinitesimal gravity wave in still shallow water.

Hydraulic jump — The sudden increase in depth that occurs when the flow passes from supercritical to subcritical, usually accompanied by turbulence and large energy loss.

Mild slope — A slope less than the critical slope.

Specific energy — The sum of the vertical component of the thickness of flow plus the velocity head.

Specific force — The total thrust per unit weight of liquid.

Steep slope — A slope larger than the critical slope.

Subcritical flow — The flow that occurs when the velocity is smaller than the critical velocity and the depth is larger than the critical depth.

Supercritical flow — The flow that occurs when the velocity is larger than the critical velocity and the depth is smaller than the critical depth.

Total thrust — The sum of the hydrostatic force on a flow area plus the momentum flowrate through that area.

Further Information

Gray (2000) provides an extended introductory treatment of open channel hydraulics.

Chow (1959) wrote an extensive text that remains the classic reference on the subject. Although Chow's numerical examples predate the computer era, his book contains much useful material which can be found nowhere else.

Henderson (1966) is a pedagogically superb textbook covering open channel flow including unsteady flows, flood routing, sediment transport, and physical hydraulic models.

French (1985), in addition to classical open channel hydraulics, provides chapters on turbulent diffusion and buoyant surface jets.

Chaudhry (1993) emphasizes unsteady flow problems and their solution by numerical methods. Also included are two-dimensional flows and finite elements applied to both one- and two-dimensional flows. Several simple Fortran computer programs are listed and provided on a diskette.

Chanson (1999) covers sediment transport, hydraulic modeling, and hydraulic structures in addition to open channel hydraulics.

Jain (2001) and **Sturm** (2001) are modern, rigorous treatments of steady and unsteady open channel hydraulics.

Yen (1992) is the proceedings of a symposium on the history of the Manning equation and on new developments in the calculation of resistance to flow in open channels.

Nezu and Nakagawa (1993) deal with open channel turbulence, boundary layers, and turbulent transport processes in rivers and estuaries.

31.1 Introduction

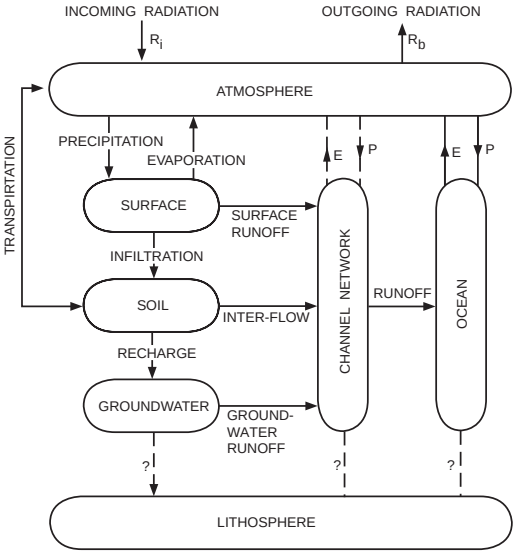
Hydrologic Cycle

Hydrologic cycle is the name given to the continuum of the movement of water in the atmosphere, hydrosphere and lithosphere. It is an intricate cycle of great complexity. A schematic diagram of the hydrologic cycle is shown in Fig. 31.1.

Water evaporates from the oceans and land and becomes a part of the atmosphere. The water vapor is either carried in the atmosphere or it returns to the earth in the form of precipitation. A portion of precipitation falling on land may be intercepted by vegetation and returned back directly to the atmosphere as evaporation. Precipitation that reaches the earth may evaporate or be transpired by plants; or it may flow over the ground surface and reach streams as surface water; or it may infiltrate the soil. The infiltrated water may flow over the upper soil regions and reach surface water or it may percolate into deeper zones and become groundwater. Groundwater may reach the streams naturally or it may be pumped, used, and discarded to become a part of the surface water system.

The general volume balance equation for the hydrologic cycle may be written as in Eq. (31.1),

$$\frac{dS}{dt} = I(t) - O(t) \tag{31.1}$$



FIGUREW 31.1 A systems representation of the hydrologic cycle. (From Dooge, 1973.)

where S is the storage including the surface, soil moisture, groundwater and interception storage, t the time. $I(t)$ is the input, which includes precipitation in all its forms and $O(t)$ is the output, which includes surface and subsurface runoff, evaporation, transpiration, and infiltration.

According to the world water balance studies (UNESCO, 1978), about 127 cm of precipitation falls on oceans of area 361.3 million km.^{2} The corresponding values for land areas are 78.74 cm and 148.8 million km.^{2} The evaporation rates are 55 and 19 in. respectively from the oceans and land areas. Of the 12 in. of water that remains on land, 0.2 in. becomes groundwater and 11.8 inches reaches the oceans as surface water. Due to the fact that a large part of the precipitation falling on the earth remains as ice, the amount of surface water that is available for use is quite limited. In this chapter several aspects of surface water hydrology are discussed.

Historical Development

Chow (1964) has classified the development of hydrology into eight periods. The first of these is called the period of speculation (Ancient - 1400 AD) during which there were many speculations about the concept of the hydrologic cycle. However, during this period, practical aspects of hydrologic knowledge were studied and used to build civil works. During the period 1400 to 1600 AD (period of observation), hydrological variables were simply observed. Leonardo da Vinci and Bernard Palissy understood the hydrological cycle during this period. Hydrologic measurements started during the period of measurement (1600–1700) and the science of hydrology may be said to have begun during this period. It continued up to nineteenth century with experiments, a period called the period of experimentation (1700–1800). The foundations of modern hydrology were laid during the period of modernization (1800–1900). Hydrology was mostly empirical during the period of empiricism (1900–1930), which gradually gave into the period of rationalization (1930–1960), during which theoretical developments in hydrograph, infiltration and groundwater processes took place. The theoretical developments accelerated from 1950 to the present, a period called the period of theorization. The recent development of computers has made it possible to construct and verify theories of increasing complexity, an endeavor that has become the mainstay of modern hydrologic research.

31.2 Precipitation

Atmospheric Processes

Air masses must be lifted and cooled for precipitation to occur. Air mass cooling can occur during the passage of fronts when warm air is lifted over cooler air (frontal cooling); the passage of warm air over mountain ranges (orographic cooling); or the lifting of air masses due to localized heating such as that in the center of a thunderstorm cell (convective cooling).

As the air is cooled, water condenses on microscopic sized particles, called nuclei and this process is called nucleation. Dust and salt particles are common condensation nuclei. Water particles resulting from nucleation grow by condensation and by coming into contact with neighboring particles. They start to descend as they become heavier and may coalesce with other water drops or they may decrease in size during descent because of evaporation. If conditions are favorable, these water drops reach the ground as rain, snow, or sleet. The particular form taken by precipitation is dictated by the atmospheric conditions extant during the descent of water drops.

Measurement of Precipitation

Rainfall and snowfall are commonly measured. Both nonrecording and recording gages are used for rainfall measurement. Recording rain gages are used to measure rainfall depth at predetermined time intervals. These intervals can be as small as a minute. Nonrecording rain gages are read at larger time intervals. Common recording rain gages are of the weighing, the tipping bucket and the float types. In each of these, a record of rainfall depth against time is obtained. Depth and density of snow packs, in addition to the water equivalent of snow, are also commonly measured, as these are useful in estimating the water yield from snow packs. Measurement of snow depth is complicated because of the strong effect of wind on snow (Garstka, 1964).

Temporal Variation of Precipitation

The unit of rainfall measurement is depth, in inches or millimeters. The rates are usually expressed as in/hr or mm/hr, although longer durations such as days, months, and years are also used. Rainfall rate, especially when the time duration is an hour, is called the intensity of rainfall. In general, rainfall intensity is highly variable with time. A plot of intensity against duration is called a hyetograph of rainfall. A plot of the sum of the rainfall depth against time is called as the mass curve. A mass curve whose abscissa and ordinate are dimensionless is called the dimensionless mass curve. Typical hyetograph, mass curve, and dimensionless mass curve are shown in Fig. 31.2.

Spatial Variation of Precipitation

Rainfall measurements are taken at different points in an area. The spatial structure of storms and their internal variation cannot be adequately represented by a point measurement or even by many point measurements made over a region. Consequently, there have been attempts to relate point rainfall measurements to spatial average rainfall. As the area represented by a point measurement increases, the reliability of the data from a point as a representative of the average over a region decreases. As drainage areas become larger than a few square miles, point data must be adjusted to estimate areal data (Hershfield, 1961). If the drainage area is larger than 8 mi^2, an area reduction factor is applied to the point rainfall depth values obtained from the rainfall atlas (Hershfield, 1961). Recently there have been attempts to measure rainfall by using radar.

Average Rainfall over an Area

The *arithmetic average* method, the *Thiessen polygon* method, and the *isohyetal* methods are commonly used to compute average rainfall over an area. These and other methods have been investigated by Singh and Chowdhury (1986) who concluded that they give comparable results, especially for longer storm durations.

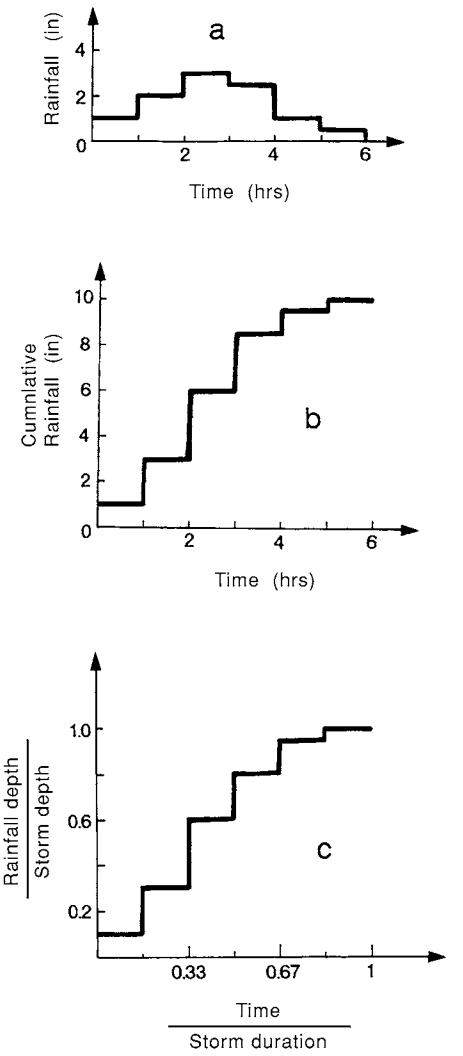


FIGURE 31.2 (a) Hyetograph: (b) mass curve; (c) dimensionless mass curve.

Let the *average rainfall* over an area be $\overline{P}$. Let the rainfall measured by N rain gages over an area A be $P_1, P_2, \ldots P_N$. The general expression for $\overline{P}$ is given in Eq. (31.2), where W_j are the weights.

$$\overline{P} = \sum_{j=1}^{N} W_j P_j, \quad W_j \varepsilon (0,1) \tag{31.2}$$

Different methods of estimation of rainfall give different W_j values. For the arithmetic average, the weights W_j are the same and are equal to $(1/N)$. To compute the *Thiessen* average rainfall, the locations of rain gages are joined by straight lines on a map of the area. These are bisected to develop a Theissen polygon such that each rain gage with rainfall P_j is located in a part of a watershed of area A_j. The sum of areas A_j equal the watershed area A. The Thiessen weights W_i are given by A_i/A and W_j add up to unity. The Thiessen average does not consider the spatial distribution of rainfall but takes into account the spatial distribution of rain gages.

In the *Isohyetal* method, lines of equal rainfall depth or *isohyetal lines* are first estimated. The variation in rainfall between rain gages may be assumed to be linear for interpolation purposes. The areas A_j between isohyetal lines are measured and these add up to A. The number of areas enclosed within isohyets is usually not equal to number of rain gages. The weights W_j are equal to A_j/A. The rainfall values P_i in Eq. (31.2) are the average rainfall values between the isohyets. In the isohyetal method the spatial distribution of rainfall variation is explicitly considered.

Intensity - Duration - Frequency (i-d-f) Curves

The largest rainfall depth measured over a specified duration, during a year, is an extreme value. Because the durations are fixed, we will have a series of rainfall extreme values. For example, we will have extreme rainfall depths corresponding to 30 min, 1 hr, 6 hr, etc. These extreme values — which are also the annual maximum values in this case — are random variables denoted by x. The probability that x is larger than a value x_T is called the exceedance probability and is indicated by $P(x \geq x_T)$ or p. The recurrence interval T is the average time elapsed between occurrences of $x \geq x_T$. The *return period* or *recurrence interval* between events exceeding or equalling x_T is the *average time T* between exceedances of the event. The exceedance probability and the return period are inversely related. The return period is also called the *frequency.*

By analyzing annual maximum rainfall intensities corresponding to a duration — such as 1 hr or 6 hr — the rainfall-intensity-frequency relationships are obtained. A set of rainfall intensity (i) frequency (f) relationships corresponding to different rainfall durations (d) are called the intensity (i) - duration (d) - frequency (f) curves. The i-d-f curves for Indianapolis, presented in Fig. 31.3, are typical of these.

It is difficult to use the i-d-f curves in computer analysis. Consequently, they are represented as empirical equations such as Eq. 31.3 where i is the intensity in in./hr, t is the duration in hours, T is the frequency in years, and C and d are constants corresponding to a location and m and n are exponents. For Indianapolis, $C = 1.5899$, $d = 0.725$, $m = 0.2271$ and $n = 0.8797$, and the resulting equation is valid for durations between 1 and 36 hours.

$$i = \frac{CT^m}{(t+d)^n} \tag{31.3}$$

These empirical equations give results that are more accurate than those obtained by interpolation of graphs.

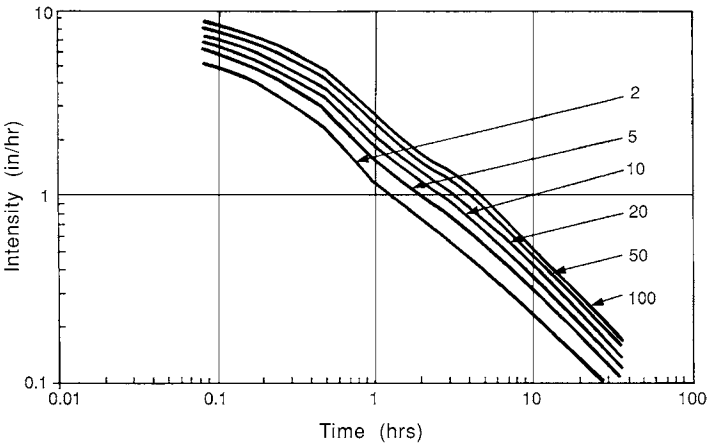

FIGURE 31.3 Intensity-duration-frequency curves for Indianapolis. (From Purdue, A.M., G.D. Jeong, A.R. Rao [1992] "Statistical Characteristics of Short Time Increment Rainfall," *Tech. Rept. CE-EHE*-92–09, School of Civil Engineering, Purdue University, W. Lafayette, IN., pp. 64. With permission.)

90	98.57	98.67	98.73	96.73
100	100.00	100.00	100.00	100.00

Dimensionless Mass Curves

To estimate hyetographs from rainfall depth-duration data, dimensionless mass curves are used. These dimensionless mass curves are developed by classifying observed rainfall data into different quartiles. For example, if the largest rainfall depth occurs during the first quartile of a storm duration then it is called a first quartile storm. The cumulative rainfall in these storms is made dimensionless by dividing the rainfall depths by the total rainfall depth and corresponding times by the storm duration. These dimensionless mass curves of rainfall are analyzed to establish their frequencies of occurrence. These are published in graphical form as shown in Fig. 31.4 and Table 31.1.

Given a rainfall depth and duration, the dimensionless mass curve information is used to generate hyetographs. These hyetographs may be used as inputs to rainfall-runoff models or with unit hydrographs to generate runoff hydrographs. The dimensionless hyetographs thus provide an easy method to generate rainfall hyetographs (Purdue et al. 1992).

Chen (1983) developed a method of generating intensity-duration curves for different frequencies or recurrence intervals. The method is based on 10 year - 1 hr, (R_1^{10}), 10 year - 24 hr, (R_{24}^{10}) and 100 year - 1 hr (R_1^{100}) rainfall *depths* for the location of interest. These are available from the NWS publications such

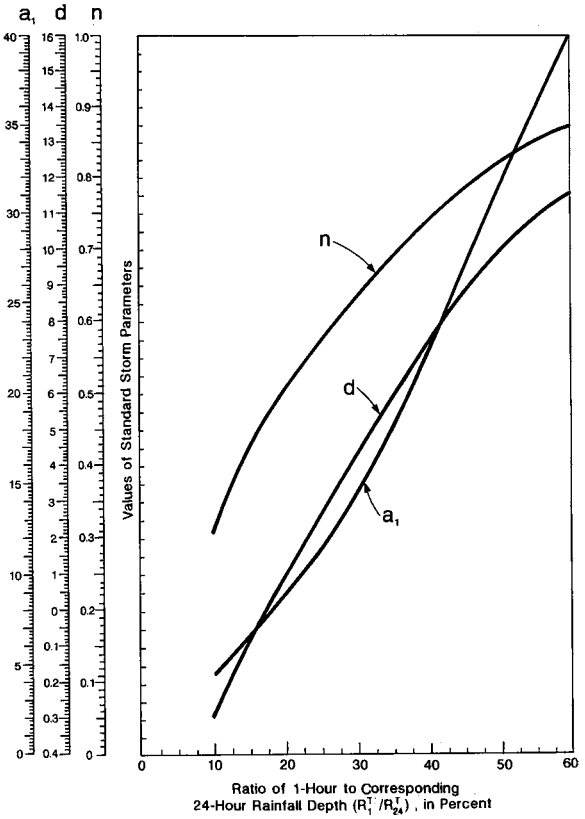

FIGURE 31.5 Coefficients and exponents for use with Chen's (1983) method.

as TP-40 or NWS HYDRO-35 or NOAA Atlas 2 in the U.S. (Hershfield, 1961; Frederick et al. 1977; Miller et al. 1973). The intensity-duration-frequency relationship used in this study is of the form of Eq. (31.3).

In this method, the ratios, R_1^{10}/R_{24}^{10} and $R_1^{100}/R_1^{10} = x$ are formed. The R_1^{10}/R_{24}^{10} ratio is the x axis of Fig. 31.5, and by using this value, a_1, d and n are read off from Fig. 31.5. The rainfall intensity corresponding to duration t and recurrence interval T is estimated by using Eq. (31.4), where r_1^{10} is the 10 year - 1 hour rainfall intensity which is the same as R_1^{10} because the duration is 1 hour.

$$r_t^T = \frac{a_1\left(r_1^{10}\right)\log\left(10^{2-x}\,T^{x-1}\right)}{\left(t+d\right)^n} \tag{31.4}$$

Chen's (1983) method has been demonstrated to give very good estimates of rainfall intensity-duration-frequency relationships.

Other Probabilistic Aspects

Numerous probabilistic models (Table 31.2) have been developed and used to characterize various rainfall properties. For analyzing annual maximum rainfall data, log-normal and extreme value (III) distributions have been successfully used. The Weibull distribution has been used to characterize the time between precipitation events. Two parameter gamma distribution and bivariate exponential distribution have been used to characterize the storm depths and durations. A discussion of these models is found in Eagleson (1970) and Bras (1990).

TABLE 31.2 Probability Distributions for Fitting Hydrologic Data

Distribution	Probability Density Function	Range	Parameters
Normal	$F(x)=\frac{1}{\sigma\sqrt{2\pi}}\exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\right)$	$-\infty \le x \le \infty$	μ, σ $\mu = \bar{x}, \sigma = s_x$

31.3 Evaporation and Transpiration

Evaporation

Evaporation is the process by which water is removed from an open water surface. The rate of evaporation depends on two factors: the energy available to provide the latent heat of vaporization, and the rate of transport of water vapor from the water surface. Evaporation from ponds, rivers, and lakes depends on solar radiation and wind velocity. The gradient of *specific humidity*, which is the ratio of the water vapor pressure, *e*, to the atmospheric pressure, *p*, also affects the evaporation rate.

Evaporation from a body of water can be estimated by using the law of conservation of energy. By using a control volume and estimating the energy inputs to and outputs from it, the evaporation rate E_1 (mm/day) can be shown to be as in Eq. 31.5, where R_w is the net short wave radiation in W/m^2,

$$E_1 = \frac{R_W}{l_v p_w} \tag{31.5}$$

where l_v = the latent heat of vaporization (kJ/kg)
ρ_w = the density of water in kg/m^3.

In deriving Eq. (31.5), the sensible heat flux and the heat transfer from the water to the ground are neglected. These assumptions are not realistic. Furthermore, there is no provision in Eq. (31.5) for

removal of water vapor from the water surface. To eliminate this strong drawback, Thornthwaite and Holzman (1939) derived an equation which includes the wind velocity to estimate evaporation from open water surfaces. This equation has been simplified for operational application and is given in Eq. (31.6) (Chow et al. 1988). In Eq. (31.6), k is the von Karman constant, usually assumed to be 0.4, ρ_a the density of air, (kg/m^3) u_2 is the wind speed (m/sec) at height z_2 (ρ_w is the density of water in kg/m^3), z_0 is a roughness height, p is the atmospheric pressure (Pa), e_{sat} is the saturated vapor pressure (Pa) and e the actual vapor pressure (Pa), E_2 is in mm/day.

$$E_2 = \frac{0.622\, k^2\, \rho_a\, u_2}{p\rho_w \left[\ln\left(z_2/z_0\right)\right]^2}\left(e_{sat} - e_a\right) \tag{31.6}$$

Penman (1948) developed a comprehensive theory of evaporation and his equation involves both the estimates E_1 and E_2. The Penman evaporation estimate E is given in Eq. (31.7), where γ is the psychrometric constant and Δ is the slope of the saturated vapor pressure curve at air temperature T_a.

$$E = \frac{\Delta}{\Delta+\gamma}E_1 + \frac{\gamma}{\Delta+\gamma}E_2 \tag{31.7}$$

$$\gamma = \frac{C_p K_h p}{0.622\, l_v K_w} \tag{31.8}$$

$$D = \frac{4098 e_{sat}}{\left(237.3+T\right)^2} \tag{31.9}$$

In Eq. (31.8) and Eq. (31.9), C_p is the specific heat at constant pressure, K_h is the heat diffusivity, K_w is the vapor eddy diffusivity and the ratio (K_h/K_w) is usually assumed to be unity, and T is the temperature (°C). Priestley and Taylor (1972) analyzed Eq. (31.7) and found that for evaporation over large areas, the second term in Eq. (31.7) is about 30% of the first one. Based on this observation they developed Eq. (31.10), the Priestley-Taylor Equation, which reduces the computations involved.

$$E = 1.3\,\frac{\Delta}{\Delta+\gamma}\,E_1 \tag{31.10}$$

The Penman equation is the most accurate of all equations used to estimate evaporation from open water surfaces. However, the data required to use it, such as solar radiation, humidity and wind speed may not be easily available. In such cases, simpler evaporation equations (ASCE, 1973; Doorenbos and Pruitt, 1977) are used.

Most commonly, evaporation is measured by using evaporation pans. The class A pan used in the U.S. is 4 ft. (120.67 cm) in diameter and 10 in (25.4 (cm)) deep. The pan is made of Monel metal or of unpainted galvanized iron. It is placed on a wooden support to facilitate air circulation beneath it. In addition to the pan, an anemometer to measure the wind speed, a precipitation gage, thermometers to measure water and air temperatures are also used. Water level in the pan is measured and reset to a fixed level each day. The change in water level, adjusted to account for precipitation, is the evaporation which has occurred during that day. Further details about evaporation pans used both in the U.S. and other countries are found in WMO (1981).

The rates measured in evaporation pans are usually greater than those measured in larger water bodies. The ratio of lake evaporation to pan evaporation is called the *pan coefficient*. To estimate evaporation from a larger water body, the pan evaporation is multiplied by the pan coefficient. In the U.S., an average pan coefficient is approximately 0.7, which varies with locations and at a location with seasons.

Evapotranspiration

The process by which water in soil, vegetation, and land surface is converted into water vapor is called evapotranspiration. Both the transpiration of water by vegetation and evaporation of water from soil, vegetation and water surfaces are included in evapotranspiration. Because it includes water vapor generated by all the mechanisms, evapotranspiration plays a major role in water balance computations. Consumptive use includes evapotranspiration and the water used by plant tissue. In practice evapotranspiration and consumptive use are used interchangeably.

The process by which plants transfer water from roots to leaf surfaces, from which it evaporates is called transpiration. The rate of transpiration greatly depends on sunshine and on seasons and moisture availability. Transpiration rates of different plant types vary. As transpiration ends up in evaporation, transpiration rates are affected by the same meteorologic variables as evaporation. Therefore, it is common practice to combine transpiration and evaporation and express the total as evapotranspiration.

Potential evapotranspiration (PET) (Thornthwaite et al., (1944)) is a concept in common usage in evapotranspiration computations. The evapotranspiration rate that occurs when the moisture supply is unlimited is called the PET. The PET is a good indicator of optimum crop water requirements. The concept of reference crop evapotranspiration (ET_0) was introduced by Doorenbos and Pruitt (1977). The reference crop evapotranspiration is similar to PET. The rate of evapotranspiration from an extended surface of 8- to 15-cm tall green grass cover of uniform height, actively growing, completely shading and not short of water is called the reference crop evapotranspiration. Thus, ET_0 is the PET of short green grass which is the reference crop.

The PET is equivalent to evaporation from free water surface of extended proportions. However, the heat storage capacity of this water body is assumed to be negligibly small. Consequently methods used to estimate PET and evaporation are similar. Evapotranspiration and PET are based on (1) temperature, (2) radiation, (3) combination or Penman, and (4) pan-evaporation methods. These are considered below.

Blaney-Criddle formula (Eq. [31.11]), which is widely used to estimate crop water requirements is typical of evapotranspiration formulas based only on temperature.

$$F = PT \tag{31.11}$$

In Eq. (31.11), F is the evapotranspiration for a given month in inches, P is the ratio of total daytime hours in a given month to the total daytime hours in a year and T is the monthly mean temperature in degrees Fahrenheit. Doorenbos and Pruitt (1977) modified the Blaney-Criddle formula to include actual insolation time, minimum relative humidity and daytime wind speed. Another well known temperature-based evapotranspiration estimation method is that proposed by Thornthwaite et al. (1944). In this method, the heat Index I_j is defined in terms of the mean monthly temperature T_j(°C). The annual temperature efficiency index J is the sum of 12 monthly heat indices I_j.

$$I_j = \left(\frac{T_j}{5}\right)^{1.514}; \quad J = \sum_{j=1}^{12} I_j \tag{31.12}$$

The potential evapotranspiration is computed by Eq. (31.13) and Eq. (31.14)

$$PET = K^* PET_0 \tag{31.13}$$

$$PET_0 = 1.6\left(\frac{10\,T}{J}\right)^c \tag{31.14}$$

$$c = 0.000000\ 675\ J^3 - 0.0000\ 771\ J^2 + 0.49239.$$

PET_0 is the *PET* at 0° latitude in centimeters per month. K^* in Eq. (31.13) varies from month to month and is given in Thornthwaite et al. (1944) and in Ponce (1989).

Priestley and Taylor (1972) developed a formula to compute *PET*, which is based only on the radiation part of the Penman's equation Eq. (31.7). Priestley and Taylor's formula is given in Eq. (31.15).

$$PET = \frac{1.260\ \Delta\left(R_n / l_v\ \rho_w\right)}{\Delta + \gamma} \tag{31.15}$$

The Penman equation is also used to calculate *PET*. Penman (1952) suggested the use of crop coefficients (0.6 in winter and 0.8 in summer) to compute the evapotranspiration rates. In pan evaporation models, the *PET* is given by the formula Eq. (31.16), where K_p is the pan coefficient and E_p is the pan evaporation.

$$PET = K_p E_p \tag{31.16}$$

The pan evaporation is widely used to estimate *PET*. Guidelines to choose appropriate pan coefficients are found in Doorenbos and Pruitt (1977).

31.4 Infiltration

Process and Variability

Water on the soil surface enters the soil by infiltration. Percolation is the process by which water moves through the soil because of gravity. As the soil exposed to atmosphere is not usually saturated, flow near the ground surface is through unsaturated medium. The percolated water may reach the ground water storage or it may transpire back to the surface.

As water travels from the surface to the groundwater, two forces act on it. The gravity forces attract the flow towards groundwater and the capillary forces attract it to capillary spaces. Consequently, rate of percolation decreases with the passage of time and leads to decreasing rates of infiltration. Infiltration capacity is the maximum rate at which infiltration can occur. The infiltration capacity f_p is affected by conditions such as the soil moisture. The actual rate of infiltration rate is f_i. The infiltration rate and capacity are the same when the rate of supply of water i_s is equal to or greater than f_p. Infiltration theories assume that i_s is equal to or greater than f_p. Under these conditions, the maximum infiltration rate f_o occurs at the beginning of a storm and approaches a constant rate f_c as the soil becomes saturated. The rate at which f_o approaches f_c and the final value of f_c depend on the characteristics of the soil and initial soil moisture (Fig. 31.6).

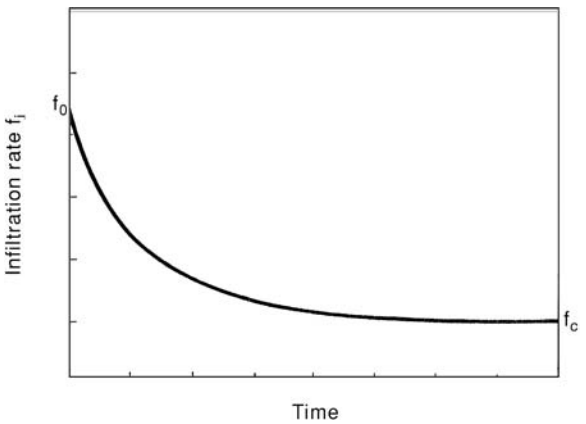

FIGURE 31.6 Infiltration curve.

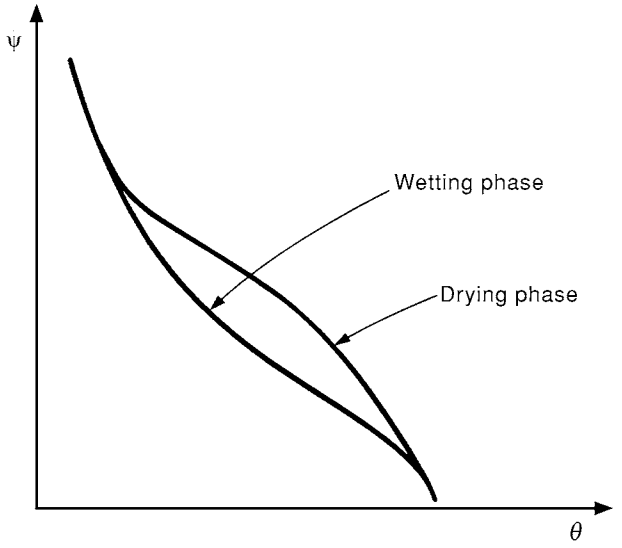

FIGURE 31.7 Capillary potential vs. soil moisture.

The energy possessed by the fluid due to soil suction forces $\psi(\theta)$ of a soil is a function of volumetric soil moisture θ and is called the capillary potential. The ratio of the volume of water in a soil volume is the moisture content θ. The capillary potential $\psi(\theta)$ is related to the piezometric head h as in Eq. (31.17), where z is the elevation head, h is the piezometric head and p_c/γ is the pressure head.

$$h = \frac{p_c}{\gamma} + z = \psi(\theta) + z \tag{31.17}$$

p_c is negative and hence p_c/γ is called the suction head. The capillary potential, for the same soil moisture θ, depends on whether the soil is in the wetting or drying phase. For the same θ, $\psi(\theta)$ is higher when the soil is drying than when it is wetting (Fig. 31.7)

Infiltration Models

Considering only the flow in the vertical direction z, the infiltration of water is governed by Eq. (31.18), where t is the time, $D_z(\theta)$ is the diffusivity and $K_z(\theta)$ is the hydraulic conductivity in the z direction (Bras, 1990).

$$\frac{\partial \theta}{\partial t} = \frac{\partial}{\partial z}\left[D_z(\theta)\frac{\partial \theta}{\partial z} + K_z(\theta)\right] \tag{31.18}$$

The diffusivity $D_z(\theta)$ is given by Eq. (31.19), where the hysterisis effects of $\psi(\theta)$ (Fig. 31.7) are ignored and $\psi(\theta)$ is considered as a single valued function of θ.

$$D_z(\theta) = K_z(\theta)\frac{\partial \psi(\theta)}{\partial \theta} \tag{31.19}$$

To simplify Eq. (31.18), $K_z(\theta)$ is considered to be a constant or that it is small in comparison with $D_z(\theta)$ $(\partial\theta/\partial z)$. If it is further assumed that $D_z(\theta)$ is constant and equal to D, Eq. (31.18) reduces to the diffusion Eq. (31.20). Assuming a semi-infinite soil system and the boundary conditions in Eq. (31.21), Eagleson (1970) shows that the solution of Eq. (31.20) is given by Eq. (31.22)

$$\frac{\partial \theta}{\partial t} = D\frac{\partial^2 \theta}{\partial z^2} \tag{31.20}$$

$$\theta = \begin{cases} \theta_i & z \le 0; \quad t = 0 \\ \theta_o & z = 0; \quad t > 0 \end{cases} \tag{31.21}$$

$$f_p = f_c + \left(f_o - f_c\right) e^{-Dl^2 t} \tag{31.22}$$

where

$$f_p = f_c \qquad z = 0, \qquad t = \infty$$

$$f_p = f_o \qquad z = 0, \qquad t_o = 0.$$

The solution in Eq. (31.22) is applicable at the soil surface ($z = 0$). The variable l in Eq. (31.22) is a characteristic length dependent on z. Equation (31.22) is a form of the infiltration equation derived by Horton (1939, 1940). Philip (1960) presented an analytical solution to the infiltration equation when the initial and boundary conditions correspond to those in Eq. (31.21) with θ_o equal to porosity n. An approximate form of Philip's solution is given in Eq. (31.23) where S, called the sorptivity, and K are parameters related to diffusivity, hydraulic conductivity and initial soil moisture.

$$f_p(t) = \frac{1}{2} S t^{-1/2} + K \tag{31.23}$$

Empirical Infiltration Equations

Although there is a strong theoretical basis from which infiltration equations such as Horton's and Philip equations are derived, there are numerous empirical equations in use. Most of these are based on the observation that there is an initial infiltration rate f_o, which depends on the soil type and antecedent moisture conditions, which decreases to infiltration capacity f_c under a supply rate i_s which is higher than f_o. The third parameter besides f_o and f_c is the rate of decay. More popular of the empirical infiltration equations are considered below. These models have also been derived by using a systems approach. Quite often, the supply rate is smaller than the infiltration capacity. In such a case all the rainfall supply is assumed to infiltrate into the soil until such time when the total rainfall and the infiltration depths are the same. The time at which the infiltration and rainfall depths are the same is called the ponding time.

Horton Equation

Horton's equation is given in Eq. (31.24), which is the same as Eq. (31.22) with $Dl^2 = k$.

$$f_p(t) = f_c + \left(f_o - f_c\right) e^{-kt} \tag{31.24}$$

The cumulative infiltration $F_p(t)$ corresponding to Eq. (31.24) is given by Eq. 31.25). If a constant rainfall rate i_s is assumed, the ponding time t_p is given by Eq. (31.26).

$$F_p = f_c t + \frac{\left(f_o - f_c\right)}{k} \tag{31.25}$$

$$t_p = \frac{1}{i_s k}\left[f_o - i_s + f_c \ln\left(\frac{f_o - f_c}{i_s - f_c} \right) \right] \tag{31.26}$$

Phillip's Infiltration Equation

Phillip's equation is not an empirical equation. The cumulative infiltration and the time of ponding for rainfall of constant intensity i_s for this equation are given by Eq. (31.27) and Eq. (31.28)

$$F_p = St^{1/2} + At \tag{31.27}$$

$$t_p = S^2\left(i_s - A/2\right)\Big/ 2i_s\left(i_s - A\right)^2, \; i_s > A \tag{31.28}$$

Green and Ampt Model

Green and Ampt (1911) proposed an infiltration model that is given by Eq. (31.29), where the cumulative infiltration is given by Eq. (31.30)

$$f_p = K\left(\frac{\psi\Delta\theta}{F(t)} + 1\right) \tag{31.29}$$

$$F_p = Kt + \psi\Delta\theta \ln\left(1 + \frac{F_p}{\psi\Delta\theta}\right) \tag{31.30}$$

In Eqs. (31.29) and (31.30), K is the hydraulic conductivity, $\Delta\theta$ is the difference between the soil porosity n and moisture content θ, ψ is the soil suction head. In practice, the hydraulic conductivity K, and the soil suction head ψ and the porosity are obtained from published sources such as Rawls et al. (1983). Instead of using $\Delta\theta$, it is expressed in terms of effective porosity θ_e and effective saturation S_e as in Eq. (31.31).

$$\Delta\theta = \left(1 - s_e\right)\theta_e. \tag{31.31}$$

Effective porosity θ_e is the difference between soil porosity and the residual moisture content θ_r after it has been thoroughly drained (Eq. [31.32]).

$$\theta_e = n - \theta_r \tag{31.32}$$

The effective saturation s_e is given by Eq. (31.33).

$$s_e = \frac{\theta - \theta_r}{n - \theta_r} \tag{31.33}$$

θ_e values are listed for different soils by Rawls et al. (1983). Consequently by knowing the effective saturation s_e of the soil and the other parameters listed by Rawls et al., (1983), the Green and Ampt model may be used to estimate infiltration.

31.5 Surface Runoff

Process and Measurement

An area that drains into a stream at a given location via a network of streams is called a watershed. Rainfall that falls on a watershed fills the depression storage, which consists of storage provided by natural depressions in the landscape, it is temporarily stored on vegetation as interception and it infiltrates into the soil. After these demands are satisfied, water starts flowing over the land and this process is called overland flow. Water that is stored in the upper soil layer may emerge from the soil and join the overland flow. The overland flow lasts only for short distances after which it is collected in small channels called rills. Flows from these rills reach channels. Flow in channels reaches the mainstream.

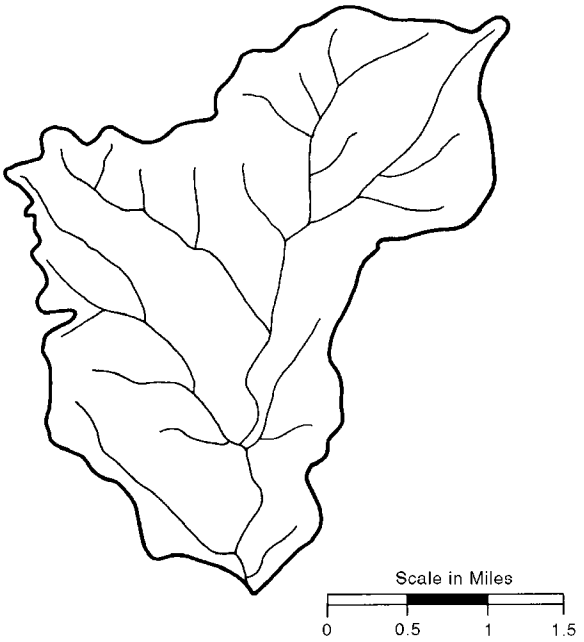

FIGURE 31.8 Drainage map of Bear Creek Basin, Indiana.

When rainfall is of low intensity, the overland-rill-channel flow sequence may not occur. In such cases, only the land near the streams contributes to the flow. These areas are called variable source or partial areas. Only a small area of watersheds contribute to stream flows in a humid region.

The transformation of rainfall to runoff is affected by the stream network, by precipitation, by soil, and land use. A watershed consists of a network of streams as shown in Fig. 31.8. Channels that start from upland areas are called the first order channels. Horton (1945) developed a stream order system, in which when two streams of order i join together the resulting stream is of order $i + 1$. There are several laws of stream orders developed by Horton (1945).

If a watershed has N_i streams of order i and N_{i+1} of order $i + 1$, the ratio N_i/N_{i+1} is called the bifurcation ratio R_B, the ratio of stream lengths L_{i+1} and L_i belonging to orders i+1 and i the ratio of stream lengths R_L, and the ratio of areas R_A and R_{A+1} the area ratio. These ratios vary over a small range for each watershed. The drainage density D of a watershed is the ratio of total stream length to the area of the watershed. Higher values of D represent a highly developed stream network and vice versa. Plots of L_i, A_i and N_i against the order i for an Indiana watershed are shown in Fig. 31.9.

The second factor that significantly affects runoff is rainfall. The spatial and temporal rainfall distribution and the history of rainfall preceding a storm affect runoff from watersheds. Rainfall is usually treated as a lumped variable because spatial rainfall data are not commonly available.

The third factor that affects runoff characteristics is the land use. As watersheds are changed from rural to urban or from forested to clear cut condition, runoff from these watersheds changes drastically. For example, when a rural watershed is urbanized, the peak discharges from the urban watershed may be more than 100% higher than runoff from the rural watershed for the same rainfall. The time to peak discharge would also be considerably shorter and the runoff volume much larger in urban watersheds compared to rural watersheds.

A plot of variation of discharge with time is called a hydrograph. A hydrograph may have different time scales such as hourly, daily, etc. Hydrographs that result from storms are called storm hydrographs (Fig. 31.10). A typical storm hydrograph may have a small flow before the discharge increases on the rising limb, reaches a peak and decreases along the recession limb. The flow that exists before the

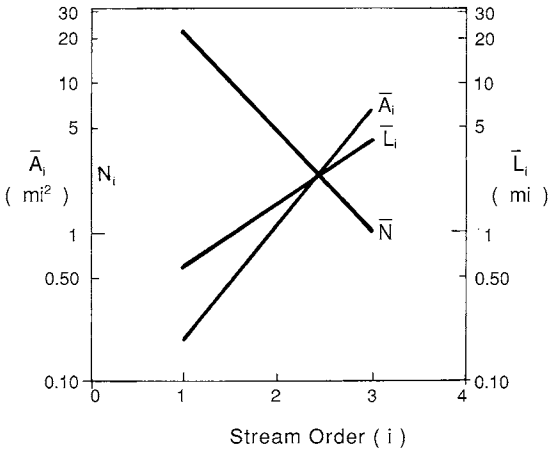

FIGURE 31.9 Horton's ratios for Bear Creek Basin, Indiana.

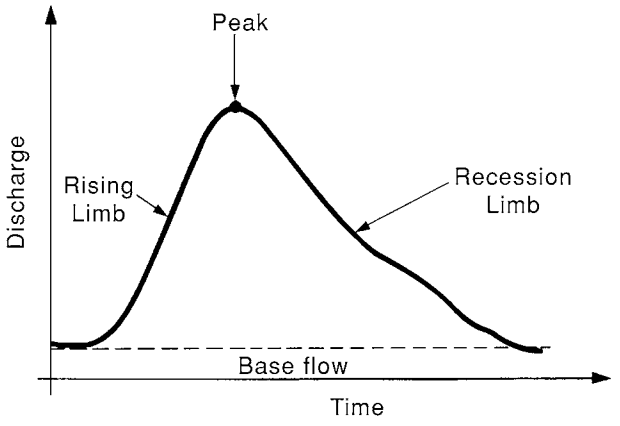

FIGURE 31.10 A single peaked hydrograph.

hydrograph starts rising is contributed by the groundwater and is called the baseflow and is not considered to be generated by the storm.

Streamflows are measured by using current meters. A stable cross section of the stream is selected and divided into a number of sections. Velocities in each section are measured and averaged. The product of the average velocity and the area of the section give the discharge in that section. Sum of discharges measured in different sections gives the discharge in the stream at that cross section.

Discharges are uniquely related to the water levels in stable stream channels. A plot of discharges against water level elevations, called river stages, is called a rating curve of a stream at a gaging station (Fig. 31.11). Once a rating curve is established for a river cross section, only the stages are measured and discharges are computed by using the rating curve. Discharges are recorded continuously or at finite time intervals. They can also be transmitted electronically to a central location where they are recorded for dissemination. Details about river gaging are found in Rantz et al. (1982).

Unit Hydrographs

One of the common and important problems in hydrology is the estimation of runoff hydrographs that result from rainfall. These hydrographs are needed for various purposes such as design of drainage and hydraulic structures and flood flow forecasting. Unit hydrograph theory is commonly used to estimate runoff hydrographs.

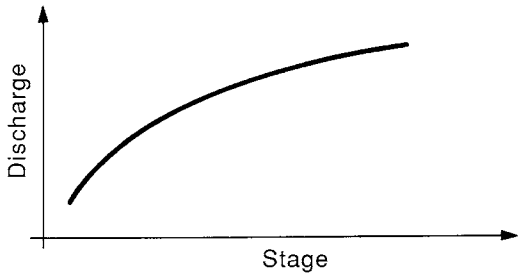

FIGURE 31.11 A rating curve.

Although surface runoff has several components such as baseflow, interflow, overland flow, etc., two components of surface runoff are commonly recognized. These are the baseflow and direct runoff. There are numerous methods of separation of base flow from the observed hydrograph to obtain the direct runoff hydrograph. The simplest among these assumes a constant baseflow value. The volume under the direct runoff hydrograph may be expressed in units of depth (centimeters or inches) by dividing it by the watershed area.

The rainfall hyetograph associated with the surface runoff hydrograph may also be separated into two components as the effective rainfall hyetograph and losses. The ϕ-index method is commonly used to derive the effective rainfall hyetograph. The rainfall depth under an effective rainfall hyetograph is the same as the depth of direct runoff.

The unit hydrograph is the direct runoff hydrograph resulting from one unit (1 in. or 1 cm) of effective rainfall occurring uniformly in space and time over a unit period of time. The duration of effective rainfall is the "unit" for which the unit hydrograph is estimated. A unit hydrograph is derived by dividing the direct runoff hydrograph ordinates by the direct runoff depth.

If a unit hydrograph of duration D_1 is available for a watershed, a unit hydrograph of duration D_2 for the same watershed may be developed by using the S-curve method. To develop an S-curve, unit hydrographs are displaced in time (or lagged) by a time interval D_1. Unit hydrograph ordinates at a given time are summed to obtain the S-curve., The S-curve is displaced by duration D_2 and the difference between the two S-curve ordinates is multiplied by D_1/D_2 to get the unit hydrograph of duration D_2.

The dependence of unit hydrographs on effective rainfall duration can be eliminated by assuming the interval between the ordinates of the runoff hydrograph to be the duration of the unit hydrograph and also of the effective rainfall pulses. Under these assumptions, the direct runoff $\boldsymbol{Q}$ is related to the effective rainfall $\boldsymbol{P}$ and unit hydrograph $\boldsymbol{U}$, as in Eq. (31.34), where $\boldsymbol{Q}$, $\boldsymbol{P}$ and $\boldsymbol{U}$ are vectors and matrices.

$$Q = P\,U \tag{31.34}$$

In Eq. (31.34), the direct runoff ordinates are $Q_1, Q_2 \ldots Q_i$, the effective rainfall ordinates are $P_1, P_2, \ldots P_j$ and the unit hydrograph ordinates are $U_1, U_2, \ldots U_k$. Equation (31.34) may be expressly written as in Eq. (31.35).

$$\begin{pmatrix} Q_1 \\ Q_2 \\ . \\ . \\ . \\ . \\ . \\ . \\ Q_i \end{pmatrix} \begin{pmatrix} P_1 & 0 & 0 & & ..... & 0 \\ P_2 & & & & ..... & 0 \\ . & & & & & \\ . & & & & & \\ . & & & & & \\ . & & & & & \\ . & & & & & \\ 0 & 0 & .... & P_{k-1} & ..... & P_{j-1} \\ 0 & 0 & ..... & & ..... & P_j \end{pmatrix} \begin{pmatrix} u_1 \\ u_2 \\ . \\ . \\ . \\ . \\ . \\ u_{k-1} \\ u_k \end{pmatrix} \tag{31.35}$$

The relationship between *i, j* and *k* is given in Eq. (31.36)

$$i = j + k - 1 \tag{31.36}$$

Expanding Eq. (31.35) we get Eq. (31.37). These equations are used to compute direct runoff given effective precipitation ***P*** and unit hydrograph ordinates ***U***. They may also be used to estimate unit hydrograph ordinates by forward substitution as shown below.

$$\begin{aligned}
Q_1 &= P_1\ U_1 \\
Q_2 &= P_2\ U_1 + P_1\ U_2 \\
Q_3 &= P_3\ U_1 + P_2\ U_2 + P_1\ U_3 \\
&\ \ \vdots \\
U_1 &= Q_1 / P_1 \\
U_2 &= \left(Q_2 - P_2\ U_1\right) / P_1 \\
U_3 &= \left(Q - P_3\ U_1 - P_2\ U_2\right) / P_1
\end{aligned} \tag{31.37}$$

The major problem with the forward substitution method of computing unit hydrograph ordinates is that the errors in the estimated unit hydrograph ordinates propagate and magnify.

To avoid the amplification of errors and to get stable unit hydrograph estimates, several other methods have been developed (Singh, 1988). One of the commonly used methods is the least squares method. The least squares estimate of the unit hydrograph is given by Eq. (31.38), where *T* is the vector transpose.

$$U = \left[P^T\ P\right]^{-1} P^T Q \tag{31.38}$$

Synthetic Unit Hydrographs

For many, especially small watersheds, rainfall-runoff data may not be available to develop unit hydrographs and use them to estimate runoff. In such cases, relationships developed between unit hydrograph characteristics derived by using observed rainfall-data and watershed and effective rainfall characteristics are used to generate unit hydrographs. These hydrographs are called synthetic unit hydrographs.

Snyder (1938) developed synthetic unit hydrographs by using data from Appalachian highlands. Watersheds, the data from which were used by Snyder, varied in size from about 10 to 10,000 mi^2. A number of studies following Snyder's study followed. Many of these are designed to develop unit hydrographs from urban watersheds. A few, representative synthetic unit hydrograph methods are discussed below.

Sarma et al. (1969) provided a set of equations to estimate the watershed time lag — defined as the time interval between the centroids of effective rainfall and direct runoff — the time to peak T_p and peak discharge Q_p of observed runoff (Eqs. [31.39] to [31.41]). In Eqs. (31.39) to (31.41), A is the area (mi^2), U is the fraction of imperviousness of the watershed, P_E is the effective rainfall depth (inches) and T_R is the duration of effective rainfall (hours).

$$t_L = 0.831\ A^{0.458}\ \left(1+U\right)^{-1.662}\ P_E^{-0.267}\ \mathrm{T_R}^{0.371} \tag{31.39}$$

$$Q_p = 484.1\ A^{0.723}\ \left(1+U\right)^{1.516}\ \ P_E^{1.113}\ \ T_R^{-0.403} \tag{31.40}$$

$$T_p = 0.775\, A^{0.323}\,(1+U)^{-1.285}\; P_E^{-0.195}\; T_R^{0.634} \tag{31.41}$$

The time lag t_L is the parameter k in the instantaneous unit hydrograph of the single linear reservoir model in Eq. (31.42). The unit hydrograph of an urban watershed can thus be estimated by Eq. (31.42) and the direct runoff can be computed by using Eq. (31.34).

$$u(t) = \frac{1}{k}\, e^{-t/k} \tag{31.42}$$

Espey et al. (1977) developed another set of equations to estimate synthetic unit hydrographs along the lines of Snyder (1938). In these (Eqs. [31.43 to– [31.37]) L is the length along the main channel (ft.), S is the main channel slope determined by $H/0.8L$ where H is the difference along two points on the main channel. The first point on the channel bottom is at a distance of 0.22 L from the downstream from the watershed boundary and the second point is on the channel bottom at the downstream point. I (percent) is the watershed impervious area (equal to 5 percent for undeveloped watershed), φ is a dimensionless conveyance factor, A is the (mi^2) watershed area, t_p (min) is the time to peak, U_p (cfs) is the peak flow of U.H., t_b (min.) is the U.H. base time, and W_{75} and W_{50} are the 75-percent (w_{75}) and 50 percent (w_{50}) of unit hydrograph peak discharge.

$$t_p = 3.1\, L^{0.23}\; S^{-0.25}\; I^{0.18}\; \varphi\, 1.57 \tag{31.43}$$

$$U_p = 31.62 \times 10^3\; A^{0.96}\; T_p^{-1.07} \tag{31.44}$$

$$t_b = 125.89 \times 10^3\; A\; Q_p^{-0.95} \tag{31.45}$$

$$W_{50} = 16.22 \times 10^3\; A^{0.93}\; Q_p^{-0.92} \tag{31.46}$$

$$W_{75} = 3.24 \times 10^3\; A^{0.79}\; Q_p^{-0.78} \tag{31.47}$$

The watershed conveyance factor φ is estimated from Fig. 31.12.

SCS Method

The SCS method is based on the time of concentration t_c (hours) and the watershed area A (square miles). The duration of the unit hydrograph ΔD (hours) is given by Eq. (31.48), the time to peak t_p (hours) and the peak discharge q_p (cfs) of the unit hydrograph are given by Eq. (31.49) and Eq. (31.50), and the base time units by Eq. (31.51).

$$\Delta D = 0.133\, t_c \tag{31.48}$$

$$t_p = 0.67\, t_c \tag{31.49}$$

$$q_p = \frac{484\, A}{t_p} \tag{31.50}$$

$$t_b = 2.67\, t_p. \tag{31.51}$$

A triangular unit hydrograph of duration ΔD can be constructed by using Eqs. (31.49) to (31.51). A unit hydrograph can also be generated by the dimensionless unit hydrograph given in SCS (1972).

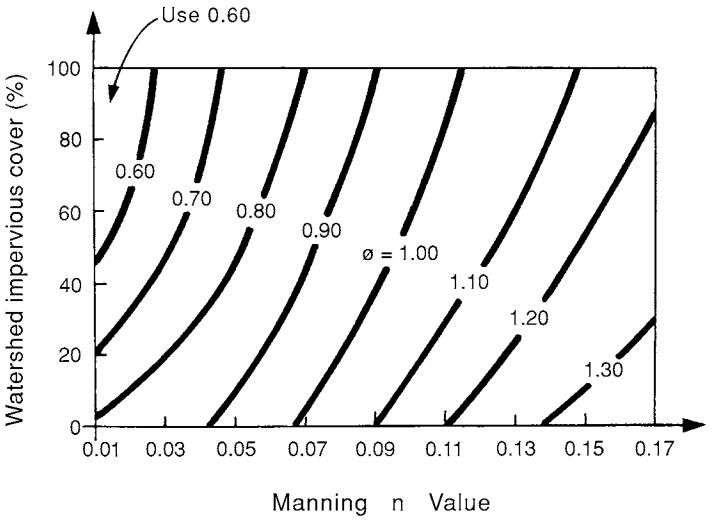

FIGURE 31.12 Watershed conveyance factor φ. (From Espey, W.H., Jr., Altman, D.G. and Graves, C.B., [1977] "Nomographs for Ten-Minute Unit Hydrographs for Small Urban Watersheds," Tech. Memo 32, *Urban Water Resources,* Res. Prog., ASCE, New York, NY. With permission.)

31.6 Flood Routing Through Channels and Reservoirs

As runoff from land enters into channels, the volume of water temporarily stored in the channel increases. After the end of precipitation water moves down the channel and the discharge decreases. At a cross section of a channel, this increase in stage and its decrease at the end of a storm is analogous to the passage of a wave and hence these are called flood waves.

Whether a flood wave moves down a channel or through a reservoir, water is temporarily stored in the channel or in the reservoir and is naturally drained out or released. Flood routing is the name given to a set of techniques that are developed to analyze the passage of a flood wave through the system. Hydraulic routing is flood routing in which equations which govern the motion of a flood wave — the St. Venant's equations — are used. In hydrologic routing, one dimensional, lumped, continuity equation is solved to estimate the passage of a flood wave. Reservoir routing is similar to hydrologic routing of flood waves.

Hydraulic Routing

The St. Venant equations that are the basic equations of motion describing the passage of a flood wave down a channel are in Eq. (31.52) and Eq. (31.53), where Eq. (31.52) is the continuity equation and Eq. (31.51) the momentum equation.

$$\frac{\partial Q}{\partial x}+\frac{\partial A}{\partial t}=0 \tag{31.52}$$

$$\frac{1}{A}\frac{\partial Q}{\partial t}+\frac{1}{A}\frac{\partial}{\partial x}\left(\frac{Q^2}{A}\right)+g\frac{\partial y}{\partial x}-g\left(s_o-s_f\right)=0 \tag{31.53}$$

In Eq. (31.52) and Eq. (31.53), Q is the discharge, A the cross-sectional area of flow, t is the time, x is the distance along the channel, y is the depth, g is the acceleration due to gravity, s_o and s_f are the slopes

of channel bottom and of the energy grade line, respectively. These equations are first order, nonlinear, hyperbolic partial differential equations. Given a set of boundary and initial conditions, they can be solved numerically for discharge and depth (Lai, 1986). Another input is the roughness coefficient, Manning's *n*. St. Venant equations are often simplified and solved as approximate solutions are sufficient in many cases. Two of these simplified solutions are the kinematic wave and diffusion approximations.

Kinematic wave approximation

In this case the momentum equation is reduced to Eq. (31.54) and the continuity equation is retained. The resulting equations are:

$$\frac{\partial Q}{\partial x} + \frac{\partial A}{\partial t} = 0 \tag{31.52}$$

$$s_o = s_f \tag{31.54}$$

In this approximation, the dynamic terms in the momentum equation are ignored. Consequently, the discharge and stage variation both in time and space must be small for the kinematic wave approximation to be valid.

Diffusion Approximation

In this case, in addition to the slope terms, the term involving $\partial y/\partial x$ in Eq. (31.53) is retained to give the system of Eqs. (31.52) and (31.55). When the stage variation with distance is significant the diffusion wave approximation gives better results than the kinematic wave approximation.

$$\frac{\partial Q}{\partial x} + \frac{\partial A}{\partial t} = 0 \tag{31.52}$$

$$\frac{\partial y}{\partial x} - s_o + s_f = 0 \tag{31.55}$$

Kinematic wave approximation has been used in urban hydrology and for modeling flows from small areas. The diffusion wave approximation is used to route floods through streams. Although a few closed form solutions are available for simple cases of kinematic wave routing, numerical methods are used to solve even these simpler equations (Singh, 1988). Hydrologic routing is often used because of its simplicity.

Hydrologic Channel Routing

The storage *S* in a channel reach is a function of both the inflow *I* and outflow *O* from a reach. The continuity equation for this system is given in Eq. (31.56)

$$\frac{dS}{dt} = I - 0 \tag{31.56}$$

The routing problem is, given the inflow and an initial outflow, to estimate the outflow. In the Muskingum method, the storage function is assumed to be a linear function of inflow and outflow as in Eq. (31.57).

$$S = K\left[xI + (1-x)0\right] \tag{31.57}$$

Writing Eq. (31.57) in a discrete form in terms of storage at times *j* and *j*+1 we get Eq. (31.58), where Δt is the time interval between *j* and *j*+1.

$$S_{j+1} - S_j = \frac{\left[I_{j+1} + I_j\right]}{2}\Delta t - \frac{\left[O_{j+1} + O_j\right]}{2}\Delta t \tag{31.58}$$

Substituting Eq. (31.59) and Eq. (31.60) into Eq. (31.58), we get Eq. (31.61), where C_1, C_2 and C_3 are defined in Eq. (31.62),

$$S_{j+1} = K\left[x\, I_{j+1} + (1-x)\, O_{j+1}\right] \tag{31.59}$$

$$S_j = K\left[x\, I_j + (1-x)\, O_j\right] \tag{31.60}$$

$$Q_{j+1} = C_1\, I_{j+1} + C_2\, I_j + C_3\, O_j \tag{31.61}$$

$$C_1 = \frac{\Delta t - 2Kx}{N},\quad C_2 = \frac{\Delta t + 2Kx}{N},\quad C_3 = \frac{2K(1-x) - \Delta t}{N} \tag{31.62}$$

where

$$N = 2K - 2Kx + \Delta t \tag{31.63}$$

$$\text{and } C_1 + C_2 + C_3 = 1. \tag{31.64}$$

To use Eq. (31.61), the coefficients C_1, C_2 and C_3, which are dependent on K, Δt and x must be known. To estimate K, by using a set of inflow and outflow hydrographs, different values of x are assumed and $x\, I_j + (1 - x)\, O_j$ values are plotted against computed storage values. The value of x, which gives a linear relationship between observed and computed storages, is selected and the slope of the fitted line is the best estimate of the K value. K and x values are also estimated by using the method of moments, least squares and optimization methods. If several sets of inflow and outflow hydrographs are used, average K and x values are used as the best estimates for the reach. These K and x values, the inflow hydrograph and the initial outflow value are used to compute the outflow hydrograph from the reach, thus completing the streamflow routing through the channel reach. A detailed discussion of these methods is found in Singh (1988).

Reservoir Routing

Reservoir routing is the procedure by which the outflow hydrograph from a reservoir is computed given the inflow hydrograph, the initial outflow or reservoir level, and the storage characteristics of the reservoir. A linear relationship between storage and inflow and outflow such as that assumed in channel routing cannot be assumed in this case.

The continuity equation, Eq. (31.56) forms the basis of the routing method in this case also. The discrete form of the continuity equation Eq. (31.58) is rewritten as Eq. (31.65).

$$\left(\frac{2S_{j+1}}{\Delta t} + o_{j+1}\right) = \left(I_{j+1} + I_j\right) + \left(\frac{2S_j}{\Delta t} - o_j\right) \tag{31.65}$$

By using the relationship between the storage and outflow relationships that are unique for each reservoir system, Eq. (31.65) is solved iteratively for discharge. Various methods have been developed to solve Eq. (31.65) and one of these methods — storage indication method — is as follows.

By using the reservoir elevation-discharge and elevation-storage data (see chapter on Hydraulic Structures), a curve relating $(2S/\Delta t + O)$ and discharge O is developed. By using the initial storage, outflow information, $2S_0/\Delta t + O_0$ value is estimated. The $2S_1/\Delta t + O_1$ is then estimated by Eq. (31.65), and by using the $2S/\Delta t + O_1$ vs. O relationship, the discharge O_1, and hence $2S/\Delta t - O_1$ is computed. By using

O_1, I_2 and I_1 in Eq. (31.65) is computed and O_2 is evaluated by the curve of vs. O. The procedure is repeated until the end of the inflow hydrograph.

31.7 Statistical Analysis of Hydrologic Data

Important hydrologic processes such as floods or droughts, which are extreme events, are treated as random events. The theory of probability is used to estimate the probabilities of occurrence of these events. The emphasis in statistical analysis is on events rather than on the physical processes that generate them. In the frequency analysis of floods the emphasis is on the frequency of occurrence of these events.

Probability Distributions and Parameter Estimates

The common probability distributions used in hydrologic analysis and their parameters are listed in Table 31.3. There are various methods of parameter estimation and the simplest among these is the method of moments. In this method, moments estimated from the data are equated to the expressions of moments of distributions and the resulting equations are solved for the distribution parameters. The mean, standard deviation and the skewness coefficient are the three moments commonly computed from the data.

The mean $\bar{x}$, standard deviation s_x and the skewness coefficient CS_x computed by using the data x_1, x_2,… x_N are given in Eqs. (31.66) to (31.68).

$$\bar{x} = \frac{\sum_{i=1}^{N} x_i}{N} \tag{31.66}$$

$$s_x = \sqrt{\frac{1}{N-1}\sum_{i=1}^{N}\left(x_i - \bar{x}\right)^2} \tag{31.67}$$

$$CS_x = \frac{N\sum_{i=1}^{N}\left(x_i - \bar{x}\right)^3}{(N-1)(N-2)\,S_x^3} \tag{31.68}$$

TABLE 31.3 Frequency Factors for Commonly Used Distributions

Distribution	k_T
Normal	For a given T, compute p = $1/T$ and $a = \sqrt{\ln\left(1/p^2\right)}$
	$k_{TN} = a - \left(\dfrac{2.525517 + 0.802853a + 0.010328\,a^2}{1 + 1.432788a + 0.189269\,a^2 + 0.001308\,a^3}\right)$
	If $p > 0.5$, $a = \sqrt{\ln\left(1/(1-p)^2\right)}$ 1 and $x_T = -x_T$.
EV(I)	$k_{TE} = -\dfrac{\sqrt{6}}{\pi}\left[0.5772 + \ln\left\{\ln\left(\dfrac{T}{T-1}\right)\right\}\right]$
LP (III)	For a given T, compute k_{TN}. $b = c_{sy}/6$,
	$k_{TL} = k_{TN} + \left(k_{TN}^2 - 1\right)b + \dfrac{1}{3}\left(k_{TN}^3 - 6k_{TN}\right)b^2 - \left(k_{TN}^2 - 1\right)b^3 + b\,k_{TN}^4 + \dfrac{1}{3}k_{TN}^5$.

Coefficient of variation CV is the ratio of the standard deviation to mean of the data. If CS_x is zero, then the distribution of x_i is symmetric; otherwise it is positively or negatively distributed depending on the sign of CS_x. Expressions relating the moments in Eqs. (31.66) to (31.68) and the parameters of the distributions are also shown in Table 31.3.

Frequency Analysis of Hydrologic Data

Frequency analysis of hydrologic data is conducted to estimate the magnitude of the variate corresponding to a recurrence interval T. The recurrence interval and the exceedance probability p or $P(x \geq x_T)$, are inversely related.

$$p = P\left(x \geq x_T\right) = \frac{1}{T} \tag{31.69}$$

The probability of occurrence of an event x_T, $F_x(x_T)$, is the probability that the random variable x is smaller than x_T, p $(x < x_T)$. Therefore, the recurrence interval T and the probability of occurrence of an event are related to each other as in Eq. (31.70).

$$P\left(x < x_T\right) = F_x\left(x_T\right) = 1 - \frac{1}{T} = \frac{T-1}{T} \tag{31.70}$$

The relationships in Eq. (31.69) and Eq. (31.70) are used to derive the relationships between x_T and the corresponding T. For example, the probability distribution of type I extreme value distribution, or the EV(I) distribution is in Eq. (31.71) (Gumbel, 1958). The function $(x_T - u)/\alpha$ is called the reduced variate y_T.

$$F_x\left(x_T\right) = \exp\left[-\exp\left(-\frac{x_T - u}{\alpha}\right)\right] \tag{31.71}$$

Solving Eq. (31.71) for y_T and substituting Eq. (31.70) for $F_x\,(x_T)$ in the resulting equation, Eq. (31.72) is obtained.

$$y_T = -\ln\left[\ln\left(\frac{T}{T-1}\right)\right] \tag{31.72}$$

$$x_T = u + \alpha\, y_T \tag{31.73}$$

Therefore, for specific values of T, u and α, y_T is computed by Eq. (31.72) and the corresponding value of the variate is computed by Eq. (31.73). If annual maximum flood data are analyzed, the corresponding resulting flood magnitude x_T is called the T-year flood.

Chow (1951) generalized relationships such as those in Eq. (31.73) for use in hydrologic frequency analysis. If observed data x_i are used, then the relationship between the magnitude of the variable x_T and the corresponding recurrence interval T is given by Eq. (31.74), where k_T is the hydrologic frequency factor which is related to T and $F_x(x_T)$ as in Eq. (31.70).

$$x_T = \bar{x} + k_T\, s_x \tag{31.74}$$

If log transformed data are used in the frequency analysis, $y_i = \log x_i$, the relationship corresponding to Eq. (31.74) is given in Eq. (31.75), where $\bar{y}$ and s_y are the mean and standard deviation of log transformed data.

$$y_T = \bar{y} + k_T\, S_y \tag{31.75}$$

The skewness coefficient of log transformed data is denoted by C_{sy}. The relationship between k_T and T for normal, EV(1) and log Pearson type (III) [LP(III)] distribution are shown in Table 31.3.

Hydrologic data are plotted on probability papers in which the ordinates represent x_T and the abscissa represent either the exceedance probability or the cumulative probability of a distribution. These exceedance probabilities are estimated by using plotting position formulas. A general representation of the plotting position formulas is given in Eq. (31.76), where i is the rank of the variate, with $i = 1$ for the largest value. Several commonly used plotting position formulas may be derived from Eq. (31.76). For example, C is equal to 0.5 for Hazen's, 0 for Weibull's, 0.3 for Chegodayev's, 0.375 for Blom's, 0.33 for Tukey's and 0.44 for Gringorten's formulas.

$$P\left(x \geq x_T\right) = \frac{1}{T} = \frac{i - C}{N + 1 - 2C} \tag{31.76}$$

If the data obey the distribution whose paper they are plotted on, they fall approximately on a straight line. Straight lines may be fitted to these data and extrapolated to estimate the x_T values corresponding to recurrence interval T.

Water Resources Council Method

The U.S. Water Resources Council (Benson, 1968) has recommended that the LP (III) distribution be used for flood frequency analysis. In this method, the annual maximum flood data are log transformed and the statistics $\bar{y}$, s_y and C_{sy} are calculated. The variance of the "station skew" C_{sy}, denoted by $V(C_{sy})$ is given by Eq. (31.77), where A and B are defined in Eqs. (31.78a-d).

$$V\left(C_{sy}\right) = 10^{A - B \log_{10}(N/10)} \tag{31.77}$$

$$A = -0.33 + 0.08\left|C_{sy}\right| \quad \text{for} \quad \left|C_{sy}\right| \leq 0.9 \tag{31.78a}$$

$$A = -0.52 + 0.3\left|C_{sy}\right| \quad \text{for} \quad \left|C_{sy}\right| > 0.9 \tag{31.78b}$$

$$B = 0.94 - 0.26\left|C_{sy}\right| \quad \text{for} \quad \left|C_{sy}\right| \leq 1.50 \tag{31.78c}$$

$$B = 0.55 \quad \text{for} \quad \left|C_{sy}\right| > 1.5 \tag{31.78d}$$

The map skewness (C_m) is interpolated from Fig. 31.13. The variance of the map skewness $V(C_m)$ for the U.S. is 0.3025. The weighted skewness coefficient C_{sw} is given by Eq. (31.79).

$$C_{sw} = \frac{V\left(C_m\right) C_{sy} + V\left(C_{sy}\right) C_m}{V\left(C_m\right) + V\left(C_{sy}\right)} \tag{31.79}$$

This skewness coefficient C_{sw} is used to compute b in Table 31.3 and k_{TL} values corresponding to recurrence interval T. The logarithm of the flow is computed by Eq. (31.75), which is used to compute the value of the flow x_T. A computer program HECWRC (U.S. Army Corps of Engineers, 1982) and its derivatives exist to perform these computations.

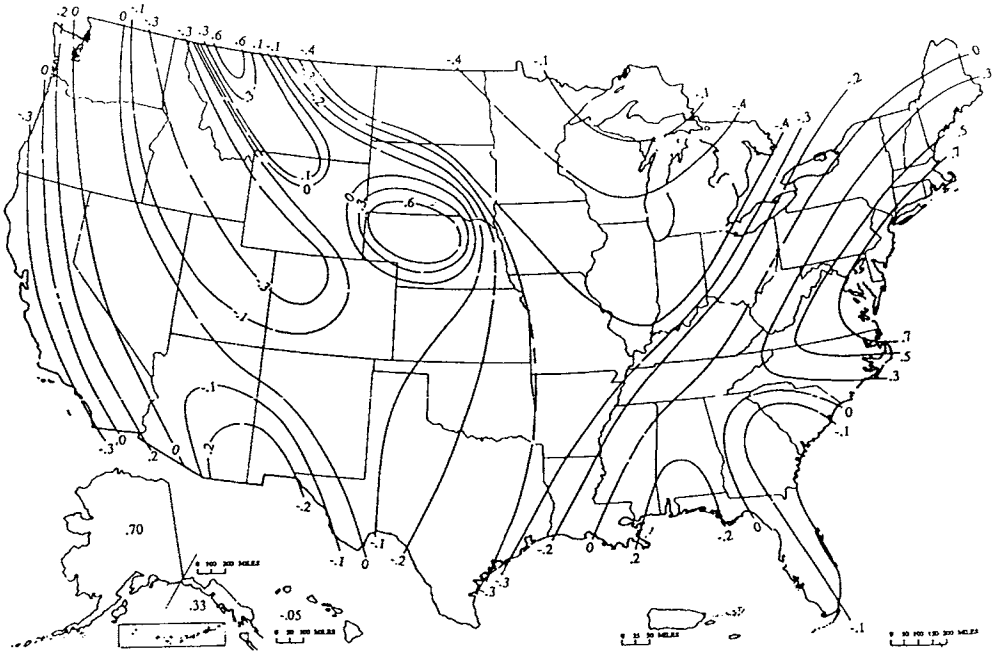

FIGURE 31.13 Map of skewness coefficients of annual maximum flows.

Defining Terms

Evapotranspiration — The process by which water in soil, vegetation and land surface is converted to water vapor.

Flood routing — A technique used to analyze the passage of a flood wave through a channel or a reservoir.

Frequency Analysis — A probabilistic analysis of hydrologic data conducted to estimate the magnitude of a variate corresponding to a recurrence interval.

Hydrograph — A plot of variation of discharge with time.

Hydrologic cycle — Continuum of the movement of water in the atmosphere, hydrosphere and lithosphere.

Infiltration — Process by which water on the soil surface enters the soil.

Isohyetal lines — Lines of equal values of precipitation measured or observed.

Pan coefficient — Ratio of lake evaporation to pan evaporation.

Percolation — Process by which water moves through the soil because of gravity.

Potential evapotranspiration — Evapotranspiration rate that occurs when the moisture supply is unlimited.

Precipitation — Water in its different phases descending from the sky.

Psychometric constant — A constant involving specific heat, latent heat of vaporization and other variables which is used in evaporation estimation.

Rainfall frequency — Time interval between occurrence of a rainfall depth over a specific duration.

Rainfall intensity — Rate of occurrence of rainfall.

SCS — Soil Conservation Service, a division of the U.S. Department of Agriculture.

Specific humidity — Ratio of water vapor pressure to the atmospheric pressure.

Surface runoff — Movement of water over land surface.

Unit hydrograph — A direct runoff hydrograph resulting from one unit of effective rainfall occurring uniformly in space and time over a unit period of time.

32.1 Introduction

Urbanization drastically alters the hydrologic and meteorological characteristics of watersheds. Because of the changes in surface and heat retention characteristics brought about by buildings and roads, heat islands develop in urban areas. Increases in nucleation and photoelectric gases due to urbanization result in higher smog, precipitation and related activities, and lower radiation in urban areas compared to the surrounding rural areas. Some of these meteorologic effects of urbanization are discussed by Lowry (1967) and Landsberg (1981).

When an area is urbanized, trees and vegetation are removed, the drainage pattern is altered, conveyance is accelerated and the imperviousness of the area is increased because of the construction of residential or commercial structures and roads. Increased imperviousness decreases infiltration with a consequent increase in the volume of runoff. Improvements in a drainage system cause runoff to leave the urbanized area faster than from a similar undeveloped area. Consequently, the time for runoff to reach its peak is shorter for an urban watershed than for an undeveloped watershed. The peak runoff from urbanized watersheds, on the other hand, is larger than from similar undeveloped watersheds. The effects of urbanization on runoff are summarized in Table 32.1.

Urban stormwater drainage collection and conveyance systems are designed to remove runoff from urbanized areas so that flooding is avoided and transportation is not adversely affected. A schematic diagram of a typical urban storm water drainage collection and conveyance system is shown in Fig. 32.1. The cost of this and similar systems is directly dependent on the recurrence interval of rainfall used in the design. Rainfall with 5 to 10 year recurrence intervals is most often used in the sizing and design of the urban stormwater drainage collection and conveyance systems. To accomodate areas that encounter frequent floods or high losses due to flooding and to reduce the potential for downstream flooding, stormwater storage facilities are developed to temporarily store the stormwater and to release it after a storm has passed over the area. Examples of large-scale facilities are the Tunnel and Reservoir Plan (TARP) of the Metropolitan Water Reclamation District of Greater Chicago and the deep tunnel project in Milwaukee. The website for the TARP project is: *www.mwrgdc.dst.il.us/engineering/ourcommunityflooding/OCFAppendix1.htm*. Smaller scale facilities to temporarily detain and release stormwater to the storm

TABLE 32.1 Potential Hydrologic Effects of Urbanization

Urbanizing Influence	Potential Hydrologic Response
Removal of trees and vegetation	Decrease in evapotranspiration and interception; increase in stream sedimentation
Initial construction of houses, streets, and culverts	Local relief from flooding; concentration of floodwaters may aggravate flood problems downstream
Complete development of residential, commercial, and industrial areas	Increased imperviousness reduces time of runoff concentration thereby increasing peak discharges and compressing the time distribution of flow; volume of runoff and flood damage potential greatly increased
Construction of storm drains and channel improvements	Decrease infiltration and lowered groundwater table; increased storm flows and decreased base flows during dry periods

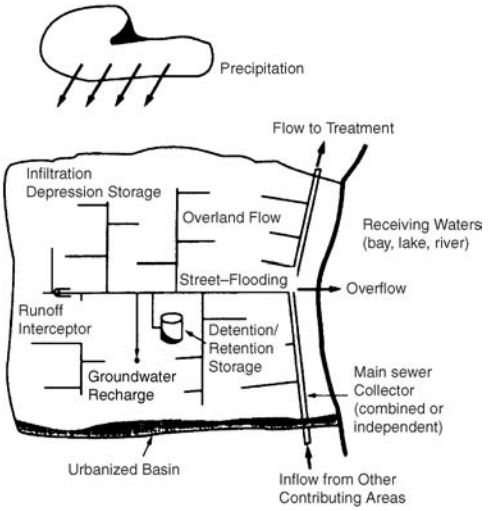

FIGURE 32.1 Schematic diagram of an urban storm-drainage system.

sewer system after the passage of storms (detention facilities) or to retain it and let the water infiltrate or evaporate (retention facilities) are commonly used in suburban flood control projects and are often required for a new development. Detention basins are commonly used to prevent downstream flooding and are often designed to increase the aesthetic appeal of areas in which they are placed.

For many watersheds, models such as TR-20 (SCS, 1982) developed by the Soil Conservation Service of the U.S. Department of Agriculture and HEC-1 (HEC, 1985), developed by the Hydrologic Engineering Center of the U.S. Army Corps of Engineers are commonly used by designers. These models are used to size collection and conveyance systems as well as stormwater storage facilities, investigate alternative scenarios, and evaluate existing drainage systems.

In this chapter, commonly used formulas and methods to compute peak discharge and runoff hydrographs, such as the rational method and the SCS method are discussed first. Methods for sizing of detention basins are discussed next, followed by a discussion of detention storage layout.

32.2 The Rational Method

The rational method is widely used to determine peak discharges from a given watershed. It was first introduced by Kuichling (1889) into the U.S.; a large majority of the engineering offices which deal with storm drainage work in the U.S. use the rational method. This popularity is due to its simplicity and perhaps to tradition.

In the rational method, the peak rate of surface flow from a given watershed is assumed to be proportional to the watershed area and the average rainfall intensity over a period of time just sufficient for all parts of the watershed to contribute to the outflow. The rational formula is shown in Eq. (32.1)

$$Q = CiA \tag{32.1}$$

where Q = the peak discharge (cfs)
C = the ratio of peak runoff rate to average rainfall rate over the watershed during the time of concentration (runoff coefficient)
i = the rainfall intensity (inches/hour)
A = the contributing area of the watershed (acres).

It should be noted that C has units.

The rational method is usually applied to drainage basins less than 200 acres in area, but should be used carefully for basins greater than five acres. The basic assumptions used in the rational formula are as follows: (1) The rainfall is uniform over the watershed. (2) The storm duration associated with the peak discharge is equal to the time of concentration for the drainage area. (3) The runoff coefficient C depends on the rainfall return period, and is independent of storm duration and reflects infiltration rate, soil type and antecedent moisture condition. The coefficient C, the rainfall intensity i and, the area of the watershed, A, are estimated in order to use the rational method.

Runoff Coefficient

The runoff coefficient C reflects the watershed characteristics. Values of the runoff coefficient C are found in drainage design manuals (Burke et. al., 1994, ASCE, 1992) and in textbooks (Chow et al. 1988). If a watershed has different land uses, a weighted average C based on the actual percentage of lawns, streets, roofs, etc. is computed and used. Values of C must be carefully selected. The C values usually found in manuals and textbooks are valid for recurrence intervals up to 10 years. These values are sometimes altered when higher rainfall frequencies are used.

Rainfall Intensity

Rainfall intensity-duration-frequency curves are used to determine rainfall intensities used in the rational method. Local custom or drainage ordinances dictate the use of a particular return period. In the design of urban drainage collection and conveyance systems, a return period of 5 to 10 years is generally selected. In high value districts (commercial and residential) and in flood protection works, a 50 or 100 year frequency is used. When more than one return period is used, the costs and risks associated with each return period must be scrutinized. In the rational method, the storm duration is equal to the time of concentration. Further details on risk/reliability models for design are found in Tung et al. (2001).

Time of Concentration and Travel Time

The *time of concentration* t_c is the time taken by runoff to travel from the hydraulically most distant point on the watershed to the point of interest. The *time of travel* T_t is the time taken by water to travel from one point to another in a watershed. The time of concentration may be visualized as the sum of the travel times in components of a drainage system. The different components include overland flow, shallow concentrated flow and channel flow. As an area is urbanized, the quality of flow surface and conveyance facilities are improved, and the times of travel and concentration generally decrease. On the other hand ponding and reduction of land slopes which may accompany urbanization increase times of travel and concentration.

Overland flows are assumed to have maximum flow lengths of about 300 ft. From about 300 ft. to the point where the flow reaches well-defined channels, the flow is assumed to be of the shallow concentrated type. After the flow reaches open channels it is characterized by Manning's formula.

TABLE 32.2 Equations for Overland Flow Travel Time

Name	Equation for t_t	Notes
Regan (1972)	$t_t = \dfrac{L^{0.6}\, n^{0.6}\, K}{i^{0.4}\, S^{0.3}}$	n is Manning's roughness coefficient
Kerby (1959)	$t_t = 0.827 \left[\dfrac{NL}{\sqrt{S}}\right]^{0.467}$	$L < 1200$ ft,
Federal Aviation Agency (1956)	$t_t = 1.8(1.1 - C)\dfrac{L}{\sqrt{100S}}$	Airport areas C = runoff coefficient
Izzard (1946)	$t_t = \dfrac{2}{60}\dfrac{.0007i + c}{S^{1/3}} L \left[\dfrac{iL}{43200}\right]^{-2/3}$ or $t_t = \dfrac{41\, cL^{1/3}}{(Ci)^{2/3}\, S^{1/3}}$	$iL < 500$,
Overton and Meadows (1970)	$t_t = \dfrac{0.007\,(nL)^{0.8}}{(P_2)^{0.5}\, S^{0.4}}$	

where t_t = the overland flow time (min), L is the basin length (ft),
S = the basin slope (ft/ft), i is the rainfall intensity (in./hr),
c = the retardance coefficient and C is the runoff coefficient,
n = Manning's n,
P_2 = the 2 year-24 hr rainfall (in)
$K = 56$
N = a roughness coefficient

Some commonly used formulas employed in the determination of the overland flow travel time are shown in Table 32.2. Most of these equations relate the overland time of travel to the basin length, slope and surface roughness. Two equations, by Izzard and Regan, include rainfall intensity as a factor, which necessitates an iterative solution.

The average velocities for shallow concentrated flow are estimated by Eqs. (32.2) and (32.3) for unpaved and paved areas respectively, where V is the average velocity in ft/sec. and S is the slope of the land surface in ft/ft. (SCS, 1986).

$$\text{unpaved:} \quad V = 16.13\ (S)^{0.5} \tag{32.2}$$

$$\text{paved:} \quad V = 20.33\ (S)^{0.5} \tag{32.3}$$

Flows in open channels are characterized by Manning's formula. In sewered watersheds, the time of concentration is calculated by estimating the overland flow travel time, which is called the *inlet time*, the gutter flow time and the *time of travel in sewers*. Often, the *inlet time*, which is the time taken by water to reach inlets, is assumed to be between 5 and 30 min. In flat areas with widely spaced street inlets, an inlet time of 20 to 30 min is assumed (ASCE, 1992). These inlet times are added to the flow time in the sewer or channel to determine the travel time at a downstream location.

The flow time in sewers is usually calculated by choosing a pipe or channel configuration and calculating the velocity. The time is then found by:

$$t = \frac{L}{60V} \tag{32.4}$$

where t = the travel time in the sewer (min.)
L = the length of the pipe or channel (ft)
V = the velocity in the sewer (ft/sec)

TABLE 32.3 Typical Velocities in Natural Waterways (AASHTO, 1991)

Average Slope of waterway (%)	Velocity In Natural Channel (not well defined) (ft/sec)	Shallow Channel (ft/sec)	Main Drainage Channel (ft/sec)
1–2	1.5	2–3	3–6
2–4	3.0	3–5	5–9
4–6	4.0	4–7	7–10
6–10	5.0	6–8	—

Mannings' formula is commonly used to estimate the travel times in sewers. The sewer is assumed to flow full and a velocity is computed. Manning's n values commonly used for this purpose are found in Chow (1959). Sometimes, natural channels are used to convey storm runoff. In these cases the velocities given in Table 32.3 (AASHTO, 1991) may be used in Eq. (32.4). The drainage area, A, used in the rational formula is determined from topographic maps and field surveys.

Application of the Rational Method

The choice of parameters in the rational method is subjective. Consequently, variations occur in designs. Since rainfall intensity values are derived from statistical analyses and may not represent actual storm events, it is impossible to have a storm of a specified design intensity and duration associated with the results from the rational method. The procedure for the application of the rational method is as follows: (1) The contributing basin area A (acres) is determined by using maps or plans made specifically for the basin. (2) By using the land use information, appropriate C values are determined. If the land has multiple uses, a composite C value is estimated by Eq. (32.5):

$$C_{comp} = \frac{\left(C_1 A_1 + C_2 A_2 + \cdots C_n A_n\right)}{A} \tag{32.5}$$

where $C_1, C_2 \ldots C_n$ = the runoff coefficients associated with the $A_1, A_2 \ldots A_n$ respectively
A = the sum of $A_1, A_2 \ldots A_n$

(3) The time of concentration is estimated by summing the travel time components. (4) The rainfall intensity is determined by using an intensity-duration-frequency diagram and the time of concentration as the storm duration. (5) The peak runoff (cfs) is computed by multiplying C, i and A. (6) If there is another basin downstream, the time of concentration from the upstream basin is added to the travel time in the channel. This time of concentration is compared to the time of concentration of the second basin and the larger of two is used as the new time of concentration. Examples of the application of rational method are found in Burke et al. (1994). Because of the assumptions and the simplistic approach on which rational method is based, its application is not recommended for watersheds larger than five acres.

32.3 The Soil Conservation Service Methods

The Soil Conservation Service has developed a method to estimate rainfall excess P_e from total rainfall P, based on the total ultimate abstraction S. In this method, P_e is given by Eq. (32.6), where P must be greater than 0.2S, which is the initial storage capacity I_a (in.).

$$P_e = \frac{\left(P - 0.2S\right)^2}{P + 0.85} \tag{32.6}$$

Antecedent moisture condition II, $I_a = 0.2S$.
Source: SCS (1972).

If P is less than 0.2S, P_e is assumed to be zero. The rainfall excess P_e has units of inches. In this method, the abstraction S is related to the "curve number" CN as in Eq. (32.7)

$$S = \frac{1000}{CN} - 10 \tag{32.7}$$

The curve number CN is also related to soil types and land uses. Soils are divided into four classes A through D, based on infiltration characteristics. Type A soils have the maximum and D soils the minimum infiltration capacity with B and C soils falling in between. Tables containing soil names and types are available in SCS (1972) and a portion of this table is shown in Table 32.4. Curve numbers for selected land use and Antecedent Moisture Condition (AMC (II) (SCS, 1972) are shown in Table 32.5.

Application of the SCS Method

In order to use this method, the area A is subdivided into subareas A_1, A_2,… A_n so that each of the subareas has a uniform land use. By identifying the soil types and land uses in each of these subareas, the CN values for the subareas are estimated from Table 32.5. The rainfall excess P_e is computed by Eq. (32.6). A rainfall excess hyetograph may then be computed by using the Huff curves as discussed in

Section 31.2. The rainfall excess hyetograph thus generated may be used with the SCS - unit hydrograph method to compute a direct runoff hydrograph. The direct runoff hydrograph can be used to size collection and conveyance systems and to estimate detention storage volumes, Mays (2001).

32.4 Detention Storage Design

The increased runoff volume produced by the urbanization of watersheds can result in downstream flooding. Storage facilities are designed to receive runoff from developed upstream watersheds and release it downstream at a reduced rate. This reduced rate is determined by using parameters fixed by local ordinance or by calculating the available capacity of the downstream storm sewer network. Some of the methods used to compute the required storage volumes of detention storages are discussed in this section.

Types of Storage Facilities

Storage facilities can be divided into two general categories as *detention* and *retention*. These are also called as dry or wet detention ponds. Detention storage is the temporary storage of the runoff that is in excess of that released. After a storm ends, the facility is emptied and resumes its normal function. Ponds, parking lots, rooftops and parks are common detention facilities, which may be designed to temporarily store a limited amount of runoff.

Retention facilities are designed to retain runoff for an indefinite period of time. Water level in retention facilities changes only due to evaporation and infiltration. Ponds and lakes are examples of retention facilities that are used in subdivisions to enhance the overall project.

Computation of Detention Storage Volumes

The primary goal in the design of detention facilities is to provide the necessary storage volume. If infiltration and evaporation are neglected during the runoff period, the continuity equation for a detention pond may be written as in Eq. (32.8),

$$I(t) - O(t) = \frac{\Delta S}{\Delta t} \tag{32.8}$$

where $I(t)$ = inflow to the pond from the sewer network at time (t) (cfs)
$O(t)$ = outflow from the pond into the downstream drainage network at time (t) (cfs)
ΔS = change in storage (ft^3) in time interval Δt (sec)
Δt = time interval

Equation (32.8) may also be written as:

$$\left(I_1 + I_2\right)\frac{\Delta t}{2} - \left(O_1 + O_2\right)\frac{\Delta t}{2} = S_2 - S_1 \tag{32.9}$$

where subscripts 1 and 2 denote the flows and storages at times t_1 and t_2.

When inflow and outflow hydrographs are known, the largest value of $S_2 - S_1$ found in Eq. (32.9) is the required storage. The following is a discussion of some of the methods used to estimate detention storage volumes. For retention facilities the outflow rate is equal to the sum of the evaporation and infiltration rates. These are negligible during a storm and the required volume is therefore equal to the runoff volume.

Storage Determination By Using the Rational Method

The rational method discussed previously is extended to compute detention storage volumes by multiplying the peak flow rate by the storm duration. The allowable peak flow rate (release rate) leaving the

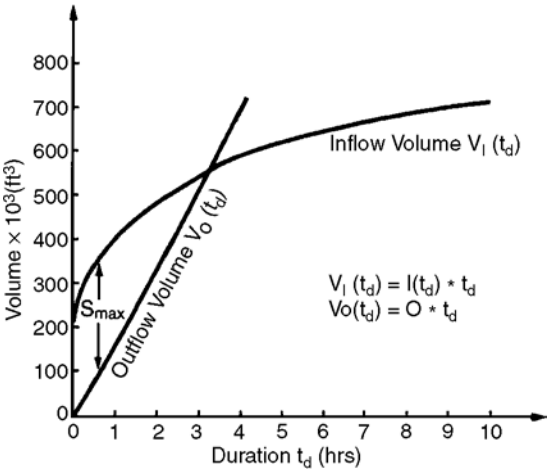

FIGURE 32.2 Graphical representation of storage volumes as determined by the rational method.

detention pond, $O(t)$, is calculated by using the contributing undeveloped area, A_U, the runoff coefficient applicable for undeveloped condition C_U, and rainfall intensity, i_U, associated with the time of concentration of the undeveloped basin. The return period for the intensity i_U is normally fixed by local ordinances or is based on the design parameters of the larger downstream drainage network. The allowable outflow rate is assumed to remain constant for all storm durations, t_d. Therefore the volume corresponding to t_d, $v(t_d)$, is the product of $O(t)$ and t_d. This is illustrated in Fig. 32.2 where the lines $V_I(t_d)$ and $V_0\ (t_d)$ are the inflow and outflow volumes at times t_d.

The rate of inflow to the detention basin, $I(t)$, is calculated by using the contributing developed area, A_D, the developed runoff coefficient, C_D, and a rainfall intensity, i_D, corresponding to storm duration, t_d, and the return period. Thus, for various durations, the peak flow and the volume of runoff are computed. The maximum difference between the inflow and outflow volumes is the required detention pond storage. This is shown in Fig. 32.2 as S_{max}. The method may also be expressed as in Eq. (32.10),

$$S(t_d) = \left[C_D i_D A_D - C_u i_u A_u\right]\frac{td}{12} \tag{32.10}$$

where $S(t_d)$ = the required storage (acre - ft)
t_d = the storm duration in hours.

Various storm durations, t_d, are selected and the largest value of $S(t_d)$ is selected as the required volume of the detention pond.

The procedure to size detention storage facility by using the rational method is as follows: (1) The area, A_U, runoff coefficient, C_U, and time of concentration for the undeveloped site are determined. By using the appropriate intensity-duration-frequency curve, the intensity, i_U, corresponding to the return period for the allowable outflow rate is estimated. (2) The runoff (O) from the undeveloped site ($O = C_U\ i_U\ A_U$) is computed. (3) The runoff coefficient corresponding to the developed conditions, C_D is estimated. (4) The rainfall intensities (i_d) for various durations, (t_d) are obtained for different return periods. Recommended durations are 10, 20, 30, 40, 50 min. and 1, 1.5, 2, 3, 4, 5, 6, 7, 8, 9 and 10 hours. (5) The inflow rate to the detention pond, $I(t_d) = C_D\ i_d\ A_D$ is computed. (6) The required storage for each duration, is calculated. (7) The largest volume $S(t_d)$ is selected as the design volume.

Various agencies have set guidelines for selection of i_U, i_D, C_U and C_d. For example, the Metropolitan Water Reclamation District of Greater Chicago (MWRDGC), uses the criteria that i_U should be is based on a 3-year return period, i_d is based on a 100-year return period, C_U should be less than or equal to 0.15 and C_D should be 0.45 for pervious areas and 0.9 for impervious areas.

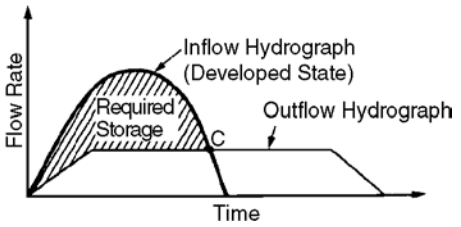

FIGURE 32.3 Inflow and outflow hydrographs for a hypothetical detention pond.

It may be impossible to collect and convey all of the runoff from a given watershed under certain conditions. The result is that some runoff is discharged directly into the downstream drainage network without being detained. To compensate for this unrestricted release, the allowable release rate, O, is reduced by that amount.

Soil Conservation Service Hydrograph Method

Methods were discussed in Section 32.3 by which the stormwater runoff hydrographs can be estimated by the SCS method. These hydrographs are used to compute detention storage volume.

As previously described, the difference between the inflow from the developed watershed and the allowable outflow from a detention pond is the required storage volume. The outflow is determined by using characteristics of the undeveloped watershed and a rainfall frequency equal to or less than that which a receiving system can handle, or is prescribed by local ordinance.

Figure 32.3 shows an inflow and a outflow hydrographs. The difference between the hydrographs, which is the required storage, is shown as the shaded region. At point C, the detention pond inflow rate is equal to the outflow rate when it will start to empty. In Fig. 32.3 the outflow rate is assumed to remain constant. The outflow rate will depend upon the depth of water in the pond and the type of outlet structure (i.e., weir, orifice or pipe). It should also be noted that for a detention pond, the inflow and outflow volumes are equal.

The following is an outline of the procedure used to determine the required storage volume by the SCS hydrograph method. (1) Calculate the curve numbers for the basin in developed and undeveloped condition. (2) Find the time of concentration t_c for the basin in undeveloped and developed condition. (3) From t_c, calculate the duration of the unit hydrograph ΔD, t_p and q_p for the developed and undeveloped basins. (4) Determine the coordinates of the inflow and outflow unit hydrographs. (5) From the design storm duration, depth, time distribution and frequency, calculate the cumulative rainfall at ΔD intervals for both the undeveloped and developed states. (6) Using the basin curve number and ultimate abstraction S, calculate the cumulative runoff, $P_e(t_d)$ at each ΔD interval by using the rainfall data in Step 5. (7) Calculate the storm hydrographs by using the effective rainfall and direct runoff data. (8) Using the peak flow from the undeveloped state as the peak outflow, calculate the outflow hydrograph as determined by the type of outflow structure. (9) Calculate the required storage by using the developed hydrograph and outflow data or by using routing methods.

Detention Storage Layout

Once the amount of detention storage is determined, a storage facility must be designed to accommodate the inflow of runoff and control the release rate. Typical detention storage layout consists of providing a detention pond with the inflow on one side of the pond and the outlet on the other side of the pond. The first criterion in sizing a detention pond is to determine the outlet elevation that is usually controlled by the elevation of the downstream receptor. The downstream receptor may be a storm sewer, water body (i.e., pond, lake, stream or channel) field tile or culvert. The hydraulic conditions of the downstream receptor must be analyzed to determine if there will be any tailwater effects (depending on the design conditions) on the outlet of the detention storage facility. Knowing the outlet elevation of the downstream receptor will give a good approximation of the elevation of the detention pond restrictor elevation. The

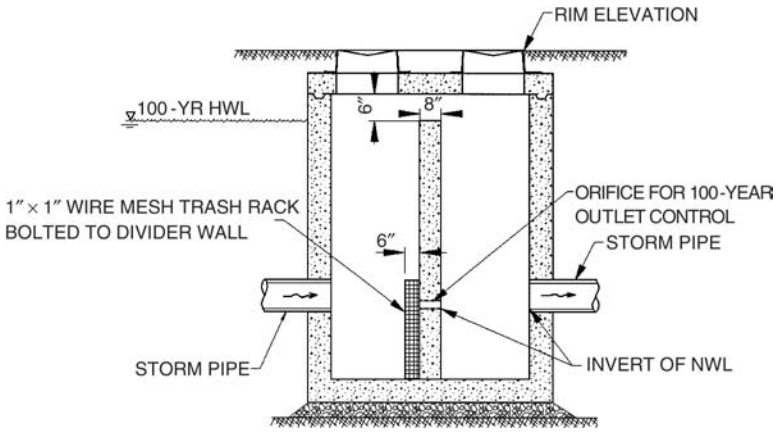

FIGURE 32.4 Detention basin control structure for single release rate.

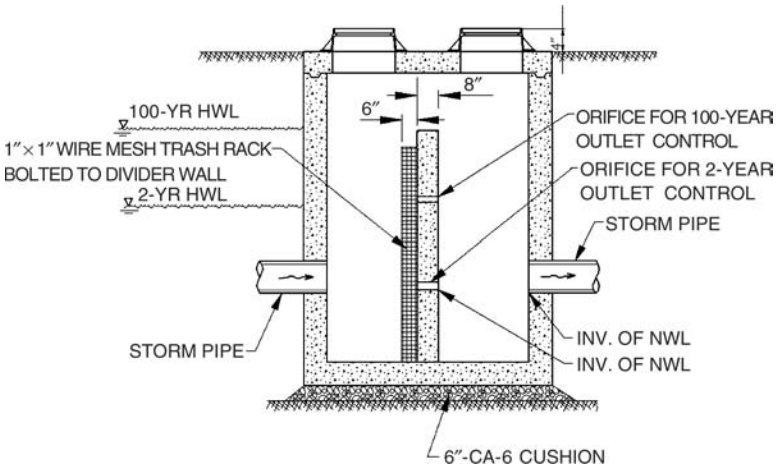

FIGURE 32.5 Detention basin control structure with concrete wall for dual release rate. NWL is the normal water level.

designer needs to decide whether the pond will be wet bottom or dry bottom depending on site characteristics (i.e., groundwater table, soil characteristics, surrounding land use, etc.). The detention pond size and layout can then be determined accounting for the site topography and available area.

The next step in designing the detention pond is to determine the restrictor size. When the regulations require a single outlet release rate for a given storm event and duration, a restrictor size is determined using the orifice equation. The restrictor is placed at the bottom elevation of the pond. Or, in the case of a wet bottom pond, at the normal water level. Figure 32.4 shows an example of a restrictor drilled through a wall constructed inside a manhole. Some regulatory agencies require a 2-stage restrictor outlet control. For example, the 2-year release rate is set at 0.04 cfs per tributary acre and the 100-year release rate is set at 0.15 cfs/acre. In this situation the 2-year release rate restrictor is set at the bottom of the pond and the 100-year release rate restrictor is set at the 2-year high water elevation. Figures 32.5 and 32.6 show two examples for the 2-stage restrictor outlet controls.

Because the controlled rate is often low, it is not uncommon to have a very small restrictor size, even in the range of 1 to 2 in. for smaller tributary areas and 5 to 6 ft of bounce (elevation between the design normal water level and high water level. Some regulatory agencies require a minimum restrictor size of 4 in. For those agencies that do not have a minimum and where the restrictor size is small, it is important to protect the opening from being blocked and provide for an overflow weir that conveys the overtopping

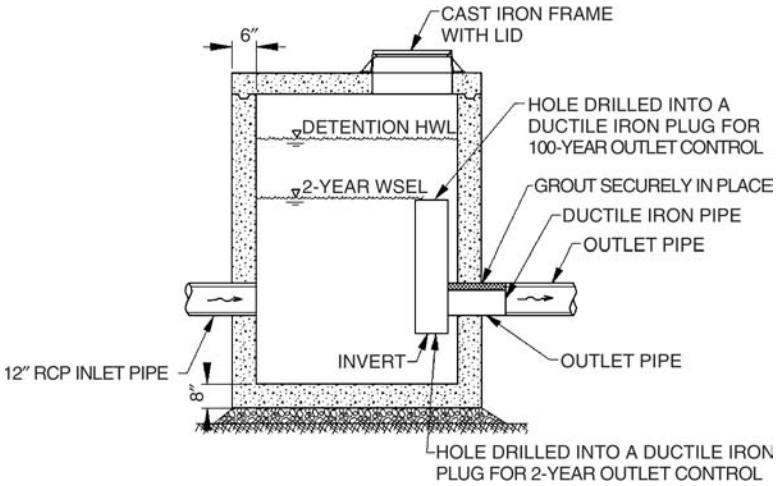

FIGURE 32.6 Detention basin control structure with ductile iron plug for dual release rate.

water to the downstream receptor. Figure 32.5 has a trash rack to collect any debris from blocking the restrictor and an overflow weir set at the high water level.

In areas where the value of the land is high enough that it is too costly to use a sizeable portion of the project site for a detention storage pond there are several alternatives. The first alternative is to refine the pond layout by using retaining walls on some or all sides of the detention pond. Another more costly alternative is to provide underground storage.

Underground storage is expensive but an economic decision that the property owner may choose to consider. The storage is usually obtained by providing laterals of storm sewers laid next to each other or by providing an underground storage vault, which could consist of concrete box culverts. The choice of storm sewer material for underground storage is one of either concrete, corrugated metal or high-density polyethylene. Pipe manufacturers have recently come out with some more efficient layouts that maximize the amount of storage provided for each lateral. There are benefits and concerns for each of the three types of storm sewers that provide underground detention that must be weighed by the design engineer for the circumstances of the particular application. Some things for the design engineer to consider when selecting the underground storage option are: conflicts with existing or proposed utilities, the experience of the contractor installing the system and the loads on top of the storm sewer system.

Defining Terms

Rational method — A method to estimate peak runoff from small watersheds.

Time of concentration — Time taken by runoff to travel from the hydraulically most distant point on the watershed to the point of interest.

Inlet time — Time taken by water to reach inlets.

Detention storage — Storage used to temporarily store storm water and to release it gradually after the storm is over.

Retention storage — A facility to store storm water. The stored water is allowed to infiltrate and evaporate.

33.1 Urban Runoff

Urban runoff is a major environmental concern. The old paradigm of only controlling flow to mitigate flood damage must be extended to incorporate preventing deterioration of water quality. For the purposes of this chapter, **urban runoff** is water flowing because of urbanization and may occur from the following sources: stormwater runoff, combined sewer overflows, sanitary sewer overflows, publicly owned treatment works and industrial outfalls, and/or miscellaneous runoff. There are other sources of runoff that contribute to the deterioration of water quality, including agricultural runoff, but those are not considered urban sources. The major volume of urban runoff is composed of water that flows from landscaped areas, driveways, streets, parking lots, roofs, and from other impervious surfaces.

This chapter provides an overview of the sources of urban runoff in terms of quantity and quality, discusses water quality regulations and criteria, and shares best management practices, which often require detailed modeling of the urban system. Relevant investigations carried out by various agencies are included, such as NURP (National Urban Runoff Program, EPA, 1983). The TMDL (Total Maximum Daily Load) program is discussed and should be viewed as a management practice to control the quality of urban runoff (EPA, 2000c).

Before considering the impacts of pollution on urban water quality, the effect of urbanization on the hydrologic cycle must be investigated. As watersheds become urbanized, hydrological characteristics drastically change. Urbanization can result in the following changes of a catchment's hydrologic cycle (WEF/ASCE, 1998):

- reducing the degree of infiltration and increased runoff volumes resulting from surface changes (altered grading, form, or cover);
- changing the available depression storage because of re-grading;

* Due to the untimely death of Dr. Wukasch, this chapter was completed by his co-authors and was reviewed by Reggie Baker of the Indiana Department of Environmental Management.

- changing evapotranspiration as vegetative cover is removed; and
- reducing the residence time of water in a catchment as a result of increased impervious areas or the construction of efficient sewer systems.

Clearly, the main cause for increased quantity of runoff when considering similar catchments in urban and rural areas is the increased impervious surface. Land use changes with urbanization cause average curve numbers and runoff coefficients to increase and the time of concentration to decrease. (A table of runoff curve numbers can be found in Chapter 32, "Urban Drainage".) The relationship between runoff coefficient (event runoff volume divided by event rainfall volume) and percent impervious area has been widely studied. A 1994 study of 40 runoff-monitoring sites in the U.S. indicated that percent watershed imperviousness is nearly equal to the runoff coefficient, and becomes a more perfect indicator of percent runoff as imperviousness increases (Schueler, 1994).

The different hydrologic responses of developed urban areas when compared to natural or rural settings are worth considering. Increased flow velocities are generated as excess water flows more rapidly over impervious surfaces. Runoff volume from an impervious parking lot is 20 times that which results from a 1% impervious measure of the same flow length and slope (Schueler, 1994). The susceptibility of sensitive catchments to development is further shown as an urban catchment generated over 250 times the peak flow and over 350 times the suspended sediment as compared to a 20% larger rural catchment (Cherkauer, 1975).

Point Sources

The terms point and nonpoint source have been used to identify types of pollution in urban runoff. The current statutory definition of a **point source** as defined by the Water Quality Act (U.S. Congress, 1987) is:

> The term "point source" means any discernable, confined and discrete conveyance, including but not limited to any pipe, ditch channel, tunnel, conduit, well, discrete fissure, container, rolling stock, concentrated animal feeding operation, or vessel or other floating craft from which pollutants are or may be discharged. This term does not include agricultural, stormwater, and return flows from irrigated agriculture.

Typically, point source pollution can be traced to a single point such as a pipe or outfall. The main components of urban runoff that are identified as point sources of pollution are **publicly owned treatment works** (POTWs) and industrial outfalls, stormwater outfalls, **combined sewer overflows** (CSOs), and **sanitary sewer overflows** (SSOs).

Historically, substandard effluent quality from POTWs and industrial facilities was a common occurrence. However, as a result of increased awareness and stricter regulations, effluents have become controlled under permits and mandates. A widespread implementation of advanced treatment methods at POTWs and industrial facilities has resulted in a higher quality of effluent. Approximately 16,000 POTWs and tens of thousands of industrial facilities discharge treated wastewater in the U.S. Although the wastewater has been treated, many pollutant residuals remain in the effluent and are considered continuous point sources of pollution.

The improved quality of treated municipal and industrial wastewater effluent has caused other point sources of pollution to be scrutinized. Much attention has been shifted to point sources that intermittently "overflow" such as CSOs and SSOs. There are many possible reasons that may cause sewer systems to overflow untreated wastewater into a receiving body and are as follows (EPA, 2001a and 2001c):

- Infiltration and Inflow: flow that infiltrates through the ground into leaky sewers during large rainfall events and flow from various diffuse sources such as broken pipes.
- Undersized Systems: pumps and sewer piping inadequately sized to handle system demand resulting from increased urbanization.
- Equipment Failures: pumps and controls either fail or are inoperable due to power outages.
- Sewer Service Connections: old or damaged sewer service connections to houses and buildings.
- Deteriorating Sewer Systems: may result from improper installation and maintenance.

FIGURE 33.1 Map showing prevalence of CSOs in U.S. (EPA, 2001a).

Combined sewers were designed to convey a mixture of stormwater, infiltration, miscellaneous runoff, and raw sanitary sewage. During dry conditions, wastewater is directed to a POTW for treatment. However, in wet weather periods the design capacity of the combined sewer system can be exceeded. Excess water is then discharged through a CSO directly to a receiving body such as a stream, river, lake, or ocean. Communities with CSOs are typically found in older cities located in Northeastern and Great Lakes regions of the U.S. Figure 33.1 not only shows a distribution of cities in the U.S. with active CSOs, but also provides an idea of which areas are most vulnerable to pollution from CSO discharges (EPA, 2001a).

It is estimated that combined sewers serve 950 communities with about forty million people in the U.S. Some cities have as many as 280 outfalls. CSOs discharge toxic materials, solids, and bacterial and viral pathogens at potentially harmful levels into receiving bodies, which may be used for recreation or drinking water. An estimated total of 15,000 CSO discharges occur annually (EPA, 2001a).

Problems with sanitary sewers also pose a threat to human health and the environment. Since sanitary sewers are designed only to convey raw municipal wastewater to POTWs, SSOs can release raw sewage wherever sewer pipes travel enroute to the treatment facility. Due to the nature of the waste discharged from SSOs, exposure could result in sickness or death caused by pathogens and toxins. It is estimated that over 40,000 SSO events occur in 18,500 municipal sewers in the U.S. annually (EPA, 2001c).

Nonpoint Sources

All sources of pollution not defined as point sources are thereby nonpoint sources. **Nonpoint source** pollution comes from many diffuse sources. Some examples of nonpoint source pollution include agricultural runoff, urban runoff from sewered and unsewered communities, construction site runoff, septic tanks, wet and dry **atmospheric deposition**, and any other activities on land that generate runoff (Novotney et. al, 1994). Nonpoint source pollution is the main reason that 40% of the surveyed water bodies in the U.S. are not suitable for basic uses such as fishing and swimming (EPA, 1997a). Three main sources of nonpoint source pollution that contribute to urban runoff are stormwater runoff, shallow groundwater runoff, and miscellaneous runoff.

Stormwater runoff is defined as surface water runoff that flows into receiving bodies or into storm sewers. Currently only a small percentage of communities in the U.S. have stormwater runoff treatment initiatives. Stormwater runoff poses a special concern given that pollutants buildup during dry weather periods and then **washoff** following runoff events.

TABLE 33.1 Comparison of Areal Loadings of Pollutants From a Hypothetical American City of 100,000 People in tons per year (Pitt and Field, 1977)

Pollutant	Stormwater	Raw Sewage	Treated Sewage
Total Solids	17,000	5200	520
COD	2400	4800	480
BOD_5	1200	4400	440
Total Phosphorus	50	200	10
TKN	50	800	80
Lead	31	—	—
Zinc	6	—	—

Shallow groundwater runoff is considered a nonpoint source of pollution given that any contaminant in contact with subsurface water may potentially be transported to receiving water bodies. Although this transport process appears slow, it may actually be accelerated as groundwater seeps onto impervious surfaces or infiltrates into faulty sewer systems. This form of nonpoint source pollution has been linked to groundwater contamination. A major nonpoint source of pollution in shallow groundwater deposits occurs due to flawed decentralized wastewater systems.

Decentralized wastewater systems are more commonly referred to as septic systems, private sewage systems, or individual sewage systems. A septic system works by retaining heavier solids and lighter fats, oils, and grease and discharging partially clarified water to a distribution and soil infiltration system. When these systems fail, it is often unnoticed and can become a significant nonpoint source concern. States report failed septic systems as the third most common source of groundwater contamination. Malfunctioning septic systems have been questioned as a potential source of contamination of drinking water that is estimated to cause 168,000 viral and 34,000 bacterial infections annually (EPA, 2000b).

Other contributions to nonpoint source pollution in urban runoff can be classified as miscellaneous runoff sources. Examples include excess water runoff from car washing or over watering of landscaped areas. Other sources consist of flushing fire hydrants, rubbish water leaking from trash, and improperly discarded oils. These sources are considered a major component of nonpoint source pollution, which carry pollutants and pose a threat to the quality of urban runoff.

33.2 Quality of Urban Runoff

The EPA recognizes that urban runoff is the leading cause of current water quality problems in the U.S. Table 33.1 provides a comparison of pollutant loadings from a hypothetical American city of 100,000 people. The data show that loadings from stormwater exceed that of the treated sewage.

Point Source Pollution

Although combined sewer systems can contain highly diluted sewage during wet weather flows, the overall quality of discharged water remains low. A 1978 investigation by the EPA provided an analysis of pollutants caused by CSOs. Table 33.2 shows nationwide average characteristics of CSOs. Pollutant concentrations are lower than typical raw wastewater composition, but the numbers exceed water quality criteria and pose an environmental threat to receiving waters. The investigation showed that CSOs contribute 15 times the lead and suspended solids of secondary wastewater treatment discharge. In addition, coliform bacteria are present in high quantity, potentially causing waterborne diseases in receiving communities.

Nonpoint Source Pollution

Nonpoint source pollution generated from various diffuse sources includes many pollutants, which are finally deposited into lakes, rivers, wetlands, coastal waters, and possibly underground aquifers. These pollutants include (EPA, 1997a):

TABLE 33.2 Nationwide Average Characteristics of CSOs (EPA, 1978)

Parameter	Average Concentration
BOD_5 (mg/l)	115
Suspended solids (mg/l)	370
Total Nitrogen (mg/l)	9–10
Phosphate (mg/l)	1.9
Lead (mg/l)	0.37
Total Coliforms (MPN/100 ml)	10^2–10^4

- Excess fertilizers and pesticides from residential areas – These compounds when conveyed downstream can contribute to algal blooms and other environmental nuisances caused by **eutrophication**.
- Oil, grease and toxic chemicals from urban runoff generated from residential or industrial activities – Oils and grease can leak onto road surfaces to be discharged into storm sewers or carried by rain or snowmelt directly to surface waters.
- Sediment from construction sites and other urban activities are eroded from the land and transported to surface waters. This causes gradual sediment deposition in streams and lakes.
- Salt and other deicing compounds that could either be distributed on roads or stored in an urban area. Melted snow containing salts or other deicing compounds can produce high sodium and chloride concentrations in ponds, lakes and bays. This could also cause fish kills.
- Heavy metals which come from various sources including the natural ones, such as minerals, sand, and rock, can degrade water quality and cause detrimental effects on aquatic life and water resources including groundwater aquifers. Industrial runoff also contributes a high concentration of heavy metals.
- Animal droppings, grass clippings and other urban wastes contribute bacteria and nutrients that lead to degradation of receiving waters.
- Other constituents deposited by atmospheric deposition. The acidic nature of urban rainfall can lead to damages in urban infrastructure and vegetation.

All pollutants contained within stormwater runoff such as toxic chemicals, heavy metals, nutrients, litter, sediments, and other constituents can pose a threat to human health and the environment.

Figure 33.2 shows the ubiquitous nature of nonpoint source of pollution resulting from urbanization. Collectively, nonpoint sources can potentially result in toxic, nutrient, and pathogenic pollutions in addition to causing negative aesthetic impacts on communities (Walesh, 1989).

Nationwide Urban Runoff Program (NURP)

NURP (EPA, 1983) provided a comprehensive investigation of the quality of urban runoff and was based on an extensive study conducted from 1978 to 1983 by the EPA and U.S. Geological Survey (USGS). The program included 2300 storm events at 81 sites in 22 different cities throughout the U.S. The principal conclusions quoted from NURP's Executive Summary are:

1. Heavy metals (especially copper, lead and zinc) are by far the most prevalent priority pollutant constituents found in urban runoff.
2. The organic priority pollutants are detected at lower concentrations than heavy metals.
3. Coliform bacteria are present at high levels in urban runoff and can be expected to exceed EPA water quality criteria during and immediately after storm events in many surface waters, even those providing a high degree of dilution.
4. Nutrients are generally present in urban runoff.

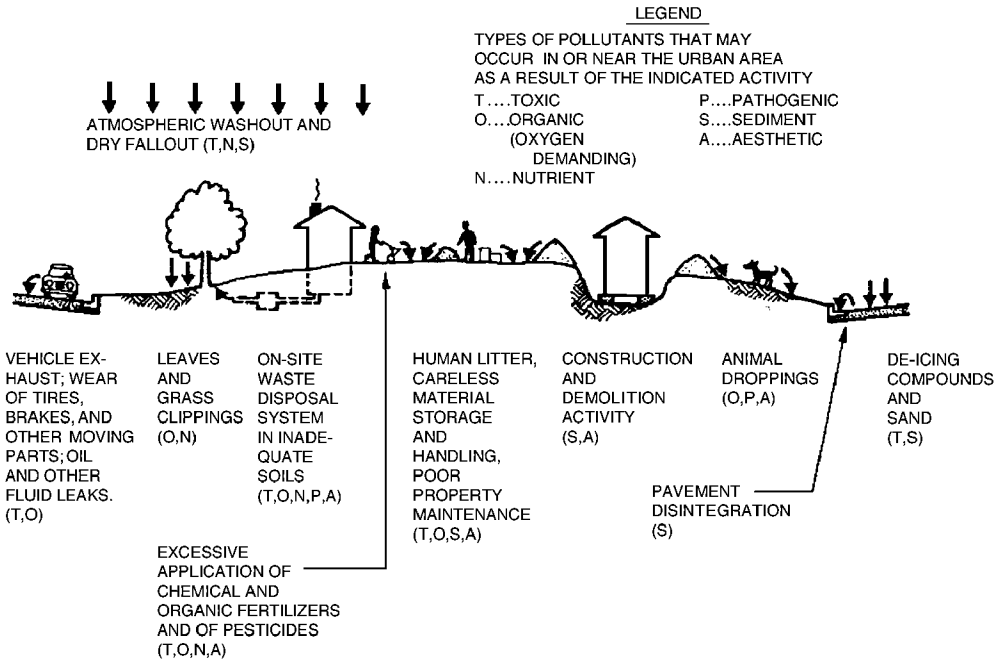

FIGURE 33.2 Nonpoint source pollution as a result of urbanization (Walesh, 1989).

5. Oxygen-demanding substances are present in urban runoff at concentrations approximating those in secondary treatment plant discharges.
6. Total suspended solids concentrations in urban runoff are fairly high in comparison to treatment plant discharges.

The EPA adopted the following constituents as standard pollutants to characterize the quality of urban runoff:

TSS	= Total Suspended Solids
BOD	= Biochemical Oxygen Demand
COD	= Chemical Oxygen Demand
TP	= Total Phosphorus (as P)
SP	= Soluble Phosphorus (as P)
TKN	= Total Kjeldahl Nitrogen (as N)
NO_{2+3}-N	= Nitrite and Nitrate (as N)
Cu	= Total Copper
Pb	= Total Lead
Zn	= Total Zinc

Using the above constituents, the study characterized the quality of urban runoff in the U.S. based on **event mean concentrations (EMC)**. EMC is the average pollutant concentration in runoff generated from a storm event. The results consist of flow-weighted average concentrations. Table 33.3 shows water quality characteristics of urban runoff based on a median and a coefficient of variation of the established EMCs. The report recommended using the data for planning purposes as a description of urban runoff characteristics.

Taking the above data and converting them to mean values produces Table 33.4, which shows EMC mean values used in load comparison. The mean range is shown for both the median and 90th percentile urban site. The difference in means reflects the dependence of the mean value on the coefficient of variability used. Load comparison values indicate a combination of the previous two columns.

TABLE 33.3 Water Quality Characteristics of Urban Runoff

Constituent	Event-to-Event Variability in EMCs (Coef Var)	Site Median EMC	
		For Median Urban Site	For 90th Percentile Urban Site
TSS (mg/l)	1–2	100	300
BOD (mg/l)	0.5–1.0	9	15
COD (mg/l)	0.5–1.0	65	140
Tot. P (mg/l)	0.5–1.0	0.33	0.70
Sol. P (mg/l)	0.5–1.0	0.12	0.21
TKN (mg/l)	0.5–1.0	1.50	3.30
NO_{2+3}-N (mg/l)	0.5–1.0	0.68	1.75
Tot. Cu (µg/l)	0.5–1.0	34	93
Tot. Pb (µg/l)	0.5–1.0	144	350
Tot. Zn (µg/l)	0.5–1.0	160	500

Comparison of Pollution Sources

Results and conclusions from the NURP investigation clearly show the high concentration of pollutants generated during wet weather flow. Exact loadings from different nonpoint sources can be analyzed and compared to that of point sources, such as CSOs, SSOs and treated wastewater effluent. Table 33.6 comparatively provides additional information on the relative strengths of potential sources of point and nonpoint source pollution within an urbanized area.

The one issue that remains critical is whether pollution exceeds water quality criteria recommended by the EPA and enforced by state agencies. The next section will provide an overview of the water quality regulations set forth for the protection of water bodies and present water quality criteria, which can be compared to runoff pollution results.

33.3 Water Quality Regulations and Policies

Water quality regulations in the U.S. have evolved over the last 30 years. The following is a summary of a few relevant federal regulations as they impact urban runoff:

- Federal Water Pollution Control Act of 1972 (PL 92–500) and the Clean Water Act (CWA) Amendments of 1977 (PL 95–217): Under Section 208 of the Act, any discharged point source pollution into navigable waters is prohibited unless allowed by an NPDES permit. The law gave EPA the authority to set effluent standards on a technology basis.
- Safe Drinking Water Act (SDWA) of 1974 (PL 93–523) and 1986 Amendments regulate injection of wastewater into groundwater aquifers. Further, it requires communities with groundwater supply to develop a Wellhead Protection Plan (WHPP). The plan calls for the delineation of potential sources of contamination. See also Chapter 34, "Groundwater Engineering".
- Resource Conservation and Recovery Act (RCRA) of 1976 (PL 94–580) and Hazardous Waste Amendments of 1984 (PL 98–616) mandate the protection of the environment from accidental or unregulated spills of hazardous substances and leading underground storage tanks.

The Federal Water Pollution Control Act of 1972 and Amendments (CWA) in 1977 provided much of the regulations concerning urban runoff, and govern pollutants discharged in streams, rivers, lakes, and estuaries. The Clean Water Act maintains that all U.S. waters must be "fishable and swimmable" at all times. Recent amendments enacted in 1987 under the Water Quality Act (PL 100–4) provided many provisions to previous regulations due to the remaining water quality problems. These provisions include:

- Establishing a comprehensive program to control toxic pollutants.
- Requiring states to develop and implement additional programs to control nonpoint source pollution.
- Authorizing a total of $18 billion in aid for wastewater treatment assistance.
- Authorizing additional programs and modifying previous ones to control water pollution in key water-resource areas including the Great Lakes.
- Revising regulatory, permit, and enforcement programs.

Receiving Water Guidance

The National Urban Runoff Program (EPA, 1983) provided principle conclusions to the impact of urban runoff on receiving waters. The effects of urban runoff on receiving waters depend on the type, size, and hydrology of the water body, the urban runoff quality and quantity, and water quality criteria for specific pollutants. NURP's principle conclusions for rivers, streams, lakes, estuaries, and groundwater, quoted from the executive summary, are:

Rivers and Streams

1. Frequent exceedances of heavy metals ambient water quality criteria for freshwater aquatic life are produced by urban runoff.
2. Although a significant number of problem situations could result from heavy metals in urban runoff, levels of freshwater aquatic life use impairment suggested by the magnitude and frequency of ambient criteria exceedances were not observed.
3. Copper, lead and zinc appear to pose a significant threat to aquatic life uses in some areas of the country. Copper is suggested to be the most significant of the three.
4. Organic priority pollutants in urban runoff do not appear to pose a general threat to freshwater aquatic life.
5. The physical aspects of urban runoff, e.g., erosion and scour, can be a significant cause of habitat disruption and can affect the type of fishery present. However, this area was studied only incidentally by several of the projects under the NURP program and a more concentrated study is necessary.
6. Several projects identified possible problems in the sediments because of the build-up of priority pollutants contributed wholly or in part by urban runoff. However, the NURP studies in the area were few in number and limited in scope, and the findings must be considered only indicative of the need for further study, particularly as to long-term impacts.
7. Coliform bacteria are present at high levels in urban runoff and can be expected to exceed EPA water quality criteria during and immediately after storm events in most rivers and streams.
8. Domestic water supply systems with intakes located on streams in close proximity to urban runoff discharges are encouraged to check for priority pollutants which have been detected in urban runoff, particularly organic pollutants.

Lakes

1. Nutrients in urban runoff may accelerate eutrophication problems and severely limit recreational uses, especially in lakes. However, NURP's lake projects indicate that the degree of beneficial use impairment varies widely, as does the significance of the urban runoff component.
2. Coliform bacteria discharges in urban runoff have a significant negative impact on the recreational uses of lakes.

TABLE 33.7 Recommended Water Quality Criteria of Freshwater for Selected Point and Nonpoint Source Pollutants (Adapted from EPA 1986 and 1991)

Pollutant	Acute (short-term) L.O.E.L.	Chronic (long-term) L.O.E.L.
Ammonia (mg/L)	15.7	3.9
Copper (mg/L)	18	12
Lead (mg/L)	82	3.2
Zinc (mg/L)	320	47
Bacteria – *E. Coli*	126 per mL	
Suspended solids	Settleable and suspended solids should not reduce the depth of the compensation point for photosynthetic activity by more than 10% from the seasonally established norm for aquatic life.	
DO (mg/L)	6.5	4.00
Nitrates/nitrites	10 mg/L for water supply	
Phosphorus	0.10 mg/L (elemental) for marine or estuarine water	

Note: L.O.E.L = Lowest Observed Effect Level

Estuaries and Embayments

1. Adverse effects of urban runoff in marine waters will be at highly specific local situations. Though estuaries and embayments were studied to a very limited extent in NURP, they are not believed to be generally threatened by urban runoff, though specific instances where use is impaired or denied can be of significant local and even regional importance. Coliform bacteria present in urban runoff is the primary pollutant of concern, causing direct impacts on shellfish harvesting and beach closures.

Groundwater Aquifers

1. Groundwater aquifers that receive deliberate recharge of urban runoff do not appear to be imminently threatened by this practice at the two locations where it was investigated.

The conclusions provided by the NURP program for receiving waters can be viewed as recommendations for the abatement of pollution on receiving water bodies in an attempt to meet water quality standards.

Water Quality Criteria (WQC)

The EPA under section 304 of the Clean Water Act (CWA) has developed recommended water quality criteria. The criteria should provide guidance for states in selecting quality standards. The standards can be used in implementing limits based on environmental programs, such as NPDES permits. Recommended water quality criteria for selected pollutants are shown in Table 33.7.

Quality of urban runoff data given by the NURP and other investigations present a range of pollutants, but show high concentrations of metals, suspended solids, nutrients and bacteria. The recommended water quality criteria can be compared to the quality of urban runoff. A noticeable gap exists between runoff concentrations and water quality criteria. This shows that additional control and treatment is needed to improve the quality of receiving waters, which requires the development of management practices and control plans.

33.4 Modeling

The development of control plans or management practices for urban catchments requires a detailed understanding of all the inputs to urban runoff quality within the watershed. Modeling allows for a greater comprehension of the integrated urban water system. For situations that are best approached through modeling, the following rationales may be considered (WEF/ASCE, 1998):

- Characterize temporal and spatial details of quality and quantity of urban runoff;
- Perform frequency analysis to determine return periods for urban runoff quality parameters such as concentrations and loads;
- Determine configurations for urban runoff control options with regard to magnitude and location;
- Provide a drive for a receiving water quality model with quality and quantity of urban runoff as inputs; and
- Provide input for cost to benefit analyses.

Modeling Categories

When considering urban runoff quality, modeling can be useful in a planning, design, or operational situation. Three general modeling categories are available for approaching situations and are as follows (EPA, 1995a):

- Land Use Loading Models: These models provide pollutant loading as a function of the distribution of land use within the watershed. In this approach, water quality parameters may either be represented as constant concentrations or as unit loadings. Overall runoff quality is determined as a weighted sum of characteristic concentrations for the catchment.
- Statistical Methods: Often called the EPA Statistical Method, this technique is a more sophisticated rendering of Land Use Loading Models discussed above. It recognizes that Event Mean Concentrations (EMCs) are not constant but rather are distributed log normally. Combining the EMC distribution with distributed runoff volumes will yield the load distribution.
- Buildup/Washoff Models: These models attempt to simulate the "buildup" process where pollutants collect during dry weather periods and then "washoff" during storm events. By considering time periods, rainfall events, and management practices, the basic processes that control the quality of urban runoff can be investigated. For additional information on buildup/washoff models, see for example Novotny and Chesters (1981) or Delleur (1998).

Data

Regardless of the selected modeling approach, two types of data will be necessary. First, fundamental input data such as rainfall information, land slope, and water quality data will be necessary to compile most models. Potential sources for necessary water quality modeling data are contained in Table 33.8. Additionally, individual state agencies (such as departments of natural resources, departments of environmental management, or EPA) may be able to provide guidance on data collection. The second type of data represents the quality and quantity parameters the model attempts to characterize. It should be collected from sites within the modeled catchment and is used for the calibration of modeling results.

Point Source Models

Models analyzing point and nonpoint source pollution have been developed. Most point source modeling techniques are designed for modeling stormwater and combined sewer overflows. The Storm Water Management Model (SWMM) is a widely used model, which provides a complete simulation of the hydrologic, hydraulic, and environmental aspects of urban drainage systems. SWMM was developed in the 1970s for the EPA, is public domain, and is frequently updated. It performs both continuous and single-event simulation throughout the model and can perform quantity and quality modeling in detail. Each block of the model can simulate an aspect of urban runoff and jointly the model simulates the integrated urban water system. Figure 33.3 provides a schematic of principal blocks in the SWMM program. Other models of similar capabilities have been developed to simulate combined sewer systems and their effects on receiving waters. Such models include Statistical by EPA, STORM by HEC (Hydrologic Engineering Center) and others developed by various agencies. In some cases a particular model to be used may be specified. Given the dynamic nature of modeling and software development, evaluation of several models is necessary to ensure an appropriate model is selected. The MOUSE system (1992) is

TABLE 33.8 Data types and possible data sources (EPA, 1997b)

Data Type	Source		
	Federal Agencies	State Agencies	Local Groups
Land Geometry	USGS US Army Corps of Eng. Division/District Offices EPA	Special studies	Planning agencies
Stream Flow	USGS gage records and low flows (available through EPA)	Publications on low flows Basin plans	Universities Planning agencies
Water Quality Data	EPA STORET USGS US Fish & Wildlife Service	Regulatory agencies TMDL studies State Department of Health	Studies by regional planning groups Discharger's studies Universities
Wastewater Loads	EPA Permit Compliance System (PCS)	Discharge Monitoring Reports (DMR)	Municipal and industrial discharger's plant records
Nonpoint source loads	EPA STORET, USGS and US Fish and Wildlife Service; urban runoff data available from EPA NURP; precipitation and meteorological data available from NOAA National Climatic Weather Center; land use data from USGS; soil characteristic data from USDA Soil Conservation Service	Urban runoff data from special studies; precipitation and meteorological data from State planning agencies and local airports; land use data from State planning, agricultural and geological agencies.	Urban runoff data from regional, city and country studies; precipitation and meteorological data from local and county planning agencies and local airports; land use and soils characteristics data from regional and county planning, agricultural, and geological agencies.

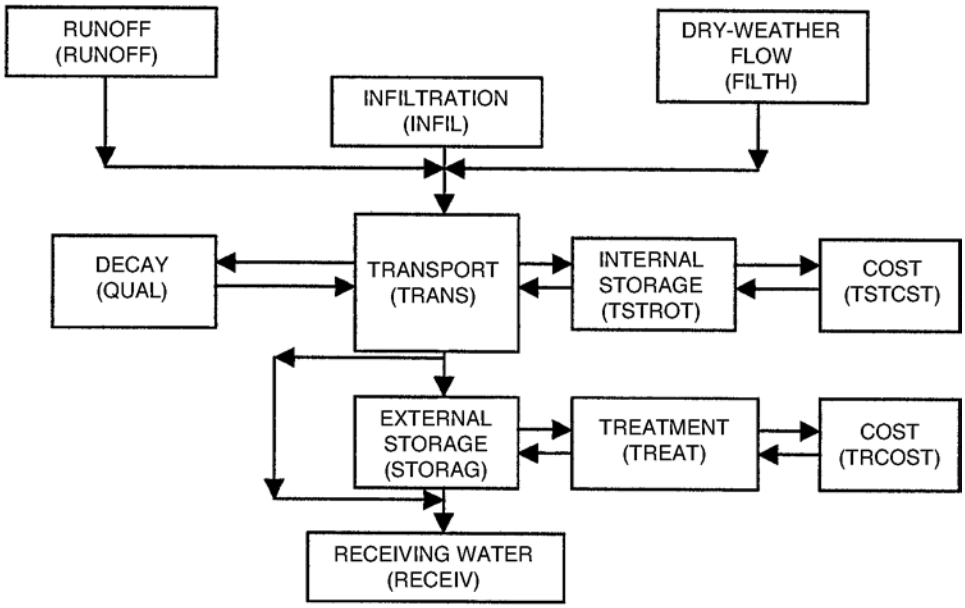

FIGURE 33.3 Components of the Storm Water Management Model (SWMM). Subroutines are in parentheses (EPA, 1971).

frequently used in Europe. Harremoës and Rauch (1996) and Krejci (1998) have advocated the integrated design and analysis of drainage systems, including sewers, treatment plants, and receiving waters.

Nonpoint Source Models

Nonpoint source modeling is a relatively new and rapidly evolving practice as much focus is being shifted towards eliminating nonpoint source pollution to improve water quality. Traditionally, models have focused on estimating the quantity of peak flow. However, much has been done recently to estimate the quality of runoff and receiving waters. A number of models have been developed to estimate and analyze urban nonpoint source pollution, and the following is a brief list of popular models:

- Storage-Treatment-Overflow-Runoff Model (STORM) (ACE, 1974)
- Stormwater Management Model (SWMM) (Huber and Dickinson, 1988)
- Hydrologic Simulation Program-FORTRAN (HSP-F) (Bicknell et al., 1997).

The above models were developed to analyze water pollution from nonpoint urban sources. Due to the geo-spatial variation involved with nonpoint source modeling, an additional tool is needed to further represent constituents over the watershed. Hence, the model can be linked to a geographic information system (GIS). Integrating the nonpoint source model with a GIS tool can provide many benefits including (Bhaduri, 2000):

- model-estimated nonpoint source pollution areas can be identified over the watershed;
- the integrated tools can produce useful information on changes in water quality following implementation of pollution reduction approaches; and
- it can also evaluate alternative management practices for the control of nonpoint source pollution.

The long-term hydrologic impact assessment (L-THIA) model has been developed to estimate the effect of urbanization on the quality of runoff and receiving waters. The nonpoint source model is based on the curve number (CN) method for estimating the quantity and quality of runoff. The model has been integrated with Arc/INFO software as a GIS (Geographic Information System) application. Figure 33.4 shows components of the L-THIA/GIS applications and steps involved in the analysis.

Modeling Considerations

The following fundamentals should be considered regardless of the model chosen or the type of pollution modeled (WEF, 1989 and WEF/ASCE, 1998):

- Develop a clear statement of the project objective. The need for quality modeling should be confirmed to prevent unnecessary modeling.
- The simplest model that will satisfy all project objectives should be chosen. A screening model, such as a statistical or regression method, may help determine if the problem calls for more complex models.
- Use a quality prediction approach that is consistent with available data.
- Predict only the quality parameters that are needed to analyze the problem. For example, do not use storm specific EMCs when the analysis only requires information to a seasonal or annual detail.
- When a model is chosen, perform a sensitivity analysis to become acquainted with the model.
- Have one data set available for calibration of the model and another to verify results obtained.

33.5 Best Management Practices

The gap between water quality criteria and pollutant concentrations found in urban runoff illustrates the urgent need to develop strategies to control runoff and improve quality of receiving waters. Regulations and public awareness have lead to the initiation of best management practices (BMPs) to provide comprehensive solutions.

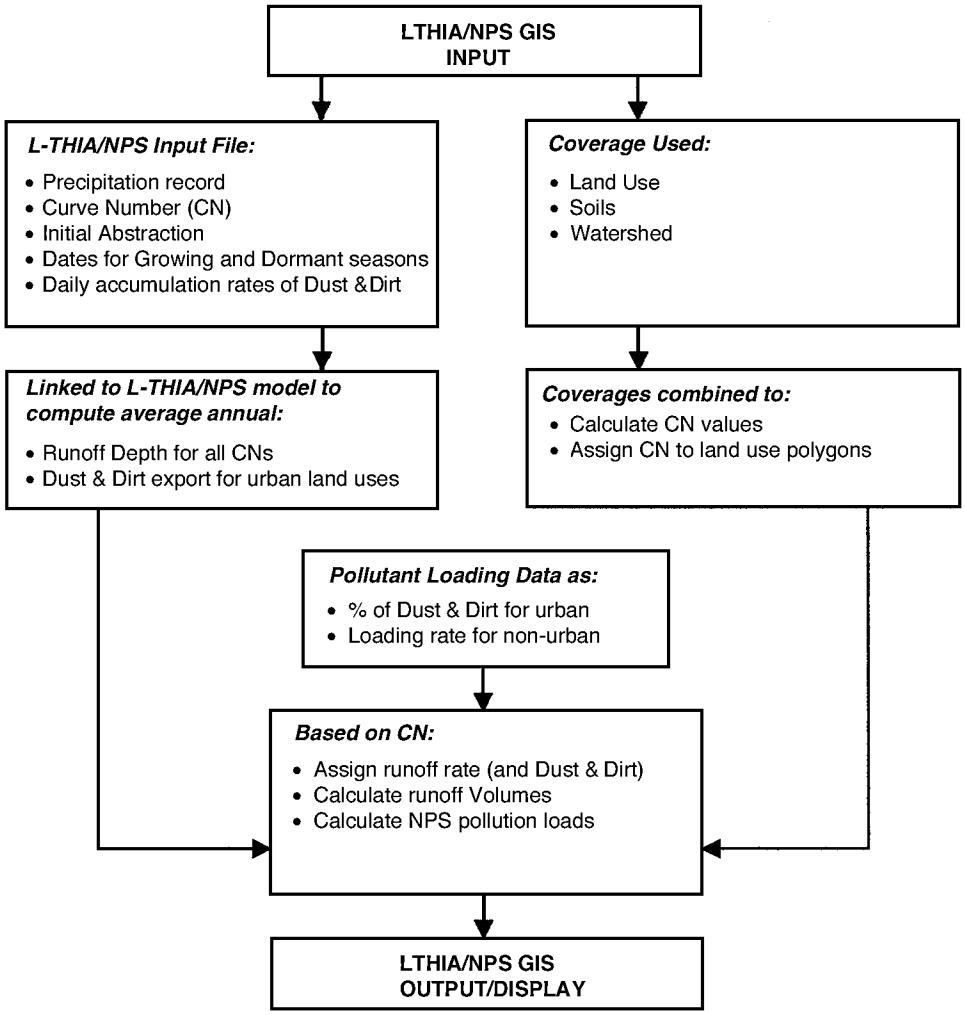

FIGURE 33.4 Components of L-THIA/nonpoint source (NPS) GIS applications and general steps involved in an analysis (Bhaduri et al., 2000).

A BMP can be viewed as a device, practice, or method for removing, reducing, or preventing stormwater runoff pollutants from reaching receiving waters (URS/ASCE/EPA, 1999). Selecting a best management practice involves technical and non-technical considerations. While technical issues are usually considered first, the non-technical issues can present many challenges. Major non-technical selection issues include federal, state, and local regulations, perceived water problems, uses of receiving water bodies, cost, and community perception. Technical issues include source control, local climate, design storm size, soil erosion, stormwater pollutant characteristics, multi-use management facilities, maintenance, and physical and environment factors (slope, area required, soil, water availability, aesthetics and safety, and additional environmental conditions) (WEF/ASCE, 1998).

Point Source Programs

The EPA has established a water quality based Combined Sewer Overflow Control Policy to serve as the framework for the control of CSOs through the NPDES (National Pollution Discharge Elimination System) permitting program. The policy encourages adoptions of overflow controls based on community need while meeting local environmental objectives. The fundamental principles are as follows (EPA, 1994):

1. clear levels of control to meet health and environmental objectives;
2. flexibility to consider the site-specific nature of CSOs and find the most cost-effective way to control them;
3. phased implementation of CSO controls to accommodate a community's financial capability; and
4. review and revision of water quality standards during the development of CSO control plans to reflect the site-specific wet weather impacts of CSOs.

EPA guidance documents for the Policy are continuously published and updated. Under the Policy, the first deadline occurred in 1997 requiring communities with CSOs to implement nine minimum technology-based controls. It was determined that implementation of the controls would reduce the prevalence and impacts of CSOs and would not require significant engineering studies or major construction. The nine minimum controls (NMC) are (EPA, 1995b):

1. Proper operation and regular maintenance programs for the sewer system and the CSOs
2. Maximum use of the collection system for storage
3. Review and modification of pretreatment requirements to assure CSO impacts are minimized
4. Maximization of flow to the publicly owned treatment works for treatment
5. Prohibition of CSOs during dry weather
6. Control of solid and floatable materials in CSOs
7. Pollution prevention
8. Public notification to ensure that the public receives adequate notification of CSO occurrences and CSO impacts
9. Monitoring to effectively characterize CSO impacts and the efficacy of CSO controls

The Policy also requires the development of a comprehensive Long Term Control Plan (LTCP). The LTCP should be integrated with review and revision of water quality standards. The following steps and Fig. 33.5 are useful in developing an effective LTCP that will ensure measures will be sufficient to meet water quality standards provided in EPA guidance documents (EPA, 2001a).

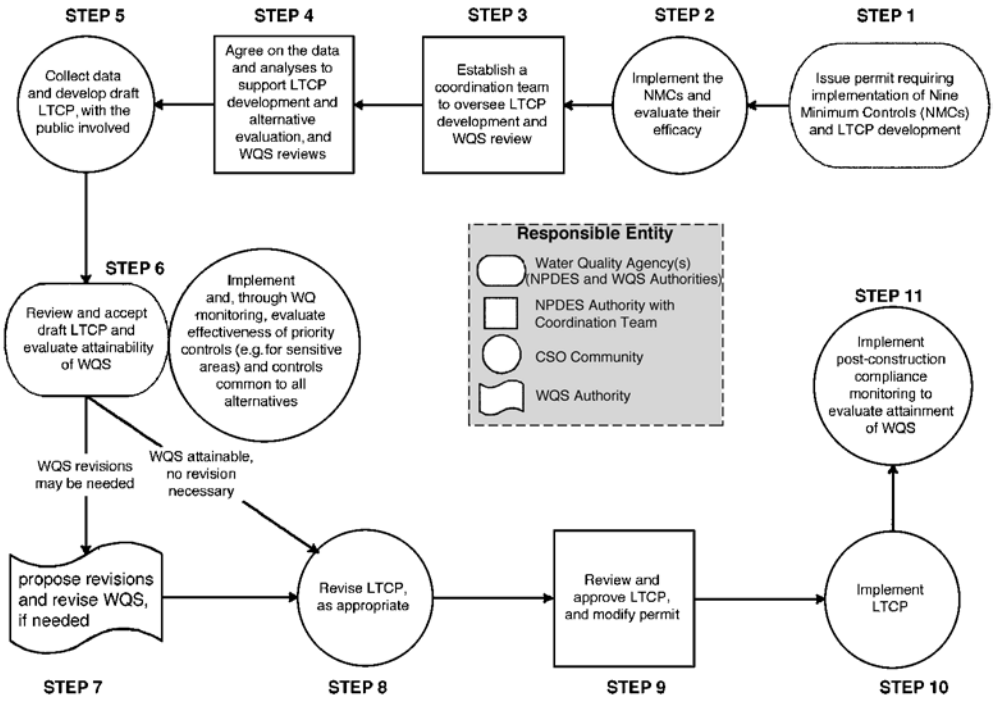

FIGURE 33.5 Steps for developing an effective long-term control plan (EPA, 2001a).

Step 1: Issue permit requiring implementation of the NMCs and LTCP. A permit or other enforceable mechanism requiring immediate action by the CSO community is issued the NPDES authority.

Step 2: Implement NMCs and evaluate their efficacy. The CSO community should evaluate the early level control of the NMCs in managing the number and quality of overflows. Ultimately the NMCs should be incorporated into the LTCP.

Step 3: Establish a coordination team to oversee LTCP development and WQS. The NPDES forms a team that will direct the development of a draft LTCP, promote timely discussion, and provide technical assistance. The coordination team should at minimum include decision-making representatives from the CSO community, State Water Director, and NPDES authority.

Step 4: Agree on the data and analyses to support LTCP development and alternative evaluation and WQS reviews. This step works toward early agreement on the planned process (i.e., milestones and dates) and scope of the LTCP. Additionally, type and amount of data and analyses necessary for control alternatives and water quality standards should be determined.

Step 5: Collect data and develop draft LTCP with public involvement. Following data collection, a draft LTCP is developed which evaluates the cost, feasibility, performance, water quality benefits, and sensitivity for each control. Other sources of pollution are identified that influence CSO receiving water quality.

Step 6: Review and accept draft LTCP and evaluate attainability of WQS. A draft LTCP is submitted to the NPDES authority and the State Water Director for review. The CSO community works with the reviewing agency to confirm the basis of the LTCP is acceptable to achieve WQS. Draft LTCP is revised if insufficient.

Step 7: Propose revisions and revise WQS if needed. To reach this step, all involved decision-making parties have agreed that the LTCP contains adequate data and information for the selection of CSO controls and needed WQS revisions have been identified. The state should quickly seek to revise WQS.

Step 8: Revise LTCP as appropriate. The CSO community would have to revise the draft LTCP if the WQS decisions differ from those anticipated or if the previously implemented controls have not performed as predicted.

Step 9: Review and modify LTCP and modify permit. The NPDES authority coordinates that review of the revisions and, if appropriate, approves the final LTCP. An enforceable permit is then issued requiring implementation of the approved LTCP.

Step 10: Implement LTCP. Approved control measures are implemented and approved operations plans and post-construction compliance monitoring program is carried out.

Step 11: Implement post-construction compliance monitoring to evaluate attainment of WQS. Monitoring data will be used to support changes to the operations plan if it is shown that implemented control measures are contributing to the non-attainment of WQS.

A similar policy (currently in the form of a rule) has been submitted by the EPA for SSO control. The rule seeks to revise existing NPDES permit regulations to improve the operation of municipal sanitary sewer collection systems, reduce the frequency and occurrence of sanitary sewer overflows, and provide more effective public notification when SSOs do occur. The rule largely addresses SSOs and will reduce overflows, provide better information for local communities, and extend lifetime for sanitary sewer systems. Requirements of the proposed rule quoted from the EPA include (EPA, 2001c):

- *Capacity Assurance, Management, Operation, and Maintenance Programs*. These programs will ensure that communities have adequate wastewater collection and treatment capacity and incorporate many standard operation and maintenance activities for good system performance. When implemented, these programs will provide for efficient operation of sanitary sewer collection systems.
- *Notifying the Public and Health Authorities*. Municipalities and other local interests will establish a locally tailored program that notifies the public of overflows according to the risk associated with specific overflow events. EPA is proposing that annual summaries of sewer overflows be made available to the public. The proposal also clarifies existing record-keeping requirements and requirements to report to the state.

- *Prohibition of Overflows*. The existing Clean Water Act prohibition of sanitary sewer overflows that discharge to surface waters is clarified to provide communities with limited protection from enforcement in cases where overflows are caused by factors beyond their reasonable control or severe natural conditions, provided there are no feasible alternatives.
- *Expanding Permit Coverage to Satellite Systems*. Satellite municipal collection systems are those collection systems where the owner or operator is different than the owner or operator of the treatment facility. Some 4800 satellite collection systems will be required to obtain NPDES permit coverage to include the requirements under this proposal

Total Maximum Daily Loads

Section 303 (d) of the Clean Water Act requires states to identify problem water bodies and develop **total maximum daily loads** (**TMDLs**), which set the maximum amount of pollution that a water body can receive without violating CWA water quality standards. The load includes end-of-pipe pollutants from point sources and nonpoint sources. Therefore, if nonpoint source pollution cannot be reduced, then more treatment is required for wastewater and more control is required for combined sewer systems. This is in response to the over 300,000 rivers and shoreline miles and five million acres of lakes across the U.S. that have been identified as polluted. The EPA defines a TMDL as a "pollution budget" and asserts that applicable water quality standards can be attained and maintained. If a state fails to develop TMDLs for their water bodies, the EPA is required under section 303 (d) of the Act to develop a priority list for the state and make its own TMDL determination. The EPA affirms that the TMDL rule will provide a comprehensive list of all U.S. polluted waters, require states to clean up polluted waters with cost-effective measures, and assure that TMDLs include implementation plans with defined milestones and timelines (EPA, 2000c).

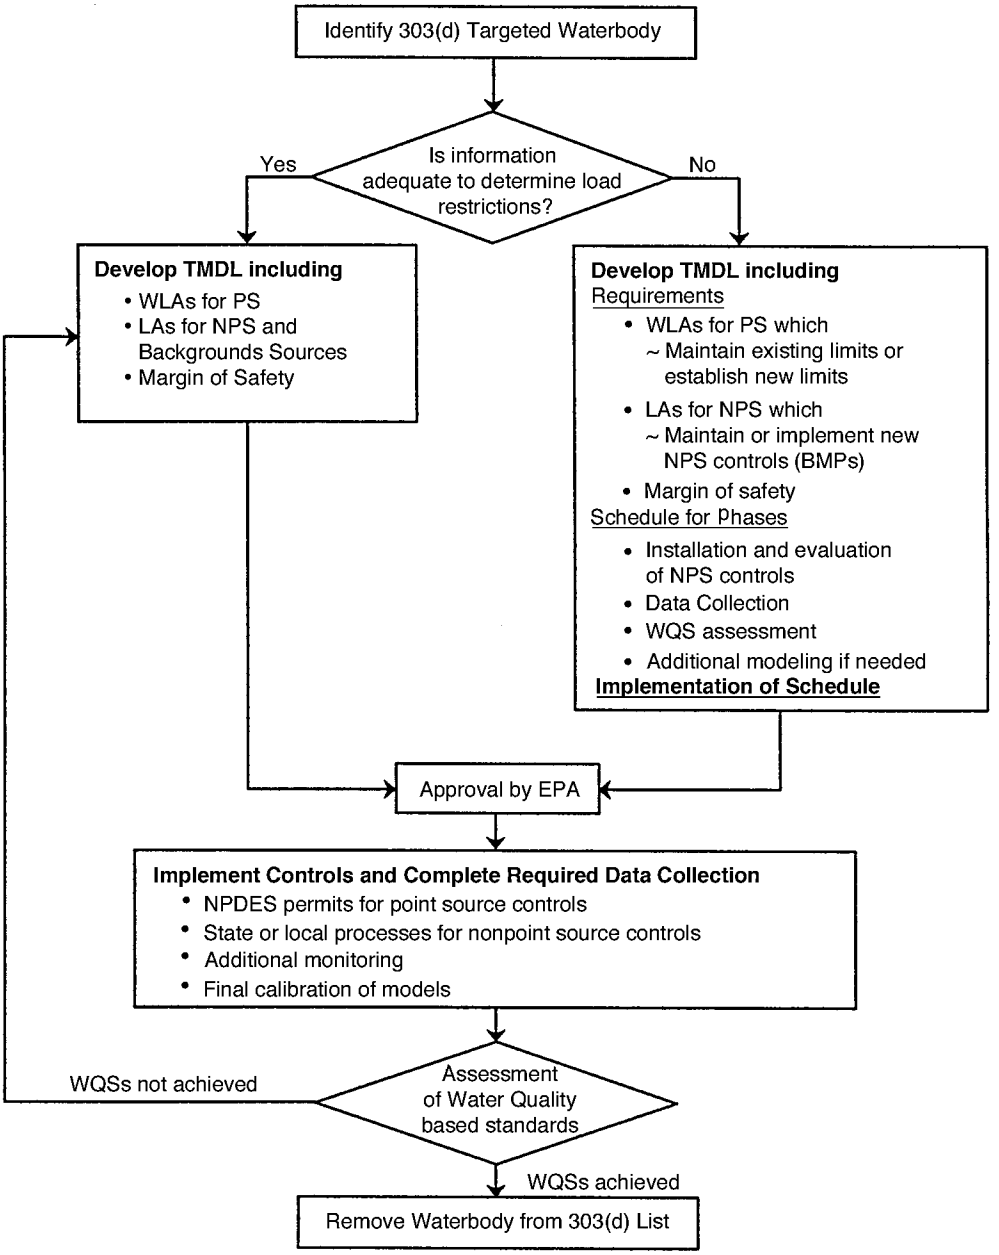
This TMDL control is likely to impact Midwestern states affected by CSOs as well as CFOs (confined feeding operations). The program requires an analysis of the watershed including developing a model to provide an accurate assessment of the pollution present within the watershed. A TMDL will consider all sources contributing to the depletion of water quality within the watershed. Therefore, developing load allocations for a TMDL plan is a critical process. Figure 33.6 illustrates the appropriate steps taken in developing load allocations for the implementation of a TMDL plan. As shown in the figure, when information needed to develop load allocations is not present, the TMDL process becomes very complicated and additional time is required (EPA, 2000c).

Components of a TMDL plan include identification of polluted waters, clean-up schedule, the TMDL program, and an implementation plan. The following are the elements of a TMDL program (EPA, 2000c):

- water body name and location, pollutant(s), and water quality standard;
- amount of pollutant allowable to meet standards, load reduction needed to meet standards, sources of pollutant, wasteload allocation for point and nonpoint sources, and an implementation plan;
- factor of safety to account for seasonal and other variations; and
- public feedback and involvement prior to submission.

The implementation plan accounting for all sources of pollution will include (EPA, 2000c):

- a list of actions needed to reduce loadings and a schedule of implementation;
- "reasonable assurances" that actions will be implemented (an NPDES permit is an assurance for point sources. For other sources, load allocations in a TMDL must apply to the pollutant, be implemented expeditiously, be accomplished through effective programs, and be supported by adequate water quality funding.);
- a monitoring plan with milestones;
- plans for revising the TMDL if no progress is made; and
- water quality standards must be met within 10 years.



NOTES:
i. LA = Load Allocation and WLA = Waste Load Allocation
ii. WQSs = Water Quality Standards
iii. PS = Point Source and NPS = Nonpoint Source

FIGURE 33.6 Flow chart showing steps taking in the development of a TMDL plan (EPA, 2000c).

A TMDL plan may require additional control measures (such as structural measures) to retrieve the quality of a waterbody to the specified criteria. The monitoring plan used to collect data will continue to assess the quality of the watershed. A waterbody is removed from the 303(d) list upon meeting water criteria. Otherwise, the TMDL must be modified by gathering additional data and information (EPA, 2000c).

Nonpoint Source Programs

A few selected nonpoint source programs are detailed below as they apply to the reduction of nonpoint source pollution.

The nonpoint source program (EPA, 2000a) is a state level program that focuses on educating the general public and implementing control measures termed BMPs to reduce nonpoint source pollution. In 1987, Congress enacted Section 319 of the Act to control nonpoint source pollution. Under Section 319, EPA provides technical and program assistance along with funding to the states. The National Monitoring Program (NMP) by the EPA as part of Section 319 establishes that the EPA shall collect information and make the following available:

- information concerning the costs and efficiencies of BMPs for the reduction of nonpoint source pollution; and
- data showing the relationship between water quality and implementation of various management practices.

The two objectives of Section 319 are to evaluate the effectiveness of watershed technologies designed to control nonpoint source pollution, and to improve the understanding of nonpoint source pollution.

Coastal Zone Management and Reauthorization Act (CZARA) of 1972 and Amendments of 1990 required coastal states and territories to develop programs to protect coastal water from runoff pollution. The program is administered by EPA and the National Oceanic and Atmospheric Administration.

The National Pollution Discharge Elimination System (NPDES) required municipal and industrial stormwater discharges to submit an NPDES permit under Phase I (1990) of Section 402 of the Clean Water Act. Phase I included municipalities with population over 100,000 and industrial stormwater discharges including construction sites of 5 acres or more. Phase II (1999) required municipalities with populations of less than 100,000 associated with commercial operations and light industries to develop stormwater management plans (EPA, 2000d).

Intermodal Surface Transportation Efficiency Act (ISTEA of 1991) is designed to improve the quality and condition of national highways and transportation systems. The act provided provisions for the mitigation of water pollution due to highway runoff.

Other nonpoint source programs include the National Estuary Program (NEP) established by the CWA and the pesticides program under the Federal Insecticide, Fungicide and Rodenticide Act. NEP focuses on pollution in high priority estuaries. The pesticides program concentrates on pesticides threatening surface and ground waters.

Structural Measures

The control of point and nonpoint source pollution may require the use of a structural measure. A structural measure is a strategy for control of the quality and quantity of urban runoff. Such measures impose additional capital and annual operations costs plus maintenance costs.

Various structural measures used to control urban runoff have evolved over the years in light of the recent regulations. Table 33.9 summarizes the opinions of senior stormwater quality management professionals about the design robustness of various stormwater quality controls. The effectiveness of such measures is site specific, and the removal of constituents from urban runoff depends on environmental and physical factors.

Wetlands can act as water retention facilities due to their capacity to store water. For example, a 1-acre wetland with a depth of 1 foot can hold over 330,000 gallons of water. Wetlands can provide several functions including water quality improvement, flood storage and the routing of stormwater runoff, cycling of nutrients and other material, habitat for fish and wildlife, recreational activities, education and research, and landscape enhancement. Performance has varied based on the location, type of wastewater, wetland design, climate, weather disturbance, and daily or seasonal variability. Therefore, it is very difficult to predict the performance of any given wetland system. Constructed wetlands can be surface flow,

TABLE 33.9 Robustness of Best Management Practice Design Technology (WEF/ASCE, 1998)

Type	Hydraulic Design	Removal of Constituents in Stormwater: Total Suspended Sediments and Solids	Dissolved	General Performance
Swale	Moderate-high	Low-moderate	None-low	Low
Buffer strip	Low-moderate	Low-moderate	None-low	Low
Infiltration basin	Moderate-high[a]	High	Moderate-high	Moderate
Percolation trench	Low-moderate[a]	High	Moderate-high	Moderate-high
Extended detention	High	Moderate-high	None-low	Moderate-high
Wet retention pond	High	High	Low-moderate	Moderate-high
Wetland	Moderate-high	Moderate-high	Low-moderate	Low-High[b]
Media filter	Low-moderate	Moderate-high	None-low	Low-moderate
Oil separator	Low-moderate	Low	None-low	Low
Catch basin Inserts	Unknown	NA[d]	NA	NA
Monolithic porous pavement[b]	Low-moderate	Moderate-high	Low-high[c]	Low-moderate
Modular porous pavement[b]	Moderate-high	Low-high	Low-high[c]	Low-high[c]

[a] Weakest design aspect, hydraulic or constituent removal, governs overall design robustness.
[b] Robustness is site-specific and maintenance dependent.
[c] Low-moderate whenever designed with an underdrain and not intended for infiltration and moderate-high when site specific permit infiltration.
[d] Not applicable.

subsurface flow, or a hybrid system. Subsurface flows have been proved to provide the highest removal efficiencies due to the presence of a substrate system, but are more expensive than surface wetlands.

Communities have several alternatives when controlling excessive flows while maintaining water quality criteria. Rehabilitation of sewers may improve the system, but will not provide additional capacity. Equalization basins are a viable alternative when CSOs and SSOs present a quality and quantity problem for a community. The combined flow is stored in the basin during wet weather flow and then discharged to the treatment plant during low peak periods. This provides for a consistent composition of wastewater (i.e., flow and constituents). An equalization basin can also store stormwater, which eventually may be discharged to a treatment plant or treated through a different system. The basin is typically designed to handle the first burst of stormwater, which carries the highest concentration of pollutants. This assures that overflow from the basin does not contribute a significant amount of pollution.

The majority of point source control practices target combined sewers. The type of CSO pollution abatement technology used may depend upon climate, topography, geologic conditions, and receiving water criteria of a particular location. A combination of technologies is often used. Most CSO structural practices can be grouped into the following four categories: offline storage/treatment, treatment, inline storage/control, and miscellaneous BMPs (WEF, 1989). Offline storage and treatment technologies divert combined flows into holding devices separated from the main flow and hold them until treatment capacity is available. In some cases, solids and floatables are removed during holding. CSO treatment facilities typically remove solids and floatables, chlorinate, and achieve some BOD removal. Inline storage and control methods work to store and divert flows online to ensure all combined flow is treated. Various best management practices, such as diversion weirs and system cleaning and rehabilitation, have been used successfully to control CSOs.

Defining Terms

Atmospheric deposition — The settling of pollutants by wind from various sources such as traffic, construction, and industrial sites.
BMP — Best Management Practice.
CFO — Confined Feeding Operation.

CSO — Combined Sewer Overflow.
CWA — Clean Water Act.
CZARA — Coastal Zone Management and Reauthorization Act.
EPA — Environmental Protection Agency.
Eutrophication — Excess nitrogen and phosphorus caused by over-fertilization. This can lead to algae blooms and other environmental problems.
Event mean concentration — The average pollutant concentration during the runoff caused by a storm event.
ISTEA — Intermodal Surface Transportation Efficiency Act.
LTCP — Long-Term Control Plan.
NEP — National Estuary Program.
NMP — National Monitoring Program.
NMC — Nine Minimum Controls.
Nonpoint source — A source of pollution, which is not considered point, generated from stormwater runoff, agricultural runoff and other sources of runoff.
NPDES — National Pollution Discharge Elimination System.
NURP — Nationwide Urban Runoff Program (EPA, 1983).
Point source — A source of pollution, which is usually traced to a pipe or outfall, such as CSOs, SSOs, POTWs, etc.
POTW — Publicly Owned Treatment Works.
Sewer infiltration — Flow that enters into the sewer system from underground sources, such as groundwater.
Sewer inflow — Flow that leaks into the sewer system from various diffuse sources.
SSO — Sanitary Sewer Overflow.
SWMM — Storm Water Management Model.
TMDL — Total Maximum Daily Load.
Urban runoff — All waters generated from urbanization including, but not limited to, stormwater runoff combined and separate sanitary overflows, and miscellaneous runoff.
Washoff — Amount of pollutant entrained by runoff from urban surfaces.
WQC — Water Quality Criteria.
WQS — Water Quality Standards.

34.1 Fundamentals

Introduction

This chapter on groundwater engineering is concerned with the occurrence, movement, use and quality of water below ground. The section on fundamentals deals with the definitions, the properties of the unsaturated and saturated zones, and the physics of the movement of subsurface water. Specific engineering applications such as well hydraulics, well construction, contaminant transport, containment of contaminants, landfills, and geostatistics are discussed in the following sections.

Subsurface Water

The **water table** is the level at which the groundwater is at atmospheric pressure. The zone between the ground surface and the water table is called the **vadose zone**. It contains some water that is held between

the soil particles by capillary forces. Immediately above the water table is the capillary fringe where the water fills the pores. The zone above the capillary fringe is often called the *unsaturated zone*. Below the capillary fringe is the *saturated zone*. The **saturation ratio** is the fraction of the volume of voids occupied by water. The water above the water table is below atmospheric pressure while the water below the water table is above atmospheric pressure. Only the water below the water table, the *groundwater*, is available to supply wells and springs. Recharge of the groundwater occurs primarily by percolation through the unsaturated zone. The geologic formations that yield water in usable quantities, to a well or a spring, are called **aquifers**. If the upper surface of the saturated zone in the aquifer is free to rise or to decline the aquifer is said to be an **unconfined aquifer**. The upper boundary at atmospheric pressure is the water table, also called the **phreatic surface**. If the water completely fills the formation the aquifer is **confined** and the saturated zone is the thickness of the aquifer. If the confining material is impermeable it is called an **aquiclude**. If the confining layer is somewhat permeable in the vertical direction, thus permitting slow recharge, it is called an **aquitard**. When a layer restricts downward infiltration towards the main water table, a *perched* aquifer with a separate **perched water** table may be formed. A perched aquifer is, in general, of limited areal extent, and if used as a water supply, extreme caution should be exerted because of its ephemeral nature. If the water in a well in a confined aquifer rises above the top of the aquifer, the water in the aquifer is under pressure, the well is called an **artesian well**, and the aquifer is in artesian condition. The *potentiometric surface,* also called the *piezometric surface* is defined as, the surface connecting the levels to which water will rise in several wells. If the piezometric surface is above the ground surface then a flowing well results.

Physical Properties

The *porosity*, *n,* is the ratio of the volume of voids, V_v, to the total volume, V_t, of the rock or soil:

$$n = V_v / V_t = \left[V_t - V_s\right] / V_t$$

where V_s is the volume of solids.

The *void ratio*, *e*, used in soil mechanics, is defined as $e = V_v/V_s$ so that $1/n = 1 + 1/e$. The fraction of void space between grains of soil or of unconsolidated rock is referred to as *primary porosity*. Porosity due to fracturing of the rock or chemical dissolution is called *secondary porosity*. Typical values of the porosity are given in the following Table 34.1. The *effective porosity*, n_e, is the pore fraction that actually contributes to the flow, isolated and dead end pores are excluded. In unconsolidated sediments coarser than 50 μm, n_e is of the order of 0.95 *n* to 0.98 *n*. When all the voids are occupied by water the soil is

TABLE 34.1 Values of Porosity, Permeability, and Hydraulic Conductivity

Material	Porosity *n* (%)	Permeability *k cm*^{2}	Hydraulic conductivity *K cm/s*
Unconsolidated deposit			
Gravel	25–40	10^{-3}–10^{-6}	10^{2}–10^{-1}
Sand	25–50	10^{-5}–10^{-9}	1–10^{-4}
Silt	35–50	10^{-8}–10^{-12}	10^{-4}–10^{-7}
Clay	40–70	10^{-12}–10^{-15}	10^{-7}–10^{-10}
Rocks			
Fractured basalt	5–50	10^{7}–10^{-11}	10^{-2}–10^{-6}
Karst limestone	5–50	10^{-5}–10^{-9}	1–10^{-4}
Sandstone	5–30	10^{-9}–10^{-13}	10^{-4}–10^{-8}
Limestone, dolomite	0–20	10^{-9}–10^{-12}	10^{-4}–10^{-7}
Shale	0–10	10^{-12}–10^{-16}	10^{-7}–10^{-11}
Fractured crystalline rock	0–10	10^{-7}–10^{-11}	10^{-2}–10^{-6}
Dense crystalline rock	0–5	10^{-13}–10^{-17}	10^{-8}–10^{-12}

saturated. Otherwise the fraction of the voids occupied by water is the volumetric *water content* designated by θ, which is dimensionless. When the soil is saturated, the soil moisture content is $\theta_s = n$. After the soil has been drained the remaining soil moisture is the *residual moisture content* θ_r. In unsaturated soils the *effective porosity* is $\theta_e = n - \theta_r$ and the *effective saturation* is defined as

$$s_e = (\theta - \theta_r)/(n - \theta_r)$$

The *hydraulic conductivity*, K, is a measure of the ability of water to flow through a porous medium. It is the volume rate of flow, Q, per unit gross area, A, of soil or rock under a hydraulic gradient $\partial h/\partial s$:

$$K = -(Q/A)(\partial h/\partial s)^{-1}$$

For *saturated flows* the hydraulic conductivity, K, depends on the porous medium through the *intrinsic permeability, k*, and on the fluid properties through the density, ρ, and the viscosity, μ. These properties are related by the following equation

$$K = k\rho g/\mu$$

so that a usual expression for k is

$$k = -(Q/A)(\mu/\rho g)(\partial h/\partial s)^{-1}$$

For spheres $k = C\,d^2$, where C is a constant, k has the dimension of L^2 and K has the units of $L/T.^{-1}$ Ranges of values of the permeability and hydraulic conductivity are given in Table 34.1. Several formulas exist in the literature that estimate the hydraulic conductivity of granular noncohesive materials. Most are of the form

$$K = (g/\nu)C\,\phi(n)\,d_e^2$$

where g = the acceleration of gravity
ν = the kinematic viscosity
C = a coefficient
$\phi(n)$ = a function of the porosity
d_e = the effective grain diameter, with the variables in a consistent set of units.

Vukovic and Soro (1992) list 10 formulas of this type. Two of the simplest formulas are the *Hazen formula* with $C = 6 \times 10^{-4}$, $\phi(n) = [1 + 10(n - 0.26)]$, $d_e = d_{10}$ which is applicable for 0.1 mm $< d_e <$ 3 mm and $d_{60}/d_{10} < 5$ and the *USBR formula* with $C = 4.8 \times 10^{-4}\, d_{20}^{0.3}$, $\phi(n) = 1$, $d_e = d_{20}$ and is applicable to medium sand grains with $d_{60}/d_{10}<5$ where d_{10} is the particle size such that 10% are finer.

When the flow occurs horizontally through a series of n equally thick layers in parallel, of hydraulic conductivities $K_1, K_2, \ldots, K_n$, the equivalent hydraulic conductivity of the system of layers is the arithmetic average of the conductivities. When the flows occurs vertically through a stack of n equal layers in series, the equivalent hydraulic conductivity of the system of layers is the harmonic mean of the conductivities

$$K = \frac{n}{\frac{1}{K_1} + \frac{1}{K_2} + \cdots + \frac{1}{K_n}}$$

For an anisotropic material with horizontal and vertical hydraulic conductivities K_x and K_y, respectively, the hydraulic conductivity at an angle α with the horizontal, K_α, is obtained from

$$\frac{1}{K_\alpha} = \frac{\cos^2\alpha}{K_x} + \frac{\sin^2\alpha}{K_y}$$

For an *unsaturated condition* the hydraulic conductivity is a function of the moisture content of the soil and is designated by $K(\theta)$. When the soil is saturated the *saturated hydraulic conductivity* is designated by K_s. The ratio of the hydraulic conductivity for a given moisture content to the saturated conductivity is the *relative conductivity*, K_r. Brooks and Corey (1964) gave the following formula for the hydraulic conductivity of unsaturated porous materials

$$K(\theta) = K_s\left[(\theta - \theta_r)/(n - \theta_r)\right]^{\lambda}$$

where λ is an experimentally obtained coefficient.

Other formulas have been given by Campbell (1974) and van Genuchten (1980).

The *transmissivity*, *T*, is the product of the hydraulic conductivity and the thickness, *b*, of the aquifer: $T = K\,b$. It has the units of L^2T^{-1} The *storage coefficient*, or *storativity*, *S*, is the volume of water yielded per unit area per unit drop of the piezometric surface. For unconfined aquifers the drop of the water table corresponds to a drainage of the pore space and the storage coefficient is also called the **specific yield**. In an unconfined aquifer the amount of water that can be stored per unit rise of the water table per unit area is called the *fillable porosity*, *f*, where $f = \theta_s - \theta$. In a confined aquifer, when the water pressure decreases the fluid expands and the fraction of the weight to be carried by the solid matrix increases, resulting in a decrease of the pore space. Since the compressibility of the water is very small its decompression contributes only a small fraction to the storage coefficient. The leakage of an overlying unconfined aquifer through an aquitard can also contribute to the yield of a semi-confined aquifer. Values of *S* typically vary between 5×10^{-2} and 10^{-5} for confined aquifers.

Darcy's Law

The *volumetric flow rate Q* $[L^3T^{-1}]$ across a gross area *A* of a formation with a hydraulic conductivity *K* $[LT^{-1}]$ under a hydraulic gradient $\partial h/\partial s$ in the *s* direction is given by Darcy's law

$$Q = -K\,A\,\partial h/\partial s = q\,A$$

where *q* is the *specific discharge* or flow rate per unit area $[LT^{-1}]$ also called *Darcy velocity*. The *hydraulic head h* is the sum of the elevation head *z* and the pressure head p/γ. The minus sign in the above equation indicates that the flow takes place from high to low head, namely in the direction of the decreasing head. The *pore velocity*, $v = q/n_e$, is the average flow velocity in the pores or the average velocity of transport of solutes that are non reactive.

The one-dimensional form of Darcy's law in a homogeneous medium of conductivity *K* is

$$q = K\left[(p_1/\gamma + z_1) - (p_2/\gamma + z_2)\right]/L$$

where the subscripts 1 and 2 refer to the two points at which the pressure head and the elevation head are considered and *L* is the distance between these points.

Darcy's law implies that the flow is laminar as is generally the case. However in some cases, as in karstic limestone and in rocks with large fractures, the flow may be turbulent. In such cases the flow rate is not proportional to the hydraulic gradient but to a power of the hydraulic gradient. Darcy's law as given above applies to *isotropic* media, that is, where the hydraulic conductivity is independent of direction. It also applies to flows where the direction of the hydraulic conductivity corresponds to the direction of the hydraulic gradient. In *non isotropic* media the hydraulic conductivity depends upon the direction. Then a hydraulic conductivity *tensor* is used and Darcy's law is expressed as a *tensor equation* (de Marsily, 1986).

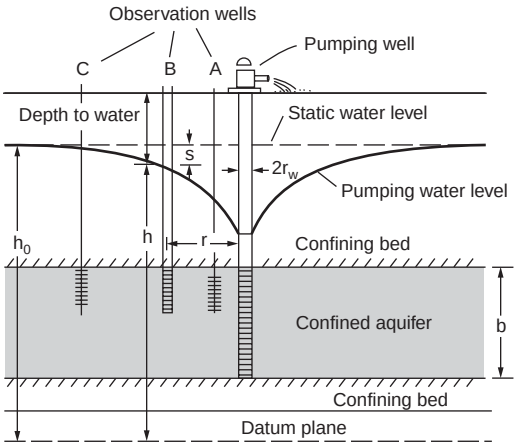

FIGURE 34.1 Well in a confined aquifer. (*Source*: Heath, R.C. 1998. *Basic Ground-Water Hydrology.* U.S. Geological Survey Water Supply Paper 2220, U.S. Government Printing Office.)

Dupuit Assumption

The one-dimensional form of Darcy's law applies to simple flow problems in the vertical or horizontal direction. In some cases with both horizontal and vertical components, the horizontal component dominates and the vertical component can be neglected. The flow can then be approximated as a horizontal flow uniform across the depth. This is the Dupuit assumption also sometimes referred to as the *Dupuit-Forchheimer* assumption.

34.2 Hydraulics of Wells

Steady Flow to a Well

The steady flow to a well of radius r_w fully penetrating a *confined* aquifer (Fig. 34.1) with a transmissivity T is given by the *Thiem equation*

$$Q = 2\pi T\left[h - h_w\right] / \ln\left(r/r_w\right)$$

where h = the hydraulic head at a distance r
h_w = the hydraulic head at the well

For a well fully penetrating an unconfined aquifer (Fig. 34.2) the equation for the flow rate obtained using the Dupuit assumption and neglecting the seepage face is:

$$Q = \pi K\left[h^2 - h_w^2\right] / \ln\left(r/r_w\right)$$

When solved for the head at the well, this equation does not yield accurate results because of the neglect of the vertical flow component.

Transient Flow to a Well

Pumping a well causes a *cone of depression*, or *drawdown*, of the water table of an unconfined aquifer or of the piezometric surface for a confined aquifer. The drawdown $s(r,t)$ at a distance r from a fully penetrating well at time t after the beginning of pumping at a constant rate Q from a confined aquifer with transmissivity T and storage constant S is given by the *Theis equation*:

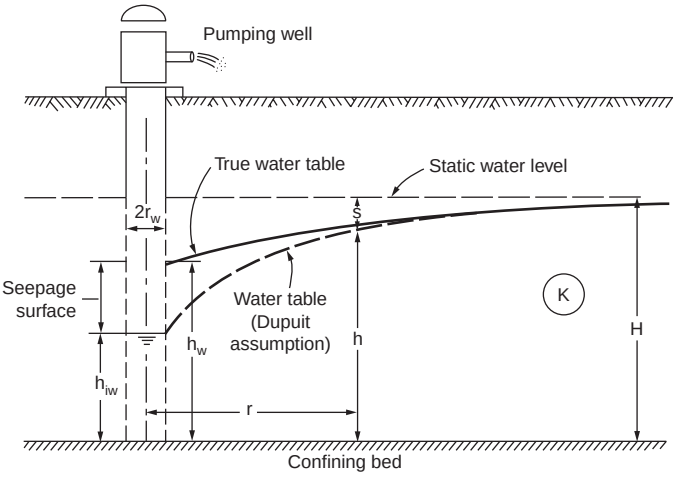

FIGURE 34.2 Well in a unconfined aquifer. (*Source:* Bouwer, H., 1978. *Ground Water Hydrology.* McGraw-Hill, New York.)

$$s(r,t) = \left[Q/(4\pi T)\right] \int_u^\infty \left(e^{-z}/z\right) dz = \left[Q/(4\pi T)\right] W(u)$$

where $u = r^2S/(4Tt)$.

The integral in this equation is the exponential integral also known as the *well function* $W(u)$. This function can be expanded as

$$W(u) = -0.577216 - \ln u + u - \frac{u^2}{2 \times 2!} + \frac{u^3}{3 \times 3!} - \cdots$$

For $u < 0.01$ only the first two terms need to be considered and the drawdown is approximated by Jacob's equation

$$s(r,t) = \left[2.30\, Q/(4\pi T)\right] \log_{10} \left[(2.25 T t)/(r^2 S)\right]$$

The drawdown from a unconfined aquifer with horizontal and vertical hydraulic conductivities K_r and K_z, respectively, has been given by Neuman (1975). A simplified form, given by Freeze and Cherry (1979), is

$$s(r,t) = \left[Q/(4\pi T)\right] W(u_a, u_b, \eta)$$

where

$$u_a = r^2 S/(4Tt), \quad u_b = r^2 S_y/(4Tt) \quad \eta = r^2 K_z/(b^2 K_r),$$

where b = the initial saturated thickness
S_y = the specific yield
S = the elastic storage coefficient

This solution is valid for $S_y \gg S$. Freeze and Cherry (1979) give a plot of the well function $W(u_a, u_b, \eta)$.

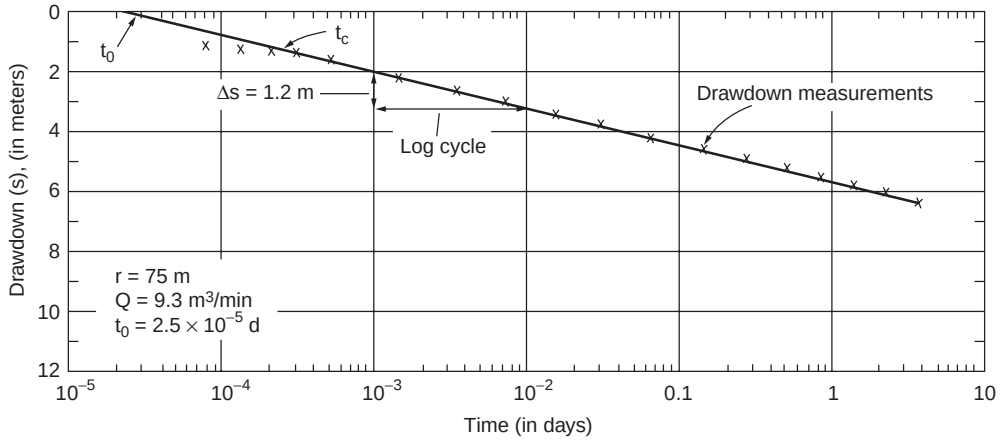

FIGURE 34.3 Time drawdown analysis (*Source*: Heath, R.C., 1998. *Basic Ground-Water Hydrology.*U.S. Geological Survey, Water Supply Paper 2220, U.S. Government Printing Office.)

For a pumped leaky confined aquifer with constants T and S, separated from an unpumped upper aquifer by an aquitard of thickness b' and constants K' and S', Hantush and Jacob (1955) obtained a relationship for the drawdown which can be written as

$$s(r,t) = \left[Q/(4T)\right] W\left(u, r/B\right)$$

where

$$u = \left(r^2 S\right)/(4Tt) \quad \text{and} \quad r/B = r\left[K'/(Tb')\right]^{1/2}$$

Values of $W(u, r/B)$ can be found in Bouwer (1978), Freeze and Cherry (1979) and Fetter (2001).

Pumping Tests

The hydraulic properties of aquifers can be determined by pumping a well at constant discharge and observing the drawdown at one or more observation wells for a period of time. For confined aquifers the Thiem *steady state* equation yields only the transmissivity

$$T = \left[Q \ln\left(r_2/r_1\right)\right]/\left[2\pi\left(s_1 - s_2\right)\right]$$

from the observed drawdowns s_1 and s_2 at distances r_1 and r_2 from the pumped well.

For confined aquifers the transient state Jacobs equation yields both the transmissivity and the storage constant based on a semi-log straight line plot (Fig. 34.3) of the observed drawdown (arithmetic scale) versus the time since pumping began (logarithmic scale) as

$$T = 2.3\, Q/(4\pi\Delta s) \qquad S = 2.25\, T\, t_o/r^2$$

where Δs = the increase in drawdown per log cycle of t
t_o = the time intercept of the straight line fitted through the drawdowns at the several times.

Only the observations corresponding to very small times violate Jacobs assumption that $u = r^2S/(4Tt) < 0.01$ and do not fall on the straight line. This approach is known as *time-drawdown* analysis. If simultaneous drawdown observations are taken at different distances, then the *distance drawdown* analysis can

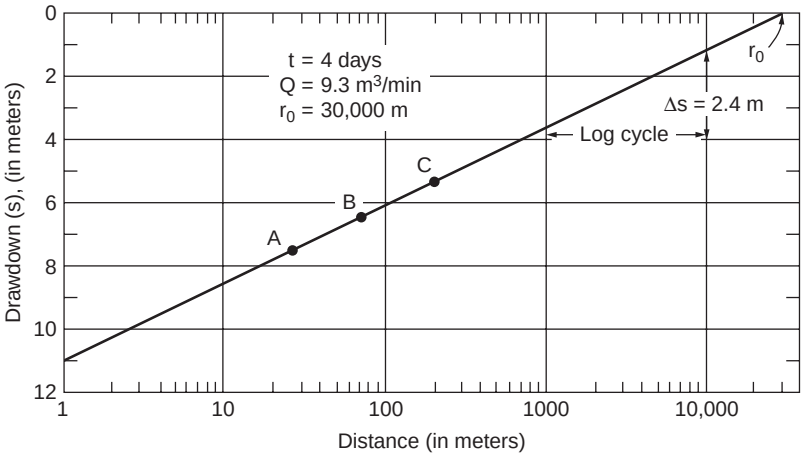

FIGURE 34.4 Distance-drawdown analysis. (*Source*: Heath, R.C. 1998. *Basic Ground-Water Hydrology.* U.S. Geological Survey, Water Supply Paper 2220, U.S. Government Printing Office.)

be used. In this latter approach a semi-logarithmic plot of the drawdown (arithmetic scale) vs. the distance r from the well (logarithmic scale) is used (Fig. 34.4) and the aquifer constants are given by

$$T = 2.3\,Q/(2\pi\Delta s) \qquad S = 2.25\,T\,t/r_0^2$$

where Δs = the drawdown across one log cycle of r
t = the time at which the drawdowns were measured
r_o = the distance intercept of the straight line fitted through the drawdowns at several distances.

Application of the Theis equation and solutions for unconfined aquifers require more elaborate graphic solutions (Bouwer, 1978; Fetter, 2001; Freeze and Cherry, 1979) or computer solutions (Boonstra, 1989, Kasenow and Pare, 1996).

The well test can also be performed using only the drawdown measurements at the pumped well without observation wells. This type of test is called the *single well test*. The previous equations assume laminar flow and a linear relationship between drawdown through the geologic formation and discharge. As the flow reaches the gravel pack around the well screen the velocity increases and the flow becomes turbulent except for very small pumping rates. The total drawdown at the well s_t is thus the sum of the formation drawdown s and the *well loss* s_w (Walton, 1962).

$$s_t = s + s_w = BQ + CQ^2$$

where the constant C is related to well characteristics.

If the well is pumped at different rates for the same length of time, a plot can be prepared of the total drawdown versus discharge. A tangent at the origin will separate the formation drawdown and the well loss. The time-drawdown plot is then performed for a constant discharge and the transmissivity is determined as before. A line is plotted parallel to the straight line portion of the time-drawdown observations at a distance s_w above the observations. This line determines the time intercept t_o used in the relationship for the storage constant S, (Fig. 34.5). For more details on well hydraulics and well tests see, for example, Boonstra (1999a).

Multiple Wells and Boundaries

For multiple wells the total drawdown s_t is the sum of the drawdowns due to the individual wells. For the case of a confined aquifer the Theis formula yields:

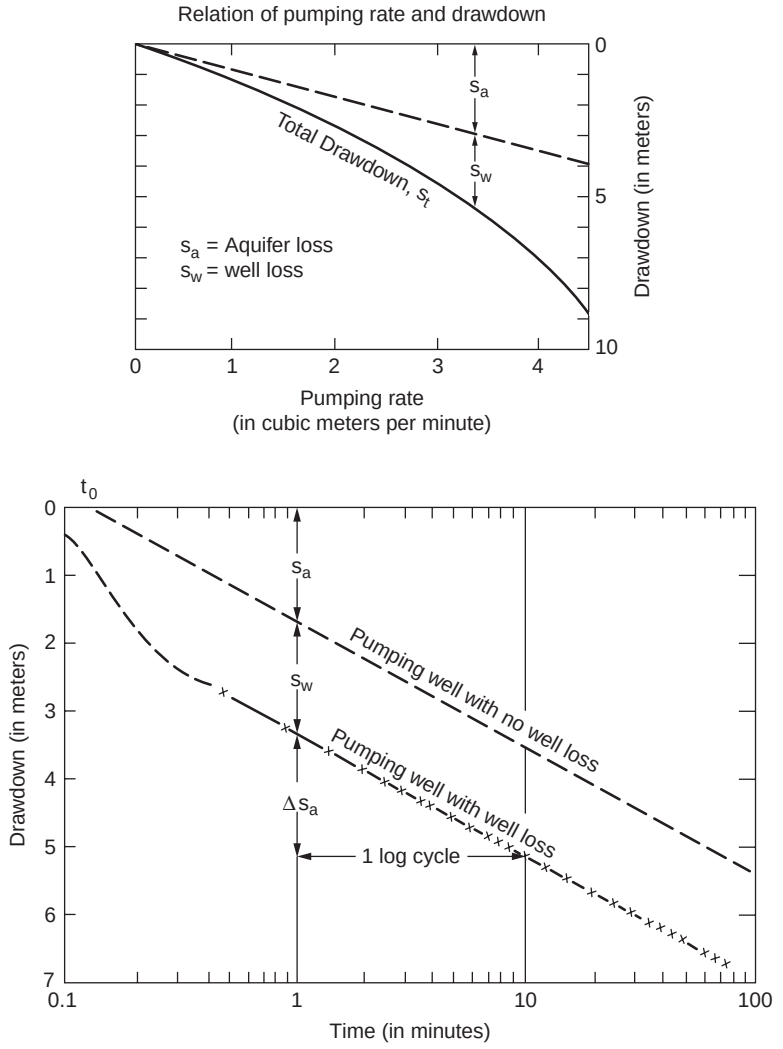

FIGURE 34.5 Single well test. (*Source*: Heath, R.C., 1998. *Basic Ground-Water Hydrology.* U.S. Geological Survey Water Supply Paper 2220, U.S. Government Printing Office.)

$$s_t = (4\pi T)^{-1}\left[Q_1 W(u_1) + Q_2 W(u_2) + \ldots\right]$$

where $u_i = r_i^2 S/(4\ Tt_i)$ in which r_i is the distance from the i th pumping well to the observation point
t_i = the time since pumping began at well i with a discharge Q_i

In the case of a pumping well and a *recharge well*, the change in the piezometric surface is the algebraic sum of the drawdown due to the pumped well and the buildup due to the recharge well. *Well interference* is an important matter in the design of well fields.

A recharge boundary or an impervious boundary within the cone of depression modifies the shape of the drawdown curve. The effect of a *perennial stream* close to a pumped well can be analyzed by considering an *image* recharge well operated at the same flow rate. The drawdown is the algebraic sum of the drawdowns due to the pumped and the image recharge wells. The resulting water level is constrained by the water surface elevation in the perennial stream. Similarly the effect of a vertical *impervious boundary* near a pumped well can be analyzed by considering an image pumping well operating at the same

discharge. The resulting drawdown is the sum of the drawdowns. The resultant water level is seen to be perpendicular to the vertical impervious boundary. This horizontal surface has no gradient at the boundary thus indicating that there is no flow, which is consistent with the requirement of an impervious boundary. More elaborate boundaries can be simulated by the method of images.

34.3 Well Design and Construction

Well Design

Well design includes the selection of the well diameter, total depth of the well, screen or open hole sections, gravel pack thickness and method of construction. The pumping rate determines the pump size, which in turn determines the well diameter. Well pump manufacturers provide information on the optimum well diameter and size of pump bowls for several anticipated well yields.

Generally water enters a well through a wire screen or a louvered or shuttered perforated casing. The screen diameter is selected so that the entrance velocity of the water does not exceed 0.1 ft/s (0.03m/s). Dividing the design discharge by this velocity gives the required open area of the screen. A safety factor of 1.5 to 2.0 is applied to this area to account for the fact that part of the screen may be blocked by gravel packed material. The manufacturers supply the open areas of screen per lineal foot for different slot sizes and screen diameters. The required length of the screen is obtained by dividing the required area by the open area per lineal foot. Screens are normally installed in the middle 70% to 80% of confined aquifers and the lower 30% to 40% of unconfined aquifers.

A gravel envelope or gravel pack (Fig. 34.6) is used around the screen to prevent fine material from entering the well. Gravel packs make it possible to use larger screen slots thus reducing the well loss. They also increase the effective radius of the well. Gravel packs are used in fine textured aquifers in which D_{90} (the sieve size retaining 90% of the material) is less than 0.25 mm and has a coefficient of uniformity $D_{40}/D_{90} < 3$. Wells dug through multiple layers of sand and clay are generally constructed with a gravel pack (Fig. 34.6). A sand bridge is usually provided at the top of the gravel pack to separate it from the impermeable grout that extends to the surface. The well casing should extend somewhat higher than the ground level and a concrete slab sloping away from the well is provided to prevent surface runoff from entering into the well.

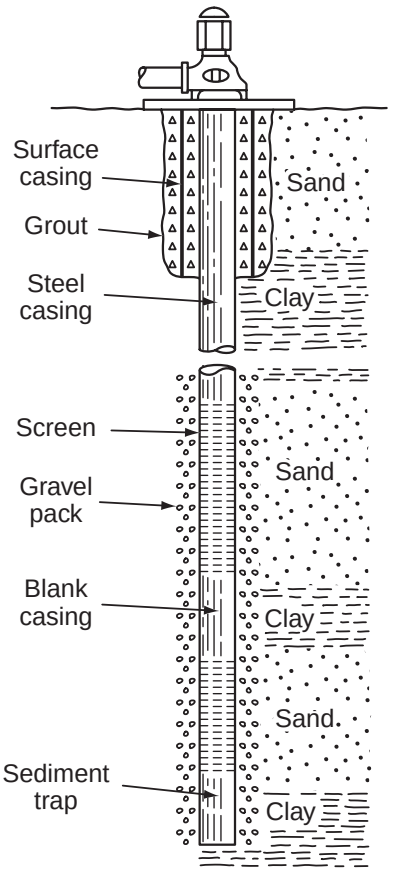

FIGURE 34.6 Supply well with multiple screen and gravel pack. (*Source*, Heath, R.C., 1998. *Basic Ground-Water Hydrology.* U.S. Geological Survey Water Supply Paper 2220, U.S. Government Printing Office.)

Construction Methods

The principal methods of well construction include digging, boring, driving, jetting, percussion drilling, hydraulic rotary drilling, and air rotary drilling. Table 34.2 indicates the suitability of the several well construction methods according to geologic conditions.

After the construction is completed the well is developed, stimulated, and sterilized. The removal of fine sand and construction mud is called *well development*. This can be accomplished by water or air

TABLE 34.2 Suitability of Different Well Construction Methods to Geologic Conditions

Characteristics	Dug	Bored	Driven	Jetted	Drilled

surging. *Stimulation* is a technique to increase the well production by loosening consolidated material around the well. For example, high-pressure liquid can be injected into the well to increase the size of the fractures in the rock surrounding the well. Finally, water supply wells should be *sterilized*. This can be done with chlorine or other disinfectant.

Centrifugal pumps are normally used for water supply wells. If the water level in the well is *below* the center line of the pump it is necessary to check that the available positive suction head exceeds the required positive suction head specified by the manufacturer in order to avoid cavitation. For high heads *multiple stage pumps* are used. *Submersible pumps* avoid the need of long shafts and are used for very deep wells. Drillers keep **well logs** or records of the geological formation encountered.

For further details about well drilling methods, well design, well screens, well pumps and their maintenance the reader is referred to the works of Driscoll (1986) and Boonstra (1999 b).

34.4 Land Subsidence

Introduction

Groundwater pumping causes a downward movement of the water table or of the piezometric surface which in turn can cause a downward movement of the land surface called subsidence or consolidation. This movement can be a few centimeters to several meters. If the subsidence is not uniform, the differential settlement can produce severe damage to structures.

Calculation of Subsidence

Consider a unit area of a horizontal plane at a depth Z below the ground surface. The total downward pressure P_t due to the weight of the overburden on the plane is resisted partly by the upward hydrostatic pressure P_h and partly by the *intergranular pressure* P_i exerted between the grains of the material:

$$P_t = P_h + P_i \quad \text{or} \quad P_i = P_t - P_h$$

A lowering of the water table results in a decrease of the hydrostatic pressure and a corresponding increase in the intergranular pressure. If P_{i1} and P_{i2} denote the intergranular pressures before and after a drop in the water table or piezometric surface, the subsidence S_u can be calculated as

$$S_u = Z\left[P_{i1} - P_{i2}\right]/E$$

where E is the modulus of elasticity of the soil.

If there are layers of different soil types, the subsidences are calculated for each layer and added to yield the total subsidence. As the modulus of elasticity of clayey materials is much less than that of sands and gravel, most of the settlement takes place in the clayey layers.

The previous equation can also be used to calculate the rebound when the intergranular pressure decreases. Caution must be exercised because the modulus of elasticity usually is not the same for decompression as for compression. This is particularly the case for clays. For Boston blue clay the rebound modulus of elasticity is only about 50% of that for compression (Bouwer,1978, p 323). If subsidence has occurred for a long time, complete rebound is unlikely to occur.

If there is an upward vertical flow, the head loss due to friction as the water flows in the pores results in an increase in the hydrostatic pressure. This in turn results in a decrease in the intergranular pressure. A condition known as *quicksand* is reached when the intergranular pressure vanishes and the sand loses its bearing capacity. Horizontal flow of the ground water can cause a lateral displacement that can result in damage to wells.

34.5 Contaminant Transport

Introduction

This section describes the transport and fate of constituents in groundwater. *Constituent* is a general term that does not necessarily imply a polluting substance. The *fate* of a constituent depends on its transport through the groundwater and includes possible decay or reactions that may occur. The nature, behavior and physicochemical characteristics of important groundwater contaminants have been described by Blatchley and Thompson (1999). Contaminant transport can occur by **advection, diffusion,** and dispersion. Transport of solutes can be accompanied by chemical processes such as precipitation, dissolution, **sorption**, radioactive decay and biochemical processes such as biodegradation.

Advection

Advection is the movement of a constituent as a result of the flow of the groundwater. It is the most important mechanism of solute transport. The average flow velocity in the pores v is obtained by dividing the Darcy or gross velocity by the effective porosity n_e or $v_x = -[K/n_e]/(\partial h/\partial x)$, where K is the hydraulic conductivity and $\partial h/\partial x$ is the hydraulic gradient. The one-dimensional differential equation for the advection transport in the x direction is given by:

$$\partial C/\partial t = -v_x\, \partial C/\partial x$$

where C is the solute concentration (M/L^3).

Diffusion and Dispersion

Diffusion is the spreading of the solute due to molecular activity. The mass flux of solute per unit area per unit time F is given by Fick's law; $F = -D_d\, (\partial C/\partial x)$, where C is the solute concentration (M/L^3) and D_d is the diffusion coefficient (L^2/T). For solutes in an infinite medium this coefficient is of the order of 10^{-9} to 2×10^{-9} m^2/s at 20° C and varies slightly with temperature. The diffusion coefficient in a porous medium is reduced by a factor of 0.1 to 0.7 for clays and sands, respectively (de Marsily, 1986, p 233) because of the *tortuosity* of the flow paths, and is designated by D^*. The variability of the pore sizes, the

multiplicity of flow paths of different lengths and the variation of the velocity distribution in the pores of different sizes result in a mechanical spreading known as dispersion. The *longitudinal* dispersion in the flow direction is larger than the *transverse* dispersion perpendicular to the flow direction. When advection and dispersion are the dominant transport mechanisms diffusion is a second order effect.

Molecular diffusion and **mechanical dispersion** are grouped under the term **hydrodynamic dispersion**. The longitudinal and transverse dispersion coefficients D_L and D_T, respectively, are given by

$$D_L = \alpha_L v_x + D^*$$

$$D_T = \alpha_T v_x + D^*.$$

where α_L and α_T = the longitudinal and transverse dynamic dispersivity
D^* = the molecular diffusion coefficient in the porous medium

The relative importance of the dynamic dispersivity and the molecular diffusion can be determined from the value of the *Peclet* number. It is defined as $P_e = v_x L/D_d$ where L is a characteristic length of the porous medium, generally taken as the mean diameter of the grains or the pores. The longitudinal advective dispersion dominates over the molecular diffusion when $P_e > 10$ and the transverse advective dispersion dominates when $P_e > 100$. The dispersion coefficients α_L and α_T are known to vary with the scale at which they are measured. Fetter (1999, p 80–86), as a first approximation, suggested the regression equation $\alpha_L = 0.1\ x$ where x is the flow distance. Other expressions can be found in the literature. For example, for the dispersivities measured in the field, called apparent dispersivities and designated by α_m, Neuman (1990) proposed $\alpha_m = 0.0175 L_s^{1.46}$ (both α_m and L_s are in meters) for travel distances L_s less than 3500 m and Xu and Eckstein (1995) proposed $\alpha_m = 0.83(\log L_s)^{2.414}$ (both α_m and L_s are in meters). This latter equation does not have the distance restriction that the Newman equation has.

The two-dimensional diffusion-dispersion in a flow in the x direction in an homogeneous aquifer is governed by the equation:

$$\partial C/\partial t = D_L\ \partial^2 C/\partial x^2 + D_T\ \partial^2 C/\partial y^2 - v_x\ \partial C/\partial x$$

Sorption

This discussion is limited to the cases of *adsorption* when the solute in the groundwater becomes attached to the surface of the porous medium and cation exchange when positively charged ions in the solute are attracted by negatively charged clay particles. The relationships relating the solute concentration C of a substance to the amount of that substance per unit mass in the solid phase, F, are called *isotherms* because they are determined at constant temperature. The simplest is the linear isotherm $F = K_d\ C$ where K_d is the distribution coefficient. Nonlinear isotherms have been proposed.

The effect of the adsorption is to retard the transport of the substance. The resulting one-dimensional advection-diffusion-dispersion equation for a flow in the x direction in an homogeneous aquifer is:

$$R\ \partial C/\partial t = D_L\ \partial^2 C/\partial x^2 - v_x\ \partial C/\partial x$$

where $R = 1 + K_d\ \rho_b/n_e$ is the *retardation factor* in which n_e is the effective porosity
ρ_b = the bulk density of the porous medium

Figure 34.7 shows a chemical spill with several constituents at similar concentrations and different retardation factors. Constituent 3 with $R = 3$ has more affinity for the soil matrix than constituents 2 or 1 with R values of 2 or 1, respectively. Thus constituent 3 will spend more time in association with the soil matrix than constituents 2 or 1. Contaminants with lower retardation factors are transported over greater distances over a given time period than contaminant with larger retardation factors. As a result, a monitoring well network has a greater chance of encountering contaminants with low retardation factors because they occupy a greater volume of the aquifer.

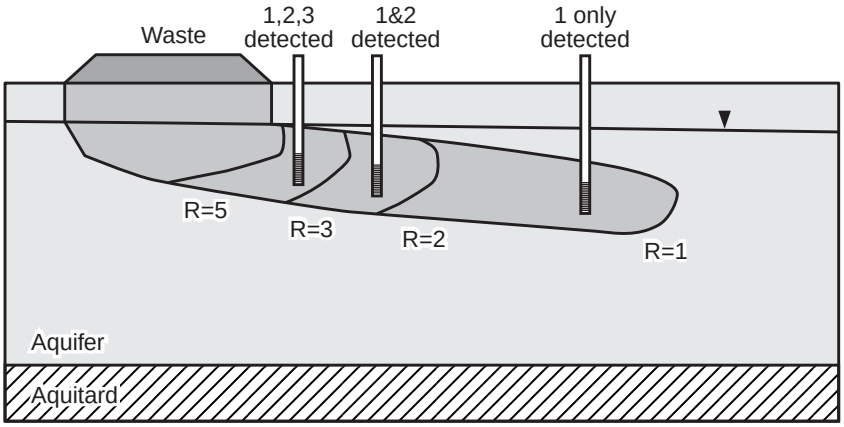

FIGURE 34.7 Transport of contaminants with several retardation factors at a waste site. (*Source:* U.S. Environmental protection Agency. 1989. *Transport and Fate of Contaminants in the Subsurface,* EPA/625/4–89/019.)

In the case of organic compounds the partition coefficient is $K_d = K_{oc} f_{oc}$ where K_{oc} is the partition coefficient with respect to organic carbon and f_{oc} is the fraction of organic carbon. A number of regression equations have been obtained that relate K_{oc} to the octanol-water partition coefficient and to the aqueous solubility (de Marsily, 1986, Fetter, 1999).

Multiphase Flow

Liquids that are not miscible with water are called **nonaqueous phase liquids** (**NAPL**). In the unsaturated zone four phases may be present: soil, water, air and NAPL. Many contaminant problems are associated with the movement of NAPL. The NAPL can have densities that are less than that of water and are called *light nonaqueous phase liquids* (**LNAPL**) or they can have densities that are larger than that of water and are called dense nonaqueous phase liquids (**DNAPL**). In an unconfined aquifer a LNAPL will tend to float near the water table whereas a DNAPL will tend to sink to the bottom of the aquifer. Figure 34.8 shows a schematic illustration of the behavior of LNAPL compounds. Under some conditions (a), the mass of an LNAPL spill is insufficient to allow penetration to the capillary fringe. With additional compound introduction (b), the LNAPL product will reach the water table and begin to spread, though the compound will not penetrate far beyond the phreatic surface. If the source of LNAPL is eliminated (c), removal of the NAPL will allow "rebound" of the water table. Figure 34.9 shows a schematic illustration of the behavior of DNAPL compounds. Under some conditions (A), the mass of DNAPL spill is insufficient to allow penetration to the capillary fringe; vertical movement of the DNAPL is by viscous fingering. With additional compound introduction (B,C), the DNAPL product will reach the water table and continue to move vertically until it reaches an impermeable boundary.

When two liquids compete for the pore space one will preferentially spread over the grain surface and wet it. The **wettability** depends upon the interfacial tension between the two fluids. In the case of oil-and-water systems, water is the wetting fluid in the saturated zone but in the unsaturated zone oil is the wetting fluid if the soil is very dry. The *relative permeability* is the ratio of the permeability of a fluid at a given saturation to the intrinsic permeability of the rock k. The relative permeability of the wetting fluid is designated by k_{rw} and that of the nonwetting fluid is k_{rnw}. For two phase flow Darcy's laws for the wetting and nonwetting liquids are respectively

$$Q_w = -\left[k_{rw} k \rho_w / \mu_w\right] A \, \partial h_w / \partial s$$

$$Q_{nw} = -\left[k_{rnw} k \rho_{nw} / \mu_{nw}\right] A \, \partial h_{nw} / \partial s$$

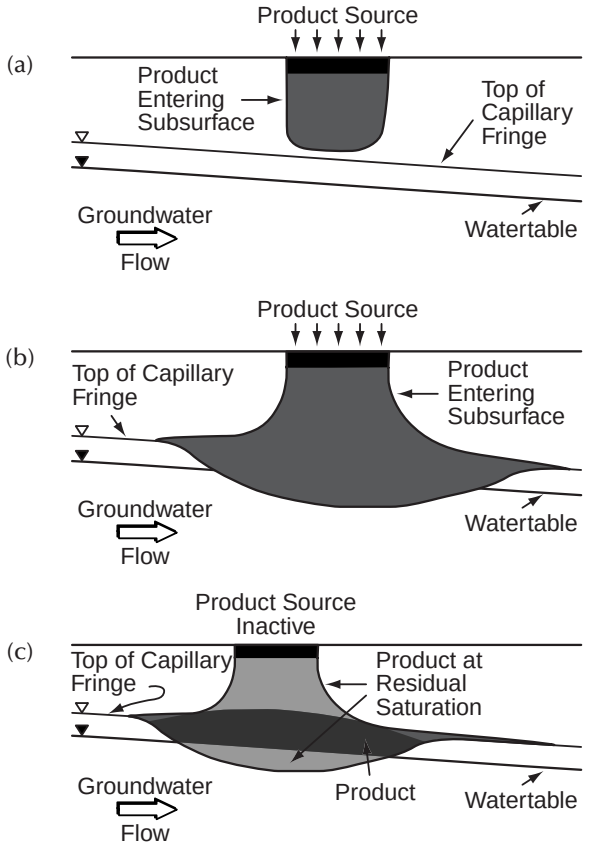

FIGURE 34.8 Movement of LNAPL into the subsurface (a) distribution of LNAPL after a small volume has been spilled; (b) depression of the capillary fringe and water table; (c) rebound of the water table as the LNAPL drains from overlying pore space. (*Source*: U.S. Environmental protection Agency. 1989. *Transport and Fate of Contaminants in the Subsurface,* EPA/625/4–89/019.)

where the subscripts *w* and *nw* refer to the wetting and nonwetting fluids, respectively, μ is the viscosity and *A* is the cross sectional area of the flow.

If an LNAPL (e.g., oil) is spilled on the ground it will infiltrate, move vertically in the vadose zone and, if sufficient quantity is available, eventually it will reach the top of the capillary fringe. Some *residual* NAPL remains in the vadose zone. As the NAPL (oil) accumulates over the capillary zone an *oil table* (oil surface at atmospheric pressure) forms and the water capillary fringe becomes thinner and eventually completely disappears. The oil table then rests on the water table (Abdul, 1988). The mobile oil below the oil table moves downward along the slope of the water capillary fringe. Soluble constituents of the LNAPL are dissolved in the ground water and are transported by advection and diffusion close to the water table. The residual NAPL left behind in the vadose zone partitions into vapor and liquid phases depending upon the degree of volatility and of water solubility. The thickness of LNAPL in a monitoring well is larger than that of free LNAPL in the subsurface.

If a DNAPL (e.g., chlorinated hydrocarbon) spills on the ground surface, under the force of gravity, it migrates through the vadose zone and through the saturated zone, eventually reaching an impervious layer. A layer of DNAPL then accumulates over the impervious layer. The mobile DNAPL then migrates along the slope of the impervious surface, which does not necessarily coincide with the slope of the water table and the direction of the ground flow. Monitoring wells placed just at the top of the impervious layer will show the presence of the DNAPL at the bottom of the well. If the well extends into the impervious

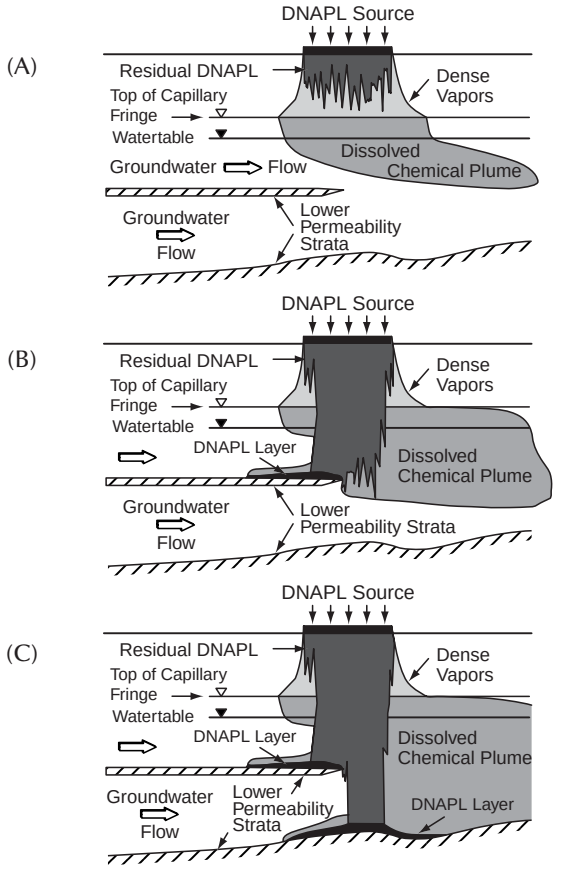

FIGURE 34.9 Movement of DNAPL into the subsurface : distributions of DNAPL after a small (A), moderate (B), and large (C) volumes have been spilled. (*Source*: U.S. Environmental Protection Agency. 1989. *Transport and Fate of Contaminants in the Subsurface,* EPA/625/4–89/019.)

layer the DNAPL will also fill that portion of the monitoring well below the impervious surface that acts as a sump.

34.6 Remediation

Monitoring Wells

Before any site remediation work is undertaken it is necessary to explore the aquifer and the extent of the ground water contamination. Monitoring wells are used principally for measuring the elevation of the water table or of the piezometric level, to collect water samples for chemical analysis and eventually observe the presence of nonaqueous phase liquids (lighter or denser than water) and to collect samples of these nonaqueous phase liquids. The equipment and supplies must be decontaminated before they are used in a water quality monitoring well.

If the purpose of the well is for observation of the water elevation only, a 1-in. casing is adequate. If water samples are required a 2-in. casing is necessary. Screens are used to allow the water into the well. In unconfined aquifers the screens must be placed so that they extend approximately from 5 ft. above the expected high water table to 5 ft below the expected low water table level. **Piezometer** screens for confined aquifers are shorter and generally have a length of 2 to 5 ft. The screen is surrounded by a *filter*

pack consisting of medium to coarse silica sand. The filter pack extends about 2 ft above the screen. A seal is placed on top of the filter pack. It consists of a 2-ft layer of fine sand and an optional 2-ft layer of granular bentonite for further sealing. If there is a leachate plume several wells with different depths and screen lengths may be necessary to intercept the plume. Multilevel sampling devices that are installed in a single casing have been developed.

Monitoring of the water quality in the vadose zone can be accomplished with *lysimeters,* which are installed in a bore hole above the water table. The lysimeter consists principally of a porous cup mounted at the lower end of a tube with a stopper at the upper end. As the soil water pressure is below atmospheric, suction must be applied so that the water penetrates the porous cup. The water accumulated in the porous cup is then pumped into a flask at ground level.

For more details on groundwater monitoring, see, for example, Houlihan and Lucia (1999a).

Removal and Containment of Contaminants

Control of the source will prevent the continued addition of pollutant. The three principal methods of source control are: removal, containment and hydrodynamic isolation. Removal of the source will require transportation of the waste and its final disposition in an environmentally acceptable manner. Containment of the waste can generally be accomplished by a cutoff wall made of soil-bentonite slurry or concrete. The waste can also be isolated hydrodynamically by installing a pumping well immediately downstream of the contaminant plume so that the flow through the contaminated zone is captured by the well. The shape of the *capture zone* with a single well at the origin of the coordinate axes has been given by Javandel and Tsang (1986) for a confined aquifer as

$$y = \pm Q/(2BU) - Q/(2\pi BU)\tan^{-1}(y/x)$$

where Q = the pumping rate
B = the thickness of the aquifer
U = the regional Darcy velocity

Javandel and Tsang (1986) also give equations for the capture zone formed by several wells. Figure 34.10 shows the capture zones for a single well for several values of Q/BU. The curve that fully encloses the plume is selected. The required pumping rate is obtained by multiplying the value of the parameter Q/BU by the product of the aquifer thickness, B, and the regional flow velocity, U.

Wellhead Protection

The Wellhead Protection Area is usually delimited as the capture zone of the well or well field limited by lines of equal travel time or *isochrones.* For a single well pumped at a rate Q in a confined aquifer of thickness B and regional Darcy velocity U, the curves of Fig. 34.10 show the capture zones in terms of the parameter Q/BU. The capture zone can thus be found for given values of Q, U, and B. The capture zone is an elongated area that extends in the up-gradient direction from a stagnation point located slightly down-gradient of the pumping well. It is possible to draw the streamlines inside the capture zone and to mark on them points of equal travel time to the well. The points with equal travel times can be connected by curves called isochrones. The one to three years isochrones are for short travel time and 5 to 10 years for long travel time. For example, the area from which the groundwater would reach the well in three years is called the three-year capture zone. In practice computer models are used to delineate the well head protection areas (see, for example, Haitjema, 1995). After the wellhead protection area is delineated, the potential sources of contaminant within the area are identified, management approaches are developed to protect the groundwater within the wellhead protection area and contingency plans are developed. In the U.S., this type of wellhead protection program is mandated by the Environmental Protection Agency for the preservation of the quality of groundwater used for production of drinking water.

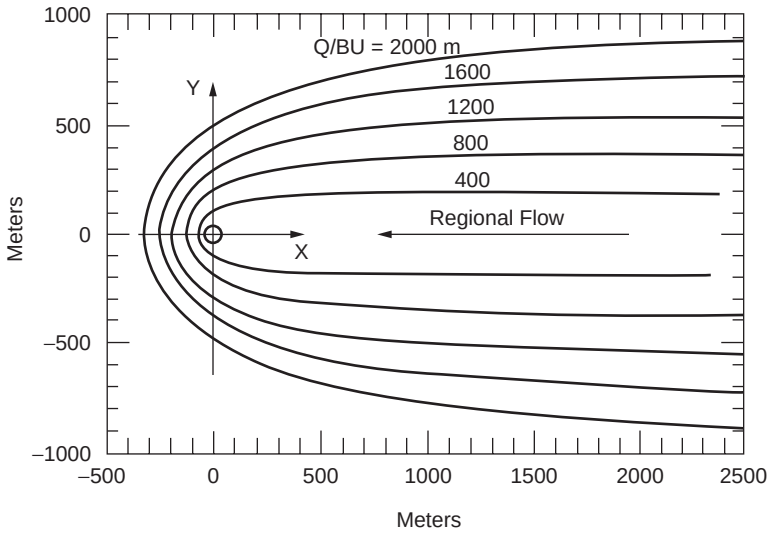

FIGURE 34.10 Capture zone for a single well in a confined aquifer. (*Source*: Javandel, I. and Tsang, C.F.,1986. Capture zone type curves: A tool for aquifer cleanup. *Ground Water* 24(5):616–625.)

Software

A modular semi-analytical model for the delineation of wellhead protection areas, WHPA, and a wellhead analytical element model, WhAEM are available from the U.S. Environmental Protection Agency (1998). The following description of WHPA is taken from the web site *http://www.epa.gov/esd/databases/whpa/abstract.htm*

"WHPA is applicable to homogeneous aquifers exhibiting two-dimensional, steady ground-water flow in an areal plane and appropriate for evaluating multiple aquifer types (i.e., confined, leaky-confined, and unconfined). The model is capable of simulating barrier or stream boundary conditions that exist over the entire depth of the aquifer. WHPA can account for multiple pumping and injection wells and can quantitatively assess the effects of uncertain input parameters on a delineated capture zone(s). Also, the program can be used as a postprocessor for two-dimensional numerical models of ground-water flow."

The following description of WhAEM is taken from the web site http://www.epa.gov/esd/databases/whaem/abstract.htm

"A computer-based tool used in the wellhead protection decision-making process to delineate ground-water capture zones and isochrones of residence times. Unlike similar programs, WhAEM can accommodate fairly realistic boundary conditions, such as streams, lakes, and aquifer recharge due to precipitation."

34.7 Landfills

A typical landfill consists of three major layers: a top, a middle and a bottom subprofile (Fig. 34.11). The purpose of the top subprofile is to cover the waste, to minimize the rainfall infiltration into the waste and to provide an exterior surface that is resistant to erosion and deterioration. The middle subprofile includes the waste layer, a lateral drainage layer with the leachate collection system underlain by a flexible membrane liner. The bottom subprofile includes an additional drainage layer, a leakage detection system and a barrier soil liner.

The design and operation of landfills are controlled by federal and local regulations. The federal regulations include Subtitle C landfill regulations of the Resource Conservation and Recovery Act (RCRA) as amended by the Hazardous and Solid Waste Amendments (HSWA) of 1984 and the Minimum Technology Guidance, (EPA 1988). The RCRA regulations mandate that below the waste layer there must

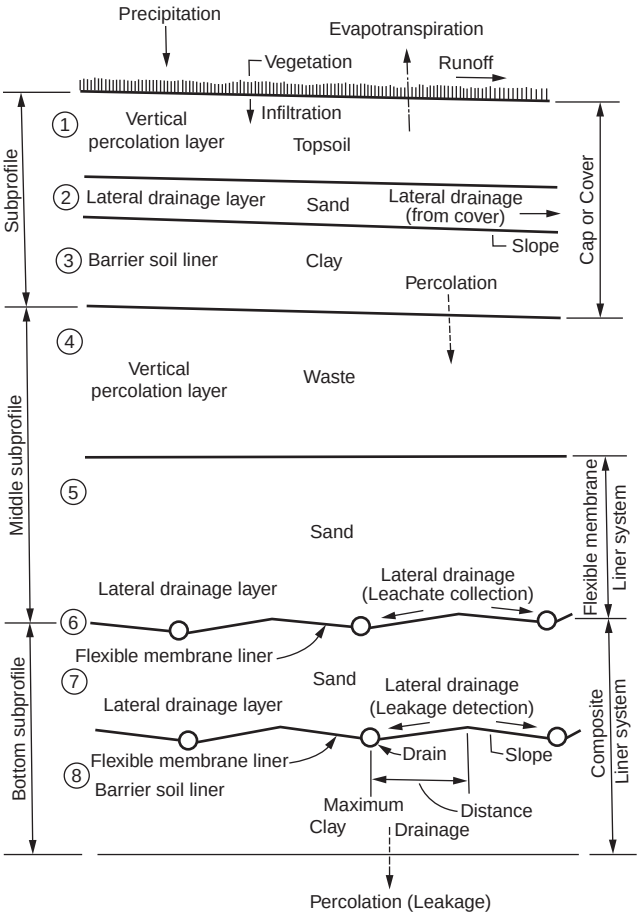

FIGURE 34.11 Landfill profile. (*Source*, Schroeder, P.R., Peyton, R.L., McEnroe, B.M., and Sjostro, J.W. 1992a, *Hydrologic Evaluation of Landfill Performance* (*HELP*) *Model, vol. III: User's Guide for Version* 2. Department of the Army.)

be double liners with a leak detection system. According to the guidance the double liner system includes a synthetic liner, a secondary leachate collection system and a composite liner consisting of a synthetic liner over a low permeability soil or a thick low permeability soil liner. The soil liner should have an in-place hydraulic conductivity not exceeding $1x10^{-7}$ cm/sec and a thickness of at least 3 ft. The primary and secondary leachate collection systems should include a drainage layer with a thickness of at least 1 ft with a saturated hydraulic conductivity of at least 1×10^{-2} cm/sec and a minimum bottom slope of 2%. The leachate depth cannot exceed 1 ft.

The simplified steady state equations governing the moisture flow through the landfill as given by Peyton and Schroeder (1990) are as follows. The lateral drainage per unit area Q_D is given by

$$Q_D = 2C_1 K_D Y h_o / L^2$$

where K_D = the saturated hydraulic conductivity of the lateral drainage layer, (Fig. 34.12)
Y = the average saturated depth over the liner (in.)
h_o = the head above the drain at the crest of the drainage layer (in.)
L = the drainage length (in.)
$C_1 = 0.510 + 0.00205\alpha L$, where α is the dimensionless slope of the drainage layer(ft/ft)

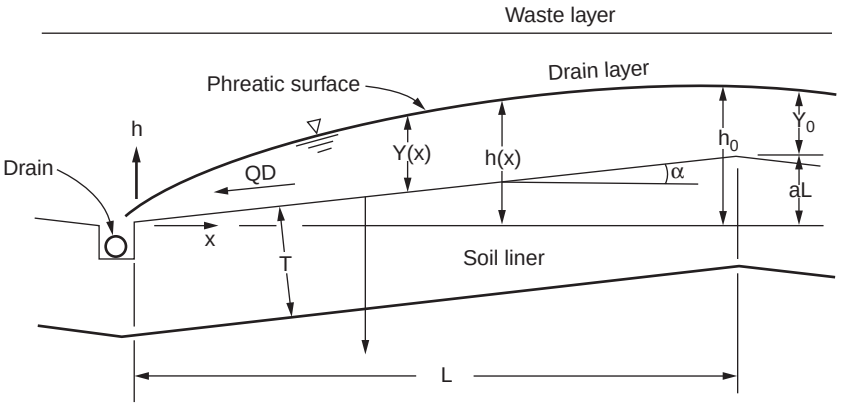

FIGURE 34.12 Landfill drainage layer. (*Source:* Peyton R.L. and Schroeder, P.R., 1990. Evaluation of landfill liner designs. *J. Environ. Eng., ASCE.* 116(3):421–437.)

The saturated depth at the crest of the drainage layer, Y_o (in.) is

$$Y_o = Y^{1.16} / [\alpha L]^{0.16}$$

and the vertical percolation rate through the soil liner Q_P is given by:

$$Q_P = L_F K_P [Y + T] / T$$

where L_F = the synthetic liner leakage factor
K_P = the saturated hydraulic conductivity of the soil liner
T = the thickness of the soil liner

Graphs for the estimation of the synthetic liner leakage factor can be found in Peyton and Schroeder (1990) and in Schroeder et al. (1992 a, b). The Hydrologic Evaluation of Landfill Performance model (HELP, Schroeder, et al. 1992 a, b) solves extended forms of the above equations for Q_P, Q_D, and Y. For more details on landfills, see, for example, Repetto (1999).

Software

The Computer program "Hydrologic Evaluation of Landfill Performance "(HELP) Version 3 can be downloaded from the U.S. Army Corps of Engineers Waterways Experiment Station web site (*http://www.wes.army.mil/el/elmodels/helpinfo.html*). The model computes estimates of water balance for municipal landfills, RCRA and CERCLA facilities and other confined facilities for dredged material disposal. Other related software is available from EPA and is listed on the Web site *http://www.epa.gov/esd/databases/datahome.htm*.

34.8 Geostatistics

Definition of Kriging

Hydrologic and hydrogeologic variables such as hydraulic conductivity, hydraulic head, storage coefficient, transmissivity, rainfall and solute concentration are functions of space. These quantities, although very variable, are not completely random and often exhibit a spatial correlation or structure. The study of such variables was developed by Matheron (1971) under the name *regionalized variables*. **Kriging** is a method of optimal estimation of the magnitude of a regionalized variable at a point or over an area,

given the observations of this variable at a number of locations. Kriging also provides the variance of the estimation error. Kriging is useful for the estimation of the variable at the nodes of a network of points to develop contour maps of the variable. An estimate of the mean value of the variable on a given block or pixel is useful in Geographic Information Systems (GIS). It is also useful in the optimization of observation networks, for example by choosing the additional location that minimizes the uncertainty or by choosing the location to be removed that minimizes the error increment. Kriging provides the best (in the mean square sense of minimizing the error covariance) linear unbiased estimate.

Stationary and Intrinsic Cases

In the stationary case the mean m of the observations $Z(\boldsymbol{x})$ at $\boldsymbol{x} = (x,y,z)$ is the same everywhere and the correlation between two observations $Z(\boldsymbol{x}_1)$ and $Z(\boldsymbol{x}_2)$ depends only on their relative separation distance $\boldsymbol{h} = \boldsymbol{x}_1 - \boldsymbol{x}_2$ or

$$E\left[Z(\boldsymbol{x})\right] = m$$

$$E\left\{\left[Z(\boldsymbol{x}_1) - m\right]\left[z(\boldsymbol{x}_2) - m\right]\right\} = C(\boldsymbol{h})$$

where $C(\boldsymbol{h})$ is called the *covariance* function.

A useful generalization is the intrinsic case in which the increments of the variables are stationary. In the intrinsic case

$$E\left[Z(\boldsymbol{x}_1) - Z(\boldsymbol{x}_2)\right] = 0$$

$$E\left\{\left[Z(\boldsymbol{x}_1) - Z(\boldsymbol{x}_2)\right]^2\right\} = 2\gamma(\boldsymbol{h})$$

where $\gamma(\boldsymbol{h})$ = the semivariogram
$2\gamma(\boldsymbol{h})$ = the variogram

The variogram must satisfy some specific mathematical requirements. Examples of acceptable semivariogram functions include the following (de Marsily, 1986, p 303 or Kitinadis, 1993, p.20.6):

the power model	ωh^{λ}	$\lambda < 2$
the spherical model	$\omega[3/2(h/a) - \frac{1}{2}(h/a)^3]$	$h < a$
	ω	$h > a$
the exponential model	$\omega[1 - \exp(-h/a)]$	
the gaussian model	$\omega\{1 - \exp[-(h/a)^2]\}$	

where h is the length of the vector $\boldsymbol{h}$ and the parameters ω, a and λ are selected to fit the empirical semivariogram.

Estimation

The pairs of observation points are classified according to distances, d_1, d_2, d_3,…, for example $0 < d_1 <$ 1 km, $1 < d_2 < 2$ km, $2 < d_3 < 4$ km, etc.. For each class the average distance and the average of $\frac{1}{2}(Z_i - Z_j)^2$ are calculated. The plot of these quantities (the mean distances against the half mean squares of the observation differences) is the *empirical semivariogram*. An acceptable semivariogram is fitted to the empirical one. The estimate Z_o^* of the variable Z at the desired point $\boldsymbol{x}_o$ based on the *observations* Z_i at the points $\boldsymbol{x}_i$, $i = 1\ldots..n$ is

$$Z_o^* = \Sigma_i \lambda_o^j Z_i$$

The kriging coefficients λ_o^j are obtained from the kriging equations (de Marsily, 1986, p. 296)

$$\sum_j \lambda_o^j \gamma(\boldsymbol{x}_i - \boldsymbol{x}_j) + \mu = \gamma(\boldsymbol{x}_i - \boldsymbol{x}_o), \quad i = 1,\ldots,n$$

and the unbiasedness constraint is

$$\sum_i \lambda_o^i = 1$$

where λ_o^j and μ = the unknowns
$\gamma(\boldsymbol{x}_i - \boldsymbol{x}_i)$ = the fitted semivariogram values for the distance between the observation points $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$
$\gamma(\boldsymbol{x}_i - \boldsymbol{x}_o)$ = fitted semivariogram values for the distances between the observation points $\boldsymbol{x}_i$ and the point $\boldsymbol{x}_o$ at which the estimate is being obtained

The variance of the error of estimation, σ^2, is

$$\sigma^2 = \sum_i \lambda_o^i \gamma(\boldsymbol{x}_i - \boldsymbol{x}_o) + \mu$$

and the 95% confidence interval of the estimate is approximately

$$Z_o^* = \sum_i \lambda_o^i Z_i \pm 2\sigma$$

Extension

The methodology can be extended to the cases of two or more observation variables that are correlated. This extended technique is known as *cokriging* and its estimate is superior to that obtained by kriging each variable independently without considering their correlation.

For more details on geostatistics, see, for example, Kitinadis (1999)

Software

Two public domain software packages have been developed by EPA: GEOEAS, which is a geostatistical environmental assessment package (Englund and Sparks, 1988), can be downloaded from the EPA web site *http://www.epa.gov/esd/databases/geo-eas/abstract.htm)* and GEOPACK, which is a geostatistical package (Yates and Yates, 1989), can be downloaded from the EPA web site *http://www.epa.gov/esd/databases/geo-pack/abstract.htm*).

The following desription of GEOEAS is taken from the web site *http://www.epa.gov/esd/databases/geo-eas/ abstract.htm.*

"A collection of interactive software tools for performing two-dimensional geostatistical analyses of spatially distributed data. The principal functions of the package are the production of grids and contour maps of interpolated (kriged) estimates from sample data. Geo-EAS can produce data maps, univariate statistics, scatter plots/linear regression, and variogram computation and model fitting."

The following description of GEOPACK is taken from the web site *http://www.epa.gov/esd/databases/geo-pack/ abstract.htm.*

"A comprehensive geostatistical software package that allows both novice and advanced users to undertake geostatistical analyses of spatially correlated data. The program generates graphics (i.e., linear or logarithmic line plots, contour and block diagrams); computes basic statistics (i.e., mean, median, variance, standard deviation, skew, and kurtosis); runs programs for linear regression, polynomial regression, and Kolomogorov-Smirnov tests; performs linear and nonlinear estimations; and determines sample semivariograms and cross-semivariograms. GEOPACK allows users to incorporate additional programs at a later date without having to alter previous programs or recompile the entire system."

34.9 Groundwater Modeling

The management of groundwater requires the capability of predicting subsurface flow and transport of solutes either under natural conditions or in response to human activities. These models are based on

the equations governing the flow of water and solutes. These equations are the conservation of mass, Darcy's equation and the contaminant transport equation. When written in two or three dimensions, these are partial differential equations.

The continuity equation is (De Smedt, 1999)

$$\rho\left[\theta(\alpha+\beta)\frac{\partial p}{\partial t}+\frac{\partial \theta}{\partial t}\right]=-\nabla\cdot(\rho \boldsymbol{q})$$

where θ = the water content
α = the elastic compressibility coefficient of the porous formation
β = the compressibility coefficient of the water, both with dimensions [L^2/F]
p = the groundwater pressure
$\boldsymbol{q}$ = the Darcian flux vector, namely the volumetric discharge which has components in the three directions *x, y, z*
ρ = the water density
$\nabla = (\partial/\partial x,\partial/\partial y,\partial/\partial z)$ is the del operator and the dot represents the scalar product

The saturated groundwater flow equation is (De Smedt, 1999)

$$\frac{\partial}{\partial x}\left(K_h\frac{\partial h}{\partial x}\right)+\frac{\partial}{\partial y}\left(K_h\frac{\partial h}{\partial y}\right)+\frac{\partial}{\partial z}\left(K_v\frac{\partial h}{\partial z}\right)=S_o\frac{\partial h}{\partial t}$$

where K_h and K_v = the horizontal and vertical hydraulic conductivities
h = the hydraulic head
S_o = the specific storage coefficient, namely the volume of water released per unit bulk volume of the saturated porous medium and per unit decline of the piezometric surface

If the flow is unsteady there is an initial condition at time $t = 0$ of the form $h(x,y,z,0) = h_o(x,y,z)$. There are three types of boundary conditions. In the first type the value of h is known at the boundary $h(x_b, y_b, z_b, t) = h_b(t)$ where the subscript b refers to the flow boundary. The second type is a flux boundary condition when the amount of groundwater exchange at the boundary is known. It is of the form $q_b(x_b, y_b, z_b, t) = q_b(t)$. The third type is a mixture of the two pervious types.

Generally these partial differential equations are solved numerically along with the boundary conditions specific to the problem. Both finite difference and finite element methods can be used.

The solute transport equation is (Konikow and Reilly, 1999) is

$$\frac{\partial(n_e C)}{\partial t}=\frac{\partial}{\partial x_i}\left(n_e D_{ij}\frac{\partial}{\partial x_i}\right)-\frac{\partial}{\partial x_i}(n_e C v_i)-C'W^*-\rho_b\frac{\partial \overline{C}}{\partial t}$$

where C = the solute concentration
n_e = the effective porosity of the porous medium
D_{ij} = the coefficient of hydrodynamic dispersion (a second order tensor)
v_i = the seepage velocity (q_i/n_e)
C' = the concentration of the solute in the source or sink of fluid
W^* = the volumetric flux (positive for outflow, negative for inflow)
$\overline{C}$ = the concentration of the species adsorbed on the solid (mass of solute/mass of solid)
ρ_b = the bulk density of the porous medium.

This equation is written for the case of linear equilibrium controlled sorption or ion-exchange reactions. The first term on the right hand side represents the change in concentration due to hydrodynamic dispersion. The last term changes in case of chemical rate control reactions or decay.

The complete solute transport model requires at least two equations: one equation for the flow and one for the solute transport. The velocities are obtained from the flow equation. For advectively dominated transport problems, the equations are hyperbolic partial differential equations. In this case the method of characteristics can be used.

For a more complete treatment of groundwater modeling, see for example, Konikow and Reilly (1999).

Software

One of the most comprehensive deterministic groundwater flow model available in the public domain is MODFOW (Harbaugh et al. 2000). The following description is taken from the web site *http://water.usgs.gov/software/modflow-2000.html*

"MODFLOW-2000 simulates steady and nonsteady flow in an irregularly shaped flow system in which aquifer layers can be confined, unconfined, or a combination of confined and unconfined. Flow from external stresses, such as flow to wells, areal recharge, evapotranspiration, flow to drains, and flow through river beds, can be simulated. Hydraulic conductivities or transmissivities for any layer may differ spatially and be anisotropic (restricted to having the principal directions aligned with the grid axes), and the storage coefficient may be heterogeneous. Specified head and specified flux boundaries can be simulated as can a head dependent flux across the model's outer boundary, which allows water to be supplied to a boundary block in the modeled area at a rate proportional to the current head difference between a "source" of water outside the modeled area and the boundary block. Currently MODFLOW is the most used numerical model in the U.S. Geological Survey for groundwater flow problems. In addition to simulating groundwater flow, the scope of MODFLOW-2000 has been expanded to incorporate related capabilities such as solute transport and parameter estimation.

The ground-water flow equation is solved using the finite-difference approximation. The flow region is subdivided into blocks in which the medium properties are assumed to be uniform. In plan view the blocks are made from a grid of mutually perpendicular lines that may be variably spaced. Model layers can have varying thickness. A flow equation is written for each block, called a cell. Several solvers are provided for solving the resulting matrix problem; the user can choose the best solver for the particular problem. Flow-rate and cumulative-volume balances from each type of inflow and outflow are computed for each time step."

The method of Characteristics Model (MOC3D) developed by Konikow, et al.(1996) simulates solute transport in flowing groundwater in three dimensions. The following summary is taken from the Web site *http://water.usgs.gov/cgi-bin/man_wrdapp?moc3d.*

> This model simulates three-dimensional solute transport in flowing ground water. The model computes changes in concentration of a single dissolved chemical constituent over time that are caused by advective transport, hydrodynamic dispersion (including both mechanical dispersion and diffusion), mixing (or dilution) from fluid sources, and mathematically simple chemical reactions (including linear sorption, which is represented by a retardation factor, and decay). The model can also simulate groundwater age transport and the effects of double porosity and zero-order growth/loss.
>
> The transport model is integrated with MODFLOW, a three-dimensional ground-water flow model that uses implicit finite-difference methods to solve the transient flow equation. MOC3D uses the method-of-characteristics to solve the transport equation on the basis of the hydraulic gradients computed with MODFLOW for a given time step. Particle tracking is used to represent advective transport and explicit finite-difference methods are used to calculate the effects of other processes.

Other groundwater models available from the U.S. Geological Survey are listed on the Web site *http://water.usgs.gov/software/ground_water.html*

Another approach to groundwater modeling consists in combining elementary analytic solutions. This *Analytic Element* method was developed by Strack (1989) and expanded by Haitjema (1995).

For more details on groundwater modeling, see, for example, Konikow and Reilly (1999).

Defining Terms

Advection — Transport of a solute due to mass movement of ground water and not dispersion or diffusion.

Artesian well — A well in which the water rises above top of the upper confining layer of an aquifer under pressure condition. If the piezometric level is above the ground the well is free flowing. Named after Artois, a former province of northern France.

Aquiclude — A geologic formation that is essentially impermeable.

Aquifer — A geologic formation that is water saturated and sufficiently permeable to yield economically important amounts of water to wells and springs.

Aquifuge — A geologic formations that does not contain nor transmit water.

Aquitard — A geologic formation that is less permeable than an aquifer and that partially restricts the flow of water.

Confined aquifer — An aquifer which is confined between two layers of impervious material.

Diffusion — Spreading of a solute in the ground water due to molecular diffusion.

Hydrodynamic dispersion — Spreading of a solute in ground water due to the combined effect of diffusion and mechanical dispersion.

Kriging — A statistical method to obtain the best (in the mean square sense) linear unbiased estimate of a hydrologic variable (such as hydraulic conductivity) at a point or over an area given values of the same variable at other locations.

Mechanical dispersion — Spreading of a solute in ground water due to heterogeneous permeability in the porous medium.

DNAPL — Denser than water non-aqueous-phase-liquid, such as chlorinated solvents.

LNAPL — Lighter than water non-aqueous-phase-liquid, such as gasoline.

NAPL — Non-aqueous-phase liquid in a multiliquid flow.

Perched water — A saturated zone of a limited extent located above the water table due to a local impermeable layer.

Phreatic surface — The water table or free surface in an unconfined aquifer.

Piezometer — A tube with a small opening penetrating an aquifer for the purpose of observing the hydraulic head.

Saturation ratio — Fraction of the volume of voids occupied by water.

Sorption — Chemical reaction between a solute in the groundwater and the solid particles which results in a bonding of part of the solute and the porous medium.

Specific yield — Volume of water drained per unit area of an unconfined aquifer due to a unit drop of the water table.

Unconfined aquifer — An aquifer without a covering confining layer in which the water surface or water table is free to move up or down.

Vadose zone — The zone between the ground surface and the top of the capillary fringe immediately over the water table.

Water Table — The water free surface at atmospheric pressure at the top of an unconfined aquifer.

Well log — A description of the types and depths of the geologic materials encountered during the drilling of a well.

Wettability — Preferential spreading of one liquid over a solid surface in a two liquid flow. In the saturated zone water is the wetting fluid. In the vadose zone the non-aqueous-phase liquid usually is the wetting fluid.

35.1 Introduction

The erosion, deposition, and transport of sediment by water arise in a variety of situations with engineering implications. Erosion must be considered in the design of stable channels or the design for local scour around bridge piers. Resuspension of possibly contaminated bottom sediments have consequences for water quality. Deposition is often undesirable since it may hinder the operation, or shorten the working life, of hydraulic structures or navigational channels. Sediment traps are specifically designed to promote the deposition of suspended material to minimize their downstream impact, e.g., on cooling water inlet works, or in water treatment plants. A large literature exists on approaches to problems involving sediment transport; the following can only introduce the basic concepts in summary fashion. It is oriented primarily to applications in steady uniform flows in a sand-bed channel; problems involving flow nonuniformity, unsteadiness, and gravel-beds, are only briefly mentioned and coastal processes are treated in the section on coastal engineering. Cohesive sediments, for which physico-chemical attractive forces may lead to the aggregation of particles, are not considered at all. The finer fractions (clays and silts, see Section 35.2) that are susceptible to aggregation are found more in estuarial and coastal shelf regions rather than in streams. A recent review of problems in dealing with cohesive sediments is given by Mehta et al. (1989 a, b).

35.2 The Characteristics of Sediment

Density, Size, and Shape

The density of sediment depends on its composition. Typical sediments in alluvial water bodies consist mainly of quartz, the specific gravity of which can be taken as $s = 2.65$. The specific weight is therefore $\gamma_s = 165.4$ lb/ft,^{3} or 26.0 kN/m.^{3} In many formulae, the effective specific weight, which includes the effect of buoyancy, is used, i.e., $(s-1)\gamma$, where γ is the specific weight of water.

The exact shape of a sediment particle is not spherical, and so a compact specification of its geometry or size is not feasible. Two practical measures of grain size are: (i) the *sedimentation or aerodynamic diameter* — the diameter of the sphere of the same material with the same fall velocity, w_s, (see below for definition) under the same conditions, and (ii) the *sieve diameter* — the length of a side of the square sieve opening through which the particle will just pass. Because size determination is most often performed with sieves, the available data for sediment size usually refer to the sieve diameter, which is taken to be the geometric mean of the adjacent sieve meshes, i.e., the mesh size through which the particle has passed, and the mesh size at which the particle is retained. The sedimentation diameter is related empirically to the sieve diameter by means of a *shape factor*, S.F., which increases from 0 to 1 as the particle becomes more spherical (for a well-worn sand, S.F. ≈ 0.7).

Size Distribution

Naturally occurring sediment samples exhibit a range of grain diameters. A characteristic diameter, d_a, may be defined in terms of the percent, a, by weight of the sample that is smaller than d_a. Thus, for a sample with $d_{84} = 0.35$ mm, 84% by weight of the sample is less than 0.35 mm in diameter. The *median* size is denoted as d_{50}. Frequently, the grain size distribution is assumed to be *lognormally* distributed, and a geometric mean diameter and standard deviation are defined as $d_g = \sqrt{d_{16} d_{84}}$, and $\sigma_g = \sqrt{d_{84}/d_{16}}$. For a lognormal distribution, $d_{50} = d_g$, and the arithmetic mean diameter, $d_m = d_g e^{0.5 \ln(2\sigma_g)}$. Similarly, d_a can be determined from d_g and σ_g from the relation, $d_a = d_g \sigma_g^{Z_a}$, where Z_a is the standard normal variate corresponding to the value of a. For example, if $a = 65\%$, $d_g = 0.35$ mm, and $\sigma_g = 1.7$, then $Z_a = 0.39$, and so $d_{65} = (0.35 \text{ mm})(1.7)^{0.39} = 0.43$ mm. In natural sand-bed streams, σ_g typically ranges between 1.4 and 2, but in gravel-bed streams, it may attain values greater than 4. Qualitative discussions of sediment size may be based on a standard sediment grade scale terminology established by the American Geophysical Union. A simplified grade scale divides the size range into cobbles and boulders ($d > 64$ mm), gravels (2 mm $< d <$ 64 mm), sands (0.06 mm $< d <$ 2 mm), silts (0.004 mm $< d <$ 0.06 mm), and clays ($d <$ 0.004 mm).

Fall (or Settling) Velocity

The *terminal velocity* of a particle falling alone through a stagnant fluid of infinite extent is called its fall or settling velocity, w_s. The standard drag curve for a spherical particle provides a relationship between d and w_s (see chapter on Fundamentals of Hydraulics). For non-spherical sand particles *in water*, the fall velocity at various temperatures can be determined from Fig. 35.1 if the sieve diameter and S.F. are known or can be assumed (note the different fall velocity scales). As an example, for a geometric sieve diameter of 0.3 mm and a shape factor, S.F. = 0.7, the fall velocity in water at 10°C is determined as ≈ 3.6 cm/s. In a horizontally flowing turbulent suspension, the actual mean fall velocity of a given particle may be influenced by neighboring particles (hindered settling) and by turbulent fluctuations.

Angle of Repose

The *angle of repose* of a sediment particle is important in describing the initiation of its motion and hence sediment erosion of an inclined surface, such as a stream bank. It is defined as the angle, θ, at which the particle is just in equilibrium with respect to sliding due to gravitational forces. It will vary

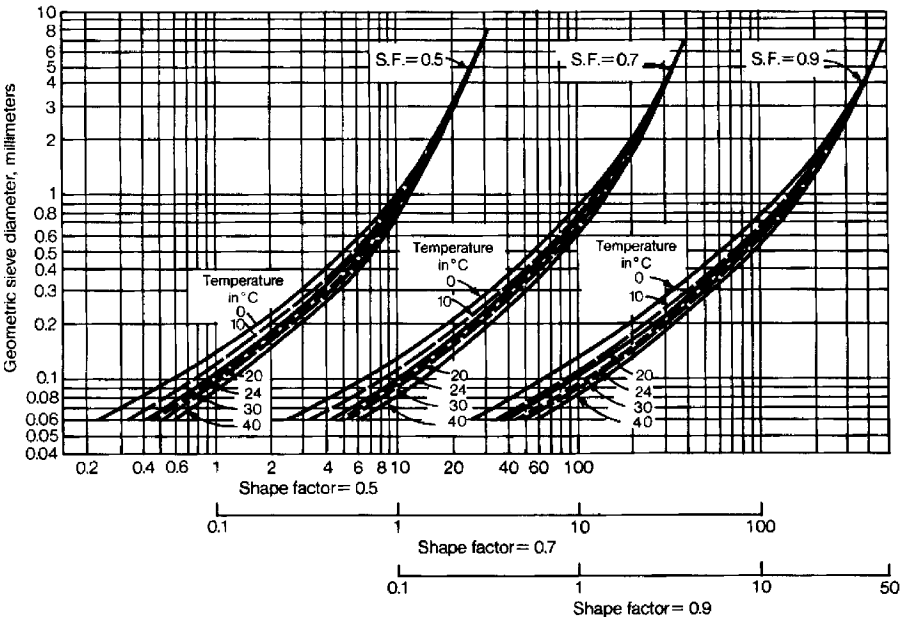

FIGURE 35.1 Relationship between fall velocity, sand-grain diameter, and shape factor (taken from Vanoni, 1975).

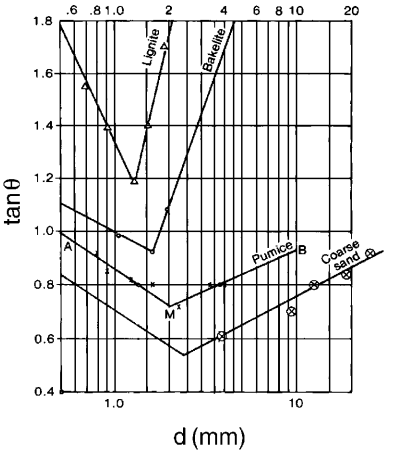

FIGURE 35.2 Angle of repose as a function of size and shape (adapted from Simon and Sentürk, 1992).

with particle size, shape, and density, and empirical curves for some of these variations are given in Fig. 35.2. The angle of repose for riprap, large stones or rock in layer(s) often used for stabilization of erodible banks, was given in simpler form (Fig. 35.3) by Anderson (1973) as part of a procedure for the design of channel linings. A value of 40° for the angle of repose is sometimes suggested as a design value for riprap.

35.3 Flow Characteristics and Dimensionless Parameters; Notation

The important flow characteristics are those associated with open-channel or more generally free-surface flows (see the chapters on Open Channel Hydraulics or the Fundamentals of Hydraulics for more details). These are the total water discharge, Q (or for wide or rectangular channels, the discharge per unit width,

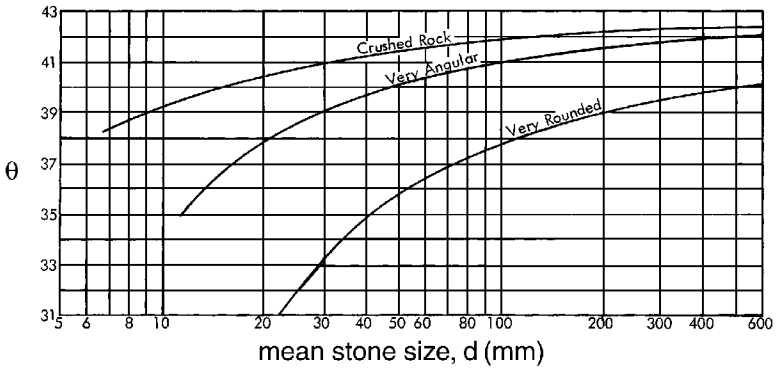

FIGURE 35.3 Angle of repose for riprap (from Anderson, 1973).

$q = Q/B$, where B is the width of the channel), the mean velocity, $V = Q/A$, where A is the channel cross-sectional area, the hydraulic radius, R_h, (or for a very wide channel the flow depth, $R_h \approx H$), and the energy or friction slope, S_f. The total bed shear stress, τ_b, and the related quantities, the *shear velocity*, $u_* = \sqrt{\tau_b/\rho} = \sqrt{gR_hS_f}$, where g is the gravitational acceleration, and friction factor, $f = 8(u_*/V)^2$, are also important.

Much of sediment transport engineering remains highly empirical, and so the organization of information in terms of dimensionless parameters becomes important (see the discussion of dimensional analysis in the chapter on Fundamentals of Hydraulics). Sediment and flow quantities may be combined in several dimensionless parameters that arise repeatedly in sediment transport. A dimensionless bed shear stress, also termed the *Shields parameter* (see Section 35.4), can be defined as

$$\Theta \equiv \frac{\tau_b}{\gamma(s-1)d} = \frac{u_*^2}{g(s-1)d} = \frac{R_hS_f}{(s-1)d} \tag{35.1}$$

Two *grain Reynolds numbers* based on the grain diameter can be usefully defined as

$$\mathrm{Re}_g \equiv \frac{\sqrt{g(s-1)d^3}}{\nu} \quad \text{and} \quad \mathrm{Re}_* \equiv \frac{u_*d}{\nu} \tag{35.2}$$

where ν is the fluid kinematic viscosity. Since $Re_g^2 \propto d^3$, a definition of a dimensionless diameter may be motivated as $d_* = Re_g^{2/3}$.

A *grain 'Froude' number* also based on grain diameter can be defined as

$$Fr_g \equiv \frac{V}{\sqrt{g(s-1)d}} = \left(\frac{V}{u_*}\right)\sqrt{\Theta} = \sqrt{\frac{8\Theta}{f}} \tag{35.3}$$

A dimensionless sediment discharge per unit width, Φ, may be defined as:

$$\Phi \equiv \frac{g_s/\gamma_s}{\sqrt{g(s-1)d^3}} \tag{35.4}$$

where $g_s = \gamma q\bar{C}$ is the weight flux of sediment per unit width and $\bar{C}$ is the flux-weighted mass or weight concentration of sediment (see Section 35.6 for more details).

In the above definitions, various characteristic grain diameters and shear velocities may be used according to the context.

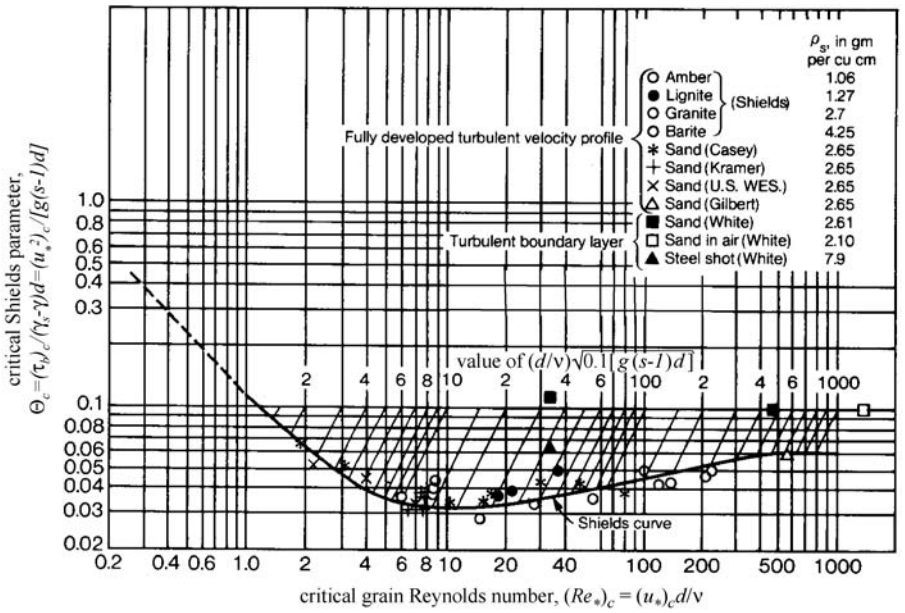

FIGURE 35.4 The Shields diagram relating critical shear stress to hydraulic and particle characteristics (adapted from ASCE Sedimentation Engineering, 1975).

35.4 Initiation of Motion

The Shields Curve and the Critical Shear Stress

A knowledge of the hydraulic conditions under which the transport of sediment in an alluvial channel begins or is initiated is important in numerous applications, such as the design of stable channels, i.e., channels that will not suffer from erosion, or bank stabilization, or remedial measures for scour. A criterion for the initiation of general sediment transport in a turbulent channel flow may be given in terms of a critical bed shear stress, $(\tau_b)_c = \rho(u_*)_c^2$, above which *general* motion of bed sediment of mean diameter, d, is observed. The *Shields curve* (Fig. 35.4) correlates a critical dimensionless bed shear stress, Θ_c, to a critical grain Reynolds number, $(Re_*)_c$, where $(u_*)_c$ is used in defining both Θ_c and $(Re_*)_c$. The Shields curve is an implicit relation, and so a solution for $(u_*)_c$ must be obtained iteratively. For large $(Re_*)_c$ (i.e., for coarse sediment), $\Theta_c \to \approx 0.06$, which provides a convenient initial guess for iteration. Also drawn on Fig. 35.4 are straight oblique lines along which an auxiliary parameter, $(d/\nu)\sqrt{0.1g(s-1)d} = \sqrt{0.1Re_g}$ is constant. This parameter does not involve $(u_*)_c$, and so, provided d and ν are known, $(u_*)_c$ can be directly determined by the intersection of these lines with the Shields curve. Various formulae or curve-fits have been proposed for describing the Shields curve; one example is due to Brownlie (1981) and involves the auxiliary parameter, $Y \equiv Re_g^{-0.6}$,

$$\Theta_c = 0.22Y + 0.06 \times 10^{-7.7Y} \tag{35.5}$$

Example 35.1

Given a sand ($s = 2.65$) grain with $d = 0.4$ mm in water with $\nu = 0.01$ cm^2/s, what is the critical shear stress? The iterative procedure based on the graphical Shields curve starts with an initial guess, $\Theta_c = 0.06$, implying $(u_*^2)_c = 2.0$ cm^2/s^2 and $(Re_*)_c = 7.9$. This is inconsistent with the Shields curve, which indicates $\Theta_c = 0.032$ for $(Re_*)_c = 7.9$. The procedure is iterated by making another guess, $\Theta_c = 0.032$, which yields $(\tau_b)_c = 0.21$ kPa corresponding to $(Re_*)_c = 5.8$. This result is sufficiently consistent with the Shield curve, and so the

iteration can be stopped. More directly, the auxiliary parameter, $(d/\nu)\sqrt{0.1g(s-1)d} = 10$, can be computed, and the line corresponding to this value intersects the Shields curve at $\Theta_c = 0.034$. The use of the Brownlie empirical formula (Eq. [35.5]) gives, with $Re_g = 32.2$ and $Y = 0.125$, more directly $\Theta_c = 0.034$.

Instead of using $(\tau_b)_c$, traditional procedures for the design of stable channels have often been formulated in terms of a critical average velocity, V_c, or critical unit-width discharge, q_c, above which sediment transport begins, because these quantities are more easily available than the bed shear stress. If a relationship between V and τ_b, namely a friction or flow resistance law, then V_c can be derived from $(\tau_b)_c$, and this is discussed in Section 35.5.

The Effect of Slope

The above criterion is applicable to grains on a surface with negligible slope, as is usually the case for grains on the channel bed. Where the slope of the surface on which grains are located is appreciable, e.g., on a river bank, its effect cannot be neglected. With the inclusion of the additional gravitational forces, a force balance reveals that $(\tau_b)_c$ is reduced by a fraction involving the angle of repose of the grain, and the ratio of the value of $(\tau_b)_c$ *including slope effects* to its value for a horizontal surface is given by:

$$K_{slope} = \frac{\left[(\tau_b)_c\right]_{slope}}{\left[(\tau_b)_c\right]_{zero\ slope}} = \left(1 - \frac{\sin^2\phi}{\sin^2\theta}\right)^{1/2} \tag{35.6}$$

where ϕ = the angle of the sloping surface
θ = the angle of repose of the grain.

On a horizontal surface, $\phi = 0$, and the ratio is unity, whereas if $\phi = \theta$, then no shear is required to initiate sediment motion (consistent with the definition of the angle of repose).

Summary

Although the Shields curve is widely accepted as a reference, controversy remains concerning its details and interpretation, e.g., its behavior for small $(Re_*)_c$ (Raudkivi, 1990) and the effect of fluid temperature (Taylor and Vanoni, 1972). The random nature of turbulent flow and random magnitudes of the instantaneous bed shear stresses motivate a probabilistic approach to the initiation of sediment motion. The critical shear stress given by the Shields curve can be accordingly interpreted as being associated with a probability that sediment particle of given size will begin to move. It should *not* be interpreted as a criterion for zero sediment transport, and design relations for zero transport, if based on the Shields curve, should include a significant factor of safety (Vanoni, 1975).

35.5 Flow Resistance and Stage-Discharge Predictors

The stage-discharge relationship or rating curve for a channel relating the uniform-flow water level (stage) or hydraulic radius, R_h, to the discharge, Q, is determined by channel flow resistance. For flow conditions above the threshold of motion, the erodible sand bed is continually subject to scour and deposition, so that the bed acts as a deformable or 'movable' free surface. The plane bed, i.e., one in which large-scale features are absent, is often unstable, and bedforms (Fig. 35.5) such as *dunes, ripples,* and *antidunes*, develop. Dunes, which exhibit a mild upstream slope and a sharper downstream slope, are the most commonly occurring of bedforms in sand-bed channels. Ripples share the same shape as dunes, but are smaller in dimensions. They may be found in combination with dunes, but are generally thought to be unimportant except in streams at small depths and low velocities. Antidunes assume a smoother more symmetric sinusoidal shape, which results in less flow resistance, and are associated with steeper streams. Antidunes differ from dunes in moving upstream rather than downstream, and in being associated with water surface variations that are *in phase* rather than out of phase with bed surface variations.

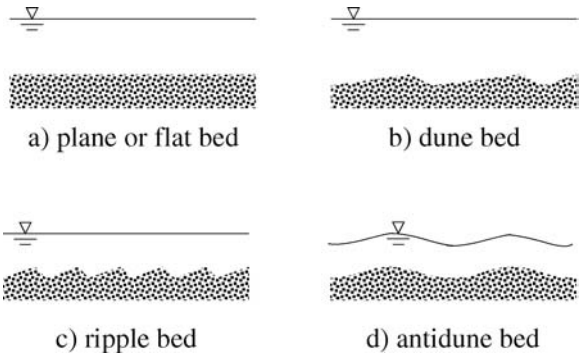

FIGURE 35.5 Various bedforms.

In fixed-bed open-channel flows, resistance is characterized by a Darcy-Weisbach friction factor, f (see chapter on Fundamentals of Hydraulics) or a Manning's n (see chapter on Open Channel Hydraulics), which is assumed to vary only slowly or not at all with discharge. For movable or erodible beds, substantial changes in flow resistance may occur as the bedforms develop or are washed out. Very loosely, as transport intensity (as measured, e.g., by the Shields parameter, Θ) increases, ripples evolve into dunes, which in turn become plane or transition beds, to be followed by antidunes. Multiple depths may be consistent with the same discharge or velocity (Fig. 35.6), and the rating curve (the relationship between stage or depth and discharge or velocity) may exhibit discontinuities. These discontinuities are attributed to a short-term transition from low-velocity high-resistance flow over ripples and dunes, termed *lower-regime flow*, to high-velocity low-resistance flow over plane, transition or antidune bed, termed *upper-regime flow* or vice-versa. Because of these two possible regimes, movable-bed friction formulae (unlike fixed-bed friction formulae) must include a method to determine the flow regime.

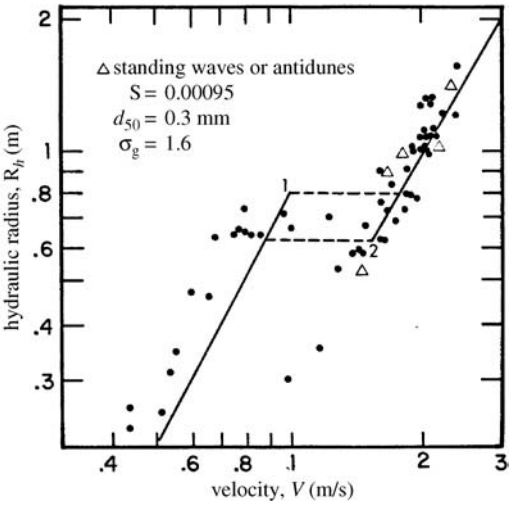

FIGURE 35.6 Stage-discharge data reported by Dawdy (1961) for the Rio Grande River near Bernalillo, New Mexico. (Adapted from Brownlie, 1981.)

Form and Grain Resistance Approach

In flows over dunes and ripples, form resistance due to flow separation from dune tops provides the dominant contribution to overall resistance. Yet the processes involved in determining bedform characteristics are more directly related to the actual bed shear stress (as in the problem of initiation of motion). Much of sediment transport modeling has distinguished between *form and grain* (*skin*) *resistance* (see the section on hydrodynamic forces in the chapter on Fundamentals of Hydraulics for the distinction between the two types of flow resistance). An overall bed shear stress, $(\tau_b)_{overall} \equiv \gamma R_j S_f$, is taken as the sum of a contribution due to grain resistance, τ', and a contribution due to form resistance, τ''. Since $(\tau_b)_{overall}$ is usually correlated empirically with τ', it remains only to determine τ' from given hydraulic parameters. The traditional approach estimates τ' from fixed-bed friction formulae for plane beds. A simple effective example of this approach to stage-discharge prediction is due to Engelund and Hansen (1967) (with extension by Brownlie (1983)) and correlates a total overall dimensionless shear stress, Θ, with a dimensionless grain shear stress, Θ':

Engelund-Hansen formula

$$\Theta = 1.58\sqrt{\Theta' - 0.06}, \qquad 0.06 \le \Theta' \le 0.55, \quad \text{(lower regime)} \tag{35.7a}$$

$$= \Theta', \qquad 0.55 \le \Theta' \le 1, \quad \text{(upper regime)} \tag{35.7b}$$

$$= \left[1.425\left(\Theta'\right)^{-1.8} - 0.425\right]^{1.8} \qquad 1 \le \Theta' \quad \text{(upper regime)} \tag{35.7c}$$

where $\Theta'(\equiv R_h' S_f/(s-1)\, d_{50})$ is related to V by a friction formula for a plane fixed bed:

$$\frac{V}{\sqrt{gR_h' S_f}} = 5.76 \log_{10} \frac{5.51 R_h'}{d_{65}} \tag{35.8}$$

The lower regime corresponds to flows over dune-covered beds with dominant contribution due to form resistance, such that $\Theta > \Theta'$ for values of Θ' not too close to 0.06, whereas in the transition or upper regime, corresponding to plane beds or beds with antidunes, $\Theta = \Theta'$, because flow resistance is expected to be due primarily to grain resistance, comparable in this respect to plane beds. The Engelund-Hansen formula was originally developed based on large-flume laboratory data with d_{50} in the range 0.19 mm to 0.93 mm, and σ_g of 1.3 for the finest sediment and 1.6 for the others.

Overall Resistance Approach

The distinction between grain (skin) and form resistance is physically sound, but the use of a plane fixed-bed friction formula such as Eq. (35.8) cannot be justified rigorously for beds with dunes and ripples, and the need for a further correlation between Θ and Θ' is inconvenient. A simpler more direct approach relating Θ (or R_h) directly to Q or other dimensionless parameters may therefore be more attractive from an engineering point of view. Guided by dimensional analysis, Brownlie (1983) performed regression analyses on a large data set of laboratory and field measurements, and proposed the following stage-discharge formulae:

Brownlie formulae

$$\frac{R_h}{d_{50}} = 0.0576\left(s-1\right)^{0.95} Fr_g^{1.89} S_f^{-0.74} \sigma_g^{0.3}, \text{ lower regime,} \tag{35.9a}$$

$$= 0.0348\left(s-1\right)^{0.83} Fr_g^{1.67} S_f^{-0.77} \sigma_g^{0.21}, \text{ upper regime,} \tag{35.9b}$$

where σ_g = the geometric standard deviation
Fr_g = the grain Froude number (Eq. [35.3])

To determine whether the flow is in lower or upper regime, the following criteria are applied:

- for $S_f > 0.006$, only upper regime flow is observed,
- for $S_f < 0.006$, additional criteria are formulated in terms of a modified grain Froude number, $Fr_g^* \equiv Fr_g/[1.74 S_f^{-1/3}]$, and a modified grain Reynolds number, $\Delta \equiv u_*' d_{50}/(11.6\nu)$, where u_*' is the shear velocity corresponding to the upper regime flow, i.e., due primarily to grain resistance.
- the **lower** limit of the **upper regime** is given as

$$\log_{10}\left(Fr_g^*\right)_{up} = -0.0247 + 0.152 \log_{10} \Delta + 0.838\left(\log_{10} \Delta\right)^2, \quad \Delta < 2 \tag{35.10a}$$

$$= \log_{10} 1.25, \qquad \Delta \ge 2 \tag{35.10b}$$

- the **upper** limit of the **lower regime** is given as

$$\log_{10}\left(Fr_g^*\right)^{low} = -0.203 + 0.0703\log_{10}\Delta + 0.933\left(\log_{10}\Delta\right)^2, \qquad \Delta < 2, \tag{35.11a}$$

$$= \log_{10} 0.8, \qquad \Delta \geq 2. \tag{35.11b}$$

- The range of conditions covered by the data set was: $3 \times 10^{-6} < S_f < 3.7$ x10^{-2}, 0.088 mm $< d_{50} <$ 2.8mm, 0.012 m^3/s/m $< q <$ 40 m^3/s/m, $0.025 < R_h < 17$ m, and temperatures between 0°C and 63°C.

Example 35.2

Given a wide alluvial channel with unit width discharge, q = 1.6 m^3/s/m, and bed slope, S_0 = 0.00025, and sand characteristics, d_{50} = 0.35 mm, σ_g = 1.7, estimate the normal flow depth. The approximation is made that, for a wide channel, $R_h \approx H$ and $V = q/H$, where H is the required flow depth. With the Brownlie formulae, substitution of the given values yields for the lower regime (Eq. [35.9a]), H_{low} = 1.80 m, and for the upper regime (Eq. [35.9b]), H_{up} = 1.30 m. Only *one* of these is the appropriate flow; to determine which, the criteria for the two regimes are examined. Since $u'_* = \sqrt{gH_{up}S_0} = 0.056$ m/s, $\Delta = u'_* d_{50}/11.6\nu = 1.70$ assuming $\nu = 10^{-6}$ m^2/s. From Eqs. (35.10) to (35.11), the limits of the flow regimes for $\Delta = 1.70$ are determined as: for the upper regime, $(Fr_g^*)_{up} = 1.13$, and for the lower regime, $(Fr_g^*)^{low} = 0.73$. The parameter, $Fr_g^* = (q/H)[1.74S_f^{-1/3}\sqrt{g(s-1)d_{50}}]$ is evaluated using $H = H_{up}$ to be $Fr_g^* = 0.59 < (Fr_g^*) = 1.13$, i.e., below the lower limit of the upper flow regime, and using $H = H_{low}$ to be $Fr_g^* = 0.59 < (Fr_g^*)^{low} = 0.73$, i.e., below the upper limit of the lower flow regime. The only consistent solution for H is therefore H_{low}, and hence, according to the Brownlie criteria, the flow must then be in the lower regime, and so the normal flow depth is estimated as $H = H_{low}$ = 1.80 m. In some (hopefully infrequent) cases, these criteria may still not be sufficient to give a unique solution.

The Engelund-Hansen procedure involves two unknowns, H as well as H' (the 'fictitious' depth related to grain resistance), which must be solved with the two available equations, namely, the flow resistance relationships (Eqs. [35.7] and [35.8]), together with the requirement that $q = VH$. The solution for H can be obtained with software tools, such as a spreadsheet simultaneous equation solver, or by the following 'manual' iterative procedure. H' is initially guessed, e.g., 1 m, from which $\Theta' = 0.43$. According to Eq. (35.7), this falls in the lower regime, and from Eq. (35.7a), $\Theta = 0.96$, so that H = 2.22 m. From Eq. (35.8), the mean velocity is computed (assuming a lognormal size distribution, $d_{65} \approx 0.43$ mm for $\sigma_g = 1.7$, see Section 35.2) as V = 1.17 m/s, and hence $q = VH$ = 2.60 m^2/s. Since this is not consistent with the given q = 1.6 m^2/s, the iteration is continued. A final iteration yields $\Theta = 0.76$ and H = 1.75 m, which agrees well with the result using the Brownlie formulae.

Critical Velocity

Given a stage-discharge predictor, a formula for the *critical velocity*, V_c, (see section 35.4 for definition) can be obtained. For example, the Brownlie lower regime equation (Eq. [35.9a]) can be expressed in terms of a critical grain Froude number, $(Fr_g)_c$ as

$$\left(Fr_g\right)_c \equiv \frac{V_c}{\sqrt{g(s-1)d_{50}}} = \frac{4.60\Theta_c^{0.53}}{S_f^{0.14}\sigma_g^{0.16}} \tag{35.12}$$

where Θ_c is obtained from the Shields curve (e.g., Eq. [35.5]).

Based on experiments, Neill (1967) gave a simpler design formula intended for zero transport of coarse particles,

$$\left(Fr_g\right)_c^2 = 2.5\left(\frac{H}{d}\right)^{0.2} \tag{35.13}$$

This gives a more conservative result than the Eq. (35.12). A design equation for sizing riprap, very similar to Eq. (35.13), and recommended by the U. S. Army Corps of Engineers (1995) is

$$\frac{d_{30}}{H} = K_R \left(\frac{V}{\sqrt{K_{slope}(s-1)H}} \right)^{2.5} \tag{35.14a}$$

where K_R is an empirical coefficient correcting for various effects such as the vertical velocity distribution and the thickness of the riprap layer, as well as including a safety factor. Although Eq. (35.6) (with θ = 40°) may be used for evaluating K_{slope}, this is found to be rather conservative, and an empirical curve for this factor has been developed.

Example 35.3

A channel is to be designed to carry a discharge of 5 m^3/s on a slope of 0.001. The bed material has a median diameter, d_{50} = 8 mm, and a geometric standard deviation, σ_g = 3. Determine the width and depth at which the channel will not erode. Assume for simplicity a rectangular channel cross-section and rigid banks. For d_{50} = 8 mm, it is found from Eq. (35.5) that Θ_c = 0.054, so from Eq. (35.12), $(Fr_g)_c$ = 2.18 and V_c = 0.78 m/s. This is substituted into the lower regime friction equation, Eq. (35.9a), to give $R_h = BH/(B+2H)$ = 0.72 m. Since $Q = V_c\, BH$ = 5 m^3/s, H is determined as 0.9 m, and so B = 7.1 m. If Eq. (35.13) is used with a Manning-Strickler friction law, then H is found to be 0.46 m, and B to be 12.4 m, with V_c = 0.86 m/s. Eq. (35.12), being based on Shields curve, is not intended to be used for design for zero transport (see previous remarks in section 35.4), while Eq. (35.13) was intended as a design equation for zero transport and so gives a more conservative value (smaller H and hence smaller bed shear stress for given bed slope).

Summary

The prediction of flow depth in alluvial channels remains an uncertain art with much room for judgement. Estimates using various predictors should be considered and the use of field data specific to the problem should be exploited where feasible to arrive at a range of predictions. *If* the regime is correctly predicted, the better stage-discharge relations are generally reliable to within 10 to 15% in predicting depth.

35.6 Sediment Transport

Three modes of sediment transport are distinguished: *wash load, suspended load,* and *bed load*. Wash load refers to very fine suspended material, e.g., silt, that because of their very small fall velocities, interacts little with the bed. It will not be further considered since it is determined by upstream supply conditions rather than by local hydraulic parameters. Suspended load refers to material that is transported downstream primarily in suspension far from the bed, but which because of sedimentation and turbulent mixing still interacts significantly with the bed. Finally, bed load refers to material that remains generally close to the bed in the bedload region, being transported mainly through rolling or in short hops (termed saltation). The relative importance of the two modes of sediment transport may be roughly inferred from the ratio of settling velocity to shear velocity, w_s/u_*. For $w_s/u_* < 0.5$, suspended load transport is likely dominant, while for $w_s/u_* > 1.5$, bedload transport is likely dominant. The sum of suspended and bed loads is termed *bed-material load* as distinct from the wash load, which may only be very weakly, if at all, related to material found in bed samples.

The total sediment load or discharge, G_T, is considered here as the sum of only the suspended-load discharge, G_S, and the bedload discharge, G_B, and is defined as the mass or more usually the weight flux of sediment material passing a given cross-section (SI units of kg/s or N/s, English units slugs/s or lb/s). A total sediment discharge (by weight) per unit width, based on the flux over the entire depth. is often used:

$$g_T = \gamma q \overline{C} = \gamma \int_0^H u\, c\, dy \tag{35.14b}$$

where u and c = the mean velocity and mass (or weight) concentration at a point in the water column
$\overline{C}$ = a mean flux-weighted mass (or weight) concentration defined by Eq. (35.14a).

Because of a nonuniform velocity profile, $\overline{C}$ is *not* equal to the *depth-averaged concentration*, $\langle C \rangle \equiv (1/H) \int_0^H c\, dy$.

Suspended Load Models

The prediction of g_T given appropriate sediment characteristics and hydraulic parameters has been attempted by treating bed load and suspended load separately, but such an approach is fraught with difficulties. The traditional approach derives a differential equation for conservation of sediment assuming uniform conditions in the streamwise direction:

$$\varepsilon_s \frac{dc}{dy} + w_s c = 0 \tag{35.15}$$

where ε_s is a turbulent diffusion or mixing coefficient for sediment.

The first term represents a net upward sediment flux due to turbulent mixing, while the second term is interpreted as the net downward flux due to settling. A solution for the vertical distribution of sediment concentration, $c(y)$, depends on a model for ε_s, and a boundary condition at or near the bed. The well-known *Rouse concentration profile*,

$$\frac{c(y)}{c_{ref}} = \left(\frac{H-y}{y} \frac{y_{ref}}{H-y_{ref}} \right)^{Z_R} \tag{35.16}$$

with the *Rouse exponent*, $Z_R \equiv w_s/\beta\kappa u_\star$, assumes an eddy viscosity mixing model with $\varepsilon_s = \beta u_\star y(1 - y/H)$, where β is a coefficient relating momentum to sediment diffusion, and the von Kármán constant, κ, stems from the assumption of a log-law velocity profile. It avoids a precise specification of the bottom boundary condition by introducing a reference concentration, c_{ref}, at a reference level $y = y_{ref}$, taken close to the bed. Here $u_\star = \sqrt{gR_hS_f}$ refers to the *overall* shear velocity (i.e., not only the shear velocity associated with grain resistance).

Although Eq. (35.16) can usually be made to fit measured concentration profiles approximately with an appropriate choice of Z_R, its predictive use is limited by the lack of information concerning β, κ, and particularly c_{ref}, which may vary with hydraulic and sediment characteristics. In the simplest models, $\beta = 1$ and $\kappa = 0.4$, which assume that sediment diffusion is identical to momentum diffusion and the velocity profile follows the log-law (see section on turbulent flows in the chapter on fundamentals of hydraulics) profile exactly as in plane fixed-bed flows without sediment. More complicated models (e.g., van Rijn, 1984a) have been proposed in which β is correlated with $w_s/u_\star$ and κ varies with suspended sediment concentration. The suspended load discharge per unit width may be computed using Eq. (35.16) as

$$g_s = \gamma \int_{y_{ref}}^H u\, c\, dy \tag{35.17}$$

with u typically assumed to be described by a log-law profile. To determine the total load (per unit width), g_T, a formula for predicting g_B, the transport per unit width in the bed-load region, $0 < y < y_{ref}$, must be coupled with Eq. (35.17), and the reference level, y_{ref}, must be chosen at the limit of the bed load region. In flows with bed forms, neither Eq. (35.15) nor Eq. (35.16) can be rigorously justified, since bed

conditions are not uniform in the streamwise direction and the log-law velocity profile is inadequate to describe velocity and stress profiles near the bed (Lyn, 1993).

Bed-Load Models and Formulae

Bed-load models are used either in cases where bed load transport is dominant, or to complement suspended-load models in total-load computations. Most available formulae can be written in terms of the dimensionless bed-load transport, Φ_b, and a dimensionless grain shear stress, Θ' (see Section 35.2 for definitions). Only two such models, one traditional and one more recent, are described. The Meyer-Peter-Muller bed-load formula was based on laboratory experiments with coarse sediments (mean diameter range: 0.4 to 30 mm) with very little suspended load.

Meyer-Peter-Muller bed-load formula

$$\Phi_b = 0.08\left(\frac{\Theta'}{\Theta_c} - 1\right)^{3/2}, \quad \frac{\Theta'}{\Theta_c} \geq 1, \tag{35.18}$$

where the dimensionless critical shear stress, $\Theta_c = 0.047$ (note the difference from the generally accepted Shields' curve value of 0.06 for coarse material) and Θ' is the fraction of the dimensionless total shear stress, $\Theta' = (k/k')^{3/2}\Theta$, that is attributed to grain resistance. Based on a plane fully rough fixed-bed friction law of Strickler type, the fraction, k/k', is computed from

$$\frac{k}{k'} = 0.12\left(\frac{d_{90}}{R_h}\right)^{1/6} \frac{U}{\sqrt{gR_hS_f}} \tag{35.19}$$

In the Meyer-Peter-Muller formula, the characteristic grain size used in defining Φ_b and Θ' is the mean diameter, d_m (which can be related to d_g if necessary, see Section 35.2).

A more recent bed-load model due to van Rijn (1984), intended both for predicting bed-load dominated transport as well as for complementing a suspended-load model, is similar in form:

van Rijn bed-load formula

$$\Phi_b = 0.053\frac{\left[\left(\Theta'/\Theta_c\right) - 1\right]^{2.1}}{\mathrm{Re}_g^{0.2}}, \quad \frac{\Theta'}{\Theta_c} \geq 1. \tag{35.20}$$

Θ_c is determined from a Shields curve relation, and Θ' is computed from a fully rough plane-bed friction formula of log-law form (cf. Eq. [35.8]),

$$\frac{V}{u'_*} = 5.75\ \log_{10}\frac{12R_h}{k_s} \tag{35.21}$$

where the equivalent roughness height, $k_s = 3\ d_{90}$. The median grain diameter, d_{50}, is used in defining Φ_b, Θ', and Re_g. In tests with laboratory and field data, Eq. 35.20 performed on average as well as other well-known bed-models including the Meyer-Peter-Muller formula. Equating q_B to a sediment flux based on a reference mass concentration, c_{ref}, at a reference level ($y = y_{ref}$), van Rijn (1984b) obtained an semi-empirical relation for c_{ref} to be used with a suspended-load model

$$c_{ref} = 0.015\ s\left(\frac{d_{50}}{y_{ref}}\right)\frac{\left[\left(\Theta'/\Theta_c\right) - 1\right]^{1.5}}{Re_g^{0.2}}, \quad \frac{\Theta'}{\Theta_c} \geq 1, \tag{35.22}$$

where y_{ref} is chosen to be one-half of a bed form height for lower regime flows, or the roughness height for upper regime flows with a minimum value chosen arbitrarily to be 0.01 H.

Example 35.4

Given quartz (s = 2.65) sediment with d_{50} = 1.44 mm, σ_g = 2.2, in a uniform flow of hydraulic radius, R_h = 0.62 m, in a wide channel of slope, S = 0.00153, and average velocity, V = 0.8 m/s, what is the sediment discharge per unit width? A bed-load dominated sediment discharge is indicated by $w/u_* \approx$ (16 cm/s)/(9.6 cm/s) = 1.6, based on d_{50}, and $u_* = \sqrt{gHS}$ = 0.096 m/s. In the Meyer-Peter-Muller formula, k/k' = 0.43, where d_{90} = 3.9 mm and u_* = 0.096 m/s. Hence, since d_m = 1.96 mm, it is found that Θ' = 0.082. This gives Φ_b = 0.052 from which $g_B = \gamma_s \Phi_b \sqrt{g(s-1)d_m^3}$ = 0.47 N/s/m or $\overline{C} = g_b/\gamma q$ = 97 ppm by mass. If the van Rijn formula is used, u_*' = 0.050 m/s, so that Θ' = 0.106. From the Shields curve, Θ_c = 0.039 for R_g = 219, so that Φ_b = 0.056 or g_b = 0.32 N/s/m or $\overline{C}$ = 66 ppm. The given parameter values correspond to field measurements in the Hii River in Japan where the reported $\overline{C}$ was 191 ppm (from the data compiled by Brownlie, 1981), which may have included some suspended load as well as wash load.

Total Load Models

The distinction between suspended load and bed load is conceptually useful, but, as has been noted previously in other contexts, this does not necessarily yield any predictive advantages since neither component can as yet be treated satisfactorily for most practical problems. As such, simpler empirical formulae that directly relate g_T (or equivalently, $\overline{C}$) to sediment and hydraulic parameters remain attractive and have often performed as well or better than more complicated formulae in practical predictions. Only two of the many such formulae will be discussed. The formula of Engelund and Hansen (1967) was developed along with their stage-discharge formula (see Section 35.5 for the range of experimental parameters). The total dimensionless transport per unit width, Φ_T, is related to Fr_g, and Θ, with characteristic grain size, d_g, by

Engelund-Hansen total-load formula

$$\Phi_T = 0.05\, Fr_g^2\, \Theta^{3/2} \tag{35.23}$$

The Brownlie formula was originally stated in terms of the mean sediment transport (mass or weight) concentration, $\overline{C}$, as:

Brownlie total-load formula

$$\overline{C} = 0.00712\, c_f \left[Fr_g - \left(Fr_g \right)_c \right]^{1.98} S_f^{0.66} \left(\frac{d_{50}}{R_h} \right)^{0.33} \tag{35.24}$$

where c_f = 1 for laboratory data and c_f = 1.27 for field data, $(Fr_g)_c$ is the critical grain Froude number corresponding to the initiation of sediment motion given by Eq. (35.12). In term of Φ_T and Θ, Eq. (35.24) can be expressed (assuming $R_h \approx H$) with rounding as

$$\Theta_T = 0.00712 \left(\frac{c_f}{s} \right) \left[Fr_g - \left(Fr_g \right)_c \right]^{2.0} Fr_g \left[(s-1)\Theta \right]^{1.5} \tag{35.25}$$

Example 35.5

The total load formulae should also be applicable to bed-load dominated transport as in Example 35.3. In that case, the Engelund-Hansen formula, with Fr_g^2 = 27.5 and Θ = 0.4, predicts Φ_T = 0.35, corresponding to g_T = 2.0 N/s/m and $\overline{C}$ = 411 ppm by weight. This is approximately twice the measured value. The Brownlie formula, with $(Fr_g)_c$ = 1.8 from Eq. 35.12 and c_f = 1.27, yields Φ_T = 0.16, corresponding to g_T = 0.91 N/s/m or in terms of $\overline{C}$ = 189 ppm by weight, which agrees well with the measured value of 191 ppm. This rather

close agreement should be considered somewhat fortuitous, and is at least partially attributed to the fact that the observed value was included in the data set on which the Brownlie formulae were based. The performance of the Brownlie formulae in practice is likely to be similar to the better recent proposals.

Measurement of Sediment Transport

In addition to, and contributing to, the difficulties in describing and predicting accurately sediment transport, total load measurements, particularly in the field, are associated with much uncertainty. Natural alluvial channels may exhibit a high degree of spatial and temporal nonuniformities, which are not specifically considered in the 'averaged' models discussed above. Standard methods of suspended load measurements in streams include the use of depth-integrating samplers that collect a continuous sample as they are lowered at a constant rate (depending on stream velocity) into the stream, and the use of point-integrating samplers that incorporate a valve mechanism to restrict sampling, if desired, to selected points or intervals in the water column. Such sampling assumes that the sampler is aligned with a dominant flow direction, and that the velocity at the sampler intake is equal to the stream velocity. In the vicinity of a dune-covered bed, these conditions cannot be fulfilled. The finite size of the suspended load samplers implies that they cannot measure the bedload discharge, which must therefore be measured with a different sampler or estimated with a bedload model. A bedload sampler, such as the U.S.G.S. Helley-Smith sampler, will necessarily interact with and possibly change the erodible bed. Questions also arise concerning the distinction between suspended and bed loads when bedload samplers are used in problems involving suspended loads. Calibration is necessary, e.g., in the laboratory using a sediment trap, but this may vary with several parameters, including the particular type of sampler used, the transport rate, grain size (Hubbell, 1987), and unless full-scale tests are performed, questions of model-prototype similitude also arise.

Expected Accuracy of Transport Formulae

The reliability of sediment transport formulae is relatively poor. Some of this poor performance may be attributed to measurement uncertainties. The best general sediment discharge formulae available have been found to predict values of g_T which are within one-half to twice the observed value for only about 75% of cases (Brownlie, 1981; van Rijn, 1984a, b; Chang, 1988). Circumspection is therefore advised in basing engineering decisions on such formulae, especially when they are imbedded in sophisticated computer models of long-term deposition or erosion. Where feasible, site-specific field data should be exploited, and used to complement model predictions.

35.7 Special Topics

The preceding sections have been limited to the simplest sediment-transport problems involving steady uniform flow. The following deals briefly with more specialized and complex problems.

Local Scour

Hydraulic structures, such as bridge piers or abutments, that obstruct or otherwise change the flow pattern in the vicinity of the structure, may cause localized erosion or scour. Changes in flow characteristics lead to changes in sediment transport capacity, and hence to a local disequilibrium between actual sediment load and the capacity of the flow to transport sediment. A new equilibrium may eventually be restored as hydraulic conditions are adjusted through scour. *Clear-water scour* occurs when there is effectively zero sediment transport upstream of the obstruction, i.e., $Fr_g < (Fr_g)_c$ upstream, while *live-bed scour* occurs when there would be general sediment transport even in the absence of the local obstruction, i.e., $Fr_g > (Fr_g)_c$, upstream. Additional difficulties in treating local scour stem from flow non-uniformity and unsteadiness. The many different types and geometries of hydraulic structures lead to a wide variety of scour problems, which precludes any detailed unified treatment. Design for local scour requires many considerations and the results given below should be considered only as a part of the design process.

Empirical formulae have been developed for special scour problems; only two are presented here, both relevant to problems associated with bridge crossings over waterways, one for contraction scour, and one for scour around a bridge pier. Consider a channel contraction sufficiently long that uniform flow is established in the contracted section, which is uniformly scoured (Fig. 35.7). The entire discharge is assumed to flow through the approach and the contracted channels. Application of conservation of water and sediment (assuming a simple transport formula of power-law form, $g_T \sim V^m$) results in

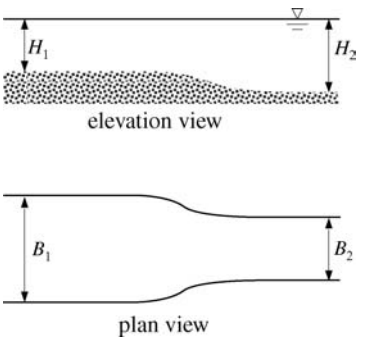

FIGURE 35.7 Channel constriction causing local scour.

$$\frac{H_1}{H_2} = \left(\frac{B_2}{B_1}\right)^{\alpha} \tag{35.26}$$

where the subscripts, 1 and 2, indicate the contracted (2) or the approach (1) channels, H the flow depth, and B the channel width.

The exponent, α, varies from 0.64 to 0.86, increasing with τ_c/τ_1, where τ_c is the critical shear stress for the bed material, and τ_1 is total bed shear stress in the main channel. A value of $\alpha = 0.64$, corresponding to $\tau_c/\tau_1 \ll 1$, i.e., significant transport in the main channel, is often used.

Scour around bridge piers has been much studied in the laboratory but field studies have been hampered by inadequate instrumentation and measurement procedures. For design purposes, interest is focused on the maximum scour depth at a pier, y_s (see Fig. 35.8 for a definition sketch). A wide variety of formulae have been proposed; only one will be presented here, namely that developed at Colorado State University, and recommended by the U. S. Federal Highway Administration,

$$\frac{y_s}{b} = 2.0\, K_p \left(\frac{H_0}{b}\right)^{0.35} Fr_0^{0.43} \tag{35.27}$$

where b = the pier width
H_0 = the approach flow depth
$Fr_0 = V_0/\sqrt{gH_0}$, the Froude number of the approach flow

The empirical coefficient, K_p, depends on pier geometry, the angle of attack or skew angle (θ in Fig. 35.8) of the flow with respect to the pier, bed condition (plane-bed or dunes), and whether armoring of the bed (see below) may occur; details of the evaluation of K_p may be found in Richardson and Davis (1995).

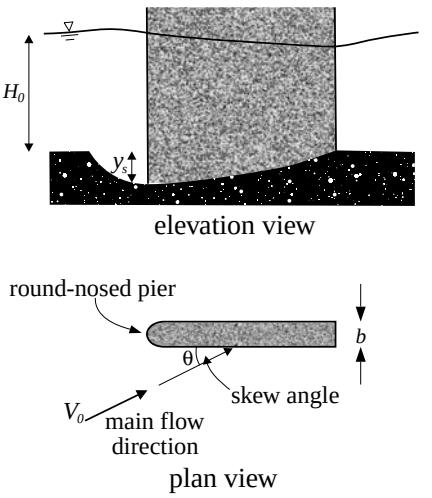

FIGURE 35.8 Bridge pier causing local scour.

Unsteady Aspects

Many problems in channels involve non-uniform flows and slow long-term changes, such as *aggradation* (an increase in bed elevation due to net deposition) or *degradation* (a decrease in bed elevation due to net erosion). The problem is formulated generally in terms of three (differential) balance equations: conservation of mass of water, of momentum (or energy), of sediment. For gradually varied flows, the first two equations are identical in form to those encountered in fixed-bed problems (see the chapter on open channel flows), except that the bed elevation is allowed to change with time.

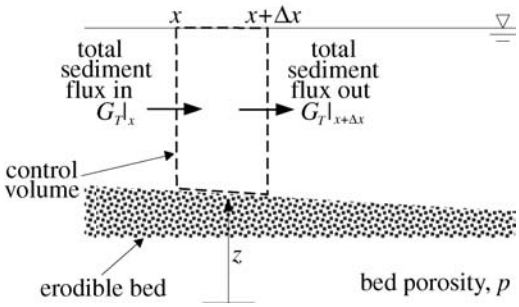

FIGURE 35.9 Control volume used in unsteady analysis.

A control volume analysis of a channel reach of cross-sectional area, A, and bed width, B_b, (Fig. 35.9) shows that conservation (continuity) of sediment over a small reach of length, Δx, in a time interval, Δt, requires

$$\Delta\left[(1-p)z\right]\left(B_b\Delta x\right) + \Delta\langle C\rangle A\Delta x + \left(G_T\big|_{x+\Delta x} - G_T\big|_x\right)\Delta t = S_s\Delta t\Delta x \tag{35.28}$$

where p = bed the porosity
z = the bed elevation
t = the time variable
$\langle C\rangle$ = the concentration of sediment averaged over the cross-sectional area
$G_T|_x$ = the total sediment discharge evaluated at a cross-section location, x
S_s = included as a possible external sediment source strength per unit length

The first term represents the change over time in the bulk volume of sediment in the bed due to net deposition or erosion (bed storage); the second term represents the change over time in total volume of suspended sediment in the water column (water column storage); the third term stems from differences in sediment discharge between the channel cross-sections bounding the control volume; and the fourth term allows for distributed sediment sources. The second term is often assumed negligible, so that in its differential form (dividing through by $\Delta x\,\Delta t$ and taking the limit as $\Delta x \to 0$, $\Delta t \to 0$), Eq. (35.28) is written as

$$\frac{\partial\left[(1-p)zB_b\right]}{\partial t} + \frac{\partial G_T}{\partial x} = S_s \tag{35.29}$$

which is referred to as the *Exner equation*. A total load computation as in Section 35.6 is performed to determine G_T. This assumes implicitly that a quasi-equilibrium has been established, in which the sediment discharge at any section is equal to the sediment transport capacity as specified by conventional total load computations. Thus, the quality of the predictions of the unsteady model depends not only on the quasi-equilibrium assumption but also on the quality of the estimates of sediment transport by the transport formula applied.

Numerical methods are used to solve Eq. (35.29) simultaneously with the flow equations (water continuity and the momentum/energy equations). In practice, numerical models often solve the flow equations first, and then the sediment continuity equation, under the implicit assumption that changes in bed elevations occur much more slowly than changes in water-surface elevation. Of the many unsteady alluvial-river models described in the literature, HEC-6 for scour and deposition in rivers and reservoirs, may be mentioned as a member of the well-known HEC series of channel models (Hydrologic Engineering Center, 1991) and hence perhaps the most widely adopted. There are plans to incorporate sediment

transport capabilities to the new generation of HEC software, HEC-RAS, but as of this writing, this has not yet been performed. An early evaluation (Comm. on Hydrodynamic Models for Flood Insurance Studies, 1983) of several models, including HEC-6, noted the following general deficiences: unreliable formulation and/or inadequate understanding of sediment-transport capacity, of flow resistance, of armoring (see below), and of bank erosion. In spite of the intervening years, this evaluation may still be taken as a cautionary note in using such models.

Effects of a Nonuniform Size Distribution

Natural sediments exhibit a size distribution (also termed gradation), and, since the grain diameter profoundly influences transport, the effects of size distribution are likely substantial. The crudest models of such effects incorporate distribution parameters, such as the geometric standard deviation, σ_g, in empirical formulae, e.g., the Brownlie formulae. An alternative approach more appropriate for computer modeling divides the distribution into a finite number of discrete size classes. Each size class is characterized by a single grain diameter, and results such as the Shields curve or the Rouse equation are applied to each separate size class, where they are presumably more valid. Total transport is then determined by a summation of the transport in each size class.

The heterogeneous bed material, which constitutes a source or sink of grains of different size classes, must be taken into account. Conventional bed load or total load transport equations or even initiation of motion criteria may not necessarily apply to individual size classes in a mixture. The transport or entrainment into suspension of one size class may influence transport or entrainment of other size classes, so individual size classes may not be treated independently of each other. This is often handled by the use of empirical 'hiding' coefficients. Finer bed material may under erosive conditions be preferentially entrained into the flow, with the result that the remaining bed material becomes coarser. This will reduce the rate of erosion relative to the case where the bed consists of uniformly sized fine material. If the available fine material is eventually depleted, suspended load transport will be reduced or in the limit entirely suppressed. Eventually, a layer of coarse material termed the armor layer consisting of material that is not erodible under the given flow condition may develop, which protects or 'armors' the finer material below it from erosion, thereby substantially reducing sediment transport and local scour. Armoring may also have consequences for flow resistance, since size distribution characteristics of the bed will vary with varying bed shear stress, and hence affect bed roughness and bed forms. In this way, episodic high-transport events such as floods may have an enduring impact on sediment transport as well as flow depths. Various detailed numerical models of the armoring process have been developed, and the reader is directed to the literature for further information (Borah et al., 1982; Sutherland, 1987; Andrews and Parker, 1987; Holly and Rahuel, 1990a, b; Hydrological Engineering Center, 1991).

Gravel-Bed Streams

Channels in which the bed material consists primarily of coarse material in the gravel and larger range are typically situated in upland mountain regions with high bed slopes ($S > 0.005$), in contrast to sand-bed channels, which are found on flatter slopes of lower lying regions. The same basic concepts summarized in previous sections apply also to gravel-bed streams, but the possibly very wide range of grain sizes introduces particular difficulties. Bedforms such as dunes play less of a role, and so grain resistance can often be assumed dominant; hence an upper regime stage-discharge relationship can be applied. The effects of large-scale roughness elements such as cobbles and boulders that may even protrude through the water surface may however not be well described by formulae based primarily on data from sand-bed channels. Instead of a gradually varying bed elevation, riffle-pool (or step-pool) sequences of alternating shallow and deep flow regions may occur. The wide size range results in transport events that may be highly non-uniform across the stream, and highly unsteady in the sense of being dominated by episodic events. Armoring may also need to be considered. The coarse grain sizes increase the relative importance of bedload transport. The highly non-uniform and unsteady nature of the transport hinders

reliable field measurements. Much debate has surrounded the topic of appropriate sampling of the bed surface material to characterize the grain size distribution. The traditional grid method of Wolman (1954) draws a regular grid over the bed of the chosen reach, with the gravel (cobble or boulder) found at each of gridpoint being included in the sample.

A friction law proposed specifically for mountain streams is that of Bathurst (1985) based on data from English streams (60 mm < d_{50} < 343 mm, 0.0045 < S < 0.037, 0.3 m^3/s < Q < 195 m^3/s) for which the friction factor, f, is given by

$$\sqrt{\frac{8}{f}} = 5.62 \log_{10} \frac{H}{d_{84}} + 4 \tag{35.30}$$

with a reported uncertainty of ±30%. An earlier formula due to Limerinos (1970) is identical in form except that R_h is used instead of the depth, H, and Manning's n is sought rather than f:

$$\frac{K_M}{\sqrt{g}} \frac{R_h^{1/6}}{n} = \sqrt{\frac{8}{f}} = 5.7 \log_{10} \frac{R_h}{d_{84}} + 3.4 \tag{35.31}$$

K_M is the dimensional constant associated with Manning's equation (see chapter on Open Channel Hydraulics). Using laboratory and field data, Bathurst et al. (1987) assessed various criteria for the initiation of motion and bedload discharge formulae (including the Meyer-Peter-Muller formula, Eq. [35.18]). They recommended a modified Schoklisch formula for larger rivers (Q > 50 m^3/s) where sediment supply is not a constraint:

$$\left(q_s\right)_b = \frac{2.5}{s} S_f^{3/2} \left(q - q_c\right) \tag{35.32}$$

where the critical unit-width discharge, q_c, is given by

$$q_c = 0.21 \frac{\sqrt{g d_{16}^3}}{S_f^{1.1}} \tag{35.33}$$

Here, $(q_s)_b$ is the *volumetric* unit width bedload discharge, and the units are metric in both equations. These gravel-bed formulae, while representative, are not necessarily the best for all problems; and they should be applied with caution and a dose of skepticism.

Defining Terms

Aggradation — Long-term increase in bed-level over an extended reach due to sediment deposition

Armoring — A phenomenon in which a layer of coarser particles that are non-erodible under the given flow condition protects the underlying layer of finer erodible particles

Bed forms — Features on an erodible channel bed which depart from a plane bed, e.g., dunes or ripples

Bed load — That part of the total sediment discharge which is transported primarily very close to the bed

Critical shear stress — The bed shear stress above which general sediment transport is said to begin

Critical velocity — The mean velocity above which general sediment transport is said to begin

Local scour — Erosion occurring over a region of limited extent due to local flow conditions, such as may be caused by the presence of hydraulic structures

Sediment discharge — The downstream mass or weight flux of sediment

Suspended load — That part of the total sediment discharge which is transported primarily in suspension

36.1 Wave Mechanics

Waves on the surface of a natural body of open water are the result of disturbing forces that create a deformation, which is restored to equilibrium by, gravitational and surface tension forces. Surface waves are characterized by their height, length, and the water depth over which they are traveling. Figure 36.1 shows a two-dimensional sketch of a sinusoidal surface wave propagating in the *x*-direction. The **wave height**, H, is the vertical distance between its crest and leading trough. Wavelength, L, is the horizontal distance between any two corresponding points on successive waves and wave period is the time required for two successive crests or troughs to pass a given point. The **celerity** of a wave C, is the speed of propagation of the waveform (phase speed), defined as C = L/T. Most ocean waves are progressive; their waveform appears to travel at celerity C relative to a background. Standing waves, their waveforms remains stationary relative to a background, occur from the interaction of progressive waves traveling in opposite directions and are often observed near reflective coastal features. Progressive deep ocean waves are oscillatory meaning that the water particles making up the wave do not exhibit a net motion in the direction of wave propagation. However, waves entering shallow-water begin to show a net displacement of water in the direction of propagation and are classified as translational. The equilibrium position used to reference surface wave motion, (Still Water Level SWL) is z = 0 and the bottom is located at z = –d (Fig. 36.1).

The free surface water elevation, η, for a natural water wave propagating over an irregular, permeable bottom may appear quite complex. However, by assuming that, viscous effects are negligible (concentrated near the bottom), flow is irrotational and incompressible, and wave height is small compared to wavelength,

* Professor William L. Wood, first author of this chapter in the first edition, died in 1997.

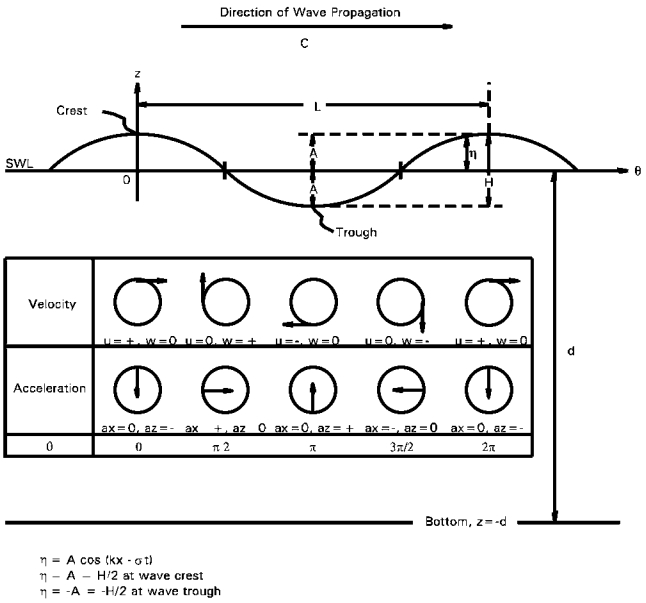

FIGURE 36.1 Definition sketch of free surface wave parameters for a linear progressive wave. Shown also are the fluid particle velocities and accelerations associated with each portion of the wave.

a remarkably simple solution can be obtained for the surface wave boundary value problem. This simplification, referred to as linear, small-amplitude wave theory, is extremely accurate and easy to use in many coastal engineering applications. Furthermore, the linear nature of this formulation allows for the free surface to be represented by superposition of sinusoids of different amplitudes and frequencies, which facilitates the application of Fourier decomposition and associated analysis techniques.

Progressive, Small-Amplitude Waves — Properties

The equation for the free surface displacement of a progressive wave is

$$\eta = A\cos(kx - \sigma t) \tag{36.1}$$

where amplitude, $A = H/2$
wave number, $k = 2\pi/L$
wave frequency $\sigma = 2\pi/T$

The expression relating individual wave properties and water depth, d, to the propagation behavior of these waves is the dispersion relation,

$$\sigma^2 = gk \tanh kd, \tag{36.2}$$

where g is the acceleration of gravity.

From Eq. (36.2) and the definition of celerity (C) it can be shown that

$$C = \frac{\sigma}{k} = \frac{gT}{2\pi}\tanh kd \tag{36.3}$$

and

$$L = \frac{g T^2}{2\pi} \tanh kd \tag{36.4}$$

The hyperbolic function *tanh kd* approaches useful simplifying limits of 1 for large values of *kd* (deep water) and *kd* for small values of *kd* (shallow water). Applying these limits to Eqs. (36.3) and (36.4) results in expressions for deep water of

$$C_o = \frac{gT}{2\pi} = 5.12T \quad \text{(English units, ft/s)}$$

or

$$C_o = 1.56T \quad \text{(SI units, m/s)}$$

and

$$L_o = \frac{gT^2}{2\pi} = 5.12\,T^2 \quad \text{(English units, ft)} \tag{36.5}$$

or

$$L_o = 1.56T^2 \quad \text{(SI units, m).}$$

A similar application for shallow water results in

$$C = \sqrt{g\,d} \tag{36.6}$$

which shows that wave speed in shallow water is dependent only on water depth. The normal limits for deep and shallow water are $kd > \pi$ and $kd < \pi/10$ ($d/L > 1/2$ and $d/L < 1/20$) respectively, although modification of these limits may be justified for specific applications. The region between these two limits ($\pi/10 < kd < \pi$) is defined as intermediate depth water and requires use of the full Eqs. (36.3) and (36.4).

Some useful functions for calculating wave properties at any water depth, from deep water wave properties, are

$$\frac{C}{C_o} = \frac{L}{L_o} = \tanh \frac{2\pi d}{L}. \tag{36.7}$$

Values of d/L can be calculated as a function of d/L_o by successive approximations using

$$\frac{d}{L} \tanh \frac{2\pi d}{L} = \frac{d}{L_o} \tag{36.8}$$

The term d/L has been tabulated as a function of d/L_o by Wiegel (1954) and is presented, along with many other useful functions of d/L in Appendix C of The Shore Protection Manual (U.S. Army Corps of Engineers, 1984).

Particle Motions

The horizontal component of particle velocity beneath a wave is

$$u = \frac{H}{2}\,\sigma\,\frac{\cosh\, k\left(d+z\right)}{\sinh\, kd} \cos\left(kx - \sigma t\right) \tag{36.9}$$

The corresponding acceleration is

$$a_x = \frac{\partial u}{\partial t} = \frac{H}{2}\sigma^2 \frac{\cosh k\left(d+z\right)}{\sinh\ kd} \sin\left(kx-\sigma t\right) \tag{36.10}$$

The vertical particle velocity and acceleration are respectively

$$w = \frac{H}{2}\sigma \frac{\sinh\ k\left(d+z\right)}{\sinh\ kd} \sin\left(kx-\sigma t\right) \tag{36.11}$$

and

$$a_z = \frac{\partial w}{\partial t} = -\frac{H}{2}\sigma^2 \frac{\sinh\ k\left(d+z\right)}{\sinh\ kd} \cos\left(kx-\sigma t\right) \tag{36.12}$$

It can be seen from Eqs. (36.9) and (36.11) that the horizontal and vertical particle velocities are 90° out of phase at any position along the wave profile. Extreme values of horizontal velocity occur in the crest (+, in the direction of wave propagation) and trough (–, in the direction opposite to the direction of wave propagation) while extreme vertical velocities occur mid-way between the crest and trough, where water displacement is zero. The *u* and *w* velocity components are at a minimum at the bottom and both increase as distance upward in the water column increases. Maximum vertical accelerations correspond to maximum in horizontal velocity and maximum horizontal accelerations correspond to maximum in vertical velocity. Figure 36.1 provides a graphic summary of these relationships.

The particle displacements can be obtained by integrating the velocity with respect to time and simplified by using the dispersion relationship (Eq. [36.2]) to give a horizontal displacement

$$\xi = -\frac{H}{2} \frac{\cosh k\left(d+z_o\right)}{\sinh kd} \sin\left(kx_o-\sigma t\right) \tag{36.13}$$

and vertical displacement

$$\zeta = \frac{H}{2} \frac{\sinh k\left(d+z_o\right)}{\sinh kd} \cos\left(kx_o-\sigma t\right) \tag{36.14}$$

where (x_o, z_o) is the mean position of an individual particle.

It can be shown by squaring and adding the horizontal and vertical displacements that the general form of a water particle trajectory beneath a wave is elliptical. In deep water, particle paths are circular and in shallow-water they are highly elliptical as shown in Fig. 36.2.

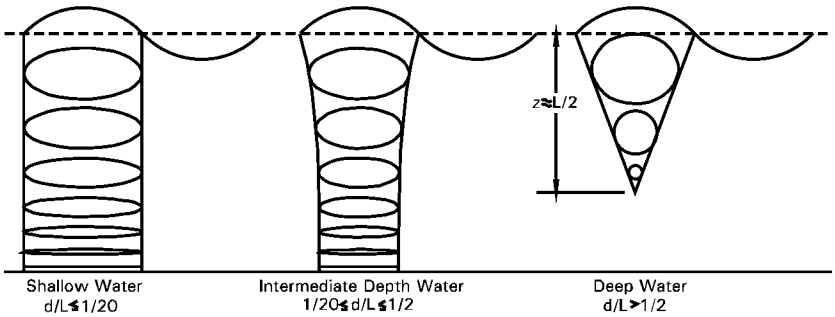

FIGURE 36.2 Fluid particle paths for linear progressive waves in different relative water depths.

Pressure Field

The pressure distribution beneath a progressive water wave is given by the following form of the Bernoulli equation

$$p = -\rho g z + \rho g \eta \, K_p(z) \tag{36.15}$$

where ρ is fluid density and K_p, the pressure response coefficient, is

$$K_p = \frac{\cosh k(d+z)}{\cosh kd} \tag{36.16}$$

which will always be less than 1, below mean still water level. The first term in Eq. (36.15) is the *hydrostatic pressure* and the second is the *dynamic pressure* term. This dynamic pressure term accounts for two factors that influence pressure, the free surface displacement η and the vertical component of acceleration.

A frequently used method for measuring waves at the coast is to record pressure fluctuations from a bottom-mounted pressure gage. Isolating the dynamic pressure (P_D) from the recorded signal by subtracting out the hydrostatic pressure gives the relative free surface displacement

$$\eta = \frac{P_D}{\rho g \, K_p(-d)} \tag{36.17}$$

where $K_p(-d) = 1/\cosh kd$.

It is necessary, therefore, when determining wave height from pressure records to apply the dispersion relationship (Eq. [36.2]) to obtain K_p from the frequency of the measured waves. It is important to note that K_p for short period waves is very small at the bottom (–d), which means that very short period waves may not be measured by a pressure gage.

A summary of the formulations for calculating linear wave theory wave characteristics in deep, intermediate, and shallow water is presented in Table 36.1. A much more comprehensive presentation of linear, small-amplitude theory is found in the classic reference Oceanographical Engineering (Weigel, 1954) The Shore Protection Manual (U.S. Army Corps of Engineers, 1984), and Water Wave Mechanics for Engineers and Scientists (Dean and Dalrymple, 1991).

Wave Energy

Progressive surface water waves possess potential energy from the free surface displacement and kinetic energy from the water particle motions. From linear wave theory it can be shown that the average potential energy per unit surface area for a free surface sinusoidal displacement, restored by gravity, is

$$\bar{E}_p = \frac{\rho g H^2}{16} \tag{36.18}$$

Likewise the average kinetic energy per unit surface area is

$$\bar{E}_k = \frac{\rho g H^2}{16} \tag{36.19}$$

and the total average energy per unit surface area is

$$\bar{E} = \bar{E}_p + \bar{E}_k = \frac{\rho g H^2}{8} \tag{36.20}$$

TABLE 36.1 Summary of Linear Wave Theory, Wave Characteristics, $\theta = (kx - \sigma t)$

Relative Depth	Shallow Water $d/L < 1/20$	Transitional Water $1/20 < d/L < 1/2$	Deep Water $d/L > 1/2$
1. Wave profile	Same as "Transitional Water" →	$\eta = \frac{H}{2}\cos[2kx - \sigma t T] = \frac{H}{2}\cos\theta$	Same as "Transitional Water" ←
2. Wave celerity	$C = \frac{L}{T} = \sqrt{gd}$	$C = \frac{L}{T} = \frac{gT}{2\pi}\tanh(kd)$	$C = C_o = \frac{L}{T} = \frac{gT}{2\pi}$
3. Wavelength	$L = T\sqrt{gd} = CT$	$L = \frac{gT^2}{2\pi}\tanh(kd)$	$L = L_o = \frac{gT^2}{2\pi} = C_o T$
4. Group velocity	$C_g = C = \sqrt{gd}$	$C_g = nC = \frac{1}{2}\left[1 + \frac{2kd}{\sinh(2kd)}\right]\cdot C$	$C_g = \frac{1}{2}C = \frac{gT}{4\pi}$
5. Water particle velocity (a) Horizontal	$u = \frac{H}{2}\sqrt{\frac{g}{d}}\cos\theta$	$u = \frac{H}{2}\sigma\frac{\cosh k(z+d)}{\sinh kd}\cos\theta$	$u = \frac{\pi H}{T}e^{kz}\cos\theta$
(b) Vertical	$w = \frac{H\pi}{T}\left(1 + \frac{z}{d}\right)\sin\theta$	$w = \frac{H}{2}\sigma\frac{\sinh k(z+d)}{\sinh kd}\sin\theta$	$w = \frac{\pi H}{T}e^{kz}\sin\theta$
6. Water particle accelerations (a) Horizontal	$a_x = \frac{H\pi}{T}\sqrt{\frac{g}{d}}\sin\theta$	$a_x = \frac{H}{2}\sigma^2\frac{\cosh k(z+d)}{\sinh kd}\sin\theta$	$a_x = 2H\left(\frac{\pi}{T}\right)^2 e^{kz}\sin\theta$
(b) Vertical	$a_z = -2H\left(\frac{\pi}{T}\right)^2\left(1 + \frac{z}{d}\right)\cos\theta$	$a_z = -\frac{H}{2}\sigma^2\frac{\sinh k(z+d)}{\sinh kd}\cos\theta$	$a_z = -2H\left(\frac{\pi}{T}\right)^2 e^{kz}\cos\theta$
7. Water particle displacements (a) Horizontal	$\xi = -\frac{HT}{4\pi}\sqrt{\frac{g}{d}}\sin\theta$	$\xi = -\frac{H}{2}\frac{\cosh k(z+d)}{\sinh kd}\sin\theta$	$\xi = -\frac{H}{2}e^{kz}\sin\theta$
(b) Vertical	$\zeta = \frac{H}{2}\left(1 + \frac{z}{d}\right)\cos\theta$	$\zeta = \frac{H}{2}\frac{\sinh k(z+d)}{\sinh kd}\cos\theta$	$\zeta = \frac{H}{2}e^{kz}\cos\theta$
8. Subsurface pressure	$p = \rho g(\eta - z)$	$p = \rho g\,\eta\frac{\cosh k(z+d)}{\cosh kd} - \rho g z$	$p = \rho g\,\eta e^{kz} - \rho g z$

The unit surface area considered is a unit width times the wavelength L so that the total energy per unit width is

$$E_T = \frac{1}{8}\rho g\, H^2 L \tag{36.21}$$

The total energy per unit surface area in a linear progressive wave is always equipartitioned as one half potential and one half kinetic energy.

Energy flux is the rate of energy transfer across the sea surface in the direction of wave propagation. The average energy flux per wave is

$$F_E = E\,Cn \tag{36.22}$$

where

$$n = \frac{C_g}{C} = \frac{1}{2}\left(1 + \frac{2kd}{\sinh 2kd}\right) \tag{36.23}$$

and C_g is the *group speed* defined as the speed of energy propagation.

In deep water $n = 1/2$ and in shallow water $n = 1$ indicating that energy in deep water travels at half the speed of the wave while in shallow water energy propagates at the same speed as the wave.

Wave Shoaling

Waves entering shallow water conserve period and, with the exception of minor losses, up to breaking, conserve energy. However, wave celerity decreases as a function of depth and correspondingly wavelength shortens. Therefore, the easiest conservative quantity to follow is the energy flux (given in Eq. [36.22]), which remains constant as a wave shoals. Equating energy flux in deep water (H_o, C_o) to energy flux at any shallow water location (H_x, C_x) results in the general shoaling relation

$$\frac{H_x}{H_o} = \left(\frac{1}{2n} \frac{C_o}{C_x} \right)^{1/2} \tag{36.24}$$

where n is calculated from Eq. (36.23) and C_o/C_x can be obtained from Eq. (36.7).

Therefore, by knowing the deep water wave height and period (H_o, T_o)1 and the bathymetry of a coastal region, the shoaling wave characteristics (H_x, C_x, L_x) can be calculated at any point, x, prior to breaking. A limitation to Eq. (36.24) is that it does not directly incorporate the effect of deep-water angle of approach to the coast.

Wave Refraction

It can be shown that a deep water wave approaching a coast at an angle α_o and passing over a coastal bathymetry characterized by straight, parallel contours refracts according to Snell's law:

$$\frac{\sin \alpha_o}{C_o} = \frac{\sin \alpha}{C} \tag{36.25}$$

Since waves in shallow water slow down as depth decreases, application of Snell's law to a plane parallel bathymetry indicates that wave crests tend to turn to align with the bathymetric contours. Unfortunately, most offshore bathymetry is both irregular and variable along a coast and the applicable **refraction** techniques involve a non-linear partial differential equation, which can be solved approximately by various computer techniques (Noda, 1974; RCPWAVE, and others). However, there are more easily applied ray tracing methods that use Snell's law applied to idealized bathymetry (bathymetry that has been "smoothed" to eliminate abrupt turns and steep gradients). The U.S. Army Corps of Engineers distributes an easy to use set of PC computational programs, Automated Coastal Engineering System (ACES), which include a Snell's law ray tracing program.

Considering two or more wave rays propagating shoreward over plane parallel bathymetry, Fig. 36.3, it is possible to have the rays either converge or diverge. Under these conditions, the energy per unit area may increase (convergence) or decrease (divergence) as a function of the perpendicular distance of separation between wave rays b_o and b_x. Using the geometric relationships shown in Fig. 36.3, Eq. (36.24) is modified to account for convergence and divergence of wave rays as

$$\frac{H_x}{H_o} = \left(\frac{1}{2n} \frac{C_o}{C_x} \right)^{1/2} \left(\frac{b_o}{b_x} \right)^{1/2} \tag{36.26}$$

also written as

$$H_n = H_o K_s K_R \tag{36.27}$$

where K_s = the shoaling coefficient
K_R = the refraction coefficient.

This expression is equally valid between any two points along a wave ray in shallow water.

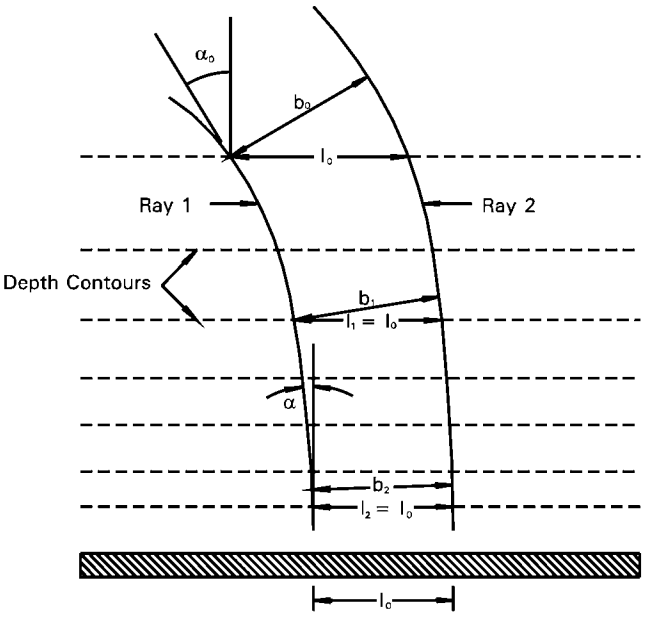

FIGURE 36.3 Definition sketch for wave rays refracting over idealized plane parallel bathymetry.

Wave Diffraction

Wave diffraction is a process by which energy is transferred along the crest of a wave from an area of high energy density to an area of low energy density. There are two important coastal engineering applications of diffraction. First, as wave rays converge and diverge in response to natural changes in bathymetry the K_R term in Eq. (36.27) will increase and decrease respectively. As a result, energy will move along the wave crest from areas of convergence to areas of divergence. It is, therefore, necessary to consider the effects of both refraction and diffraction when calculating wave height transformation due to shoaling. The U.S. Army Corps of Engineers RCPWAVE is a PC compatible program capable of doing these calculations for "smoothed" bathymetry.

The fundamental equations used to carry out diffraction calculations are based on the classical Sommerfield relation

$$\eta = \frac{AkC}{g}\cosh kd\left|F(r,\Psi)\right|e^{ikCt} \tag{36.28}$$

where

$$K' = \frac{H_o}{H_i} = \left|F(r,\Psi)\right| \tag{36.29}$$

The second, and perhaps most important, application of wave diffraction is that due to wave-structure interaction. For this class of problems, wave diffraction calculations are essential for obtaining the distribution of wave height in harbors or behind engineered structures. There are three primary types of wave-structure diffraction, important to coastal engineering (Fig. 36.4a-c): (a) diffraction at the end of a single breakwater (semi-infinite); (b) diffraction through a harbor entrance (gap diffraction); and (c) diffraction around an offshore breakwater.

The methods of solution for all three of these wave-structure interactions are similar, but are restricted by some important assumptions. For each case there is a *geometric shadow zone* on the sheltered side of

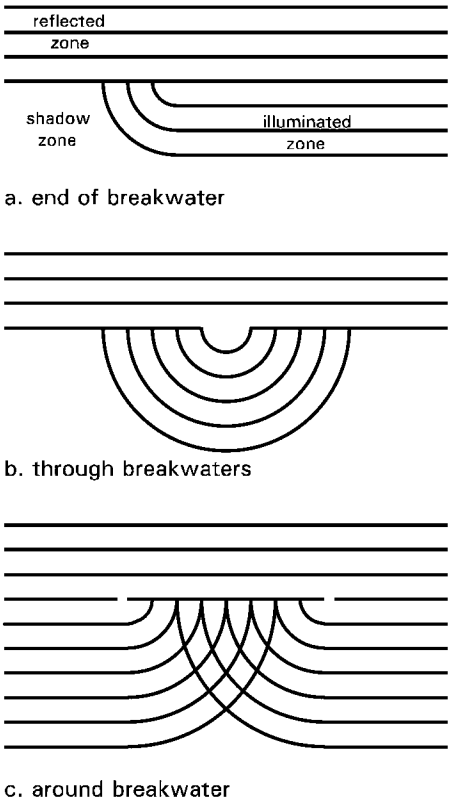

FIGURE 36.4 Wave diffraction patterns around breakwaters.

the structure, a *reflected wave zone* on the front or incident wave side of the structure, and an "*illuminated*" *zone* in the area of direct wave propagation (Fig. 36.4a). The solution to $F(r, \Psi)$ is complicated, however, The Shore Protection Manual (1984) provides a series of templates for determining diffraction coefficients K', defined as the ratio of wave height in the zone affected by refraction to the unaffected incident wave height, for semi-infinite breakwaters and for breakwater gaps between 1 and 5 wave lengths (L) wide. For breakwater gaps greater than 5L the semi-infinite templates are used independently and for gaps 1L or less, a separate set of templates are provided (The Shore Protection Manual (U.S. Army Corps Of Engineers, 1984)). A basic diffraction-reflection calculation program is also provided in the Automated Coastal Engineering System (ACES, 1992).

Wave Breaking

Waves propagating into shallow water tend to experience an increase in wave height to a point of instability at which the wave breaks, dissipating energy in the form of turbulence and work done on the bottom. Breaking waves are classified as**: spilling breakers** generally associated with low sloping bottoms and a gradual dissipation of energy; **plunging breakers** generally associated with steeper sloping bottoms and a rapid, often spectacular, "explosive" dissipation of energy; and *surging breakers* generally associated with very steep bottoms and a rapid narrow region of energy dissipation. A widely used classic criteria (McCowan, 1894) applied to shoaling waves relates breaker height H_b to depth of breaking d_b through the relation

$$H_b = 0.78\, d_b \tag{36.30}$$

However, this useful estimate neglects important shoaling parameters such as bottom slope (m) and deepwater wave angle of approach (α_o). Dean and Dalrymple (1991) used Eq. (36.26) and McCowan's breaking criteria to solve for breaker depth (d_b), distance from the shoreline to the breaker line (x_b) and breaker height (H_b) as

$$d_b = \frac{1}{g^{1/5}\kappa^{4/5}}\left(\frac{H_0^2\, C_0 \cos\alpha_0}{2}\right)^{2/5} \tag{36.31}$$

$$x_b = \frac{d_b}{m} \tag{36.32}$$

and

$$H_b = \kappa\, d_b = \kappa m x_b = \left(\frac{\kappa}{g}\right)^{1/5}\left(\frac{H_0^2\, C_0 \cos\alpha_0}{2}\right)^{2/5} \tag{36.33}$$

where m = beach slope
$\kappa = H_b/d_b$

Dalrymple et al. (1977) compared the results of a number of laboratory experiments with Eq. (36.32) and found it under predicts breaker height by approximately 12% (with $\kappa = 0.8$). Wave breaking is still not well understood and caution is urged when dealing with engineering design in the active breaker zone.

36.2 Ocean Wave Climate

The Nature of the Sea Surface

As the wind blows across the surface of the sea, a large lake, or a bay, momentum is imparted from the wind to the sea surface. Of this momentum, approximately 97% is used in generating the general circulation (currents) of the water body and the remainder supplies the development of the surface wave field. Although this surface wave momentum represents a small percentage of the total momentum, it results in an enormous quantity of wave energy.

Within the region of active wind-wave generation, the sea surface becomes very irregular in size, shape, and direction of propagation of individual waves. This disorderly surface is referred to as **sea**. As waves propagate from their site of generation, they tend to sort themselves out into a more orderly pattern. This phenomenon, known as dispersion, is due to the fact that longer period waves tend to travel faster, while short period waves lag behind (see Eq. [36.2]). Therefore, **swell** is a term applied to waves, which have propagated outside the region of active wind wave generation and are characterized by a narrow distribution of periods, and regular shape and a narrow direction of travel.

Given these distinctions between sea and swell it is reasonable to expect that the statistical description of the sea surface would be very different for each case. The wave spectrum is a plot of the energy associated with each frequency ($f = 1/T$) component of the sea surface. The difference between sea and swell spectra is shown schematically in Fig. 36.5. Note that the sea spectrum is typically broadly distributed in frequency while the swell spectrum is narrowly distributed in frequency (tending toward monochromatic waves).

The directional distribution of wave energy propagation is given by the two-dimensional directional wave energy spectrum. Just as in the case of the one-dimensional wave energy spectrum, the two-dimensional spectrum provides a plot of wave energy versus frequency; however, the spectrum is further defined by the direction of wave propagation.

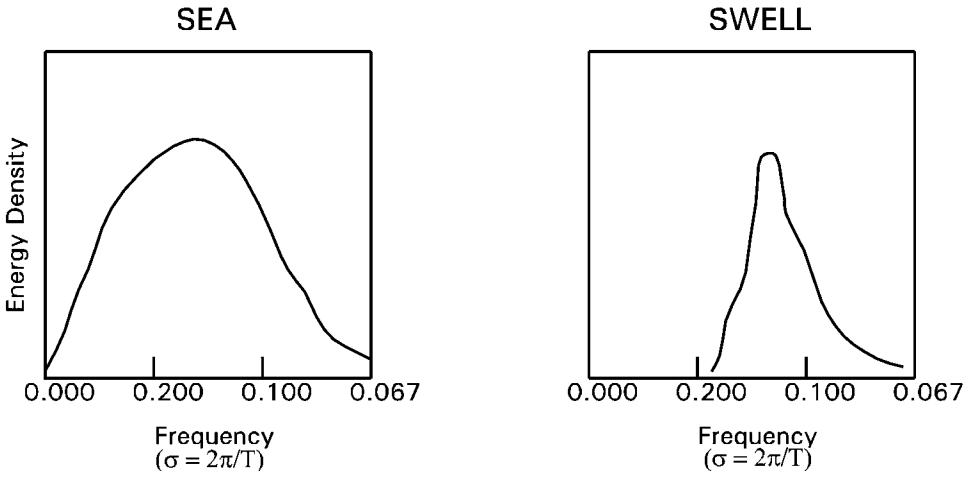

FIGURE 36.5 Characteristic energy diagrams showing the difference between sea and swell.

TABLE 36.2 One-Dimensional Wave Prediction Formulae

SMB	$H_s = 0.283\, g^{-1}\, U^2 \tanh\left[0.0125\left(\frac{gx}{U_{10}^2}\right)^{0.42}\right]$
	$T = 7.54\, g^{-1}\, U \tanh\left[0.077\left(\frac{gx}{U_{10}^2}\right)^{0.25}\right]$
JONSWAP	$H_s = 0.0016\, g^{0.5}\, U_x^{0.5}$
	$T = 0.286\, g^{0.62}\, U_{10}^{0.33}\, x^{0.33}$
Donelan	$H_s = 0.00366\, g^{-0.62}\, U_{10}^{1.24} \times x^{0.38}\left(\cos\phi\right)^{1.24}$
	$T = 0.54\, g^{-0.77}\, U_{10}^{0.54}\, x^{0.23}\left(\cos\phi\right)^{0.54}$
where:	H_s = significant wave height (in meters) T = peak energy wave period (in seconds) U_{10} = wind speed at 10m height (in meters per second) x = fetch length (in wave direction for Donelan formulas) φ = angle between wind and waves g = 9.8 m/s^2

Wave Prediction

The wave height and associated energy contained in the sea surface is generally dependent on three parameters: the speed of the wind, U, measured at 10 m above the sea surface, the open water distance over which the wind blows, **fetch** length, x and the length of time the wind does work on the sea surface, duration, t. The growth of a wind driven sea surface may be limited by either the fetch or duration, producing a sea state less than "fully arisen" (maximum energy) for a given wind speed.

One-dimensional wave prediction models generally consist of equations, which estimate wave height and wave period at a particular location and time as a function of fetch length and wind speed. Three examples of one-dimensional wave prediction formulas are provided in Table 36.2. It should be noted that the wind speed utilized in these wave prediction models must be obtained from, or corrected to, a height of 10 m above the water surface. A widely used approximation for correcting a wind speed, measured at height z over the open ocean, to 10 m is

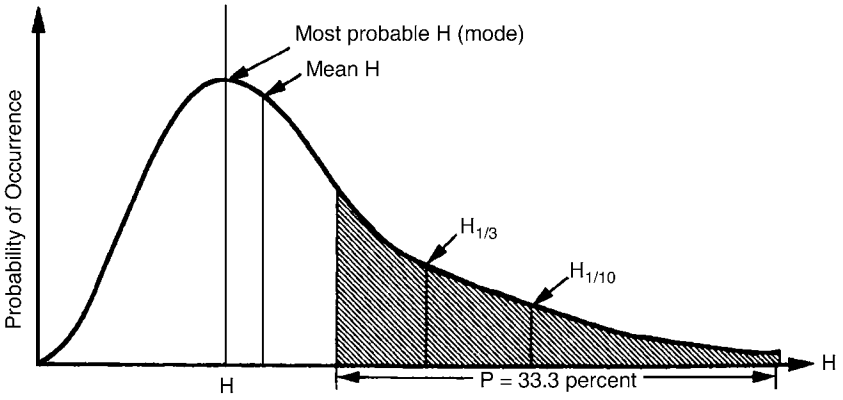

FIGURE 36.6 Statistical distribution of wave heights.

$$U_{10} = U_z \left(\frac{10}{z} \right)^{1/7} \tag{36.34}$$

If the wind speed is measured near the coast, the exponent used for this correction is 2/7. In the event that over water winds are not available, over land winds may be utilized, but need to be corrected for frictional resistance. This is due to the fact that the increased roughness typically present over land sites serves to modify the wind field. A concise description of this methodology is presented in the Shore Protection Manual (1984).

Since the natural sea surface is statistically complex, the wave height is usually expressed in terms of the average of the one-third largest waves or the **"significant wave height,"** H_s. The significant wave period corresponds to the energy peak in the predicted wave spectrum. Other expressions for wave height which are commonly used in design computations are H_{max}, the maximum wave height, H_{rms}, the root mean square wave height, $\bar{H}$, the average wave height, H_{10}, the average of highest 10 percent of all waves, H_1, the average of the highest 1 percent of all waves (Fig. 36.6). The energy-based parameter commonly used to represent wave height is H_{10}, which is an estimate of the significant wave height fundamentally related to the energy distribution of a wave train. Table 36.3 summarizes the relationship between these various wave height parameters.

When predicting wave generation by hurricanes, the determination of fetch and duration is much more difficult due to large changes in wind speed and direction over short time frames and distances. Typically, the wave field associated with the onset of a hurricane or large storm will consist of a locally generated sea superimposed on swell components from other regions of the storm (see The Shore Protection Manual [U.S. Army Corps Of Engineers, 1984]).

TABLE 36.3 Summary of Approximate Statistical Wave Height Relations

	$\overline{H}3$	H_{rms}	H_s	H_{10}	H_1	$H_{\max}$
$\overline{H}2$		.89	.63	.49	.38	0.33
H_{rms}	1.13		.71	.56	.42	0.38
H_s	1.60	1.42		.79	.60	0.53
H_{10}	2.03	1.80	1.27		.76	0.68
H_1	2.67	2.37	1.67	1.31		0.89
$H_{\max}$	2.99	2.65	1.87	1.47	1.12	

See accompanying text for explanations of various wave height designations.

Wave Data Information Sources

Several sources of wave data exist in both statistical and time series form. The National Climatic Data Center (NCDC) has compiled summaries of ship observations, over many open water areas, into the series: Summary of Synoptic Meteorological Observations (SSMO). These publications present statistical summaries of numerous years of shipboard observations of wind, wave and other environmental conditions. These publications may be purchased through NCDC/NOAA Asheville, North Carolina.

The National Data Buoy Center (NDBC) is responsible for the archiving of wave and weather data collected by their network of moored, satellite reporting buoys. These buoys report hourly conditions of wave height and period, as well as wind speed and direction, air and sea temperature and other meteorological data. This information can be obtained in time series form (usually hourly observations) from the NDBC office.

Another statistical summary of wind and wave data is available from the U.S. Army Corps of Engineers, Waterways Experiment Station, Coastal and Hydraulics Laboratory. The primary purpose of the Wave Information Study (WIS) is to provide an accurate and comprehensive database of information of the long-term wave climate. The WIS generally uses a complete series of yearly wind records, which varies in length from 20 to 40 years. The study considers the effects of ice cover where applicable and reflects advances in the understanding of the physics involved in wave generation, propagation, and dissipation, employing currently developed techniques to model these processes. The summary tables generated from the WIS hindcast include: percent occurrence of wave height and period by direction, a wave "rose" diagram, the mean significant wave height by month and year, the largest significant wave height by month and year and total summary statistics for all of the years at each station. In addition, the study also provides return period tables for the 2-, 5-, 10-, 20-, and 50-year design waves. WIS reports for ocean coastal areas of the U.S. and the Great Lakes can be obtained from CERC.

36.3 Water Level Fluctuations

Long period variations of water level occur over a broad range of time scales, greater than those of sea waves and swell. These types of fluctuations include astronomical tides, **seiches**, **tsunamis**, wave setup, and storm surge as well as very long period (months to years) variations related to climatologic and eustatic processes.

Tides

Tides are periodic variations in mean sea level caused by gravitational attraction between the earth, moon and sun and by the centrifugal force balance of the three-body earth, moon, sun system. Although complicated, the resultant upward or downward variation in mean sea level at a point on the earth's surface can be predicted quite accurately. Complete discussions of tidal dynamics are given in Defant (1961), Neumann and Pierson (1966), Apel (1990). The specific computational approach currently being used for official tide prediction in the United States is described in Pore and Cummings (1967). Tide tables for the coastlines of the United States can be obtained for the U.S. Department of Commerce, National Ocean Service, Rockville, MD.

Tides tend to follow a lunar (moon) cycle and thus show a recurrence pattern of approximately 1 month. During this one month cycle there will be two periods of maximum high and low water level variation, called **spring tides** and two periods of minimum high and low water level variation, called **neap tides** (Fig. 36.7). Figure 36.7 also illustrates the different types of tides that may occur at the coast. These tides may be: diurnal, high and low tide occur once daily; semi-diurnal, high and low tides occur twice daily; or mixed, two highly unequal high and low tides occur daily. Diurnal tides occur on a lunar period of 24.84 hours and semi-diurnal tides occur on a half lunar period of 12.42 hours. Therefore, the time of occurrence of each successive high of low tide advances approximately 50 (diurnal) or 25 (semi-diurnal) minutes.

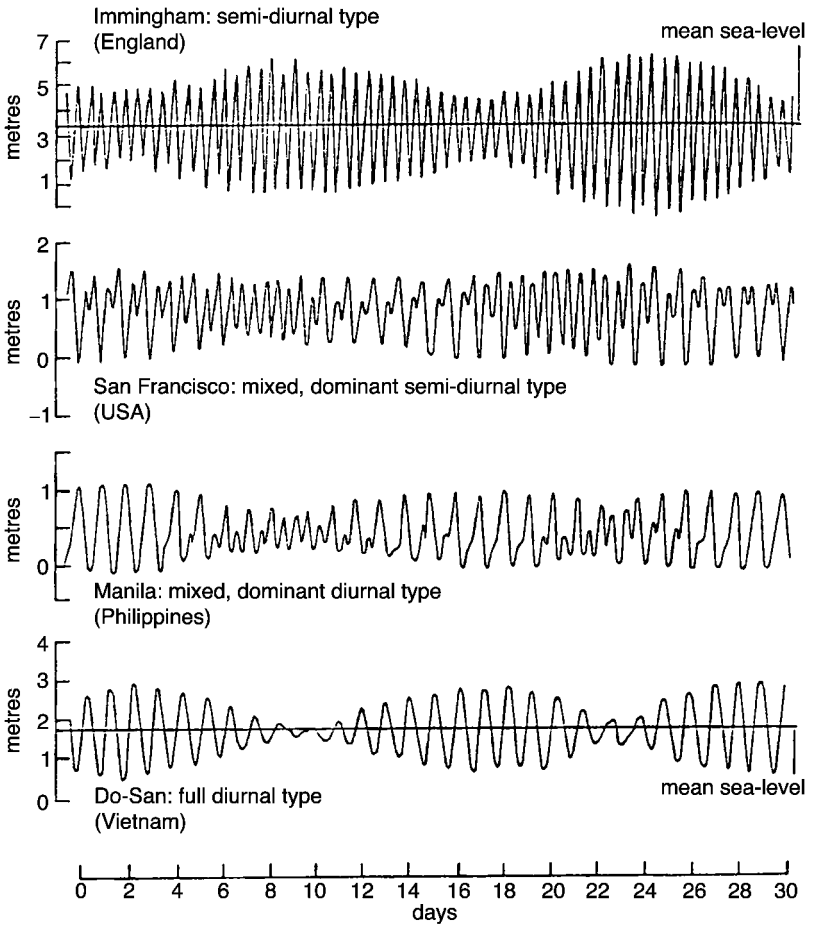

FIGURE 36.7 Different types of tides that may occur at a coast.

Seiches

Seiches are long period standing waves formed in enclosed or semi-enclosed basins such as lakes, bays, and harbors. Seiches are usually generated by abrupt rapid changes in pressure or wind stress. The natural free oscillation period, T_n, of a seiche in an *enclosed* rectangular basin of constant depth is

$$T_n = \frac{2l_b}{n\sqrt{g\,d}} \tag{36.35}$$

where l_b = the basin length in the direction of travel
n = the number of nodes along the basin length

The maximum period occurs at the fundamental, where $n = 1$. The natural free oscillation period for an *open* rectangular basin (analogous to a bay or harbor) is

$$T'_{n'} = \frac{4l_{b'}}{(1+2n')\sqrt{g\,d}} \tag{36.36}$$

where n' is the number of nodes between the node at the opening and the antinode at the opposite end.

A complete discussion of seiches is presented in Huthinson (1957).

Tsunami

Tsunamis are long period progressive gravity waves generated by sudden violent disturbances such as earthquakes, volcanic eruptions, or massive landslides. These long waves usually travel across the open seas at shallow water waves speeds, $c = \sqrt{g\ d}$, and thus can obtain speeds of hundreds of kilometers per hour. These relatively low waves (10s cm) on the open ocean are greatly amplified at the coast and have been recorded at heights in excess of 30 m.

Wave Setup

Wave setup is defined as the superelevation of mean water level caused by wave action at the coast (The Shore Protection Manual, U.S. Army Corps Of Engineers, 1984). This increase in mean water level occurs between the breaking point and the shore. The Shore Protection Manual (1984) gives the following formula for calculating wave setup

$$S_w = 0.15\ d_b - \frac{g^{0.5}\left(H_{o'}\right)^2\ T}{64\ \pi\ d_b^{0.66}} \tag{36.37}$$

where d_b = the depth of breaking
$H_{o'}$ = the unrefracted deep water wave height

Wave setup is typically of the order of centimeters.

Storm Surge

Storm conditions often produce major changes in water level as a result of the interaction of wind and atmospheric pressure on the water surface. Severe storms and hurricanes have produced surge heights in excess of 8 m on the open coast and can produce even higher surges in bays and estuaries. Although prediction of storm surge heights is dependent upon many factors (see The Shore Protection Manual, U.S. Army Corps Of Engineers, 1984), an estimate of sea surface slope at the coast, caused by wind-stress, τ_s, effects, can be calculated as

$$\frac{dz}{dx} = \lambda\ \frac{\tau_s}{\gamma d} \tag{36.38}$$

where λ, an experimentally determined variable, ranges from 0.7 to 1.8 (average value of 1.27) and

$$\tau_s = 0.58\ U_{10}^{2.22} \tag{36.39}$$

where τ_s = kg-m^2
U_{10} = the wind speed in m/s measured at 10 m above the sea surface

A similar simple estimate of pressure setup (P_s) in meters at the storm center for a stationary storm can be made using the relation

$$P_s = 0.0136\ \Delta P \tag{36.40}$$

where ΔP is the difference between the normal pressure and the central pressure of the storm measured in millimeters of mercury.

Climatologic Effects

For most coastal engineering on ocean coasts, climatologic effects on sea level change are small and may be neglected. However, on large lakes such as the Great Lakes water levels may vary tens of centimeters per year and meters per decade. The National Oceanic and Atmospheric Administration provide Great

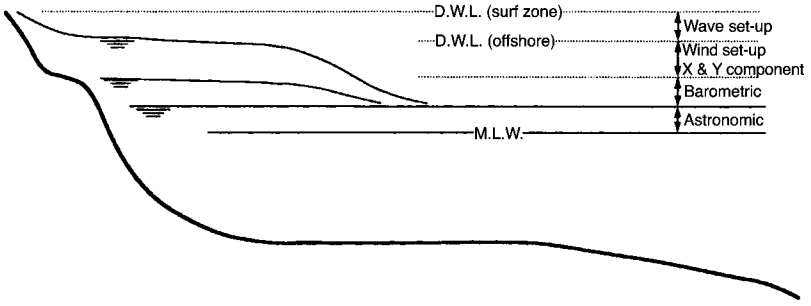

FIGURE 36.8 Schematic of the design water level components.

Lakes water level information monthly and local large lake water level information is usually available from state agencies. Accurate knowledge of sea and lake level change is essential to successful coastal engineering design.

Design Water Level

Design of coastal structures usually requires the determination of a maximum and minimum design water level (D.W.L.). Design water level is computed as an addition of the various water level fluctuation components as follows:

$$D.W.L. = d + A_s + S_w + P_s + W_s \tag{36.41}$$

where d = chart depth referenced to mean low water
A_s = the astronomical tide
S_w = wave set-up defined in Eq. (36.37)
P_s = the pressure set-up as defined in Eq. (36.40)
W_s = the wind set-up calculated using Eq. (36.38)

It is important to recognize that all of these components may not occur in phase and, therefore, Eq. (36.41) will tend to result in extreme maximum and minimum DWL values. It should also be recognized that some of these component effects are amplified at the shore. Figure 36.8 shows a schematic illustration of the design water level components and their relative magnitude.

36.4 Coastal Processes

Coastal region can take a wide variety of forms. Of the total U.S. shoreline, 41% is exposed to open water wave activity the remainder is protected. Outside of Alaska, about 30% is rocky and approximately 14% of the shoreline has beaches. Approximately 24% of the shoreline of the United States is eroding.

Beach Profiles

Nearshore profiles oriented perpendicular to the shoreline have characteristic features, which emulate the influence of local littoral processes. A typical beach profile possesses a sloping nearshore bottom, one or more sand bars, one or more flat beach berms and a bluff or escarpment. As waves move towards shore, they first encounter the beach profile in the form of a sloping nearshore bottom. When waves reach a water depth of approximately 1.3 times the wave height, the wave will break. Breaking results in the dissipation of wave energy by the generation of turbulence and the transport of sediment. As a result, waves suspend sediment and transport it to regions of lower energy, where it is deposited. In many cases, this region is a sand bar. Therefore, the beach profile is constantly adjusting to the incident wave conditions.

The Equilibrium Beach

Although beaches seldom reach a "steady state" profile, it is convenient to consider them as responding to variable incident wave conditions by approaching an "ideal" long-term configuration dependent upon steady incident conditions and sediment characteristics. Bruun (1954) and Dean (1977), in examining natural beach profiles, found that the "typical" profile was well defined by the relationship:

$$d(x) = Ax^q \tag{36.42}$$

where A = a scale coefficient dependent upon the sediment characteristics
q = a shape factor, found both theoretically and experimentally to be approximately 2/3
x = the distance offshore
d = the water depth

It is this concept of the equilibrium profile, which serves as a basis for many models of coastal sediment movement and bathymetric change. When a profile is disturbed from equilibrium by a short-term disturbance, such as storm-induced erosion, the profile is then hypothesized to adjust accordingly towards a new equilibrium state defined by the long-term incident wave conditions and sediment characteristics of the site.

Beach Sediments

Beach sediments range from fine sands to cobbles. The size and character of sediments and the slope of the beach are related to the forces to which the beach is exposed and the type of material available on the coast. The origin of coastal materials can be from inland or offshore sources or from erosion of coastal features. Coastal transport processes and riverine transport bring these materials to the beach and nearshore zone for disbursement through wave and current activity. Beaches arising from erosion of coastal features tend to be composed of inorganic materials while beaches in tropical latitudes can be composed of shell and coral reef fragments. Finer particles are typically kept in suspension in the nearshore zone and transported away from beaches to more quiescent waters such as lagoons and estuaries or deeper offshore regions.

Longshore Currents

As waves approach the shoreline at an oblique angle, a proportion of the wave orbital motion is directed in the longshore direction. This movement gives rise to longshore currents. These currents flow parallel to the shoreline and are restricted primarily between the breaker zone and the shoreline. Longshore current velocities vary considerably across the surf zone, but a typical mean value is approximately 0.3 m/s. Expressions for calculating longshore current velocity range from theoretically based to completely empirical expressions. However, all of the expressions are calibrated using measured field data. Two accepted formulations for calculating mean longshore current velocities $(\overline{V})$ are: the theoretically based formulation of Longuet-Higgins (1970)

$$\overline{V} = 20.7\, m \left(g\, H_b\right)^{1/2} \sin 2\alpha_b \tag{36.43}$$

where m = beach slope
H_b = wave height at breaking
H_b = wave crest angle at breaking
g = gravitational acceleration

and the empirical formulation of Komar and Inman (1970)

$$\overline{V} = 2.7\, u_{\max} \sin \alpha_b \cos \alpha_b \tag{36.44}$$

where u_{max} is the maximum particle velocity at breaking.

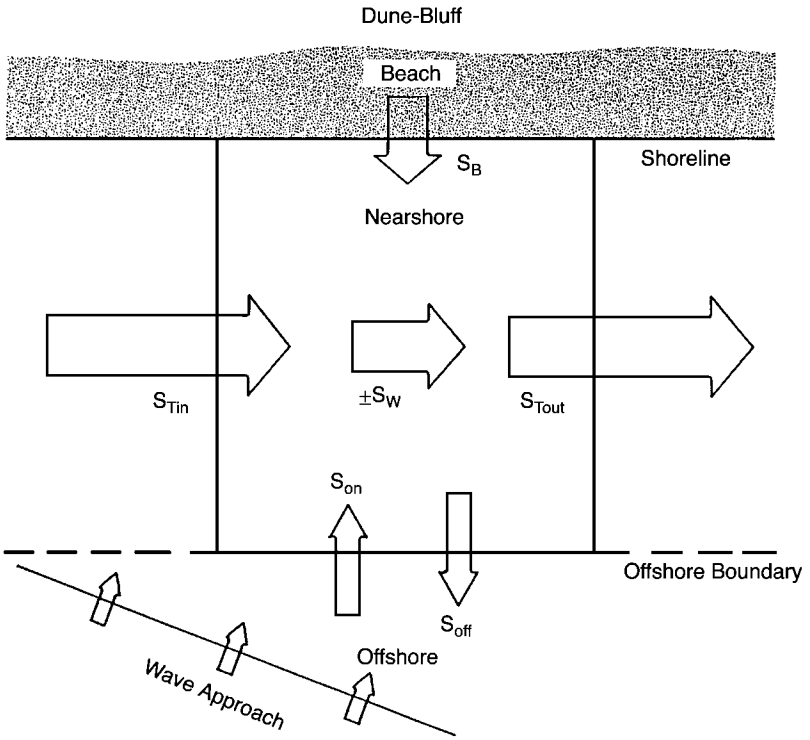

FIGURE 36.9 Box diagram of sediment transport components at the coast.

Cross-shore Currents

Cross-shore currents and resultant transport can be caused by: (a) mass transport in shoaling waves, (b) wind-induced surface drift, (c) wave-induced setup, (d) irregularities on the bottom, (e) density gradients. These factors can produce cross-shore currents ranging in intensity from diffuse return flows, visible as turbid water seaward of the surf zone, to strong, highly organized, rip currents. Rip currents are concentrated flows, which carry water seaward through the breaker zone. There is very little information on the calculation of cross-shore current velocities in the breaker zone.

Sediment Transport

A schematic drawing of the sediment transport (littoral transport) along a coast is shown in Fig. 36.9. This diagram depicts the distribution of sediments for an uninterrupted length (no shoreline structures) of natural coastline. When there is sufficient wave energy, a system of sediment erosion, deposition, and transport is established as shown in Fig. 36.9.

A finite amount of sediment S_{Tin} is transported by longshore currents into a section of the coast (nearshore zone). Wave action at the shore erodes the beach and dune-bluff sediment (S_B) and carries it into the longshore current. This same wave action lifts sediment from the bottom (S_w) for potential transport by the longshore current. Finally, wave action and cross-shore currents at the offshore boundary move sediment onshore or offshore (S_{on} and S_{off}) depending on wave and bottom conditions. This transport at the outer limit of the nearshore zone can usually be assumed negligible with respect to the other transports. The summation of these various transports over time provide a measure of the net sediment budget for a section of coast.

An estimate of the longshore sediment transport rate can be obtained by the energy flux method using deep water wave characteristics applied to calculate the longshore energy flux factor entering the surf zone (P_{ls})

$$P_{ls} = 0.05\,\rho\, g^{3/2}\, H_{so}^{5/2} \left(\cos \alpha_o\right)^{1/4} \sin 2\,\alpha_o \tag{36.45}$$

where ρ = the density of water
H_{so} = the deep water significant wave height
α_o = the deep water wave angle of approach

The actual quantity of sediment transported can be calculated directly from P_{ls} as

$$Q\left(\frac{m^3}{yr}\right) = 1290\; P_{ls}\left(\frac{J}{m-s}\right) \tag{36.46}$$

or

$$Q\left(\frac{yd^3}{yr}\right) = 7500\; P_{ls}\left(\frac{ft-lb}{ft-s}\right). \tag{36.47}$$

These calculations should be carried out using an offshore wave climatology distributed in wave height and angle. A complete description of this methodology is given in Chapter 4 of the The Shore Protection Manual (U.S. Army Corps Of Engineers, 1984).

36.5 Coastal Structures and Design

There are four general categories of coastal engineering problems that may require structural solutions: shoreline stabilization, backshore (dune-bluff) protection, inlet stabilization, and harbor protection (Shore Protection Manual, 1984). Figure 36.10 shows the types of structures or protective works in each of these four coastal engineering problem areas. A listing of factors that should be considered in evaluating

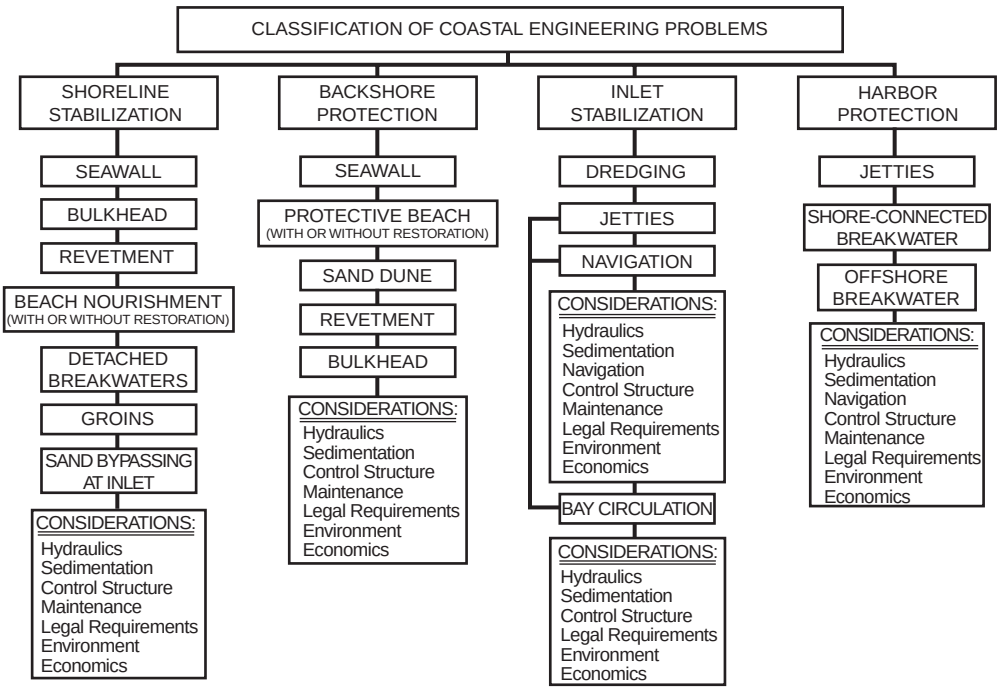

FIGURE 36.10 Classification of coastal engineering problems at the coast (Shore Protection Manual, 1984).

each of these problem areas is also given in Fig. 36.10. Hydraulic considerations include wind, waves, currents, storm surge or wind set-up, water-level variation, and bathymetry. Sedimentation considerations include: sediment classification, distribution properties, and characteristics, direction and rate of littoral transport; *net* versus *gross* littoral transport; and shoreline trend and alignment. Control structure considerations include selection of the protective works with respect to type, use, effectiveness, economics and environmental impact (The Shore Protection Manual, U.S. Army Corps of Engineers, 1984). The other factors listed in Fig. 36.10 are more generally understood and will not be elaborated upon further. It is important to remember that a "no action" alternative should also be considered as a possible solution for any one of these categories of coastal problems.

Structural Selection Criteria

There are a diverse set of criteria that need to be considered in the selection and design of coastal structures. Structural stability criteria and functional performance criteria encompass two areas of primary concern for selection and evaluation of coastal structures.

Structural stability criteria are usually associated with extreme environmental conditions, which may cause severe damage to, or failure of a coastal structure. These stability criteria are, therefore, related to episodic events in the environmental (severe storms, hurricanes, earthquakes) and are often evaluated on the basis of risk of encounter probabilities. A simple method for evaluating the likelihood of encountering an extreme environmental event is to calculate the encounter probability (E_p) as

$$E_p = 1 - \left(1 - \frac{1}{T_R}\right)^{\Lambda} \tag{36.48}$$

where T_R = the return period
Λ = the design life of the structure (see Borgman, 1963)

The greatest limitation to structural stability criteria selection is the need for a long-term data base on critical environmental variables sufficient enough to determine reasonable return periods for extreme events. For example coastal wave data for U.S. coasts is geographically sparse and in most locations where it exists the period of collection is in the order of 10 years. Since most coastal structures have a design life well in excess of 10 years, stability criteria selection often relies on extrapolation of time limited data or statistical modeling of environmental processes.

Functional performance criteria are generally related to the desired effects of a coastal structure. These criteria are usually provided as specifications for design such as the maximum acceptable wave height inside a harbor breakwater system or minimum number of years for the protective lifetime of a beach nourishment fill project. Functional performance criteria are most often subject to compromise because of initial costs.

The U.S. Army Shore Protection Manual (1984) provides a complete discussion of coastal structures, their use, design and limitation. A P-C based support system entitled Automated Coastal Engineering System (ACES) is also available through the USAE Waterways Experiment Station, Coastal and Hydraulics Laboratory, Vicksburg, MS 39180–6199.

Environmental Impacts of Coastal Structures

The placement of engineered structures on or near the coastline must be contemplated with extreme care. In general, alteration of the natural coastline comes with an associated environmental penalty. Hard (structures made of stone, steel, concrete, etc.) or soft (beach nourishment, sediment filled bags, etc.) engineering structures can alter many physical properties of the beach to often induce undesired effects. These alterations of natural processes can take the form of increased reflectivity to incident waves,

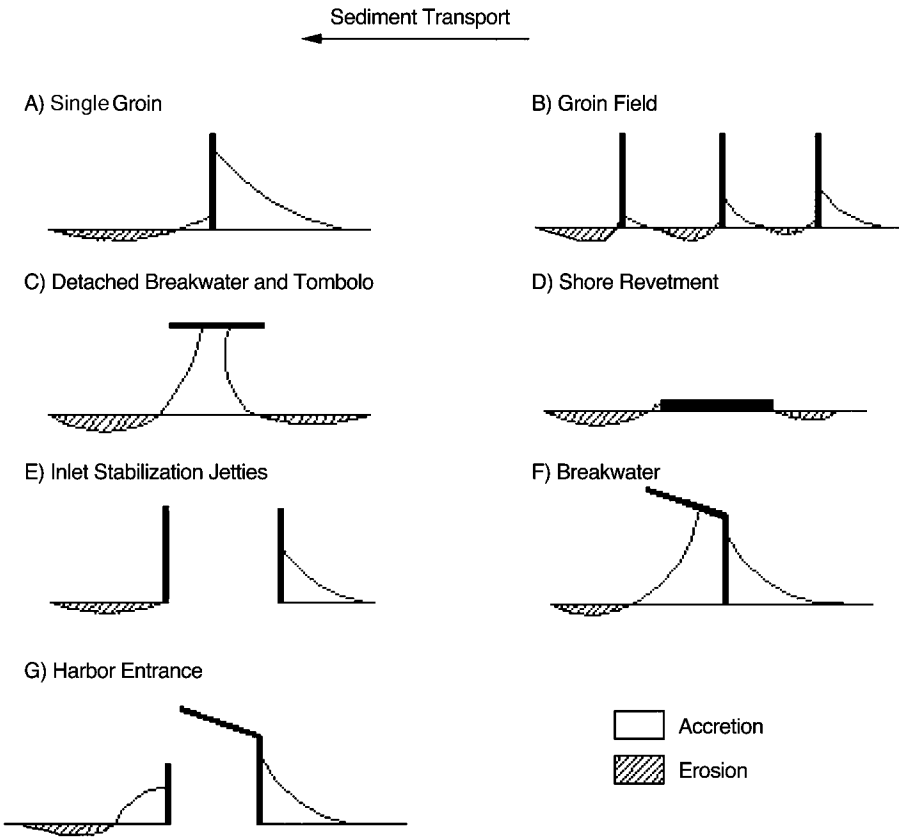

FIGURE 36.11 Classification of "typical" coastal engineering structures and associated regions of shoreline impact.

interruption of longshore currents and resulting longshore sediment transport, alteration of incident wave patterns and the generation of abnormal underwater topography.

Figure 36.11 presents a suite of "typical" coastal engineering structures found along the world's coastlines. These coastal engineering structures range from simple, single component shore protection structures to complex harbor entrance structures. In each case, the primary direction of wave induced, longshore sediment transport is from right to left. These coastal engineering structures increase in scope and complexity, moving down the page. Anticipated regions of shoreline sediment accretion and erosion are also indicated for each type of structure. A significant body of recent research has indicated that these regions of structural impact along the shoreline extend between five and ten times the length of the structure. Hence, for a structure protruding from the undisturbed shoreline a distance of 100 m, the anticipated region of impact should be expected to extend from 500 to 1000 m either side of the structure.

Further Information

The field of coastal engineering is far from a mature science. This is a time of rapid and significant advances in our understanding of the physical processes, which control the response of the nearshore region to wind, waves and water level changes. Furthermore, advances in the design, implementation and in predicting the response of coastal structures and fortifications are made almost daily. Hence, it is nearly impossible to provide a comprehensive review of the most current material.

To further aid the reader, following are some of the most reliable and current, electronic sources of information for the coastal engineer. Within the United States, several government agencies have at least

partial responsibility for engineering along the coastline. These include, within the Department of Defense, U.S. Army Corps of Engineers, Coastal and Hydraulics Laboratory, Coastal Engineering Research Center (CERC), (http://chl.wes.army.mil/research/centers/cerc/) and within the Department of Commerce, the National Oceanic and Atmospheric Administration's, Office of Oceanic and Atmospheric Research (http://www.oar.noaa.gov/) and the Office of the National Ocean Service (http://www.nos.noaa.gov/). CERC has published the Automated Coastal Engineering System (ACES, 1992), which provides an integrated software package to solve a variety of coastal engineering problems.

In addition, within the public sector, most major coastal and Great Lakes Universities offer advanced study in Coastal Engineering. Published studies can be found, for example, in the Journal of Waterways, Ports, Coastal and Ocean Engineering, of the American Society of Civil Engineers (ASCE) (http://www.pubs.asce.org/journals/ww.html) and in the Coastal Engineering Journal. Professor Dalrymple of the University of Delaware has provided a very useful and fully tested set of coastal engineering applications for common use. These may be found at: Dalrymple's Coastal Engineering Java Page (http://rad.coastal.udel.edu/faculty/rad/). Similarly, the Coastal Guide provides a quick reference to coastal engineering software and can be found at: (http://www.coastal-guide.com/). Finally, a simple web search of the key words "coastal engineering" will provide the reader with several hundred relevant sources of current information.

Defining Terms

Celerity — Speed that a wave appears to travel relative to its background.

Fetch — The distance over the water that wind transfers energy to the water surface.

Group speed — Speed of energy propagation in a wave.

Neap tide — A tide occurring when the sun and moon are at right angles relative to the earth. A period of minimal tidal range.

Plunging breaker — A wave that breaks by curling over and forming a large air pocket, usually with a violet explosion of water and air.

Sea — A term used to describe an irregular wind generated wave surface made up of multiple frequencies.

Seiche — A stationary oscillation within an enclosed body of water initially caused by external forcing of wind or pressure.

Significant wave height (H_s) — The average height of the one-third highest waves in a wave height distribution.

Spilling breaker — A wave that breaks by gradually entraining air along the leading face and slowly decays as it moves shoreward.

Spring tide — A tide occurring when the sun and moon are inline relative to the earth. A period of maximum tidal range.

Surging breaker — A wave that breaks by surging up the beach face instead of breaking in the conventional manner.

Swell — A term used to describe a very regular series of wind generated surface waves made up of a single dominant frequency.

Tsunami — A long period, freely traveling wave usually caused by a violent disturbance such as an underwater earthquake, volcanic eruption, or landslide.

Wave diffraction — The spread of energy laterally along a wave crest usually due to the interaction of a wave with a barrier.

Wave height — The vertical distance from a wave crest to the trough of the preceding wave.

Wave refraction — The bending of a wave crest as it enters shallow-water caused by a differential in speed between the deeper and shallower portions of the crest.

Wave ray — A line drawn perpendicular to a wave crest indicating the direction of propagation of the wave.

37.1 Introduction

This chapter covers the principles of the hydraulic design of the more usual hydraulic structures found in Civil Engineering practice. These include reservoirs, dams, spillways and outlet works, energy dissipation structures, open channel transitions, culverts, bridge constrictions, pipe systems, and pumps.

37.2 Reservoirs

Classification According To Use

Reservoirs are used for the storage of water, for the purpose of conservation for later use, for mitigation of flood damages, for balancing a time varying supply and a time varying demand (for water supply or

generation of hydropower), for maintenance of downstream flow (for water quality preservation, navigation, fisheries or wildlife habitat) and for storing excess runoff in urbanized areas, and so on. If a reservoir is built for one purpose only, it is said to be a *single objective* reservoir; and if it is built to satisfy multiple purposes it is called a *multiobjective* reservoir.

For example a single purpose reservoir could be built for water supply and a multipurpose reservoir could be built for flood control and hydropower. In the latter example the two objectives yield contradictory requirements. For flood control it is desired to have the reservoir as empty as possible in order to have as much free capacity as possible for a forthcoming flood, whereas the hydropower generation requires a reservoir nearly full in order to have the maximum head over the turbines and thus generate the maximum amount of power possible. These conflicting objectives are reconciled by assigning certain portions of the reservoir to the respective objectives. These proportions can vary throughout the year. For example, there are rainy seasons when the danger of flood is high and the reservoir portion assigned to flood control should be larger than during drought seasons. These time-varying storage assignments and the constraints on the amounts of water that can be released downstream at a certain time form the operating rules of the reservoir.

Reservoir Characteristics

The capacity-elevation and the area-elevation relationships are fundamental. Figure 37.1 shows the area and capacity curves for Lake Mead obtained from two surveys in 1935 and in 1963–1964. The decrease in capacity between the two surveys is due to the accumulation of sediment. The minimum pool level corresponds to the invert of the lowest outlet or sluiceway (Fig.37.2). The volume below this level is called **dead storage** and can be used for accumulation of sediments. The level corresponding to the crest of the spillway is the normal pool level and the volume difference between the normal pool level and the minimum pool level is the useful storage. When there is overflow over the spillway the additional storage above the normal pool is the **surcharge storage**. The discharge that can be guaranteed during the most critical dry period of record is the safe yield. Any additional release is the secondary yield.

For flood routing in reservoirs (see Chapter 31, "Surface Water Hydrology" for details) the water surface in reservoirs is generally assumed to be horizontal. However, this is not the case when the reservoir is narrow and long like a wide river. In such cases the water surface has a gradient that increases with

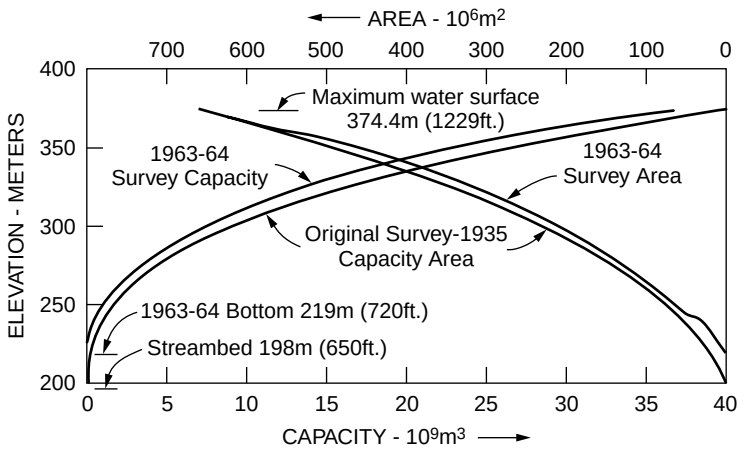

FIGURE 37.1 Area and capacity curves for Lake Mead. (*Source:* U.S Department of the Interior, Bureau of Reclamation. (*Design of Small Dams*. 1987. p. 531.U.S. Government Printing Office, Denver, CO.)

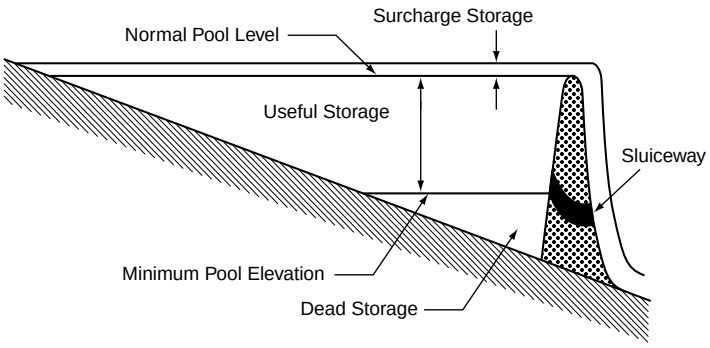

FIGURE 37.2 Storage pools of a typical reservoir. (*Source:* Martin, J.L. and Mc Cutcheon, S.C. *Hydrodynamics and Transport for Water Quality,* Lewis 1999, Fig. 2 p. 340.)

increasing discharge. Techniques for the calculation of water surface profiles under steady and time varying flows are discussed in Chapter 30, "Open Channel Hydraulics".

Capacity of a Reservoir

The simplest method of estimating the capacity of a reservoir to meet a specified demand uses the Rippl diagram or mass curve. The procedure involves the determination of the largest cumulative difference between a sequence of specified demands and a sequence of reservoir inflows. Series of historic or simulated inflows, Q_t, at a selected time interval are used. Monthly intervals are common for large reservoirs. The cumulative inflow in the reservoir is plotted as a function of time. This curve exhibits segments with steep upward slopes during periods of large inflow in the reservoir and segments with relatively flat slopes during periods of low inflows or droughts. This inflow is generally adjusted to account for the evaporation and seepage losses and required releases downstream. When the losses plus the downstream requirements exceed the inflow, the curve shows periods of decreasing cumulative adjusted inflow. After a sharp rise in the curve it may exhibit a sharp decrease in slope. When such changes occur, the reservoir is usually full. At these several bends in the adjusted cumulative inflow, lines are traced with a common slope equal to the demand, D_t, in volume per unit of time. These accumulated demand lines will be above the accumulated adjusted inflow curve for some periods of time (starting at time i and ending at time j). For such periods, the largest positive departure between the accumulated demand line and the cumulative adjusted inflow curve over a time horizon T represents the required storage of the reservoir, S. The procedure is generally performed graphically as shown in Fig. 37.3. Mathematically, the required storage is given by

$$S = \max_{T}\left[\sum_{t=i}^{j}\left(D_t - Q_t\right)\right] \tag{37.1}$$

When long data series are analyzed, or, if the demand varies, the computationally efficient sequent peak algorithm of Thomas and Fiering (1963) is preferred. The accumulated differences between inflows and demand are plotted as a function of time. The curve exhibits a sequence of peaks and troughs. The first peak and the next higher peak, called the sequent peak, are located. The difference between the first peak and the lowest subsequent valley represents the storage for the period. The next sequent peak is identified and the required storage after the first sequent peak is found. The process is repeated for the whole study period and the maximum storage is identified. Mathematically, the required storage capacity, S_t,at the beginning of period t is calculated from

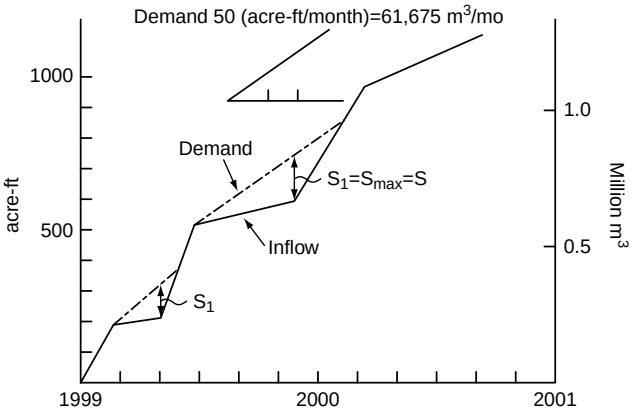

FIGURE 37.3 Estimation of reservoir capacity by mass curve method. 1 acre-ft = 1,233.5 m.[3]

$$S_t = \begin{cases} D_t - Q_t + S_{t-1} & \cdots if \quad D_t - Q_t + S_{t-1} > 0 \\ 0 & \cdots if \quad D_t - Q_t + S_{t-1} \le 0 \end{cases} \tag{37.2}$$

where D_t and Q_t are the demand and the inflow during the interval t.

Starting with $S_0 = 0$, consecutive values of S_t are calculated. The maximum value of S_t is the required storage capacity for the specified demand D_t.

Reservoir Sedimentation

The accumulation of sediments limits the useful life of a reservoir. The larger particles of sediments carried by the streams leading to reservoirs are deposited at the head of the reservoirs forming deltas. The smaller particles are carried in density currents and eventually are deposited in the lower parts of the reservoir near the dam. Methods of determining the suspended sediment carried by streams are discussed in Chapter 35 "Sediment Transport in Open Channels." Using these methods, theoretical predictions of the development of deltas over time can be made. One such approach can be found in Garcia (1999, p. 6.89–6.97). Instead, an empirical approach developed from observations of existing reservoirs is presented here. It can be used in a preliminary analysis.

The results of sediment samplings in streams can often be summarized by rating curves of the type

$$Q_s = aQ_w^b \tag{37.3}$$

where Q_s = the suspended transport (tons per day)
Q_w = the flow (cfs or cms)
a and b = coefficients

The trap efficiency of reservoirs is a function of the ratio of reservoir capacity to annual inflow volume. Envelopes and medium trap efficiency curves have been given by Brune (1953). The medium curve is shown in Fig. 37.4. Also shown is a relationship obtained by Churchill (1949) for Tennessee Valley Authority Reservoirs. The number of years to fill a reservoir can be estimated from the sediment inflow and the trap efficiency. For this purpose successive decreasing capacities of the reservoir are considered and the respective capacity-inflow ratios are calculated along with the trap efficiencies. By dividing the increments in reservoir capacity by the volume of sediment trapped, the life of each increment is calculated. These are then summed to obtain the expected life of the reservoir. Further discussion on Reservoir Sedimentation can be found in Appendix A of *Design of Small Dams,* U.S. Department of the Interior, Bureau of Reclamation (1987) and in Morris and Fan (1988).

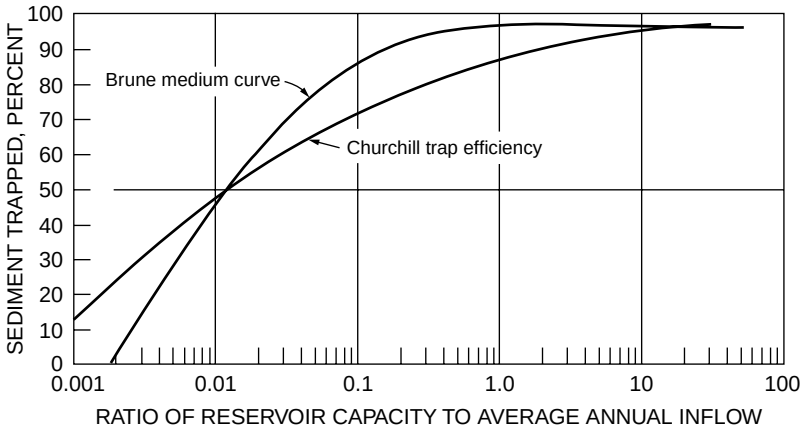

FIGURE 37.4 Trap efficiency curves. (Adapted from U.S Department of the Interior, Bureau of Reclamation, (1987) Design of Small Dams p. 542, Fig A.9.)

Many dams that have outlived their usefulness are decommissioned. Decommissioning is the complete or partial removal of a dam or substantial change in its operation. A primary issue to be considered in the removal of a dam is the disposal of the sediments that have accumulated in the reservoir. ASCE (1997) provides guidelines for retirement of dams and hydroelectric facilities.

Impacts of Dams and Reservoirs

Impacts due to the existence of a dam, and reservoir include: changes in upstream and downstream river bed morphology due to changed sediment load, changes in downstream water quality due to change in released water temperature and in constituent concentrations in the impounded water and a reduction in biodiversity due to decrease of freedom of movement of fish and organisms.

A reservoir induces a reduction in the upstream sediment transport capacity due to the decreased water velocity. Downstream of the reservoir, the trap efficiency of the pool reduces the sediment load below the transport capacity of the stream. As a result aggradation tends to occur upstream of the reservoir and degradation tends to occurs downstream. These effects are discussed in detail, for example, in Simons and Sentürk (1992) and in Sentürk (1994).

Reservoir water quality is affected by surface heating and by the absence of complete vertical mixing, at least during part of the year. The net thermal flux at the reservoir surface, H_n, is the algebraic sum of the absorbed short wave solar radiation, H_{sw}, the long wave atmospheric radiation, H_H, the back radiation from the lake surface, H_B, the heat loss due to evaporation, H_L, and the net flux due to conduction or sensible heat transfer:

$$H_n = H_{sw} + H_H - H_B - H_L - H_S \tag{37.4}$$

Formulas for the calculation of each of these heat transfer components can be found, for example, in Martin and McCutcheon (1999).

In the summer time, large reservoirs (with a depth of at least 10 m and a mean residence time of more than 20 days) tend to stratify in three main layers as shown in Fig. 37.5. The epilimnion or upper layer of relatively warm water is well mixed as a result of wind and convection currents. Below it is the thermocline or metalimnion, the layer in which the temperature decrease with depth is greater than in the overlying and underlying layers. At the bottom is the hypolimnion, characterized by a temperature that is generally cooler than the other strata of the reservoir. A criterion to determine the stratification potential is the densimetric Froude number, F_d. It is the ratio of the inertia forces of the horizontal flow to the gravity forces within the stratified impoundment and is a measure of potential of the horizontal flow to alter the thermal density structure of the reservoir from its gravitational equilibrium. It is given by

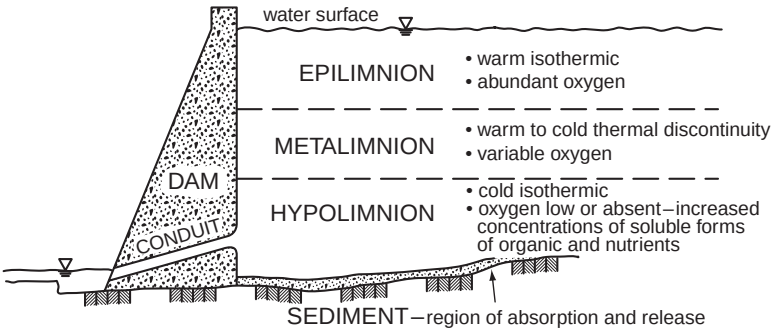

FIGURE 37.5 Typical summer stratification. (*Source:* Martin, J.L. and Mc Cutcheon, S.C., *Hydrodynamics and Transport for Water Quality,* Lewis 1999, Fig. 5, p. 343, taken from U.S. Army Engineers Waterways Experiment Station, Vicksburg, MS.)

$$F_d = \frac{LQ}{hV}\sqrt{\frac{\rho_o}{g(\Delta\rho/h)}} = \frac{U}{\sqrt{gh(\Delta\rho/\rho_o)}} \tag{37.5}$$

where L = the reservoir length (unit L)
Q = the average flow through the reservoir ($L^3\ T^{-1}$)
h = the mean depth (L)
V = the reservoir volume (L^3)
g = the acceleration of gravity (LT^{-2})
ρ_o = the reference density (ML^{-3})
$\Delta\rho$ = the density difference over depth h (ML^{-3})
$\Delta\rho/h$ = the average density gradient (ML^{-4})
U = the average flow velocity (LT^{-1})

The average density gradient typically is of the order of 10^{-3} kg m^{-4} and the water density is 1000 kg m^{-3}. The reservoir is well mixed if $F_d \gg 1/\pi$, it is strongly stratified if $F_d \ll 1/\pi$, and it is weakly stratified or stratified off and on if $F_d \cong 1/\pi$. (Orlob, 1983). The stratification varies seasonally as shown in Fig. 37.6.

The density of tributary inflow usually differs from that of the surface water of the reservoir. Therefore, currents of water with slightly different densities, called density currents, are created. Depending upon the sign and magnitude of this density difference, the density currents can enter the epilimnion, the metalimnion or the hypolimnion, as shown in Fig. 37.7. When the inflow density is less than the surface water density, the inflow will float over the surface water. This condition often occurs in the spring when the inflows are warmer than the water in the reservoirs. If the inflow is cooler or carries larger concentrations of dissolved or particulate materials, then its density will be larger that that of the reservoir surface water. The inflow will then push the reservoir water ahead until the (negative) buoyancy force dominates and the inflow plunges beneath the surface as shown in Fig. 37.8. The plunge point can often be observed because of the accumulation of floating debris. After the flow plunges it follows the river channel as an underflow. This condition typically occurs in the fall when riverine waters are cooler than reservoir waters. If the underflow is not as dense as the bottommost layer in the reservoir, the underflow will separate from the bottom to form an interflow or intrusion as shown in Fig. 37.7. When cool water plunges as underflow or interflow it entrains some of the reservoir water creating a circulation pattern in the overlying surface waters. These reverse flows transport floating debris towards the plunge point where they remain. For further discussion on density currents in reservoirs see Alavian at al. (1992) and Martin and McCutcheon (1999).

Selective withdrawal release structures with a series of outlets at different elevations, as shown schematically in Fig. 37.9, can be used to select the layer(s) from which the water is released. This makes it possible to improve water quality within a reservoir and to reduce adverse impacts that temperature and

other water quality constituents may have on downstream water quality. Figure 37.10 shows a schematic withdrawal pattern. The U.S. Army Corps of Engineers has developed a computer program called SELECT to predict the vertical extent and distribution of withdrawal from a reservoir of known density and quality distribution for a given discharge from a specified location. Using this prediction for the withdrawal zone, SELECT computes quality parameters of the release such as temperature, dissolved oxygen, turbidity and iron (U.S. Army Engineer Waterways Experiment Station, 1992).

In winter ice begins to form when water is cooled to 0°C. When the air temperature T_a (°C) is lower than the melting point of ice, T_m (0°C), there is a thickening of the ice cover. The ice thickness h_i (m) after a time increment t (s) of freezing can be roughly estimated from

$$h_i \approx \alpha\left[\left(T_m - T_a\right)t\right]^{0.5} \tag{37.6}$$

where $\alpha = (2k_i/\rho_i \lambda_i)^{0.5}$ where k_i is the thermal conductivity of ice (2.24 W m^{-1} °C^{-1}), ρ_i is the ice density (916 kg m^{-3}), and λ_i is the latent heat of fusion of the ice (3.34×10^5 J kg^{-1}), (Ashton, 1982).

37.3 Dams

Classification and Physical Factors Governing Selection

Dams are generally classified according to the material used in the structure, and the basic type of design. Concrete gravity dams depend on their weight for their stability, concrete arch dams transfer the hydrostatic forces to their abutments by arch action, and in concrete buttress dams the hydrostatic force is resisted by a slab that transmits the load to buttresses perpendicular to the dam axis. Embankment dams can be subdivided into earth-fill dams and rock-fill dams.

The principal physical factors governing the choice of dam type are: the topography, the geology, the availability of materials and the hydrology. The topography usually governs the basic choice of dam. Low rolling plains would suggest an earth-fill dam, whereas a narrow valley with high rock walls would suggest a concrete structure or a rock-fill dam. Saddles in the periphery of the reservoir may provide ideal locations for spillways, especially emergency spillways. The foundation geology is also of major significance in the selection of the dam type. Good rock foundations are excellent for all types of dams, while gravel foundations are suitable for earth-fill and rock-fill dams. Silt or fine sand foundations are not suitable for rock-fill dams but can be used for earth-fill dams with flat slopes. The availability of materials (soils and rock for the embankments, riprap and concrete aggregate near the dam site) weigh heavily in the economic considerations. The hydrologic condition of stream flow characteristics and rainfall will influence the method of diversion of the flows during construction and the construction time. Finally, if the dam is located in a seismic-prone area the horizontal and the vertical components of the earthquake acceleration on the dam structure and on the impounded water must be considered in the analysis of the dam stability.

Stability of Gravity Dams

The principal forces to be considered are the weight of the dam, the hydrostatic force, the uplift force, the earthquake forces, the ice force and the silt force. The gravity force is equal to the weight of concrete, V_C plus the weight of such appurtenances as gates and bridges. This force passes through the center of gravity of the dam. The horizontal component of the hydrostatic force per unit width of the dam is (see Chapter 29, Fundamentals of Hydraulics, Application 29.1) is

$$H_w = \gamma h^2/2 \tag{37.7}$$

where γ = the specific weight of the water
h = the depth of water at the vertical projection of the upstream face of the dam

This force acts at a distance $h/3$ above the base of the dam (Fig. 37.11). The vertical component of the hydrostatic force, V_w, is equal to the weight of water vertically above the upstream face of the dam. This force passes through the center of gravity of this wedge of water. There also can be horizontal and vertical hydrostatic forces, H'_w and V'_w, respectively, on the downstream face of the dam. Water may eventually seep between the dam masonry and its foundation creating an **uplift pressure**. The most conservative design assumes that the uplift pressure varies linearly from a full hydrostatic pressure at the upstream face to the full tailwater pressure at the downstream face. The uplift force is then

$$U = \gamma\left[\left(h+h'\right)/2\right]T \tag{37.8}$$

where h and h' = the water depths at the upstream and downstream faces, respectively
T = the thickness or width of the dam base

The uplift force acts vertically upward through the center of gravity of the trapezoidal uplift pressure diagram. If there is a drain located at about 25% of the base width from the heel of the dam, the uplift

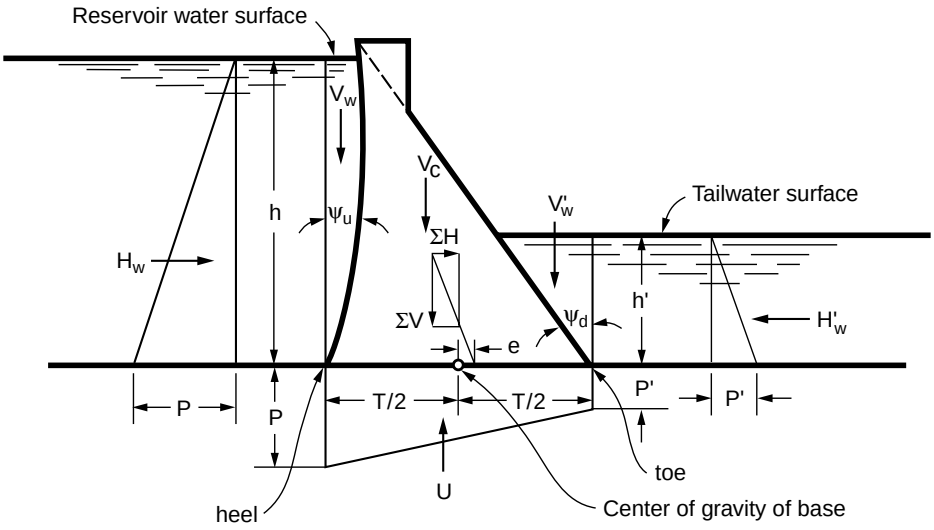

FIGURE 37.11 Forces acting on a concrete gravity dam. (Adapted from U.S. Department of the Interior, Bureau of Reclamation, *Design of Small Dams*, p.317, U.S. Government printing Office, Denver, CO.)

pressure can be assumed to decrease to 2/3 of the full upstream hydrostatic pressure at the drain and then to zero at the toe, assuming no downstream hydrostatic pressure. Field measurements of uplift pressures are quoted in Yeh and Abdel-Malek (1993). Suggested values of the earthquake accelerations in terms of the distance from the source of energy release and of the Richter scale magnitude as well as information on the increase in water pressure can be found in US Department of the Interior, Bureau of Reclamation, (1987). According to the same source an acceptable criterion for ice force is 10,000 lb/ft of contact between the dam and the ice for an assumed ice depth (see Eq. [37.6]) of 2 ft or more. An acceptable criterion for saturated silt pressure is to use an equivalent fluid with a specific weight of 85 lb/ft^3 for the horizontal component and 120 lb/ft^3 for the vertical component.

The stability analysis includes the following steps:

- Calculate the resultant vertical force above base of section, ΣV,
- Calculate the resultant horizontal or sliding force above base of section, ΣH,
- Calculate the overturning moment (clockwise in Fig. 37.11) about the toe of the section, ΣM_o,
- Calculate the stabilizing moment (counterclockwise in Fig. 37.11) about the toe, ΣM_s,
- Calculate the safety factor against overturning, $FS_o = \Sigma M_s/\Sigma M_o$,
- Calculate the available friction force $F_f = \mu\Sigma V$, where μ is the friction coefficient,
- Calculate the safety factor against sliding $FS_s = F_f/\Sigma H$,
- Calculate the distance from the toe to the point where the resultant of the vertical forces cuts the base $x = [M_s - \Sigma M_o]/\Sigma V$,
- Calculate the eccentricity of the load $e = T/2 - x$,
- Calculate the normal stress $\sigma = \Sigma V/A \pm Mc/I$ where c is the distance from the center of the section to its edge, I is the moment of inertia of the section about its centroidal axis and $M = e\Sigma V$ is the moment due to the eccentricity of the load,
- Calculate the stress parallel to the face of the dam $\sigma' = \sigma/cos^2\psi_u$,
- Verify that $FS_o > 2$,
- Verify that $FS_s > 1.0$,
- Verify that the stresses are within specifications.

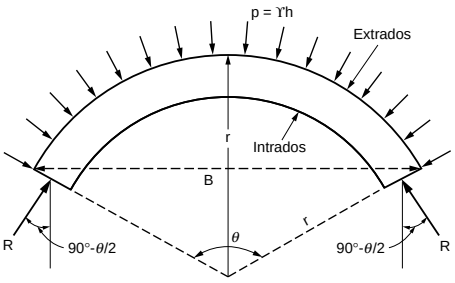

FIGURE 37.12 Hydrostatic pressure and resulting thrust on an arch rib.

Arch Dams

Arch dams are curved in plan so that they transmit part of the water pressure to the canyon walls of the valleys in which they are built. The arch action requires a unified monolithic concrete structure. Arch dams are classified as thin if the ratio of their base thickness to their structural height is less than 0.2 and thick if that ratio is larger than 0.3. The upstream side of an arch dam is called the **extrados** and the downstream side is the **intrados** (Fig. 37.12).

The structural analysis of arch dams assumes that it can be considered as a series of horizontal arch ribs and a series of vertical cantilevers. The load is distributed among these two actions in such a way that the arch and cantilever deflections are equal. This analysis is a specialized subject of structural engineering. The US Department of the Interior, Bureau of Reclamation (1977) has published an extensive book on the subject. Only the simplified cylinder theory is summarized below.

The forces acting on an arch dam are the same as on a gravity dam, but their relative importance is not the same. The uplift is less important because of the comparatively narrow base and the ice pressure is more important because of the large cantilever action. If the arch has a radius r and a central angle θ, the horizontal hydrostatic force due to a head h is $H_h = \gamma\, h\, 2r \sin(\theta/2)$. (See Chapter 29 on Fundamentals of Hydraulics, Application 29.2). This force is balanced by the abutment reaction in the upstream direction $R_y = 2R\ sin\ (\theta/2)$. By equating the two forces the abutment reaction (Fig. 37.12) becomes $R = \gamma\, hr$. If the working stress of the concrete is σ_w, the thickness of the arch rib is $t = \gamma\, hr/\sigma_w$. It is seen that with this simplified theory the thickness increases linearly with the depth. The volume of a single arch rib with a cross section A is $V = rA\theta$, where θ is in radians. Because of the relationship between the thickness t and the radius, the angle that minimizes this volume of concrete can be shown to be $\theta = 133°34'$. For this angle the radius r of the arch in a valley of width B is $r = (B/2) \sin(66°47') = 0.544\ B$. One could select an arch of constant radius with an average angle around 133°34′. The angle would be larger at the top and smaller at the base. Alternatively one could select a fixed angle and determine the valley width B at various depths and calculate the radius r required and then the necessary thickness t. A compromise between these two cases consists in keeping the radius fixed for a few sections and varied in others.

Earth Dams

Rolled-fill earth dams are constructed in lifts of earth having the proper moisture content. Each lift is thoroughly compacted and bonded to the preceding layer by power rollers of proper design and weight. Rolled-fill dams are of three types: homogeneous, zoned and diaphragm. Early earth dams were homogeneous simple embankments as are many levees today. Most earth dams are zoned embankments. They can have an impermeable core made out of clay or a combination of clay, sand and fine gravel. This core can be flanked on the upstream and downstream sides by more pervious zones or shells. These zones support and protect the impervious core. The upstream zone provides stability against rapid drawdown while the downstream zone controls the seepage and the position of the lower phreatic surface. In addition there can be filters between the impervious zone and the downstream shell and a drainage layer below

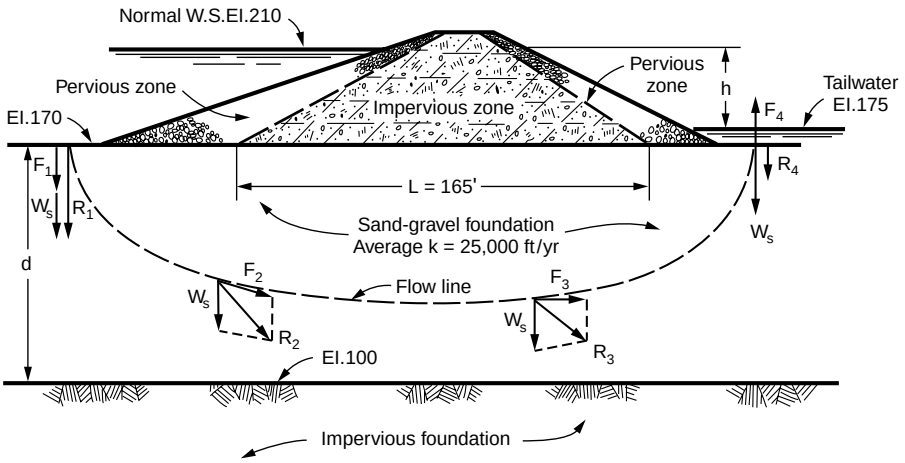

FIGURE 37.13 Seepage under an earth dam. (Adapted from U.S. Department of the Interior, Bureau of Reclamation, 1987, *Design of Small Dams*, p. 204, 205, U.S. Government Printing Office, Denver, CO.)

the downstream shell. Diaphragm-type dams are generally built on pervious foundations. Their impervious core is extended downward by a cutoff wall generally made of concrete. This wall is often accompanied by a horizontal impervious clay blanket under the base of the upstream face and extending further in the upstream direction. This lengthens the seepage path and reduces its quantity. The Bureau of Reclamation does not recommend this type of design for small dams because of potential cracking of the concrete wall due to differential movement induced by consolidation of the embankment.

The amount of seepage under a dam can be approximated roughly using Darcy's formula (see Chapter 34, Groundwater Engineering and Chapter 18 Groundwater and Seepage), $Q = K\,Ah/L$, where K is the hydraulic conductivity of the foundation material, A is the gross cross sectional area of the foundation through which the flow takes place and h/L is the hydraulic gradient, the difference of head divided by the length of the flow path. For the conditions shown in Fig. 37.13 with a hydraulic conductivity K of 25,000 ft/yr = 0.00079 ft/s, a head differential $h = 210 - 175 = 35$ ft over a distance $L = 165$ ft resulting in a hydraulic gradient $h/L = 35/165 = 0.212$ ft/ft, and a flow cross section area of $(170 - 100) \times 1 = 70$ sq ft per ft of width, the discharge per unit width is $Q = (0.00079)\ (0.212)\ (70) = 0.012$ cfs.

The flow through the foundation produces seepage forces due to the friction between the water and the pores of the foundation material. These forces on soil segments are labeled F_1, F_2 in Fig. 37.13 and W_s is the submerged weight of the soil segment. As the flow section is restricted, the flow velocity and the friction forces increase so that F_2 and F_3 are larger than F_1 and F_4. As the water percolates upward at the toe of the dam the seepage force tends to lift the soil. If F_4 is larger than W_s the soil could be "piped out." This is referred to as a piping failure.

The amount of seepage through an earth dam and its foundation, if the latter is pervious, can be estimated from a flow net. This is a network of streamlines (see Chapter 29, Fundamentals of Hydraulics, subsection on Description Fluid Flow) that are everywhere tangent to the flow velocity vector and the equipotential lines that are normal to the streamlines and are lines of equal pressure head. The network of lines form figures that tend to be squares when the number of lines becomes large. The streamlines are drawn in such a way that the amount of flow between consecutive streamlines is the same. The energy or head drop between consecutive equipotential lines is also the same. The exterior streamline along which the pressure is atmospheric is the phreatic line. It can be approximated by a parabola (Morris and Wiggert, 1972, p. 243). The amount of flow through a unit width of dam is $q = N'Kh/N$ where N is the number of equipotential drops, N' is the number of flow paths, i.e., the number of spaces between streamlines, and K is the hydraulic conductivity of the material. (For further details on flow nets, see Chapter 18, Groundwater and Seepage).

A simple method of stability analysis for small earth dams assumes that the surface of failure is cylindrical. The slide mass above an arbitrary slip-circle is divided into a number of vertical slices. The safety factor is equal to the ratio of the sum of the stabilizing moments to the sum of the destabilizing moments of the several slices about the center of the slip circle (for details see Chapter 21, Stability of Slopes).

The upstream face of earth dams must be protected against erosion and wave action. This can be achieved by covering the upstream face with riprap or a concrete slab. Both should be placed over a filter of graded material and the slab should have drainage weep holes. Likewise the downstream face should also be protected against erosion using grass or soil cement. Geotextiles are porous synthetic fabrics that do not degrade. They can be used for separation of materials in a zoned embankment, to prevent the migration of fines and to relieve pore pressure. Geomembranes are impervious and are used to reduce seepage (see Chapter 24, Geosynthetics). Additional information on earthfill and rockfill dams can be found, for example, in U.S. Department of the Interior, Bureau of Reclamation, (1987) and ASCE (1999).

Although flow overtopping an embankment is considered unacceptable, embankment protection consisting of specially designed concrete blocks has been tested for the Bureau of Reclamation (Frizell et al. 1994).

37.4 Spillways

Spillway Design Flood

Spillways are structures that release the excess flood water that cannot be contained in the allotted storage. In contrast *outlet works* regulate the release of water impounded by dams. As earth-fill and rock-fill dams are likely to be destroyed if overtopped, it is imperative that the spillways designed for these dams have adequate capacity to prevent overtopping of the embankment. For dams in the high hazard category, (i.e., those higher than 40 ft., with an impoundment of more than 10,000 acre-feet and whose failure would involve the loss of life or damages of disastrous proportions) the design flow is based on the probable maximum precipitation (PMP). Based on the PMP, the flood hydrograph is estimated and routed through the reservoir assumed to be full to obtain the spillway design flood. (See Chapter 31, Surface Water Hydrology for details on hydrograph estimation and flood routing).

The U.S. National Weather Service has developed generalized PMP charts for the region east of the 105th meridian (Schreiner and Reidel, 1978) and the National Academy of Sciences (1983) has published a map that indicates the appropriate NWS hydrometeorological reports (HMR) for the region west of the 105th meridian. (HMR 38 for California, HMR 43 for Northwest States, HMR 49 for Colorado River and Great Basin Drainage). The U.S. Army Corps of Engineers (1982) has issued hydrologic evaluation guidelines with recommended spillway design floods for different sizes of dams and hazard categories. For minor structures, inflow design floods with return periods of 50 to 200 years may be used if permitted by the responsible control agency (Hawk, 1992). Economic risk analysis is another approach in which the safety level and the design flood magnitude are determined simultaneously (Afshar and Mariño, 1990). Recent studies have indicated a tendency towards a modification of the policy requiring dams to accommodate the full probable maximum flood (Graham, 2000). For the UK, additions to the 1975 Flood Studies were reported by Reed and Field (1992). They also summarize procedures in nine other countries.

It is often economical to have two spillways: a *service spillway* designed for frequently occurring outflows and an *emergency spillway* for extreme event floods. Modifications of dams to accommodate major floods have been reviewed by USCOLD (1992).

Overflow Spillways

The overflow spillway has an ogee-shaped profile that closely conforms to the lower **nappe** or sheet of water falling from a ventilated sharp crested weir (See Chapter 29, Fundamentals of Hydraulics). Thus,

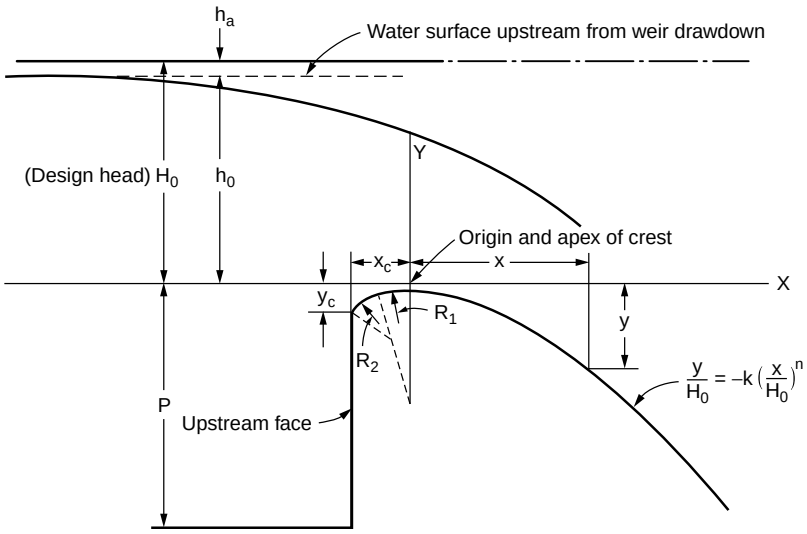

FIGURE 37.14 Ogee shaped overflow spillway profile. (Adapted from U.S. Department of the Interior, Bureau of Reclamation, *Design of Small Dams*, p. 366, U.S. Government Printing Office, Denver, CO.)

for flow at the design discharge, the water glides over the spillway crest with almost no interference from the boundary. Below the ogee curve the profile follows a tangent with the slope required for structural stability (see "Stability of Gravity Dams" earlier in this chapter). At the bottom of this tangent there is a reverse curve that turns the flow onto the apron of a stilling basin or into a discharge channel. The shape of the ogee is shown in Fig. 37.14 and can be expressed as

$$y/H_o = -K\left(x/H_o\right)^n \tag{37.9}$$

where x and y = the horizontal and vertical distances from the crest
H_o = the design head including the velocity head of approach h_a
K and n = coefficients that depend upon the slope of the upstream face of the spillway and h_a

For a vertical face and a negligible velocity of approach $K = 0.5$ and $n = 1.85$. Other values can be found in U.S. Department of the Interior, Bureau of Reclamation (1987). The discharge over an overflow spillway is given by (see Chapter 29, Fundamentals of Hydraulics, Application 29.11)

$$Q = C\,L\,H_e^{3/2} \tag{37.10}$$

where Q = the discharge
C = the discharge coefficient (units $L^{1/2}\,T^{-1}$)
H_e = the actual head over the weir including the velocity head of approach h_a
L = the effective length of the crest

The basic discharge coefficient for a vertical faced ogee crest is designated by C_o and is shown in Fig. 37.15 as a function of the design head H_o. For a head H_e other than the design head, H_0, for an ogee with sloping upstream face and for the effect of the downstream flow conditions the U.S. Department of the Interior, Bureau of Reclamation (1987) gives correction factors to be applied to C_o to obtain the discharge coefficient C. When the flow over the crest is contracted by abutments or piers the effective length of the crest is

$$L = L' - 2\left(N\,K_p + K_a\right)H_e \tag{37.11}$$

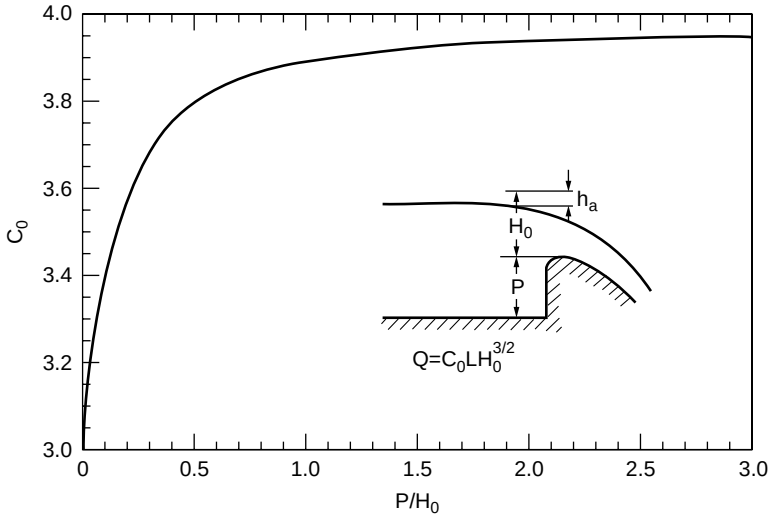

FIGURE 37.15 Discharge coefficient for Q in ft^3/s, L and H_o in feet for vertical faced ogee crest. (Adapted from U.S. Department of the Interior, Bureau of Reclamation, 1987, *Design of Small Dams*, p. 370, U.S. Government Printing Office, Denver, CO.)

where L' = the net crest length
N = the number of piers
K_p = the pier contraction coefficient with a value of 0.02 for square nosed piers with rounded corners (radius = 0.1 pier thickness), of 0.01 for rounded nose piers and of 0.0 for pointed nose piers
K_a = abutment contraction coefficient

K_a has a value of 0.20 for square abutments with headwall perpendicular to the flow and 0.10 for rounded abutment ($0.5\ H_o \le r \le 0.15\ H_o$) with headwalls perpendicular to the flow. For additional details concerning the hydraulics of spillways, see, for example, ASCE (1995) or Sentürk (1994) or Coleman et al. (1999).

Other Types of Spillways

In straight drop or free overfall spillway the flow drops freely from the crest, which has a nearly vertical face. The underside of the nappe must be ventilated. Scour will occur at the base of the overfall if no protection is provided. A hydraulic jump will form if the overfall jet impinges upon a flat apron with sufficient tailwater depth.

Chute spillways convey the discharge through an open channel placed along dam abutments or through saddles in the reservoir peripheries. They are often used in conjunction with earth dams. Generally, upstream of the crest the flows are subcritical, passing through critical at the control section and accelerating at supercritical velocity until the terminal structure is reached. Because of the high flow velocity all vertical curves and changes in alignment must be very gradual. Concrete floor slabs are provided with expansion joints that must be kept watertight and drains are provided at intervals under the slab to prevent piping.

Side channel spillways are placed parallel to and along the upper reaches of the discharge channels. Thus flows pass over the crest and then turn approximately 90°to run into the parallel discharge channel. This layout is advantageous for narrow canyons where there is not sufficient space to accommodate an overflow or a chute spillway. Flows from the side channel can be directed to an open channel as shown in Fig. 37.16 or to a closed conduit or to a tunnel leading to the terminal structure. Discharge in the side channel increases in the downstream direction. Details of the analysis of such spatially varying flows are treated, for example, in Chow (1959), French (1985) and in Sentürk (1994).

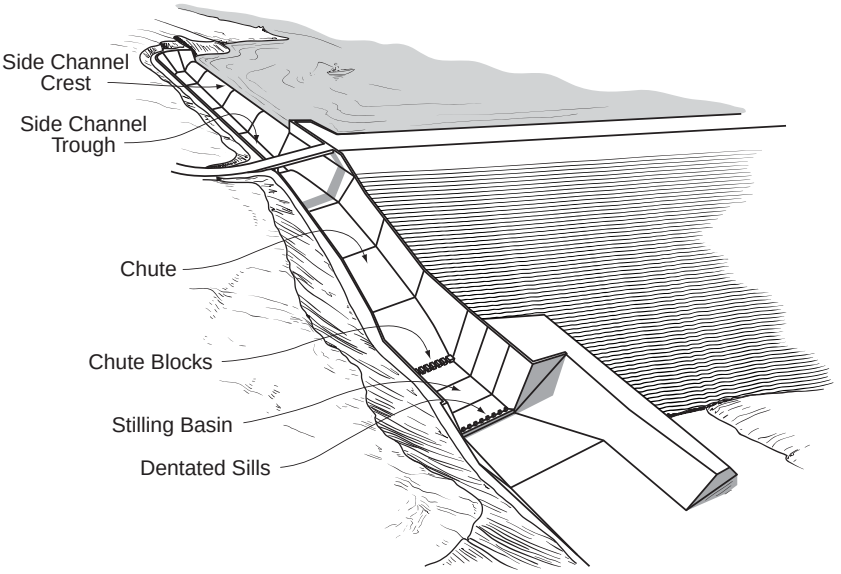

FIGURE 37.16 Typical side channel and chute spillway arrangement. (Adapted from Department of the Interior, Bureau of Reclamation, *Design of Small Dams*, p. 355, from Department of the Interior, Bureau of Reclamation.)

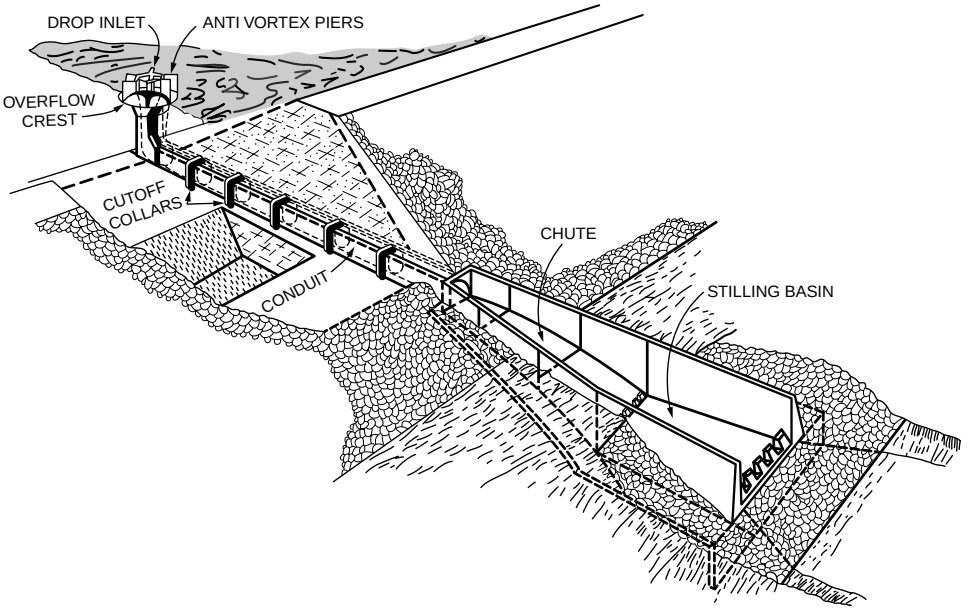

FIGURE 37.17 Shaft spillway. (*Source*: from U.S. Department of the Interior, Bureau of Reclamation, 1987, *Design of Small Dams*, p.358.)

In shaft or **morning glory spillways** the water first passes over a circular weir discharging into a vertical or sloping shaft followed by a horizontal or nearly horizontal tunnel leading to the terminal structure. The overflow crest is often provided with anti-vortex piers as shown in Fig. 37.17. At low flows the discharge over the spillway is $Q = C\,L\,h^{3/2}$ in which h is the head over the crest and L is the crest length. When the shaft is full and the inlet is submerged the spillway functions as a pipe flowing full. The

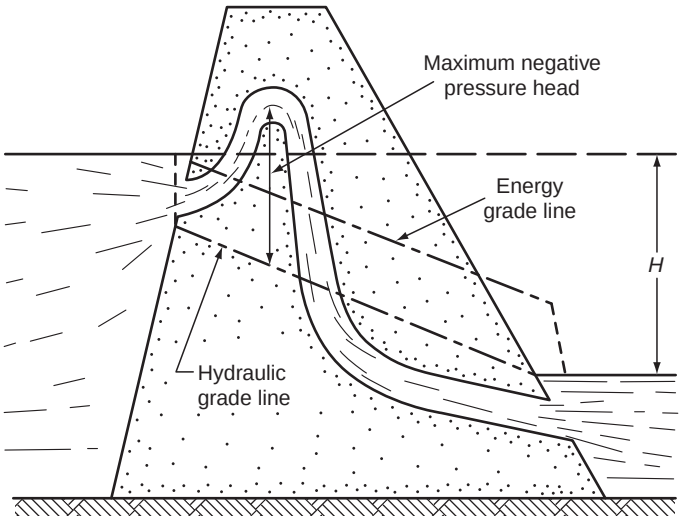

FIGURE 37.18 Siphon spillway. (*Source*: Morris, H.M. and Wiggert, J.M. *Applied Hydraulics in Engineering,* 1972, Wiley, Fig. 6–20, p. 265.)

discharge is then proportional to $H^{1/2}$, where H is the difference between the reservoir elevation and the elevation of the pipe outlet. Trash racks may be desirable to avoid clogging or damage by debris. In high shaft spillways there is the possibility of **cavitation** in the bend between the vertical shaft and the conduit. This situation must be avoided.

Siphon spillways can be used when large capacities are not required, space is limited and fluctuations of reservoir level must be maintained within close limits. (Fig. 37.18). When the siphon flows full the discharge is given by an orifice equation (see Chapter 29, Application 29.5).

$$Q = C_d A\left[2gH\right]^{1/2} \tag{37.12}$$

where the coefficient of discharge C_d is approximately 0.9, H is the difference in elevation between the reservoir and the tailwater surface if the siphon outlet is submerged, or if it is free flowing H is the difference in elevation between the reservoir and the siphon outlet.

In order to avoid cavitation the maximum velocity in the siphon must be limited to

$$V = \left[90.5\, r_i \log\left(r_o/r_i\right)\right]\Big/\left(r_o - r_i\right) \tag{37.13}$$

in which V is the maximum velocity (in feet per sec), r_o and r_i are the outside and inside radii at the crown of the siphon, assuming a free vortex at the crown (Morris and Wiggert, 1972).

Without contraction at the outlet, the maximum permissible head, H, associated with this velocity is

$$H = \left(1 + k_e + k_f + k_b\right)V^2\Big/\left(2g\right) \tag{37.14}$$

in which k_e, k_f, k_b are the coefficients for entrance, friction and bend losses, respectively.

Labyrinth spillways are particularly advantageous when the available width is limited and large discharges must be passed. They concentrate the discharge into a narrow chute. They are particularly well suited for rehabilitation of spillways when the capacity has to be increased. They are more economical than gated structures. The total length of the crest, L_T, is

$$L_T = N\left(2\,L1 + A + D\right) \tag{37.15}$$

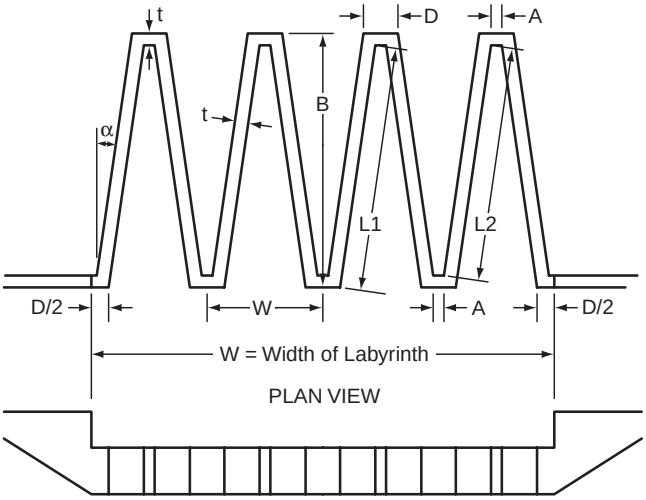

FIGURE 37.19 Labyrinth weir. (*Source*: Tullis, J.P., Amanian, N. and Waldron, D. 1995. ASCE, *Jour. of Hydraulic Engineering*, 121, 3, 247–255.)

where $L1$ is the actual length of the side leg and A and D are shown in Fig. 37.19 and N is the number of cycles (4 shown).

The effective length L of the crest in Eq. (37.10) is

$$L = 2N\left(A + L2\right) \tag{37.16}$$

where $L2$ is the effective length of the side.

Values of the discharge coefficient and details about the design of Labyrinth spillways can be found in Tullis et al.(1995) and in Zerrouk and Marche (1995).

Stepped spillways and channels have been used since antiquity. The steps significantly increase the energy dissipation over the spillway face thus reducing the size of the downstream stilling basin. Their design has been reviewed by Chanson (1993).

Cavitation

High spillways can experience flow velocities of 10 to 15 m/s or more. When the high velocity flow encounters a rapid convergence of the streamlines (perhaps caused by a surface irregularity or a bend), then cavitation is likely to occur. Cavitation is the formation and subsequent collapse of vapor cavities that occur when the fluid pressure gets below the vapor pressure. (Values of the vapor pressure head as a function of temperature are given in Chapter 29, Fundamentals of Hydraulics, Tables 29.1 and 29.2). On a spillway surface, when the streamlines of high velocity flow curve significantly at a surface irregularity, then the pressure drops along the converging streamlines. Abrupt convergence of the streamlines can produce pressure drops to the vapor pressure and vapor cavities begin to form. As the bubbles are swept downstream in a region of higher pressure, they collapse near the concrete boundary. The implosion of the bubbles creates a myriad of small high velocity jets that destroy the concrete surface. Measures to control caviatation include close construction tolerance and aeration of the flow by means of aeration devices. For further discussion of spillways considering cavitation and aeration see, for example, Wei (1993). Cavitation in pipes is discussed in a subsequent section.

Spillway Crest Gates

Several types of gates can be installed on spillway crests in order to obtain additional storage. By opening the gates, partial or full spillway discharge capacity can be obtained. The radial or **Tainter gate** has an

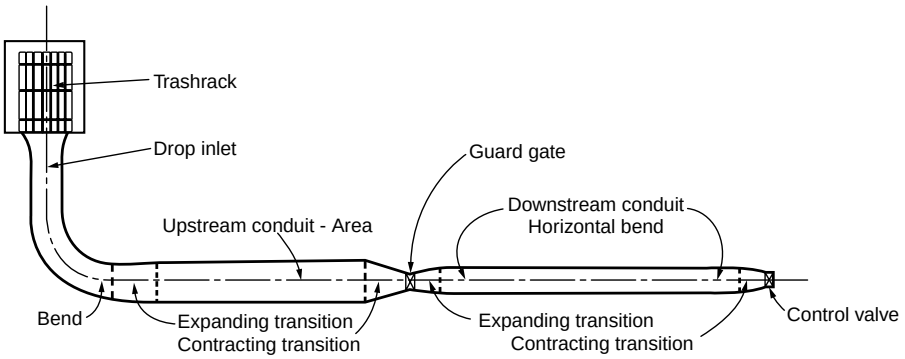

FIGURE 37.20 Outlet works pressure conduit. (Adapted from Department of the Interior, Bureau of Reclamation, 1987, *Design of Small Dams* Fig. 10.11, page 457, U.S. Government Printing Office, Denver, CO.)

upstream surface which is a sector of a cylinder. Thus the hydrostatic force goes through the pivot or trunnion located at the center of the circular arc. (see Chapter 29 on Fundamentals of Hydraulics, Application 29.3). Other types of crest gates include vertical lift gates, flap gates, drum gates, roller gates and inflatable gates. Design guidelines for spillway gates can be found in Sehgal (1996, 1993) and Sagar (1995). Gates that overturn when the reservoir level exceeds a specified elevation are called fuse gates (Falvey and Treille, 1995). Several gates are used and each gate is set to overturn with increasing reservoir levels so that only the number of gates needed to pass the flow are overturned. The fuse plug performs a similar function. It is an embankment that is designed to wash out in a predictable and controlled manner when capacity is needed in excess of that of service spillway and outlet works (Pugh and Gray, 1984). In this case the entire fuse plug fails. Horizontal boards or stop logs laid between grooved piers can be used in small installations. Flashboards or wooden panels held by vertical pins anchored on the crest of the spillway are sometimes used in small installations to temporarily raise the water surface.

37.5 Outlet Works

Components and Layout

The purpose of the outlet works is to regulate the operational outflows from the reservoir. The intake structure forms the entrance to the outlet works. It may also include trash racks, fish screens, and gates. The conduit entrance may be vertical, inclined or horizontal. The conduit may be free flowing or under pressure. For low dams the outlet may be a gated open channel. For higher earth dams the outlet may be a cut-and-cover conduit or a tunnel through an abutment. For concrete dams the outlet is generally a pipe embedded in the masonry or the outlet is formed through the spillway using a common stilling basin to dissipate the excess energy of both the spillway and outlet works outflows. Diversion tunnels used for the construction can in some cases be converted to outlet works. Examples of layout of outlet works may be found in U.S. Department of the Interior, Bureau of Reclamation (1987).

Hydraulics of Outlet Works

When the outlet is under pressure it performs as a system of pipes and fittings in series as shown in Fig. 37.20. It typically includes trash racks, an inlet, conduits, expansions, contractions, bends, guard gates that are usually fully open or fully closed for the purpose of isolating a segment of the system and control valves for the regulation of the flow. The total head H_T, the difference in elevation between the reservoir and the centerline of the outlet, is used in overcoming the losses and producing the velocity head at the exit

$$H_T = \sum h_i + h_v \tag{37.17}$$

where $\sum h_i$ = the sum of the applicable losses due to trash racks, entrance, bends, friction, expansion, contraction, gate valves
h_v = the exit velocity head

These losses are expressed as $h_l = KV^2/(2g)$, except for the contraction and expansion losses which are expressed as $h_l = K(V_1^2 - V_2^2)/(2g)$. Appropriate values of the coefficient K may be found in Table 29.9, Chapter 29 on Fundamentals of Hydraulics as well as in U.S. Department of the Interior, Bureau of Reclamation (1987) or in handbooks (Brater et al., 1996). Additional information on design of trashracks may be found in ASCE (1993).

When the outlet functions as an open channel, the flows are usually controlled by head gates. As the channel can be nonprismatic, the flow profile is calculated by the procedure described in the section on standard step method for gradually varied flow in nonprismatic channels (Chapter 30 on Open Channel Hydraulics). An example of design can be found in U.S. Department of the Interior, Bureau of Reclamation 1987. Guidelines for the design of high head gates that may be used in outlet works have been reviewed by Sagar (1995). The experiences of outlet works in the UK have been reviewed by Scott (2000).

37.6 Energy Dissipation Structures

When spillways or outlet works flows reach the downstream river a large portion of the static head has been converted into kinetic energy. Energy dissipation structures are therefore needed to prevent scour at the toe of the dam or erosion in the receiving stream or damage to the adjacent structures. As the flow from the spillway or the outlet works is usually supercritical, the hydraulic jump provides an efficient way of dissipating energy as the flow goes from supercritical to subcritical. The ratio of the depth d_1 before the jump to the conjugate depth d_2 after the jump is

$$d_2/d_1 = 1/2\left[\left(1+8\,F^2\right)^{1/2} - 1\right] \tag{37.18}$$

where $F = V_1/(gd_1)^{1/2}$ is the Froude number of the incoming flow and the head dissipated in the jump, h_j, is

$$h_j = \left(d_1 + V_1^2/2g\right) - \left(d_2 + V_2^2/2g\right) \tag{37.19}$$

where V_1 and V_2 are the velocities before and after the jump.

The US Bureau of Reclamation has developed several types of **stilling basins** to stabilize the position of the jump and improve the energy dissipation. Figure 37.21 shows a Type III stilling basin for $F > 4.5$ and $V_1 < 60$ ft/s. The tailwater depth in the downstream channel is taken equal to the conjugate depth d_2. Similar information for other ranges of Froude numbers can be found in U.S. Department of the Interior, Bureau of Reclamation (1987).

Usually the conjugate depth d_2 and the tailwater depth TW in the discharging stream cannot be matched for all discharges. The elevation of the floor of the stilling pool can be set such that d_2 and TW match at the maximum discharge. If $TW > d_2$ at lower discharges the conjugate depth d_2 can be raised by widening the stilling basin and a closer fit between the two rating curves can be obtained. For some rating curves the tailwater and the conjugate depth rating curves can be matched for an intermediate discharge (see U.S. Department of the Interior, Bureau of Reclamation, 1987, p. 397). Whether the basin is widened depends on hydraulic and economic considerations.

The submerged bucket dissipator can be used when the tailwater is too deep for the formation of a hydraulic jump. There are two types: the solid bucket and the slotted bucket. Figure 37.22 shows the geometry of these dissipators. The dissipation is due to the formation of two rollers rotating in opposite

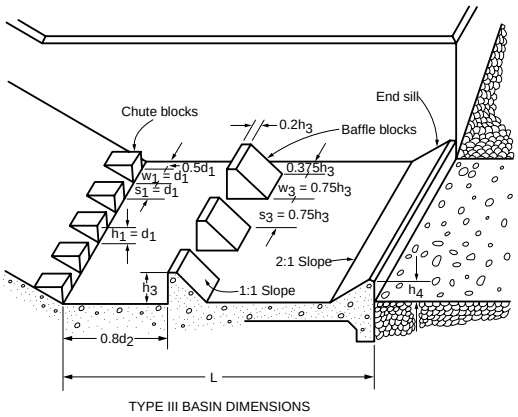

FIGURE 37.21 USBR stilling basin type III for Froude numbers larger than 4.5 and incoming flow velocity less than 60 ft/s. (*Source*: U.S. Department of the Interior, Bureau of Reclamation, 1987 *Design of Small Dams* Fig 9.41, page 391.)

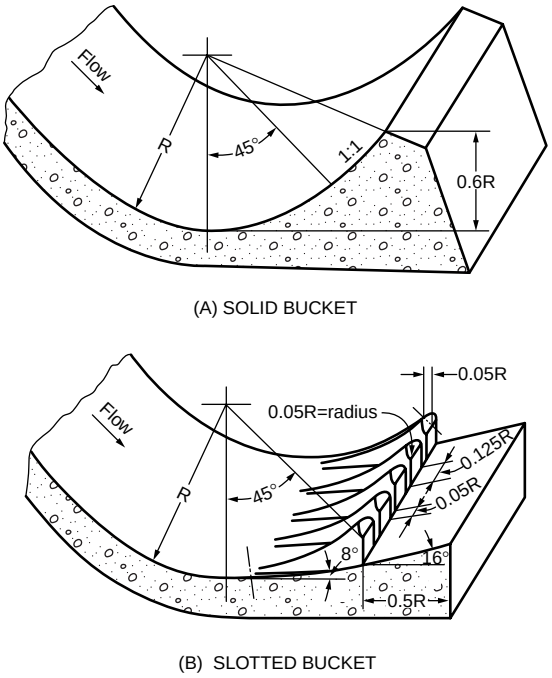

FIGURE 37.22 Submerged bucket dissipators.(*Source* U.S. Department of the Interior, Bureau of Reclamation, 1987, *Design of Small Dams*. Fig 9.45, page 398 U.S. Government Printing Office, Denver, CO.)

directions. Curves for their design can be found in U.S. Department of the Interior, Bureau of Reclamation (1987). The slotted bucket is the preferred design although the range of acceptable discharges is more limited. Other types of smaller dissipation structures are the straight drop spillway, the slotted grating dissipator and the impact type stilling basin. The latter type can be used with an open chute or a closed conduit and its performance does not depend on the tailwater.

The high flow velocity and air mixing below spillways and plunge pools can result in a supersaturation of nitrogen and oxygen in the water. This in turn can be a threat to anadromous fish. Geldert et al. (1998) have developed relationships to predict the dissolved gasses below spillways and stilling basins. This information can assist in the design and operation of such structures in order to mitigate high dissolved gas concentrations below them.

37.7 Diversion Structures

Construction of a dam across a perennial river generally requires the diversion of the flow so that the site can be dewatered and the foundation excavation can proceed in the dry. The diversion works typically include an upstream **cofferdam**, a downstream cofferdam and a conveyance structure. The upstream cofferdam directs the flow towards the conveyance structure and the downstream cofferdam protects the construction site from below. Cofferdams are temporary dams. Typically, they consist of circular cells connected to one another. The periphery of the cells is made of flat-web steel sheetpilings that reach the rock and provide effective water cutoff. The cells are filled with sand, gravel or a mix. The pressure of the fill material produces a hoop tension in the interlocks that provides watertightness and structural integrity. Free-standing cofferdams, without stabilizing inside berms, have been built to a height of 35 m (115 ft) (Fetzer and Swatek, 1988). The conveyance structure can be a channel, or a single tunnel or multiple tunnels. These conveyances can take the flow around the dam abutments or through the dam itself. In some cases part of the conveyance structure can be integrated in the outlet works. The discharge used for the diversion structures typically ranges from the 5-, 10-, 25- or the 50-year frequency flood depending on the risk of flooding that can be tolerated. The higher frequencies are used if the site is upstream of an urban area and if the cost of possible damage to completed work is important. Examples of diversion structures can be found in U.S. Department of the Interior, Bureau of Reclamation (1987), Swatek (1993) and Sentürk (1994).

37.8 Open Channel Transitions

Subcritical Transitions

Transitions are needed to connect channels of different cross sections, for example, to connect a trapezoidal channel to a rectangular flume or to a circular conduit to cross over a valley on an aqueduct or under a valley with an inverted siphon, respectively. These typically are contracting transitions. Likewise the transition from a rectangular flume or a circular conduit to a trapezoidal channel usually is through an expanding transition. Chow (1959) recommends an optimum maximum angle between the channel axis and a line connecting the channel sides of 12.5°. The drop of water surface, $\Delta y'$, for an inlet structure is given by

$$\Delta y' = \left(1 + c_i\right)\Delta h_v \tag{37.20}$$

and the rise in water surface, $\Delta y'$, in an outlet transition is given by

$$\Delta y' = \left(1 - c_o\right)\Delta h_v \tag{37.21}$$

where Δh_v is the change in velocity head and the coefficients c_i, c_o have the following values (Chow, 1959):

Transition Type	c_i	c_o
Warped	0.10	0.20
Cylinder quadrant	0.15	0.25
Simplified straight line	0.20	0.30
Straight line	0.30	0.50
Square ended	0.30+	0.75

The following Bureau of Reclamation formula can be used for the preliminary estimates of freeboard in channels less than 12 ft deep: $F = [C\,y]^{1/2}$ in which F is the freeboard, y is the depth, both in feet, and C is a coefficient varying from 1.5 to 2.5 for channels with discharges varying from 20 to 3000 ft^3/s, respectively. There are two approaches to the design of transitions: (1) a free water surface is assumed

(for example two reversed parabolas) and the depth is calculated for assumed width and side slope (Chow, 1959, p. 310–317 and French, 1985); or (2) the boundaries are set first and the surface is calculated (Vittal and Chiranjeevi, 1983; French, 1985). Swamee and Basak (1991, 1992) have developed designs of rectangular and trapezoidal expansion transitions that minimize the head losses.

Supercritical Contractions

Contractions designed for subcritical flows will not function properly for supercritical flows. Generally, with supercritical flow, wave patterns are formed in the contraction and propagate in the downstream channel. Supercritical flow contractions are best designed for rectangular channels. The converging angles on each side produce two oblique hydraulic jumps that makes an angle with the original flow direction. A second pair of oblique jumps is created by the diverging angle at the downstream end of the contraction. Ippen and Dawson (1951) devised a design such that the disturbances caused by the converging angles are canceled by the disturbances caused by the diverging angles so that there is no wave pattern in the channel downstream of the contraction. This design will function properly only for the specified Froude number in the upstream channel. Additional details on the design of supercritical transitions can be found in Ippen (1950), Chow (1959), Henderson (1966), French (1985) and Sturm (1985). Numerical simulation of supercritical flow transitions has been discussed by Rahman and Chaudhry (1997).

37.9 Culverts

Flow Types

Culverts are short conduits that convey flows under a roadway or other embankment. They are generally constructed of concrete or corrugated metal. Common shapes include circular, rectangular, elliptical, and arch. Culverts can flow full or partly full. When the culvert flows full it functions as a pipe under pressure. When it flows partly full it functions as an open channel and the flow can be subcritical, critical or supercritical. (See Chapter 30, "Open Channel Hydraulics".) A culvert operates either under inlet or outlet control. If the culvert barrel has greater capacity than the inlet, then the culvert functions under inlet control. Conversely, if the barrel has less capacity than the inlet, the culvert operates under outlet control. Figures 37.23 and 37.24 illustrate inlet and outlet control flows, respectively. Partly full flow can occur with inlet control or with outlet control.

When operating under inlet control the flow becomes critical just inside the entrance and the flow is supercritical through the length of the culvert if the outlet is unsubmerged; if the outlet is submerged a hydraulic jump forms in the barrel. For low unsubmerged headwater the entrance of the culvert operates as a weir (Eq. [37.10]). When the headwaters submerge the entrance it performs as an orifice (Eq. [37.12]). From tests by the National Bureau of Standards, performed for the Bureau of Public Roads (now Federal Highway Administration), equations have been obtained to calculate the headwater above the inlet invert, for unsubmerged and submerged inlet control (Normann et al., 1985). These equations can be presented in a regression form that gives a direct solution for the inlet head given the discharge, the span and the rise of the culvert for the several culvert types. The equation and a table of regression coefficients can be found in U.S Federal Highway Administration (1999).

When operating under outlet control, for a full flow condition the total loss, H_L, through the conduit is

$$H_L = \left[1 + k_e + 2g\, n^2 L \Big/ \left(K_M^2\, R^{1.33}\right)\right] V^2 / 2g \tag{37.22}$$

where k_e = an entrance loss coefficient
L = the length of the culvert
R = the hydraulic radius
n = Manning's roughness coefficient
V = the flow velocity

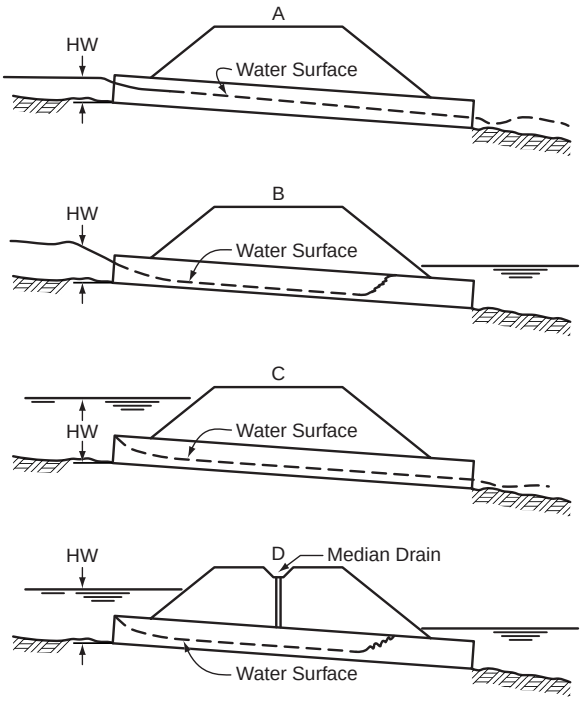

FIGURE 37.23 Types of inlet control: (A) inlet and outlet outlet unsubmerged, critical flow at entrance, supercritical flow along barrel, (B) inlet unsubmerged and outlet submerged, critical flow at entrance and supercritical flow upstream of hydraulic jump in culvert, (c) inlet submerged, outlet unsubmerged, critical depth at entrance and supercritical flow along barrel, (D) inlet and outlet submerged, similar to (B) with hydraulic jump in culvert. (*Source*: Normann et al. 1985.)

K_M has a value of 1 for metric units and 1.486 for customary English units (See Chapter 30, "Open Channel Hydraulics," Section 30.3).

For a full flow condition the energy and hydraulic grade line are shown in Fig. 37.25 and the relation between points at the free surface upstream and downstream of the culvert is

$$HW_o + V_u^2/(2g) = TW + V_d^2/(2g) + H_L \tag{37.23}$$

where HW_o = the headwater depth about the outlet invert
V_u = the upstream velocity of approach
TW = the tailwater depth above the outlet invert
V_d = the downstream velocity
H_L = the total loss through the conduit given in the preceding equation

For further details on the hydraulics and design of culverts see, for example, Tuncock and Mays (2001).

Inlets

For culverts operating under inlet control, the performance can be improved by reducing the contraction at the inlet and by increasing the effective head. These objectives can be achieved with tapered inlets. The simplest design is the side tapered inlet in which the side walls are flared between the throat and the face resulting in an enlarged face section. In addition, the effective head can be increased by depressing the inlet. This can be achieved by an upstream depression between the wingwalls or a sump upstream of the face section. A more elaborate design is the slope tapered inlet that has flared sidewalls. A fall is incorporated between the throat and the face sections, (Normann et al, 1985).

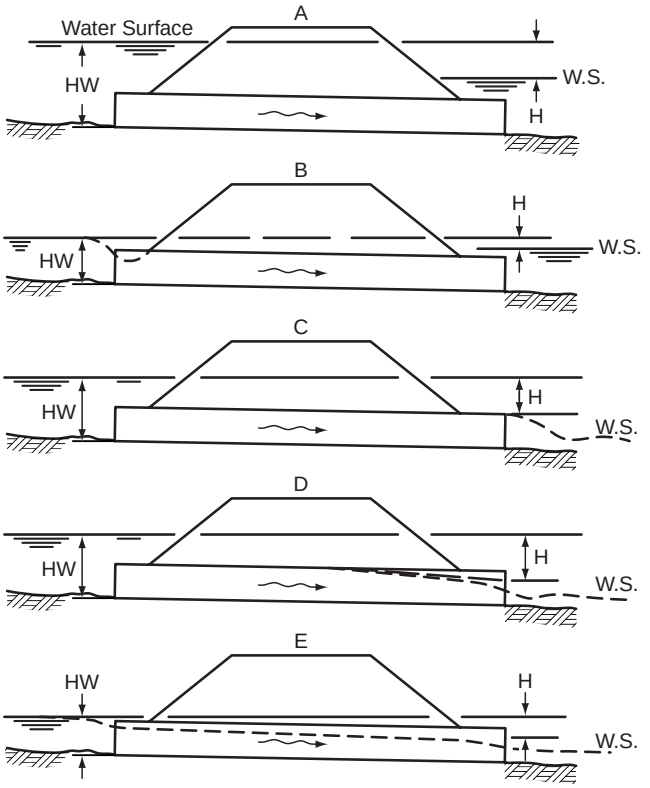

FIGURE 37.24 Types of outlet control: (A) inlet and outlet submerged, pipe flow, (B) inlet unsubmerged and outlet submerged, with surface drop at the entrance and contraction, (c) inlet submerged, pipe flow along barrel, no tailwater, (D) inlet submerged and outlet unsubmerged, outlet depth grater than critical, (E) inlet and outlet unsubmerged, subcritical flow over entire length, critical condition at outlet. (*Source*: Normann et al. 1985.)

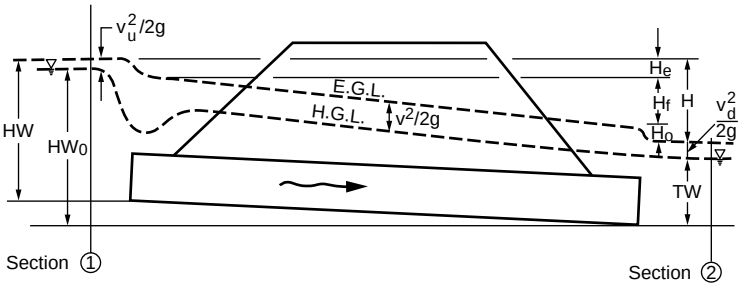

FIGURE 37.25 Energy and hydraulic grade line for full flow condition (*Source*: Normann et al. *Hydraulic Design of Highway Culverts*. 1985. Fig. III-8, p.36 Federal Highway Administration Report No. FHWA-IP-85–15.)

Sedimentation and Scour

Special consideration must be given to the transport of sediments. Low flow velocities within the culvert may result in deposition of sediments, whereas high velocities may produce erosion at the outlet of the culvert. For further details on sediment transport see Chapter 35, "Sediment Transport in Open Channels" and Yang (1996). Protection against scour include cutoff walls, riprap armoring and energy dissipators. These protection devices are used if the outlet velocities are larger than 1.3 times the natural stream velocity, between 2.3 and 2.5 or greater than 2.5 times the natural stream velocity, respectively (Tuncock and Mays, 2001).

Software

The principal public domain computer program for the hydraulic design and analysis of culverts is: the interactive program HY8 that is part of the HYDRAIN (U.S. Federal Highway Administration, 1999), an integrated drainage design computer system. HY8 consists of four modules: (1) culvert analysis and design, (2) hydrograph generation,(3) routing, and (4) energy dissipation. HYDRAIN (version 6.1) can be downloaded from http://www.fha.dot.gov/bridge/hydrain.htm. The software package HEC-RAS, River Analysis System, developed by the US. Army Corps of Engineers, Hydrologic Engineering Center (2001) is a comprehensive suite of computer programs for water surface and river hydraulics calculations and includes hydraulics of bridges and culvert openings. HEC-RAS can be downloaded from http://www.wrc-hec.usace.army.mil/. These programs are discussed in more detail in Chapter 38, "Simulation in Hydraulics and Hydrology".

37.10 Bridge Constrictions

Backwater and Discharge Approaches

The hydraulics of bridges can be approached from the point of view of the highway engineer or from that of the hydrologist. The highway engineer is concerned with the amount of backwater created by a bridge constriction. Approach embankments are often extended in the flood plain to reduce the span of the bridge proper and thus decrease the cost of bridge crossings. The flow is thus forced to pass through a constriction that may produce a backwater. In contrast the hydrologist is concerned with the indirect determination of the discharge of a large flood from high water mark observations and from the geometry of the constriction. Indirect methods of discharge determination are needed when the flow rate is beyond the range of the rating curves at gaging stations.

Flow Types

Three different types of flow can occur at a bridge constriction. The first occurs when the flow is subcritical both in the stream and through the constriction. This is the flow type most generally encountered, illustrated in Fig. 37.26 and is discussed below. In the second type the flow is subcritical upstream of the bridge but goes through critical in the constriction. The flow can then immediately return to subcritical as it exits the constriction or the water surface can dip below the critical depth downstream of the constriction and then return to its normal depth through a hydraulic jump. Finally, the third type occurs when the flow is supercritical through both the stream and the constriction.

Backwater Computation

The backwater superelevation, h_1^*, upstream of a constriction with subcritical flow is given by Bradley (1978)

$$h_1^* = K^* \alpha_2 V_{n2}^2/(2g) + \alpha_1\left[(A_{n2}/A_4)^2 - (A_{n2}/A_1)^2\right] V_{n2}^2/(2g) \tag{37.24}$$

where K^* = the backwater coefficient
A_{n2} = the gross water area in constriction measured below normal stage
V_{n2} = Q/A_{n2} is the average velocity in the constriction
A_4 = the area at section 4 where the normal depth is reestablished
A_1 = the water area at section 1 including that produced by the backwater
α_1 and α_2 = the kinetic energy corrections factors at sections 1 and 2, respectively (See Eq. [29.11] in Chapter 29, "Fundamentals of Hydraulics")

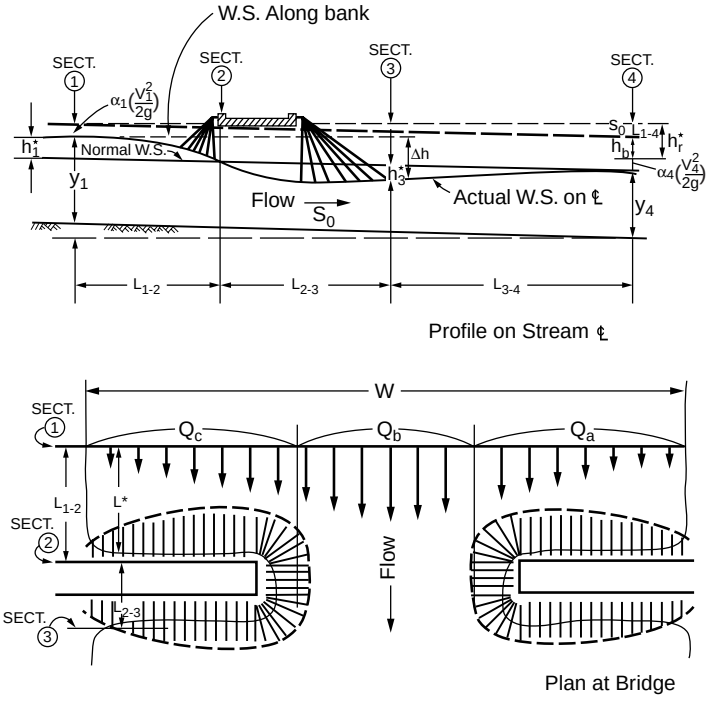

FIGURE 37.26 Normal bridge crossing with spillthrough abutments. (*Source*: Bradley, 1978, *Hydraulics of Bridges*. FIGURE 3 p. 7, Hydraulic Series No.1, Federal Highway Administration.)

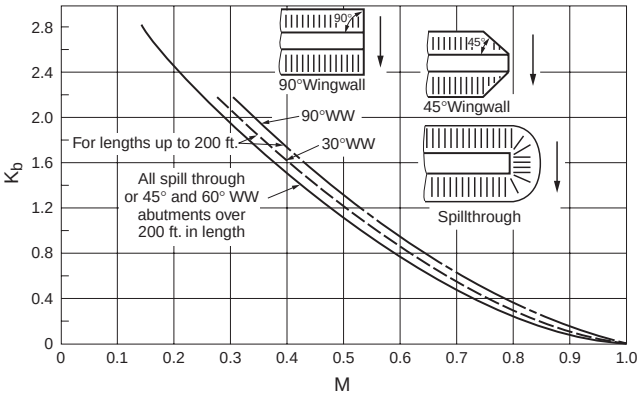

FIGURE 37.27 Backwater coefficient for wingwall (WW) and spillthrough abutments. (*Source*: Bradley, 1978, *Hydraulics of Bridges*, Fig 6, p. 14, Hydraulic Series No.1, Federal Highway Administration.)

α_1 can be approximated as $\alpha_1 = \Sigma q v^2/(QV_1^2)$ where q and v are the discharge and velocity in subsections of section1, respectively. Similarly α_2 can be approximated for section 2. In Fig. 37.27, the basic backwater coefficient K_b is given as a function of the bridge opening ratio, $M = Q_b/Q$, where Q_b is the flow in the portion of channel within the projected length of the bridge (Fig.37.26) and Q is the total discharge. Incremental coefficients to account for the effects of the piers, opening eccentricity, skewed crossing, dual bridges, bridge girder submergence, and backwater in the stream can be found in Bradley (1978). The sum of K_b and the incremental coefficients yields K^*.

Discharge Estimation

The discharge, Q, through a bridge constriction, under subcritical flow condition, can be calculated from Chow (1959)

$$Q = C\,A_3\left[2g\left(\Delta h - h_f + \alpha_1 V_1^2/(2g)\right)\right]^{1/2} \tag{37.25}$$

where C = a discharge coefficient
A_3 = the flow area at section 3
Δh = the drop in water surface between section 1 and section 3
V_1 = the mean velocity at section 1
h_f = the head loss between sections 1 and 3

This loss is calculated from

$$h_f = L_a\left[Q/\left(K_1K_3\right)^{1/2}\right]^2 + L\left[Q/K_3\right]^2 \tag{37.26}$$

where L_a = the approach length from section 1 to the upstream face of the abutment
L = the length of the contraction
$K_1 = (K_M/n)\,A_1 R_1^{2/3}$ is the conveyance at section 1 in which $K_M = 1$ for metric units and $K_M = 1.486$ for customary English Units

Similarly, K_3 is the conveyance at section 3. The discharge coefficient, C, depends on the shape of the abutment, the ratio of the contraction length to the contraction width, L/b, and the contraction ratio $m = 1 - K_b/K_1$, where b is the constriction width, K_b is the conveyance of the contracted section and K_1 is the conveyance of the approach section 1. Figure 37.28 gives the base discharge coefficient for the bridge opening with spillthrough abutments. Chow (1959) and Kindsvater et al. (1953) give curves for determination of the discharge coefficient for different abutment types and multiplicative correction factors to account for the effects of the Froude number, the rounding and chamfering of the abutment, the skewness and eccentricity of the bridge, the possible submergence of the bridge girders, the piers and piles.

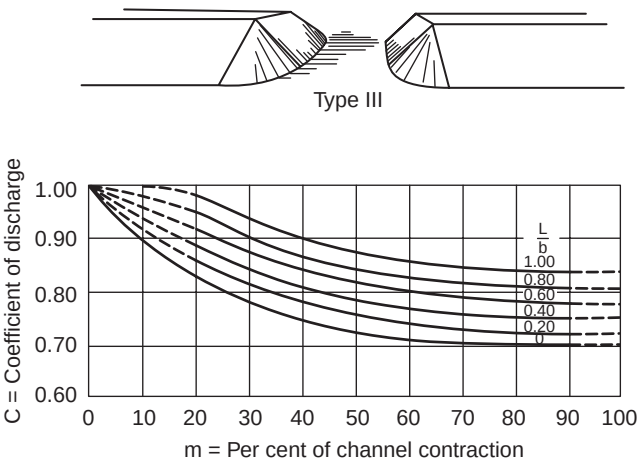

FIGURE 37.28 Discharge coefficient for spillthrough abutment bridge opening. (*Source:* Kindsvater, C.E., Carter, R.W. and Tracy, H.J., *Computation of Peak Discharge at Contractions,* U.S. Geological Survey, Circular No. 284.)

Scour

The previous discussion assumes that the channel is rigid, that is it does not aggrade nor degrade. However, long-term stream bed degradation and local scour may take place. Aggradation occurs when the sediment load supplied to a river reach exceeds its transport capacity. Aggradation can cause a reduction of bridge waterway openings. This in turn can result in increased upstream flooding and increased scour at the contraction (Johnson et al. 2001). Scour can occur during rapid flow events, when sediments are transported by the currents eventually undermining bridge pier foundations. Erosion and deposition can occur during the same flood event. (See Chapter 35, "Sediment Transport in Open Channels").

The Federal Highway Administration current practice in the determination of scour at bridges can be found in Richardson and Davis, (1995) and has been summarized by Tuncock and Mays (2001). This is a deterministic approach. Instead, Johnson and Dock (1998) propose a probabilistic approach for determining the likelihood of various scour depths for storm events of specified return periods. Monitoring scour is difficult; however, frequency modulated–continuous wave (FM-CW) reflectometry has potential for continuous monitoring of sediment depths (Yankielun and Zabilansky, 2000).

Software

The principal public domain computer programs for hydraulics of bridges are: HEC-RAS and WSPRO. The software package HEC-RAS, River Analysis System, developed by the US. Army Corps of Engineers, Hydrologic Engineering Center (2001), is a comprehensive suite of computer programs for water surface and river hydraulics calculations and includes hydraulics of bridges and culvert openings. HEC-RAS can be downloaded from http://www.wrc-hec.usace.army.mil. WSPRO is part of the HYDRAIN, an integrated drainage design computer system (U.S. Federal Highway Administration, 1999). It performs backwater calculations by the standard step method (see Chapter 30, "Open Channel Hydraulics"). HYDRAIN can be downloaded from http://www.fhwa.dot.gov/bridge/hydrain.htm. These programs are discussed in more detail in Chapter 38, "Simulation in Hydraulics and Hydrology."

37.11 Pipes

The hydraulics of flow in pipes is discussed in Chapter 29, "Fundamentals of Hydraulics."

Networks

For pipe network calculations it is convenient to express the friction loss, h_L, in a pipe by an equation of the form

$$h_L = KQ^n \tag{37.27}$$

where K includes the effects of the pipe diameter, length and roughness as well as the fluid viscosity.

For the Darcy-Weisbach formula (Eq. [29.21] in Chapter 29, "Fundamentals of Hydraulics")

$$K = 8fL/\left(\pi^2 gD^5\right) \quad \text{and} \quad n = 2 \tag{37.28}$$

where L = the pipe length
D = the diameter
Q = the discharge

The friction factor f is obtained from the Moody diagram (see Chapter 29). The formula is valid for consistent metric and English units. For the Hazen-Williams formula

TABLE 37.1 Williams-Hazen Coefficients

Pipe Material	Condition	Size	C
Cast Iron	New	all	130
	5 years old	≥ 12 in.	120
		8 in.	119
		4 in.	118
	10 years old	≥ 24 in.	113

$$K = C_u C^{-1.852} L D^{-4.87} \quad \text{and} \quad n = 1.852 \tag{37.29}$$

where C_u = 10.654 for metric units and C_u = 4.727 for English units
C = the Hazen-Williams coefficient, typical values of which are given in Table 37.1

Two basic relationships must be satisfied in a network: the continuity or conservation of mass at each junction and the energy relationship around any closed loop. The continuity relationship requires that the sum of the flows entering a node be equal to the sum of the flows leaving it. The energy relationship requires that the algebraic sum of the head losses in any loop be zero using an appropriate sign convention, for example flows are positive in the counterclockwise direction. The same sign convention applies to all loops of the network. Minor losses due to fittings and valves, etc. and energy gains due to pumps are included in the appropriate segments.

The first systematic numerical procedure for the calculation of the flows of liquids in pipe networks was proposed by Hardy Cross (1936). It includes the following steps: (1) assume a discharge in each pipe, Q_g, so that the continuity requirement is satisfied at each node, (2) for each pipe loop calculate a first order correction to the discharge

$$\Delta Q = -\Sigma K Q_g^x \Big/ \left[\Sigma \left| x K Q_g^{x-1} \right|\right] \tag{37.30}$$

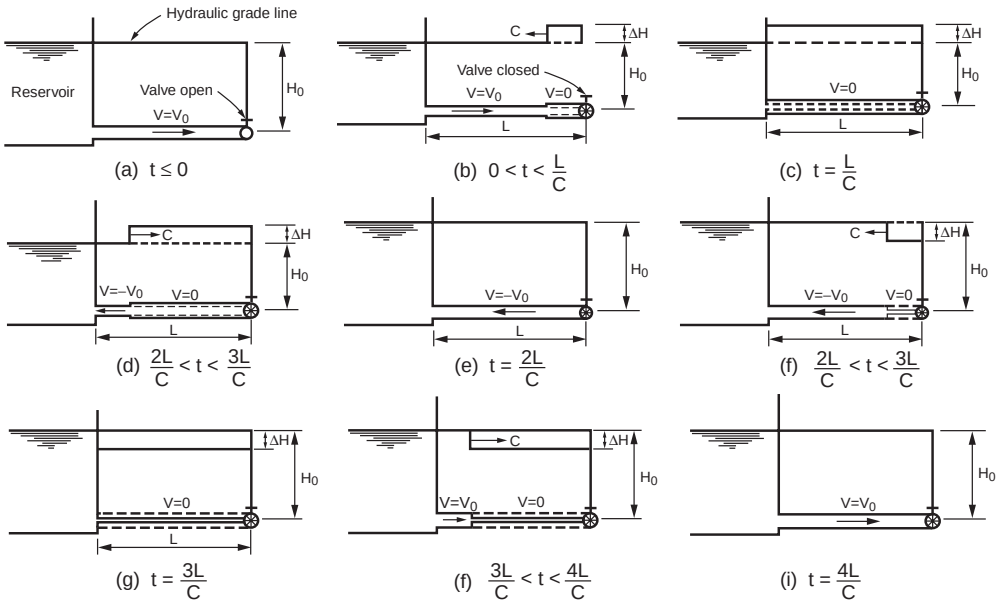

FIGURE 37.29 Water hammer cycle due to instantaneous valve closure.

taking into account the sign convention in the numerator of the right hand side,(3) in each pipe loop add the corrections algebraically to flow in each pipe (note that a pipe that is common to two loops has different signs depending upon which loop is considered and this pipe will receive two corrections), (4) with Q_g being the new flows, calculate a new correction ΔQ for each loop, (5) in each loop add the correction algebraically to each pipe, (6) repeat steps 4 and 5 until the correction becomes sufficiently small. An example involving 7 pipes, 2 reservoirs, and 1 pump can be found in Lansey and Mays (1999). The main advantages of the Hardy cross method are that it provides an understanding of the procedure and that the calculations can be done by hand for small networks. Its main limitation is that it solves the equations one at a time. More recent methods use more efficient numerical techniques such as the linear theory, the Newton-Raphson method or the gradient method to solve the large system of equations for the nodes and loops. For large networks computer programs are used. (see section on software later in this chapter). For further discussion on pipe networks see, for example, Lansey and Mays (1999).

Hydraulic Transients and Water Hammer

A hydraulic transient is a situation where conditions, such as flow velocity and pressure, are time varying. Some of the common conditions creating a transient are: a change in a valve opening; operation of check valves or pressure relief valves; starting or stopping of pumps; changes of power demand on hydraulic turbines; pipe break; trapped air in pipeline; filling or flushing of pipes, etc. Large and rapid changes in velocity can create high transient pressures. If the pipe is not designed to withstand the high transient pressures or if controlling devices are not included to limit the increase in pressure head, damage (including rupture) can occur to the pipe or to the connected equipment and machinery.

When the flow of a liquid in a pipe is stopped abruptly due to a rapid valve closure, for example, the kinetic energy is transformed into elastic energy and a train of positive and negative pressure waves travels up and down the pipe until the energy is dissipated by friction. (Fig. 37.29). When the liquid is water this is known as **water hammer** because the transient noise in small pipes sounds as if it is being hit by a hammer. The elasticity of the liquid and of the pipe material need to be taken into account. Consider the elastic properties of the water and the pipe: the bulk modulus of the liquid, E,(about 3×10^5 psi or

2 GN/m^2 for water) and the modulus of elasticity of the pipe material E_p (about 30×10^6 psi or 200 GN/m^2 for steel). The velocity or *celerity, c*, of the pressure wave is given by

$$c^2 = (E/\rho)\left[1 + E\,D/\left(E_p t_p\right)\right]^{-1} \qquad (37.31)$$

in which ρ is the fluid density, t_p is the thickness of the pipe wall and D is the pipe diameter.

For an initial flow velocity V, the rise in pressure head due to the sudden valve closure is obtained from the momentum principle as

$$\Delta H = \Delta p/\gamma = V\,c/g \qquad (37.32)$$

This is the pressure head obtained when the time of closure of the valve, t_c, is less than the time for the round trip travel of the pressure wave $2L/c$. For a longer closing time, t, the pressure head can be approximated as $(t/t_c)\,\Delta H$. However, more accurate results can be obtained by numerical integration of the transient flow equations. (Morris and Wiggert (1972), Wylie and Streeter (1993), and Borg (1993).

Figure 37.29 illustrates the pressure wave propagation without friction. Diagram (a) shows the initial steady state hydraulic grade line and velocity V_0 with the valve open. When the valve is suddenly closed the head rise Δh is calculated by Eq. (37.32) and the pressure wave travels upstream with the celerity c calculated from Eq. (37.31). Diagram (b) illustrates the condition for $0 < t < L/c$. Behind the wave the velocity is zero, the pressure is increased, and the pipes expands. The mass of water entering the pipe is equal to the increased volume of the pipe plus the added mass stored due to the increased water density. When $t = L/c$ the pressure wave arrives at the reservoir as shown in diagram (c). The pressure in the pipe is $H_0 + \Delta H$, the velocity is zero and the increased pressure exists all along the pipe. This is a non-equilibrium situation, the compressed fluid then flows from the pipe into the reservoir at a velocity $-V_o$ and the reflected pressure wave recedes. The cycle continues as shown in diagrams (e) to (i). For an in-depth treatment of water hammer see, for example, Martin (1999), Wylie and Streeter (1993), Borg (1993), Rich (1963), Parmakian (1963), Chaudhry (1987), and Jaeger (1977). There are computer programs for the analysis of water hammer (see section on software).

Surge Protection and Surge Tanks

There are two types of transient events that need to be controlled: the downsurge or low pressure event that occurs with pump power failure and the upsurge or high pressure event caused by the closure of a downstream valve. Surge control protection devices include several types of valves such as check valves and surge relief valves (Martin, 1999). Another device is the surge tank or standpipe. A surge tank is a vertical tank connected to the pipeline that typically extends above the maximum grade line. The surge tank diameter is substantially larger than that of the pipe to avoid spilling. The standpipe has a smaller diameter, possibly less than the pipe, and is used if spillage can be allowed. Normally the standpipe is designed high enough so as to avoid spillage during normal shutdown.

Surge tanks are standpipes that are installed in large piping systems to relieve the water hammer pressure when a valve is suddenly closed and to provide a reserve of liquid when a valve is suddenly opened. In hydropower installations they are located close to the turbine gates. In pumping installations they are located on the discharge side of the pumps to protect against low pressures during stoppage of the pumps. A simple surge tank is connected directly to the penstock (Fig. 37.30). An orifice surge tank has an orifice in the connection between the tank and the pipe, often with a larger coefficient of discharge for flow out of the tank. A differential surge tank consists of two concentric surge tanks, the inner one is usually a simple surge tank that provides a rapid response but has a small volume. The outer and larger tank is usually an orifice tank.

Consider a horizontal pipe of cross-sectional area A and length L between a reservoir and a surge tank of cross section S, in which the instantaneous water level is at an elevation y above that of the reservoir

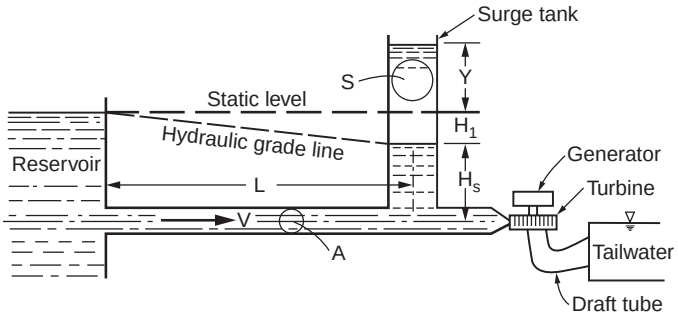

FIGURE 37.30 Simple surge tank.

(Fig. 37.30). V_o is the steady state flow velocity in the pipe. At the time of closure the surge water elevation obtained neglecting friction, is

$$y_{\max} = V_o\left[\left(A/S\right)\left(L/g\right)\right]^{1/2} \tag{37.33}$$

If the pipe is fairly long the friction should be included. This results in a differential equation that requires numerical solution (Morris and Wiggert, 1972). The minimum cross-sectional area required for stability of the surge tank derived by Thoma and cited by Rich (1963) and by Coleman et al. (1999) is

$$S = \left(AL\right)/\left(2gkH_s\right) \tag{37.34}$$

where $k = H_l/V^2$ is the ratio of the head loss between the reservoir and the surge tank to the square of the flow velocity in the conduit

H_s = the steady state head in the surge tank

This area is multiplied by a minimum safety factor of 1.5 for simple surge tanks and 1.25 for orifice surge tanks, to obtain reasonably fast damping of the water oscillations according to Coleman et al. (1999), Borg (1993) and Rich (1963). For a more detailed treatment of surge tanks and other surge suppressing devices see Coleman et al. (1999), Wylie and Streeter (1993), Borg (1993), Rich (1963), Chaudhry (1987), and Jaeger (1977).

Valves

Valves are used to regulate the flow and pressure in pipes and to perform many other functions. These include prevention of reverse flow through pumps, protection of pipes and pumps from overpressurization, prevention of transients etc. Head loss coefficients for several types of valves are shown in Table 29.9 (Chapter 29, "Fundamental of Hydraulics"). Some valves are used to prevent flow in certain sections of pipe. They are normally fully open or fully closed. The gate valves are of this type. Other valves are used to control the flow. Examples of control valves are the butterfly valve, the cone, ball and plug valves, the globe valves. Howell-Bunger valves and hollow jet valves are free discharge valves used to release water from reservoirs, for aerating water, for flood control or irrigation. Check valves are used to prevent reversal of the flow. Figures 37.31 and 37.32 show simplified sketches of several types of control and check valves.

Cavitation

Cavitation is a process similar to boiling. It consists of rapid vaporization and condensation. For boiling, vapor cavities are formed due to temperature increase. The vapor cavities rise to the surface and explode releasing vapor to the atmosphere. For cavitation, the vapor cavities are formed when the fluid pressure drops below the vapor pressure. The cavity will collapse if there is a local pressure in the cavitation region

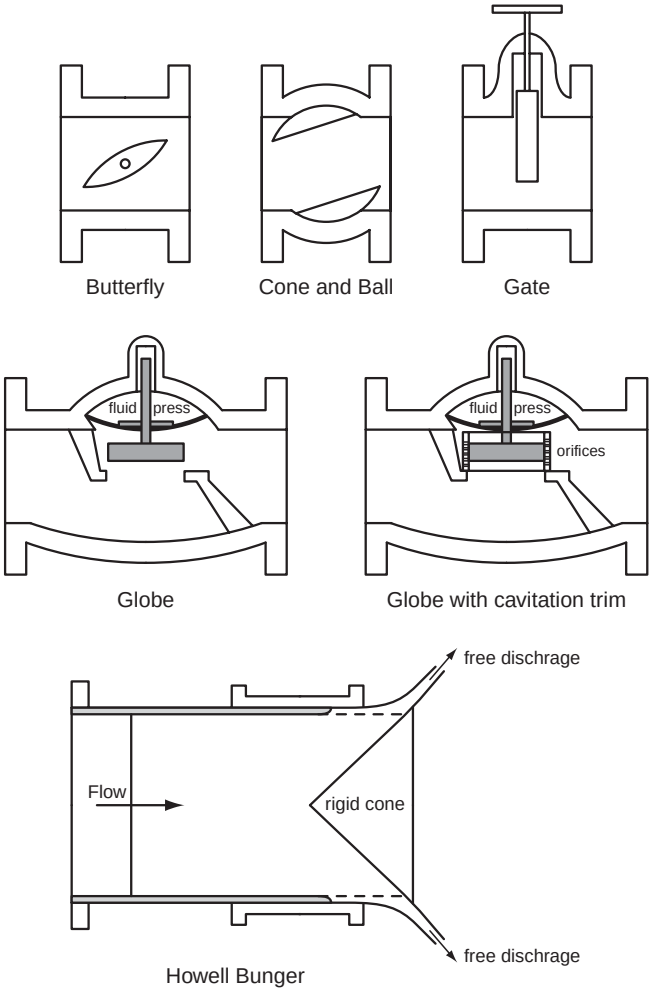

FIGURE 37.31 Schematic of typical control valves. (*Source:* Tullis, J.P., 1989, *Hydraulics of Pipelines, Pumps, Valves, Cavitation, Transients.* John Wiley & Sons, New York, NY. Fig 4.1 p.83.)

that is greater than the vapor pressure. In a venturi, for example, the pressure is minimum at the throat where the cavity may form and collapse occurs as the cavity moves from the throat into the diffuser where the pressure increases with distance. The shock waves produced by the collapsing cavities produce pressure fluctuations that can induce vibration of the system. Cavitation creates noise. The noise created by cavitating valves can be quite intense, varying from a hissing or crackling sound to loud roars with intermittent explosions. The collapse of cavities close to solid boundaries can causes considerable damage to almost any surface. It also causes corrosion of metal surfaces. Cavitation can also occur in hydraulic machinery reducing its efficiency and damaging the impellers. The onset of cavitation can be expressed by a cavitation number. For valves the cavitation number σ is generally defined as

$$\sigma = \left(p_d + p_b - p_{va}\right) / \Delta p \tag{37.35}$$

where p_d = the pressure downstream (10 diameters)
p_b = the barometric pressure
p_{va} = the absolute vapor pressure
Δp = the net pressure drop

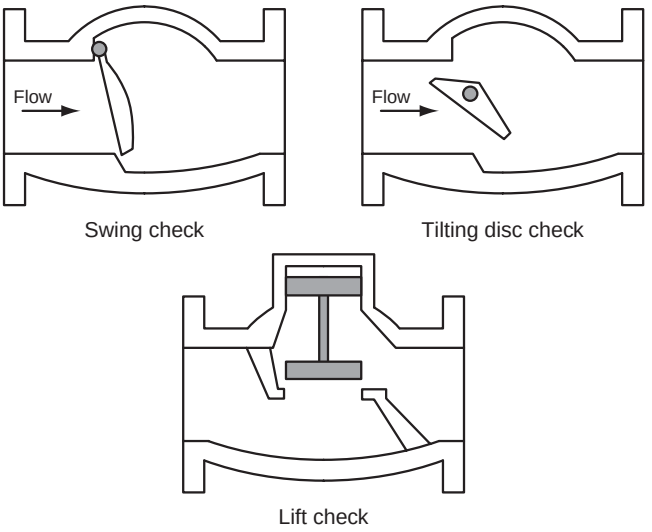

FIGURE 37.32 Schematic of typical check valves. (*Source:* Tullis J.P., 1989, *Hydraulics of Pipelines, Pumps, Valves, Cavitation, Transients.* John Wiley & Sons, Nrew York, NY. Fig 4.10, p.112.)

The cavitation parameter for pumps is discussed in the section on pumps. The vapor pressure head of water as a function of temperature is given in Chapter 29, "Fundamentals of Hydraulics," Tables 29.1 and 29.2. Tullis (1989) gives experimental values of the cavitation parameter for several types of valves and for several intensities of cavitation.

Forces on Pipes and Temperature Stresses

The fluid pressure in a pipe creates a circumferential tension stress called hoop stress given by

$$s = (pD)/(2t) \tag{37.36}$$

where p = the pressure (static plus water hammer)
D = the inside diameter
t = the thickness of the pipe wall

Unsupported pipe segments act as beams. The loads include the weight of the pipe, the weight of the fluid and any superimposed load. Forces on pipe bends and anchor blocks are obtained by the momentum equation as illustrated in Chapter 29 (Application 29.8).

Buried pipes must support the loads due to gravity earth forces and live loads. Load and supporting strength depend on installation conditions. Design details and specifications can be found in ACI, ASTM, AASHTO or FHWA specifications and industry manuals. ASCE (1992) Manual of Practice 77 (Chapter 14 on structural requirements) gives a good state-of-the-art review.

For concentrated and distributed loads superimposed on buried pipes the reader is referred to the AASHTO Code, the Portland Cement Association 1951) and the American Concrete Pipe Association (1988) for wheel loads, as well as to ASCE (1992) for a discussion of the Boussinesq theory for concentrated loads.

A temperature change ΔT on a pipe of modulus of elasticity E and coefficient of thermal expansion α will induce a longitudinal stress, assuming fixed ends, given by

$$\sigma = \alpha E \Delta T \tag{37.37}$$

For steel approximate values of the physical constants are $E = 30 \times 10^6$ psi and $\alpha = 6.5 \times 10^{-6}$ °F.$^{-1}$

Software

EPANET, developed by the U.S. Environmental Protection Agency (2000), is a public domain software. It performs extended period simulation of hydraulics and water quality behavior in a pressurized pipe network. In the hydraulic analysis it places no limit on the size of the network, computes friction headloss using the Hazen-Williams, Darcy-Weisbach or Chézy-Manning formulas, includes minor losses, constant or variable speed pumps, variable geometry surge tanks, etc. It uses a gradient algorithm for the solution of the hydraulic equations. In addition to the hydraulic modeling, EPANET models the movement of non-reactive tracer material through the network over time, models the movement and fate of a reactive material as it grows or decays (e.g., chlorine residual) with time, models the age of water throughout a network, tracks the percent of flow from a given node reaching all other nodes over time, etc. EPANET 2 can be downloaded from http://www.epa.gov/ORD/NRMRL/wswrd/epanet.html.

KYPIPE, is a computer program for the solution of pipe networks developed at the University of Kentucky (Wood, 1980). It uses a Newton method for the solution of the hydraulic equations.

FORTRAN computer programs for water hammer analysis can be found in Wylie and Streeter (1993) and in Chaudhry (1987). A FORTRAN program for water level oscillations in a simple surge tank is given in Chaudhry (1987). Tabular presentations of the numerical integration of the unsteady flow equations that can be adapted to spread sheet software such as EXCEL, LOTUS, QUATTRO PRO, etc. can be found in Morris and Wiggert (1972, p. 335) for water hammer and in Rich (1963) for water hammer, surge tanks and stability analysis.

37.12 Pumps

Centrifugal Pumps

Centrifugal pumps are those most commonly used in civil engineering applications. The rotating part of the centrifugal pump is the impeller. It consists of blades or vanes attached to the hub. If the blades are enclosed by plates or shrouds on the top and bottom sides, the impeller is closed. Impellers without shrouds (i.e., open impellers) are less prone to become clogged when the liquids contain suspended matter. Closed impellers, however are more efficient. In radial flow impellers the fluid is forced outward in the radial direction, which is perpendicular to the axis (see Fig. 37.33), while in axial flow impellers the fluid exits along the axis. In the mixed flow pumps the impeller imparts velocities that have both radial and axial components. The flow exits from the impeller into a casing called the volute. Centrifugal pumps can be single stage or multistage. Deep well pumps often are multistage, which is equivalent to several stages or impellers in series so that the total head generated by the pump is the sum of the heads imparted to the fluid at each stage.

The impeller exerts a torque on the fluid. This torque can be calculated as the change in angular momentum. This is obtained by multiplying the terms of the momentum equation (Eq. [29.15])) by the lever arm r, to yield

$$T = \rho Q\left(V_{t2} r_2 - V_{t1} r_1\right) \tag{37.38}$$

where V_{t1} and V_{t2} = the tangential components of the flow velocities at the entrance and at the exit of the impeller, respectively
r_1 and r_2 = the radii at the entrance and exit of the vane

If e is the pump efficiency, then the power to be supplied to the pump shaft by the motor is ($1HP$ = 550 ft.lb/s in English units and $1kW$ = 1000 N.m/s in SI units)

$$HP = \left(T\omega\right)/\left(550e\right) = \left(\gamma Q H_p\right)/\left(550e\right);\quad kW = T\omega/1000e = \gamma Q H_p/1000e \tag{37.39}$$

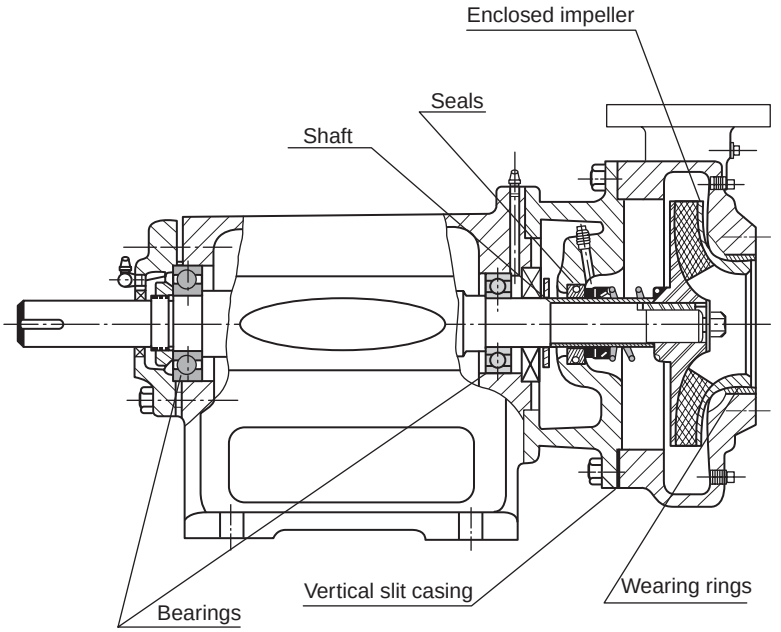

FIGURE 37.33 Radial pump cross section (Adapted from Peerless Pump Co.)

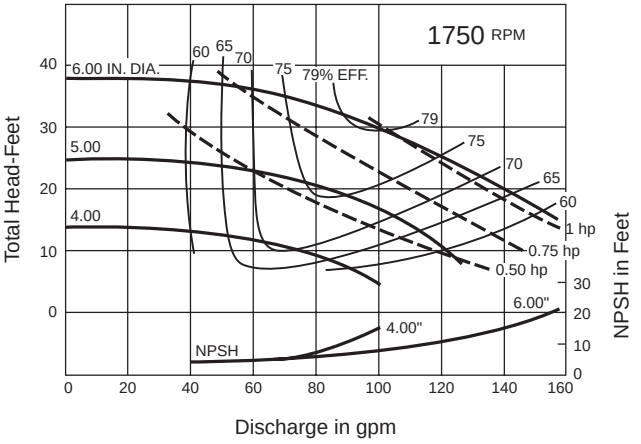

FIGURE 37.34 Characteristic Curves of a Centrifugal Pump. (Adapted from Peerless Pump Co.)

where H_p is the head imparted by the pump to the fluid. H_p can be obtained from the energy equation written between the suction side (subscript s) and the discharge side (subscript d) of the pump:

$$z_s + p_s/\gamma + V_s^2/2g + H_p = z_d + p_d/\gamma + V_d^2/2g \tag{37.40}$$

Pump Characteristics

Figure 37.34 is an example of pump characteristic curves. Pump manufacturers supply characteristic curves for their several designs and operating speeds. The head at zero discharge is called the shutoff

head. The head and capacity corresponding to the maximum efficiency are the nominal head and discharge of the pump. Also shown is the Net Positive Suction Head (NPSH) curve. The NPSH is the difference between the total head on the suction side of the pump above the atmospheric head, p_a/γ, and the vapor pressure head, p_v/γ:

$$NPSH = p_a/\gamma + p_s/\gamma + V_s^2/(2g) - (p_v)/\gamma \tag{37.41}$$

If the liquid surface elevation in the supply reservoir is below the axis of the impeller by a distance z_s, there is a suction lift equal to $z_s + h_{fs}$ (where h_{fs} is the friction head loss in the suction pipe) and the pressure head on the suction side of the pump will be negative, i.e., below atmospheric:

$$p_s/\gamma = -z_s - h_{fs} - V_s^2/(2g) \tag{37.42}$$

To avoid cavitation, the suction pressure head, p_s/γ, must be such that the available NPSH calculated by the above equation be larger than the required NPSH determined from the manufacturer curves or specifications. Equivalently, the calculated value of the cavitation parameter defined as $\sigma = NPSH/H_p$ must be below the critical value supplied by the manufacturer. H_p is the head developed by the pump:

$$H_p = (z_d - z_s) + (p_d - p_s)/\gamma + (V_d^2 - V_s^2)/2g \tag{37.43}$$

where the subscripts d and s refer respectively to the discharge and suction sides of the pump.

The basic similarity parameter for pumps is the specific speed defined as

$$N_s = N Q^{1/2}/H_p^{3/4} \tag{37.44}$$

where N_s = the specific speed
N = the rotational speed in rpm
Q = the discharge in gp
H_p = the head in feet

The specific speed can be interpreted as the rpm of a homologous pump operating at a discharge of 1 gpm under a head of 1 ft. For multistage pumps, H_p is the head per stage. The specific speed can be derived from the similarity parameter $W_p/(\rho D^5 n^3)$ obtained in Chapter 29 by noting that the power W_p is proportional to $\gamma Q H_p$ and that the discharge Q is proportional to $D^2 H_p^{1/2}$ or equivalently that the diameter D is proportional to $Q^{1/2}/H_p^{1/4}$. Figure 37.35 shows the optimum efficiency of water pumps as a function of the specific speed.

Pump Systems

Pumps generally operate as a part of a system including one or more pipes and perhaps other pumps in series or in parallel. When pumps operate in series the discharge is the same through each pump but the head imparted to the fluid is the sum of the heads imparted by each pump. When the pumps operate in parallel the head is the same but the system discharge is the sum of the discharges of the individual pumps. The operating head and discharge of a pump-pipe system is at the intersection of the pump and pipe discharge-head curves as shown in Fig. 37.36, where Δz is the static lift and Σh_f is the sum of the head losses in the suction and discharge pipes. For further details on pumps and hydraulic machinery see, for example, Krivchenko (1994).

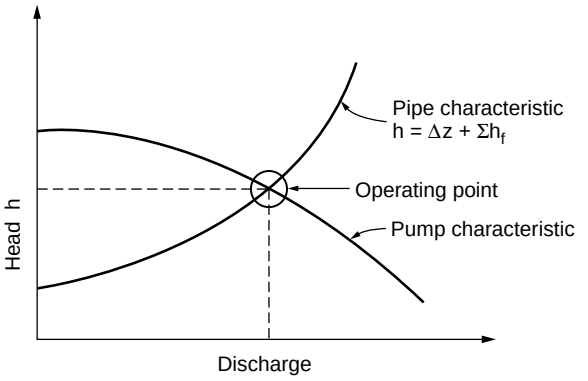

FIGURE 37.36 Pump and pipe system.

Defining Terms

Cavitation — The formation of water vapor cavities due to reduction of local pressure in the water. The cavitation bubbles collapse as they are swept into regions of higher pressure. Continuous implosion of cavitation bubbles severely damages concrete and metal surfaces.

Cofferdam — A temporary dam used to maintain dewatered a portion of a construction site.

Dead storage — That part of the reservoir storage below the elevation of the lowest outlet.

Diversion of flow — Rerouting of flow so that portion of a dam site can be dewatered during construction.

Extrados — Upstream side of an arch dam.

Freeboard — Vertical distance between the maximum probable flood water level or the maximum reservoir setup and wave action level and the crest of the dam.

Intrados — Downstream side of an arch dam.

Kaplan turbine — An axial flow turbine with adjustable runner blades.

Morning glory spillway — A spillway consisting of a circular overflow section leading into a vertical shaft connected to a horizontal tunnel. The vertical cross section resembles that of a morning glory flower.

Nappe — The upper and lower nappes are the upper and lower water surface profiles that water takes as it flows over an ventilated sharp crested weir.

Penstock — A large pipe to carry water to the turbines of a hydroelectric power plant.

Roller compacted concrete (RCC) — A mixture of portland cement, water, aggregate and pozolan with zero slump used in RCC dams.

Run-up — Height to which a wave will rise when it hits a sloping surface.

Setup — Rise in water surface on leeward side of reservoir due to tilting caused by wind.

Stilling basin — A structure, usually located at the foot of a spillway, to dissipate energy over a short distance and reduce flow velocity by means of a hydraulic jump.

Surcharge storage — That part of the reservoir storage above the maximum operating level, usually taken as the elevation of the spillway crest.

Surge tank — Tank designed to contain pressure upsurges due to rapid reduction of flow velocity in a pipeline due to, for example, a quick valve closure.

Tainter gate — A radial gate used to control flow over a spillway.

Uplift pressure — Upward vertical hydrostatic pressure at the interface between the bottom of a dam and foundation or at other interface.

Water hammer — A pressure transient in a pipe system due to a rapid reduction of flow velocity caused, for example, by an adjustment of the setting of a control valve or a change in the operation of a turbine or a pump.

Further Information

Davis' Handbook of Applied Hydraulics (Zipparro and Hasen, 1993) provides a detailed treatment of reservoirs, natural channels, canals and conduits, dams, spillways, fish facilities, hydroelectric power, navigation locks, irrigation, drainage, water distribution and wastewater conveyance.

Mays' "*Hydraulic Design Handbook*" (1999) contributes design information on many topics including pipe and open channel flows, sedimentation and erosion hydraulics, spillways and energy dissipators, pump and water distribution systems, urban and highway drainage, risk/reliability of hydraulic structures as well as environmental hydraulics and treatment plant hydraulics.

Sentürk's text "*Hydraulics of Dams and Reservoirs*" (1994) presents an extensive treatise on the hydraulic design of reservoirs, dams, spillways and associated structures. Each chapter presents solved examples and proposed problems.

The textbook entitled "*Hydraulic Structures*" by Novak et al. (1996) gives an excellent coverage of dam engineering and other hydraulic structures such as diversion works, drainage and drop structures, hydroelectric power development and pumping stations as well as some discussion of coastal and offshore engineering. Several worked examples are included.

Sturm's textbook entitled "*Open Channel Hydraulics*"(2001) contains a chapter on Hydraulic structures dealing with spillways, culverts and bridges.

The U.S. Army Corps of Engineers "Hydraulics Design Criteria" (1955–70) includes practical formulas, nomographs, design standards on most hydraulic structures.

USCOLD (1991) lists key references for hydraulic design on the following subjects: cavitation in hydraulic structures, increasing discharge capacity of existing projects, spillway design floods, fish passage, gas transfer at hydraulic structures, trashrack vibrations, energy dissipation and terminal structures for spillways and outlet works and thermal stratification and instream thermal simulation.

ICOLD (1980, 1992) has published several bulletins (35, 37, 50, 65, 66 and 86) on the environmental effects of dams and reservoirs. Bulletin 35 is technical while the other reports include case histories in several countries.

The International Association of Hydraulic Research (IAHR, 1987–1995) has published a series entitled *Hydraulic Structures Design Manual* which includes 9 volumes on the following specialized topics:

1. J. Knauss (ed), 1987. Swirling flow problems at intakes.
2. H.N.C. Breuaers and A.J. Raudkivi, 1991. Scouring.
3. E. Naudascher,1991. Hydrodynamic forces.
4. I.R. Wood (ed), 1991. Air entrainment in free surface flows.
5. M. Hino (ed) Water quality and its control.
6. A.J. Raudkivi, 1993. Sedimentation: Exclusion and removal of sediment from diverted water.
7. E. Naudascher and D. Rockwell, 1993 Flow induced vibrations: An engineering guide.
8. D.S. Miller (ed) 1994. Discharge characteristics.
9. Visher & W.H. (eds) 1995. Energy dissipators.

Each important hydraulic structure built by the Bureau of Reclamation of the U.S. Department of the Interior or by the U.S. Army Corps of Engineers is the object of detailed reports. As an example see the "Technical Record of Design and Construction, Glen Canyon Dam and Power Plant" by the U.S. Department of the Interior, Bureau of Reclamation (1970).

38.1 Introduction

During the past three decades, computer models have become ubiquitous in hydraulics and hydrology. These models have been of invaluable help in hydrologic and hydraulic analysis and design. In this chapter several models are briefly introduced and four models (TR-20, HEC-HMS, HEC-RAS and XP-SWMM) are illustrated in depth.

Many of these models are quite complex. Books such as that by Hoggan [1989] have been written to explain and illustrate them. It is not possible to discuss these models in the depth required to illustrate their full capabilities. Consequently the approach taken in this section is to give synoptic descriptions of more important uses of the models. The detailed illustrations of TR-20, HEC-HMS, HEC-RAS, and XP-SWMM are given to demonstrate their characteristics and utility.

SWMM is a comprehensive simulation model of urban runoff quantity and quality including surface and subsurface runoff, snow melt, routing through the drainage network, storage, and treatment. Single event and continuous simulation can be performed. Basins may have storm sewers, combined sewers, and natural drainage. The model can be used for planning and design purposes. In the planning mode, continuous simulation is used on a coarse schematization of the catchment, and statistical analyses of the hydrographs and pollutographs are produced. In the design mode simulation is performed at shorter time steps using a more detailed schematization of the catchment and specific rainfall events.

The model consists of an executive block, four computational blocks (Runoff, Transport, EXTRAN, and Storage/Treatment), and five service blocks (Statistics, Graph, Combine, Rain, and Temp). The EXECUTIVE block performs a number of control tasks such as an assignment of logical units and files, sequencing of computational blocks and error messages. The RUNOFF block generates runoff given the hydrologic characteristics of the catchment, the rainfall, and/or the snowmelt hyetographs and the antecedent conditions of the basin. The runoff quality simulation is based on conceptual buildup and washoff relationships (see Chapter 33). The TRANSPORT block routes the flows and pollutants through the drainage system. It also generates dry-weather flow and infiltration into the sewer system. As kinematic wave routing is used (see Chapter 30, Section 30.9), backwater effects are not modeled. The EXTENDED TRANSPORT block (EXTRAN) simulates gradually varied unsteady flow using an explicit finite difference form of the Saint Venant Equations (see Chapter 30, Eqs. [30.50] and [30.51]). EXTRAN can handle backwater effects, conduit pressurization, and closed and looped networks. EXTRAN is limited to quantity simulation and consequently does not perform quality simulation. The STORAGE/TREATMENT block routes flows and up to three different pollutants through storage and a treatment plant with up to five units or processes. The STATISTICS block calculates certain statistics such as moments of event data and produces tables of magnitude, return period, and frequency. The COMBINE block combines the output of SWMM runs from the same or different blocks to model larger areas. The RAIN block reads National

Weather Service rainfall data and therefore can be used to read long precipitation records and can perform storm event analysis. The TEMP block reads temperature, evaporation, and wind speed data that can be obtained from the National Weather Service data base.

Name: Flood Damage Analysis System (HEC-FDA)

www.hec.usace.army.mil

The User's Manual can be downloaded from the Website.

The HEC-FDA program provides the capability to perform plan formulation and evaluation for flood damage reduction studies. It includes risk-based analysis methods that follow Federal and Corps of Engineers policy regulations (ER 1105–2–100 and ER 1105–2–101). Plans are compared to the condition without flood protection by computing expected annual damage for each plan. Computations and display of results are consistent with technical procedures described in EM 1110–2–1619. HEC-FDA will only run on computers using Windows 95/98 or Windows NT.

MODFLOW is a finite-difference groundwater model that simulates flow in three dimensions. The modular structure of the program consists of a main program and a series of highly independent subroutines called *modules*. The modules are grouped into *packages*. Each package deals with a specific feature of the hydrologic system which is to be simulated, such as flow from rivers or flow into drains, or with a specific method of solving linear equations that describe the flow system, such as strongly implicit procedure or slice-successive overrelaxation.

Groundwater flow within the aquifer is simulated using a block-centered finite-difference approach. Layers can be simulated as confined, unconfined, or a combination of the two. Flow associated with external entities, such as wells, areal recharge, evapotranspiration, drains and streams, can also be simulated. The finite-difference equations can be solved using either the strongly implicit procedure or slice-successive overrelaxation.

Application of the computer program to solve groundwater flow problems requires knowledge of the following hydrogeologic conditions: (1) hydraulic properties of the aquifer, (2) the shape and physical boundaries of the aquifer system, (3) flow conditions at the boundaries, and (4) initial conditions of groundwater flow and water levels.

The accuracy of the calibrated mathematical model is dependent on the assumptions and approximations in the finite-difference numerical solutions and the distribution and quality of data. Hydraulic properties of the aquifer deposits (estimated by model calibration) can be used to define the flow system and evaluate impacts that would be produced by changes in stress, such as pumping. However, three main limitations that constrain the validity of the model are:

1. The inability of the numerical model to simulate all the complexities of the natural flow system. The assumptions used for construction of the model affect the output and are simple compared to the natural conditions.
2. The distribution of field data; for example, water level or lithologic data may not be areally or vertically extensive enough to define the system adequately.
3. The model is probably not unique. Many combinations of aquifer properties and recharge-discharge distributions can produce the same results, especially because the model is usually calibrated for a predevelopment (steady state) condition. For example, a proportionate change in total sources and sinks of water with respect to transmissivity would result in the same steady state model solution.

HEC-6 is a member in the series of numerical models developed by the U.S. Army Corps of Engineers Hydrologic Engineering Center for studies of hydraulic or hydrologic problems. It is a one-dimensional model of a river or reservoir where entrainment, deposition, or transport of sediment occur. It is intended for use in the analysis of long-term river or reservoir response to changes in flow or sediment conditions. In HEC-6, models change as a sequence of steady states; the hydraulic and sediment parameters of each may vary during the sequence. It can be applied to analyze problems arising in or from stream networks, channel dredging, levee design, and reservoir deposition.

The hydraulic model is essentially identical to that used in HEC-RAS (see the description of HEC-RAS for more details), in which water-surface profiles are computed by using the standard step method and with flow resistance modeled with Manning's equation. Although flow resistance due to bed forms is not separately considered, Manning's n can be specified as a function of discharge. In a "fixed bed" mode, the sediment transport model can be turned off, and HEC-6 can be used as a limited form of HEC-RAS without capabilities for special problems such as bridges or islands. The input format of HEC-6 is very similar to the format of HEC-2, which is the program for computing water-surface profiles which preceded HEC-RAS.

The sediment transport model is based on the Exner equation (see Chapter 35, Eq. [35.29]). It treats graded sediments, ranging from clays and silts to boulders up to 2048 mm in diameter, by dividing both inflow and bed sediments up to 20 size classes. Several standard transport formulas for sand and gravel sizes are available and provision for a user-developed formula is included. Additional features include the modeling of armoring, clay and silt transport, and cohesive sediment scour. Because it is a one-dimensional model, it does not model bank erosion, meanders, or non-uniform transport at a given cross section.

38.3 TR-20 Program

The TR-20 computer program was developed by the Natural Resources Conservation Service (1982) to assist in the hydrologic evaluation of storm events for water resource projects. TR-20 is a single-event model that computes direct runoff resulting from synthetic or natural rainfall events. There is no provision for recovery of initial abstraction or infiltration during periods without rainfall. The program develops runoff hydrographs from excess precipitation and routes the flow through stream channels and reservoirs. It combines the routed hydrograph with those from tributaries and computes the peak discharges, their times of occurrence, and the water elevations at any desired reach or structure. Up to nine different rainstorm distributions over a watershed under various combinations of land treatment, flood control structures, diversions, and channel modifications may be used in the analyses. Such analyses can be performed on as many as 200 reaches and 99 structures in any one continuous run (NRCS, 1982). The program can be obtained from National Technical Information Service, U.S. Department of Commerce, 5285 Port Royal Road, Springfield, VA 22161, (703) 487-4600.

Summary of TR-20 Input Structure

The input requirements of TR-20 are few. If data from actual rainfall events are not used, the depth of precipitation is the only required meteorological input. For each subarea, the drainage area, runoff curve number and time of concentration are required; the antecedent soil moisture (AMC) condition (i.e., I, II, or III) can be specified, although the NRCS now recommends only AMC II, the so-called average runoff condition (NRCS, 1986). For each channel reach, the length is defined; the channel cross section is defined

by the discharge and end area data at different elevations; a routing coefficient, which is defined by the discharge and end area data at different elevations; a routing coefficient, which is optional, may also be specified. If the channel-routing coefficient is not given as input, it will be computed by using a modified Att-Kin (attenuation-kinematic) procedure.

The modified Att-Kin routing procedure is described in TR-66 (NRCS, 1982). It uses storage and kinematic models to attenuate and translate natural flood waves. For each channel reach, the Att-Kin procedure routes an inflow hydrograph through the reach using a storage model. With the storage and kinematic models, flows are routed as a linear combination so that the outflow hydrograph satisfies the conservation of mass at the time to peak of the outflow hydrograph. Used separately, the storage routing provides only attenuation without translation; the kinematic routing provides only translation and distortion without attenuation of the peak (NRCS, 1982).

For each structure it is necessary to describe the outflow characteristics with an elevation-discharge-storage relationship. The time increment for all computations and any baseflow in a channel reach must be specified.

Input Structure

The input for a TR-20 consists of the following four general statement types: Job Control, Tabular Data, Standard Control statements, and Executive Control statements.

Job Control

The Job Control statements are the JOB statement, two TITLE statements, ENDATA statement, ENDCMP statement, and ENDJOB statement. The JOB and two TITLE statements *must* appear first and second, respectively, in a run and the ENDJOB statement must appear last. The ENDATA statement separates the standard control and the tabular data from the executive control statements. The ENDCMP statement is used to signify the end of a pass through a watershed or a sub-watershed thereby allowing conditions to be changed by the user before further processing.

Input data are entered according to the specifications in a blank form. Each line of data on the form is a record entered into the computer file. The 80 columns across the top of the form represent the 80 positions on a record. Each statement is used to perform a specific operation. The order of records determines the sequence in which the operations are performed.

A name appears in columns 4 through 9 of all lines except those containing tabular data. These names identify the type of operation performed or type of data entered. A number corresponding to the name in columns 4 through 9 is placed in columns 2 and 11. The digit in column 11 is the operation number and identifies the type of operation, which must be entered unless it is a blank.

Tabular Data

The tabular data serve as support data for the problem description. These data precede both the Standard and Executive Control and have six possible tables:

1. *Routing coefficient table*: the relationship between the streamflow routing coefficient and velocity.
2. *Dimensionless hydrograph table*: the dimensionless curvilinear unit hydrograph ordinates as a function of dimensionless time.
3. Cumulative rainfall tables.
4. *Stream cross-section data tables*: a tabular data summary of the water surface elevation-discharge-cross sectional end area relationship.
5. *Structure data table*: a tabular summary of the water surface elevation-discharge-reservoir storage relationship.
6. *Read-discharge hydrograph data table;* a hydrograph that is entered directly into the program as data.

For example, the data needed to support a cumulative rainfall table include a rainfall table number, time increment, runoff coefficient (if desired), and the cumulative rainfall values for the modeled rainfall event. The cumulative rainfall values used in the following examples are the SCS Type II distribution.

TABLE 38.1 Output Options for TR-20

Output Option	A "1" in Column	Produces the following printout
PEAK	61	Peak discharge and corresponding time of peak and elevation (maximum storage elevation for a structure)
HYD	63	Discharge hydrograph ordinates.
ELEV	65	Stage hydrograph ordinates (reach elevations for a cross section and water surface elevation for structures).
VOL	67	Volume of water under the hydrograph in inches depth, acre-feet, and ft^3/sec-hours.
SUM	71	Requests the results of the subroutine be inserted in the summary tables at the end of the job.

Standard Control Operations

Standard Control consists of the following six subroutine operations. There can be up to 600 Standard Control statements for each TR-20 program.

1. RUNOFF: an instruction to develop a subbasin runoff hydrograph
2. RESVOR: an instruction to route a hydrograph through a structure or reservoir
3. REACH: an instruction to route a hydrograph through a channel reach
4. ADDHYD: an instruction to combine two hydrographs
5. SAVMOV: an instruction to move a hydrograph from one computer memory storage location to another
6. DIVERT: an instruction for a hydrograph to be separated into two parts.

As an example, the data needed to support the standard RUNOFF control operation are the area, curve number, and time of concentration. The operations are indicated on the input lines in columns 2, 4–9, and 11. The number 6 is placed in column 2 to indicate standard control. The name of the subroutine operation is placed in columns 4–9. The operation number, which is placed after the operation name (e.g., 1 for RUNOFF, 6 for DIVERT), is placed in column 11.

Column 61, 63, 65, 67, 69, and 71 of standard control records are used to specify the output. The individual output options are selected by placing a 1 in the appropriate column. If either the column is left blank or a zero is inserted, the corresponding option will not be selected. Table 38.1 summarizes the output options. If only a summary table is desired, it is convenient to place SUMMARY in columns 51–57 in the JOB statement and leave all the output options on the standard control records blank.

Executive Control

The Executive Control has two functions: (1) to execute the Standard Control statements, and (2) to provide additional data necessary for processing. The Executive Control consists of six types of statements. They are LIST, BASFLO, INCREM, COMPUT, ENDCMP, and ENDJOB. The Executive Control statements are placed after the Standard Control statements and tabular data to which they pertain.

The Standard Control is used to describe the physical characteristics of the watershed. The Executive Control is used to prescribe the hydrologic conditions of the watershed including the baseflow. The performance for the Executive Control is directed by the COMPUT statement. Its purpose is to describe the rainfall and the part of the watershed over which that rainfall is to occur (NRCS, 1982).

For the examples discussed in this section, the INCREM, COMPUT, ENDCMP, and ENDJOB will be the only executive control statements required to fulfill the operations requested.

Preparation of Input Data

Preparation of input data can be divided into the following requirements and functions:

1. Prepare a schematic drawing that conveniently identifies the locations, drainage areas, curve numbers (CN), times of concentration (t_c), and reach lengths for the watershed. It should display all alternate structure systems together with the routing and evaluation reaches through which they are to be analyzed.

2. Establish a Standard Control list for the watershed.
3. List the tabular data to support the requirements of the Standard Control list. This may consist of structure data, stream cross section data, cumulative rainfall data, and the dimensionless hydrograph table.
4. Establish the Executive Control statements that describe each storm and alternative situation that is to be analyzed through the Standard Control list.

Calculations

For a large watershed it may be necessary to divide the watershed into subbasins. Each subbasin is determined by finding the different outlet points or design points within the watershed, then finding the area contributing to those points.

1. *Area*. The area of each subbasin in square miles (mi^2).
2. *Curve number*. The curve number (CN) for each subbasin.
3. *Time of concentration*. Following the curve number, the time of concentration (t_c) is specified for each subbasin.

Forms for Input Data

Blank forms for the TR-20 data are found in NRCS (1982). The example problems therein demonstrate how the forms are completed. The process is straightforward because of the instructions given and the preselected columns for the data. The output options are shown in Table 38.1.

Examples

A 188.5-acre basin in modeled to determine the discharge and required storage as a result of development. The first example models a subbasin with existing conditions. The third example incorporates the entire basin to determine the peak discharge at the outlet. The area is located in Indianapolis and is shown in Fig. 38.1.

Example 38.1

Referring to Fig. 38.1, drainage area 1 is modeled to determine the runoff for present conditions. This area is a small part of the total drainage area of the watershed in Fig. 38.1.

Hydrological Input Data

The cumulative rainfall data used is the SCS Type II rainfall distribution. The intensity-duration-frequency tables for Indianapolis, Indiana, are used with the 6-hour rainfall depth for the 10-year event to generate the surface-runoff hydrograph for the subbasins. The SCS 24-hour distribution was scaled to give a 6-hr hyetograph. The point rainfall depth is 3.23 in./hr.

Calculations

Area. The area of subbasin 1 is 13.5 acres or 0.021 $mi.^2$

Curve number. There are two different land uses for this subbasin; therefore both areas must be calculated and a composite curve number determined for the respective area. An open area of 7.6 acres has a CN of 74. The other land use is commercial with 5.9 acres and a CN of 94. The product of curve number and area is 1117. The sum of the product of the curve numbers and areas is then divided by the total area of the drainage area 1 to find an overall composite CN of 83.

Time of concentration. The time of concentration is computed by assuming 300 ft. of sheet flow, 350 ft. of shallow concentrated flow over unpaved surface, and channel flow length of 1150 ft. The channel flow is computed to the lake, not the watershed boundary. The time is 0.24 hr.

Computer Input

The following section demonstrates where, for this example, the information is input to the computer. The following discussion is based on the input file shown in Fig. 38.2.

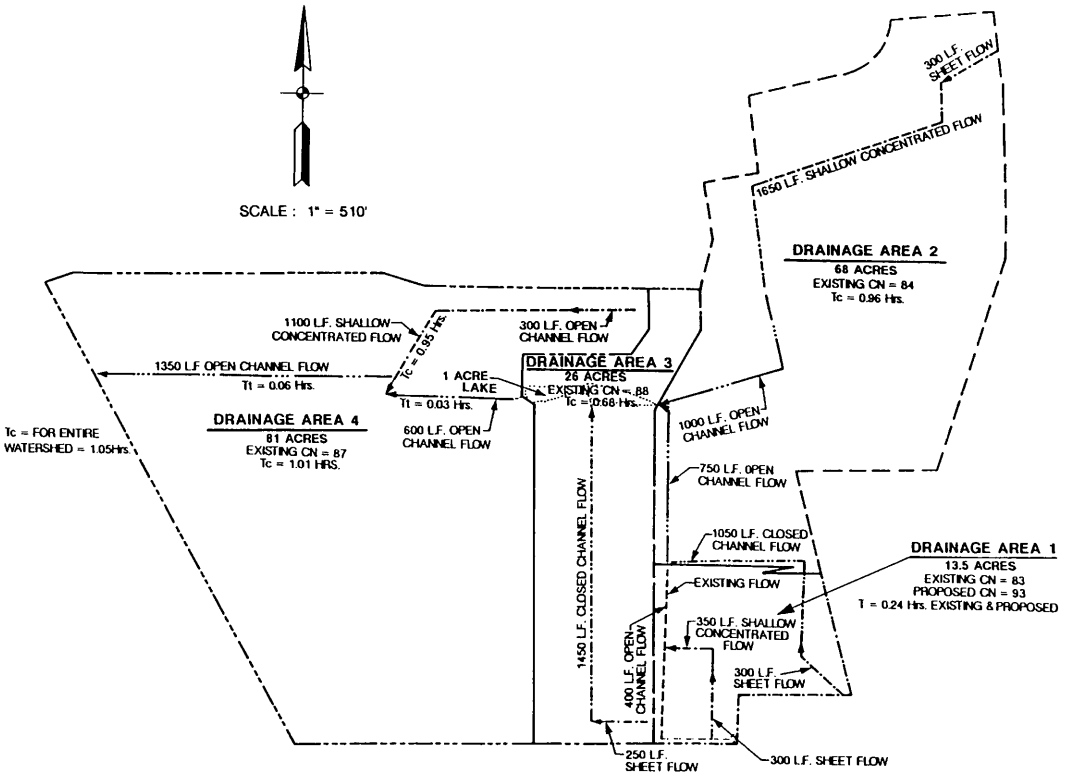

FIGURE 38.1 Location map.

FIGURE 38.2 Input for Example 38.1.

1. The first input is the JOB and TITLE. For this example NOPLOTS is entered in columns 61–67, which indicates that cross section discharge-area plots are not desired. Two TITLE statements are used to describe the problem and the rainfall information.
2. Next the cumulative rainfall table is used to describe the rainfall event. The statement describing this operation is RAINFL. There are six standard rainfall distributions which may be used and these are preloaded into TR-20. The user need not input these tables, but use only the proper rain table identification number on the COMPUT statement, in column 11. The user may override any of these tables by entering a new RAINFL table and entering 7, 8, or 9 in column 11. For this example a 7 is placed in column 11 indicating that a rainfall table will be specified by the user. Rainfall depths in inches can also be used. If these are used, the data code in column 2 needs to be changed to 8. The rainfall table of SCS Type II distribution is placed in the proper columns below the RAINFL statement as shown in Fig. 38.2. The time increment used for this example is 0.05 hr, determined by the number of cumulative rainfall points and the storm duration. The number of rainfall increments is 20, so that each increment is 0.05 of the total. This number, 0.05 is entered into columns 25–36. The 6-hour storm duration is entered on the COMPUT statement.
3. For this example, the runoff from area 1 is computed with the RUNOFF statement with the proper codes, described previously. This is the only standard control statement needed for this example. ENDATA indicates that the input information for the runoff is complete. Comments in columns 73 through 80 are helpful reminders.
4. The Executive Control statement is then used to indicate which computations are desired. This runoff from area 1 is computed for the 10-year rainfall. The INCREM statement causes all the hydrographs generated within the TR-20 program to have a time increment of 0.1 hours, as specified in columns 25–36, unless the main time increment is changed by a subsequent INCREM statement. The 7 in column 61 refers the COMPUT to rainfall table 7, the cumulative rainfall table. The AMC number is given in column 63 for each COMPUT (computation). For this example the AMC is 2. The starting time, rainfall depth, and rainfall duration are given for each recurrence interval. In this example, the starting time is 0.0, the rainfall depth is 3.23 in., and the duration is 6 hr. These values are placed in their corresponding columns. A COMPUT and an ENDCMP statement are necessary for each recurrence interval. ENDJOB is then used to signify that all the information has been given and the calculations are to begin. The Executive Control data are shown on Fig.38.2.

Output

The type and amount of output are controlled by input options on the JOB record and by the output options on the Standard Control records. For this example, by declaring NOPLOTS in columns 61–67 of the JOB record, plots are suppressed. The RUNOFF statement requested to have the peak discharge, volume of water under the hydrograph, and a summary table of the results, because a "1" was placed in columns 61, 67, and 71 in this statement. The output for this example is shown in Fig. 38.3.

Summary/Explanation

The table in Fig. 38.3 summarizes all of the information obtained. From this table it can be seen that, for a rainfall event with a 10-year recurrence interval, the amount of runoff from Area 1 is 1.64 in. for a 6-hour duration. The peak discharge occurs after 3.08 hours and has a flow rate of 30.72 cfs.

Example 38.2

Description

The runoff from area 1 is computed for developed conditions and a pond is added inside area 1. A stage-storage-discharge relationship is required for the structure, and the attenuation effects are evaluated. The hydrologic input data area the same as that which was used in Example 38.1. The input for example 38.2 is shown in Fig. 38.4.

FIGURE 38.4 Input for Example 38.2.

Calculations

Once the proposed pond is designed, the discharge and storage is computed at different elevations by the user. The discharge from the pond is controlled by the outlet structure. Table 38.2 shows the stage-storage-discharge relationship for the pond. For example, at elevation 783.0 feet, the discharge is 15.0 cfs and the storage is 0.88 acre-ft. This is an ungated control structure with headwater control.

The CN for the developed condition is 93 and the time of concentration is 0.24 hours.

1. The TITLE statement is adjusted to show the proper example problem number and description.
2. As mentioned previously, the same rainfall table will be used.
3. After the ENDTBL statement of the rainfall table, the structure table for the pond is added. The initial values for the stage-storage-discharge relationship must have the elevation of the invert of the outlet structure and 0.0 values for the discharge and storage. All data entered in this table must have decimal points and must increase between successive lines of data. The STRUCT table

TABLE 38.2 Stage-Storage-Discharge Relationship for Pond in Example 38.2

Stage	Discharge	Storage
780.5	0	0.0
781.0	2	0.004
781.5	4	0.014
782.0	8	0.019
782.5	12	0.046
783.0	15	0.88
783.5	20	1.33
784.0	23	1.67
784.5	28	2.07
785.0	30	2.46
785.5	32.5	2.85
786.0	35	3.23
786.5	36	3.49
787.0	40	4.52

must have a number placed in columns 16 and 17 of the first row of the STRUCT statement. This number, 01, should be the same as the structure number on the RESVOR standard control statement.

4. The RUNOFF Standard Control statement for area 1 is used to obtain the runoff from the 0.021 square miles. The CN and t_c for the developed conditions replace the numbers used in Example 38.1.
5. A RESVOR Standard Control statement is used to have the hydrograph calculated from area 1 routed through the pond structure. This is done by placing "01" (the pond structure number) in columns 19 and 20. The routed hydrograph is placed in a computer memory location by placing a number 1 through 7, not already used, in column 23. Therefore, a 2 is placed in column 23.
6. The INCREM and COMPUT Executive Control statements are the same as in Example 38.1. With these statements, the peak discharge rate and time will be computed, as well as the peak elevation in the pond. In order for the flow in pond to be analyzed, the last cross section must be specified as the pond structure. This is done by placing the cross section number of the culvert in columns 20 and 21 of the COMPUT statement. Again, ENDJOB is the last statement.

Output

The output format is the same as in Example 38.1 because the output options in columns 61–70 are the same, with the addition of the options chosen for the RESVOR statement. A condensed version of the output is shown on Fig. 38.5 and Table 38.3.

Summary

As in Example 38.1, the summary table on the last page of the output summarizes all of the information obtained. This table contains the developed runoff information for area 1 and for peak flow and elevation through the pond. The pond used to control the runoff from area 1 is checked to see if it is sufficient. The peak discharge elevation is 783.07 feet for the 10-year storm. This indicates that the pond does not overtop for the storm event modeled.

Example 38.3

Description

The entire watershed is analyzed to determine the amount of runoff from the 0.3 square miles. This example incorporates the same area as Example 38.1, but also includes the runoff from the three other subbasins under existing conditions from the entire watershed. The watershed is subdivided into 4 subbasins as shown on Fig. 38.1. Area 1 has been analyzed with and without the pond in the two previous examples. There is a 1-acre lake in the middle of the watershed, which takes in the runoff from

Areas 1, 2, and 3. The discharge from this lake is routed through a channel to the outlet of the watershed. Table 38.4 shows the stage-storage-discharge relationship for the 1-acre lake.

The hydrologic input data is the same as in the previous examples. This refers to the rainfall data for the SCS Type II distribution and the rainfall amount for a 10-year recurrence interval in Indianapolis. Another storm, the 100-year 12-hour event, was used to demonstrate how easy it is to add additional storms.

Calculations

Table 38.5 contains the information from the computation of the CN and t_c values. The longest t_c is for drainage area 4. The total time of concentration for the entire watershed is 1.05 hours.

Computer Input

The input file from Example 38.1 is edited to include the information for the additional subbasins. A reach is added by using the tabular control XSECTN and the corresponding codes. The STRUCT table is changed to reflect the 1-acre lake. The Standard Control statements, RUNOFF and ADDHYD, are needed for the additional subbasins. The area, CN, and t_c are described on each RUNOFF statement. COMPUT and ENDCMP statements are used to add the 100-year storm event values. The ADDHYD statement is used to combine two hydrographs computed from the respective RUNOFF statement. The ADDHYD is used because there are only two input hydrographs entries for each RUNOFF statement. The input is shown in Fig. 38.6.

For example, the hydrographs from areas 1, 2, and 3 are combined and routed through the 1-acre lake before adding runoff from area 4. Therefore, two ADDHYD statements are used to combine the hydrographs computed from the pond in area 1 and the runoff from area 2. Another ADDHYD statement is used to combine the previously obtained hydrographs with the hydrograph computed from area 3. The 1-acre pond in area 3 is then described by a RESVOR statement. This statement refers to STRUCT 02 for the stage-storage-discharge relationship. The runoff from all three subbasins is routed through the

pond by placing a "1," the combined hydrograph number, in column 19 of the RESVOR statement. The discharge from the pond is then routed through a channel to the outlet of the watershed. The routing is described by a REACH statement which refers to XSECT 006. The XSECT is the stage-discharge and area relationship for the 2050-foot channel. The relationship is computed by using the channel cross section shown in Fig. 38.7. The RUNOFF statement is then used to describe the runoff from area 4. Finally, the hydrograph from the REACH and area 4 runoff are added together with the ADDHYD statement.

The Executive Control statements are the same as those used in the previous two example problems, except the last cross section number used must be placed in columns 20 and 21 and the additional COMPUT and ENDCMP. The COMPUT statements require the input of the initial and final cross sections that are to be analyzed. Because the ADDHYD was the last Standard Control statement, its cross section number (columns 14 and 15) is placed in columns 20 and 21 of the COMPUT statement.

Output

The type and amount of output can be controlled by input options on the JOB record and by the output options on the Standard Control records. All of the output options on the Standard Control statements were left blank because only a summary table is desired. To accomplish this, SUMMARY is placed in columns 51–57 of the JOB statement. The output is shown in Fig. 38.8.

Summary

From the summary table of the output shown in Fig. 38.8, it is determined that, for a 10-year storm, the peak discharge is 233 cfs, which occurs after 3.71 hours. For the 100-year 12-hour storm, the peak discharge is 361 cfs with a time to peak at 6.46 hours. Output from each subbasin can be inspected to determine the amount it contributes to the overall runoff from the watershed. The outflow from drainage areas 1, 2, and 3 are routed through the 1-acre pond and then through a channel. The reach had very little effect on the time to peak or the discharge. The channel would have to be much wider and longer for any attenuation to be realized. The results are also summarized below in Table 38.6.

38.4 The HEC-HMS Model

Uses of HEC-HMS

HEC-HMS is a precipitation-runoff simulation model developed by the U.S. Army Corps of Engineers Hydrologic Engineering Center (HEC) that is a "new generation" software to supercede the HEC-1 Flood Hydrograph Package. Similar to HEC-1, HEC-HMS can be used: (1) to estimate unit hydrographs, loss rates, and streamflow routing parameters from measured data and (2) to simulate streamflow from historical or design rainfall data. Several new capabilities are available in HEC-HMS that were not available in HEC-1: (1) continuous hydrograph simulation over long periods of time and (2) distributed runoff computation using a grid cell depiction of the watershed. Capabilities for snow accumulation and melt, flow-frequency curve analysis, reservoir spillway structures, and dam breach are under development for HEC-HMS but not yet incorporated.

HEC-HMS consists of a graphical user interface, integrated hydrologic analysis components, data storage and management capabilities, and graphics and reporting facilities. The program features a completely integrated work environment including a database, data entry utilities, computation engine,

and results reporting tools. A graphical user interface allows the user seamless movement between different parts of the program. The HEC Data Storage System (DSS) [HEC, 1993] allows the transfer of data between HEC programs. The data are identified by unique labels called PATHNAMES, which are specified when the data are created or retrieved. For example, a hydrograph computed by HEC-HMS can be labeled and stored in DSS for later retrieval as input to HEC-RAS. The DSS program has several utility programs for manipulating data. HEC-HMS is an easier tool to develop a hydrologic model for first time users because of its graphical user interface. Those familiar with and who routinely use HEC-1 may be frustrated with the set-up and complexity of running design storm events with user defined cumulative rainfall distributions. The more complex the hydrologic model is, the more liable the program is to crashing. It is anticipated that these problems will be improved upon with each new release of HEC-HMS. The graphics and reporting facilities is a very valuable tool that saves time and makes the presentation of results easy to produce.

Summary of HEC-HMS Input Structure

A project serves as a container for the different parts that together form the complete watershed model in HEC-HMS. The three components required for a hydrologic simulation are: (1) Basin Model, (2) Meteorologic Model, and (3) Control Specifications. A project file may contain more than one of these three components and is useful for running scenario analysis.

Each run of the model combines a basin model, meteorologic model, and control specifications. The user should be cautious, as some of these components may not be compatible with each other, depending on methods and time intervals chosen. Runs can be re-executed at any time to update results when data in a component is changed. The Run Manager is used to manage and execute runs, proportionally adjust flow or precipitation results, and save or start the basin model in differing states.

Basin Models

The physical representation of watershed or basins and rivers is configured in the basin model. Hydrologic elements are connected in a dendritic network to simulate runoff processes. Available elements are: (1) subbasin, (2) reach, (3) junction, (4) reservoir, (5) diversion, (6) source, and (7) sink. Computation proceeds from upstream elements in a downstream direction. Hydrologic elements are added to the model by dragging the appropriate icon from the element palette to the schematic in the Basin Model screen. Elements are connected to each other within the stream network from upstream to downstream elements. Elements may also be duplicated and deleted within the Basin Model Screen.

When developing a precipitation-runoff model using HEC-HMS, boundaries of the basin are initially identified. Most often, the basin is subdivided into smaller subbasins depending on the study objectives, drainage pattern, and other factors. Points where runoff information is needed are identified. The model can be structured to produce hydrographs at any desired location. As different areas of a large basin may have different hydrologic response characteristics, it is important to select an appropriate computational time interval and subdivide the watershed so that lumped parameters provide a reasonable depiction of the subbasins.

There are several methods that may be used in HEC-HMS to compute surface runoff. These are based on: (1) initial and constant excess precipitation, (2) SCS curve number, (3) gridded SCS curve number, (4) and Green and Ampt. The one-layer deficit and constant model can be used for simple continuous modeling. The five-layer soil moisture accounting model can be used for continuous modeling of complex infiltration and evapotranspiration environments.

Several methods are included for transforming excess precipitation into surface runoff. Unit hydrograph methods include the Clark, Snyder, and SCS technique. User-specified unit hydrograph ordinates can also be used. The modified Clark method, ModClark, is a linear quasi-distributed unit hydrograph method that can be used with gridded precipitation data. An implementation of the kinematic wave method with multiple planes and channels is also included.

A variety of hydrologic routing methods are included for simulating flow in open channels. Routing with no attenuation can be modeled with the lag method. The traditional Muskingum method is included.

TABLE 38.7 HEC-HMS Meteorologic Model Precipitation Methods

	Precipitation Method	Explanation
Historical Precipitation	User-specified hyetograph	Precipitation data analyzed outside of the program
	Gage weights	Uses Precipitation data from rainfall gages
	Inverse-distance gage weighting	Precipitation data from rainfall gages can be used to proceed when missing data is encountered
	Gridded precipitation method	Uses radar rainfall data
Synthetic Precipitation	Frequency storm	Uses statistical data from technical sources to produce balanced storm with given excedence probability
	Standard project storm	Implements regulations for precipitation when estimating the standard project flood
	SCS hypothetical storm	Implements the primary precipitation distributions for design analysis using Natural Resource Conservation Service (NRCS) criteria
	User-specified hyetograph	Used with a synthetic hyetograph resulting from analysis outside the program

The modified Puls method can be used to model a reach as a series of cascading level pools with a user-specified storage-outflow relationship. Channels with trapezoidal, rectangular, triangular, or circular cross sections can be modeled with the kinematic wave or Muskingum-Cunge method and an 8-point cross section.

Meteorologic Model

Meteorologic data analysis is performed by the meteorologic model and includes precipitation and evapotranspiration. Seven different historical and synthetic precipitation methods are included: (1) User Hyetograph, (2) User Gage Weighting, (3) Inverse-Distance Gage Weighting, (4) Gridded Precipitation, (5) Frequency Storm (6) Standard Project Storm – Eastern US, and (7) SCS Hypothetical Storm. These methods are summarized in Table 38.7. One evapotranspiration method is included in the model.

The four historical storm methods and the Gage Weights and User-Specified Hyetograph Methods for Synthetic Precipitation require entry of time-series precipitation data into the program. Time series data is stored in a project at a gage. Gage data has to be entered only once. The gages are owned by the project and can be shared by multiple basin or meteorologic models. The gage data is also stored in the DSS file created for the project and may be accessed by other projects.

An example of implementing time-series precipitation gage data in HEC-HMS would be using the Illinois State Water Survey (ISWS) Bulletin 70 rainfall depths with the Huff Rainfall Distributions. The Huff Rainfall Distribution for a 24-hour design storm event falling over an area of less than 10 square miles does not vary with different design frequency events. For this reason, the Huff 3rd Quartile Distribution may be entered as a precipitation gage using the cumulative storm percent precipitation data from 0–1 over the 24 hour design storm event duration. However, the Huff Rainfall Distributions are given in cumulative storm percent distributions rather than cumulative time series distributions that HEC-HMS accepts for precipitation gage data. Therefore, the cumulative storm percent distributions must be converted to time series precipitation distributions before being entered into HEC-HMS. The Huff Distributions in this example is specifically for northeastern Illinois (Huff and Angel).

Using the User-Specified Hyetograph precipitation method, this precipitation gage may be assigned to the subbasins in the model. When running the simulation, the precipitation may be weighted in the Run Manager to correspond to different design frequency events. The weighted precipitation is the depth of rainfall for a given design storm event.

Control Specifications

The control specifications set the starting date and time of a run as well as the ending date and time. The time interval, also called the computation step, is also included.

Preparation of Input Data

Preparation of input data can be divided into the following requirements and functions for using the SCS Methodology in HEC-HMS:

1. Prepare a schematic drawing that conveniently identifies the locations, drainage areas, curve numbers (CN), lag times (t_L), and reach lengths for the watershed. It should display all alternate structural systems together with the routing and evaluation reaches through which they are to be analyzed.
2. List the tabular data to support the requirements of the *Basin Model*. This may consist of structure data, stream cross section data, source or sink data and diversion data.
3. Establish the *Control Specifications* based on the time duration of the storm event to be simulated.
4. Develop a *Meteorological Model* to be used in the watershed analysis. This may require importing synthetic or historical rainfall data or developing synthetic rainfall distributions within HEC-HMS. The starting and ending time and date of the Meteorological Model, as well as the time interval, should be set in conjunction with the *Control Specifications*.

Calculations

For a large watershed it may be necessary to divide the watershed into subbasins. Each subbasin is determined by finding the different outlet points or design points within the watershed, then finding the area contributing to those points.

1. *Area*. The area of each subbasin in square miles (mi^2).
2. *Curve Number*. The curve number (CN) for each subbasin.
3. *Lag Time*. The lag time (t_L) is specified for each subbasin. Lag time (t_L) is 0.6 times the time of concentration (t_c).

The program is currently only set up to use English units.

HEC-GeoHMS Applications

HEC-GeoHMS has been developed as a geospatial hydrology tool kit for engineers and hydrologists with limited GIS experience. It combines the functionality of ArcInfo programs into a package that is easy to use with a specialized interface.

The program allows users to visualize spatial information, document watershed characteristics, perform spatial analysis, delineate subbasins and streams, construct inputs to hydrologic models, and assist with report preparation. Working with HEC-GeoHMS through its interfaces, menus, tools, buttons, and context-sensitive online help, in a windows environment, allows the user to effectively create hydrologic inputs that can be used directly with HEC-HMS. It is intended that these hydrologic inputs provide the user with an initial HEC-HMS model. The user can estimate hydrologic parameters from stream and watershed characteristics, gaged precipitation, and streamflow data. The user has full control in HEC-HMS to modify the hydrologic elements and their connectivity to more accurately represent field conditions.

HEC-HMS Example

A 60-acre basin in the Chicagoland area is modeled to determine the adequacy of a stormwater detention basin to which the area drains. This analysis will use SCS methodologies to determine the runoff hydrograph characteristics with the Illinois State Water Survey (ISWS) Bulletin 70 rainfall depths and the Huff rainfall distribution for the 100-year 24-hour design storm event. The 60-acre basin is composed of 40 acres of residential area and 20 acres of commercial area.

Hydrologic Input Data

The hydrologic parameters of the two subbasins within the 60-acre basin are given in Table 38.8.

The stormwater detention basin and control structure were sized based on the DuPage County, Illinois stormwater detention requirements. The runoff from the developed area must be released at 0.1 cfs per acre. The elevation-storage-discharge relationship for the detention basin is given in Table 38.9.

TABLE 38.8 Hydrologic Model Subbasin Parameter

Subbasin Name	Area (acres)	Runoff Curve Number	Time of Concentration (minutes)
Commercial	20	94	15
Residential	40	83	45

TABLE 38.9 Stage-Storage-Elevation Relationship for Example Detention Basin

Elevation (ft)	Storage (ac-ft)	Outflow (cfs)
683	0.0	0.0
684	5.87	2.70
685	11.92	4.08
686	18.16	5.10
687	24.60	5.95

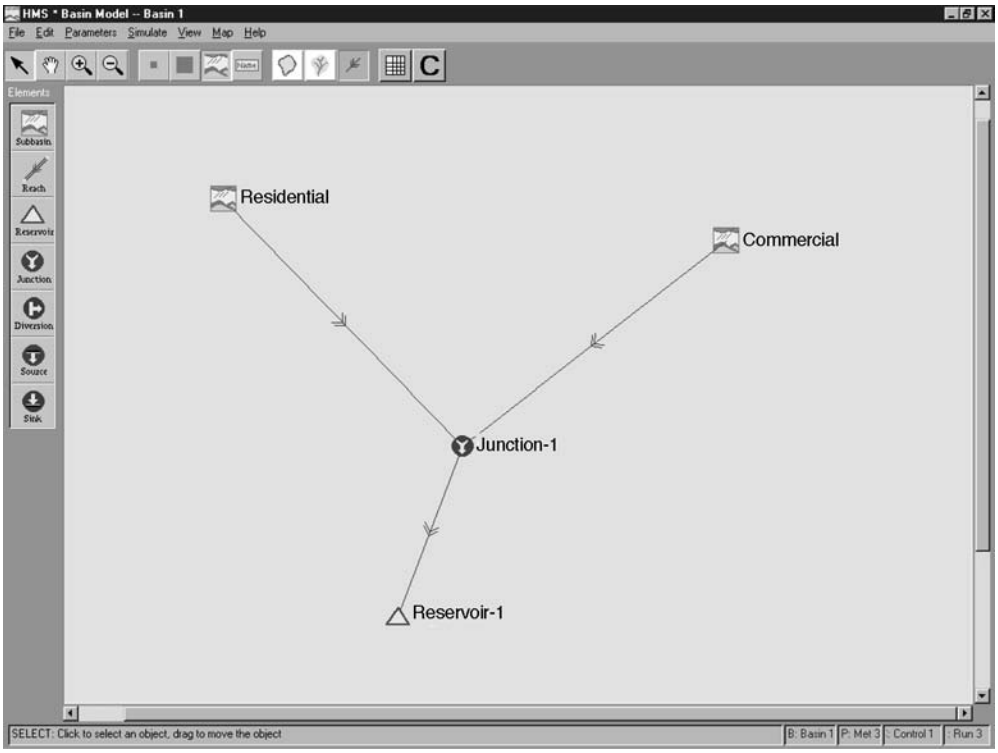

FIGURE 38.9 HEC-HMS example problem basin schematic.

Using the subbasin hydrologic parameters and the stage-storage-elevation relationship for the storm-water detention pond, a basin model was constructed in HEC-HMS. The basin model schematic that is generated within HEC-HMS is shown as Fig. 38.9.

The pictured map icons represent the subbasins, the arrows represent the upstream and downstream orientation of the basin model, the circle junction icon represents the combination of the Residential and Commercial hydrographs and the triangle represents the reservoir routing of the combined hydrographs. By clicking on the icons, the data from Tables 38.8 and 38.9 can be added to the Basin Model.

11	0.33	23	0.975
12	0.38	24	1.00

The next step is to specify a starting and ending date and time in the Control Specifications. A Control Specifications file with a starting date of 01/01/2001 and ending date of 01/03/2001 has been used for this example. The time for both the starting and ending date is 0:00.

The cumulative rainfall data to be used are the Bulletin 70 rainfall depths and Huff 3rd Quartile rainfall distributions. For the 60-acre basin in the Chicagoland area and the 100-year 24-hour design storm event, the corresponding storm code is 5 and the Sectional (zone) code is 2. This corresponds to a rainfall depth of 7.58 inches and the Huff 3rd Quartile distribution for areas less that 10 square miles. The Huff distribution is given in cumulative storm percent in increments of 5% of storm duration. This cumulative storm percent distribution must be converted to a cumulative time series distribution for input into HEC-HMS. This can be done with linear interpolation in a spreadsheet program, and the results of this analysis are given in Table 38.10. Note that the precipitation time increment chosen for this example problem is 1 hour.

This rainfall distribution is entered as a precipitation gage with an hourly time interval. The time window for the precipitation gage is set to match the time window for the Control Specifications. In this example, the precipitation start date is 01/01/2001. The distribution is left as a scaled distribution from 0–1, and the appropriate rainfall depth multiplier will be specified in the Run Manager later in the example.

Using the precipitation gage created for the Huff Rainfall Distribution and the subbasins from the Basin Model, a Meteorological Model is created for the 60-acre basin. In the Meteorological Model, User-Hyetograph is specified as the method and the precipitation gage created above is assigned to each subbasin.

Finally, a model run is created in Run Configuration by selecting a Basin Model, Meteorological Model and Control Specifications. Using the Run Manager, a total precipitation depth can be chosen to match a design storm event. In this example, we set the precipitation ratio to 7.58 inches.

Output

HEC-HMS produces both graphical and tabular output for viewing and report generation as well as detailed tabular output that is automatically stored in DSS. It also generates a run log that contains details of Errors and Warnings produced in the model computations. The tabular output for each location within the hydrologic model is shown in Fig. 38.10.

Tabular output is also available for each individual element of the hydrologic model. The tabular output for the stormwater detention basin called Reservoir-1 is shown in Fig. 38.11.

The output from each element of the hydrologic model may also be presented graphically in the form of a hydrograph. Figure 38.12 shows the graphical output for the Residential subbasin.

38.5 The HEC-RAS Model

Uses of HEC-RAS

The U.S. Army Corps of Engineers' River Analysis System (HEC-RAS) is a computer model enables one-dimensional steady and unsteady flow river hydraulic calculations. The HEC-RAS software supercedes the HEC-2 river hydraulics package, which was a one-dimensional, steady flow water surface profiles program. HEC-2 hydraulic models may be imported into HEC-RAS, although differences in the way HEC-RAS computes conveyance, losses at hydraulic structures and critical depth will cause results in the two programs to be slightly different. The HEC-RAS software is a significant advancement over HEC-2 in terms of both hydraulic engineering and computer science, but an imported HEC-2 hydraulic model should be carefully analyzed before using it for simulations in HEC-RAS.

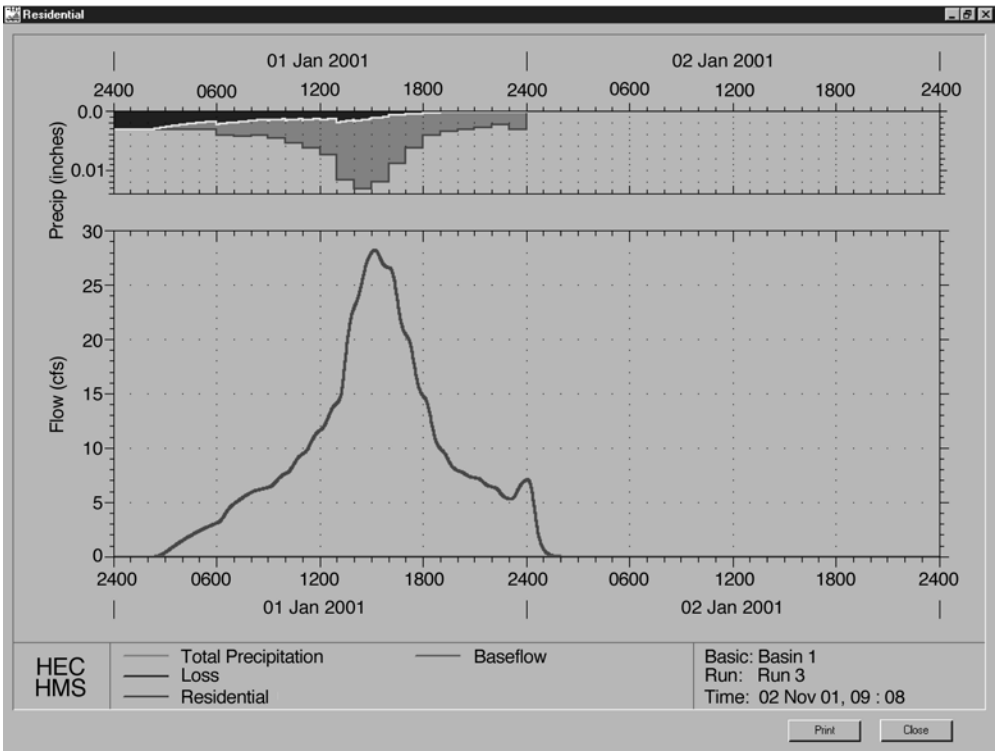

FIGURE 38.12 Graphical output for residential subbasin.

HEC-RAS consists of a graphical user interface (GUI), separate hydraulic analysis components, data storage and management capabilities, graphics and reporting facilities. The hydraulic analysis components will ultimately contain three one-dimensional components for: (1) steady flow water surface profile computations; (2) unsteady flow simulation; and (3) movable boundary sediment transport computations. All three of these components will use a common geometric data representation and common geometric and hydraulic computation routines.

HEC-RAS Hydraulic Analysis Components

Steady Flow Water Surface Profiles

This component of the modeling system is intended for calculating water surface profiles for steady gradually varied flow based on the solution of the one-dimensional energy equation. The effects of various obstructions such as bridges, culverts, weirs, and structures in the floodplain may be considered in the computations. The steady flow system is also designed for application in floodplain management to evaluate floodway encroachments. Special features of the steady flow component include: multiple plans analyses; multiple profile computations; multiple bridge and/or culvert opening analysis; and split flow optimization.

Unsteady Flow Simulation

This component of the HEC-RAS modeling system is capable of simulating one-dimensional unsteady flow through a full network of open channels. The hydraulic calculations for cross-sections, bridges, culverts, and other hydraulic structures that were developed for the steady flow component were incorporated into the unsteady flow module. The unsteady flow equation solver was adapted from Dr. Robert L. Barkau's UNET model (Barkau, 1992 and HEC, 2001).

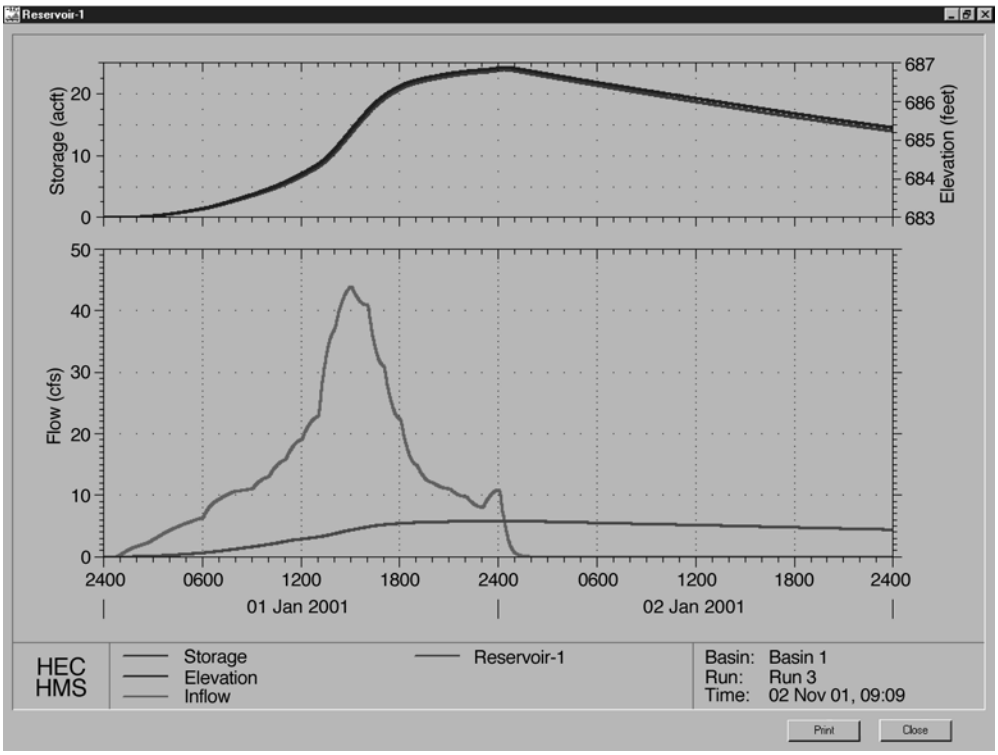

FIGURE 38.13 Graphical output for stormwater detention basin.

There are three components used in performing an unsteady flow analysis within HEC-RAS. These components are: (1) a geometric data pre-processor; (2) the unsteady flow simulator; and (3) an output post-processor. The pre-processor is used to process the geometric data into a series of hydraulic properties tables and rating curves, the unsteady flow simulation is performed by a modified version of UNET, and the post-processor is used to compute detailed hydraulic information for a set of user specified time lines during the unsteady flow simulation period.

Sediment Transport/Movable Boundary Computations

This component of the modeling system is intended for the simulation of one-dimensional sediment transport/movable boundary calculations resulting from scour and deposition over time. The sediment transport potential is computed by grain size fraction, thereby allowing the simulation of hydraulic sorting and armoring. The model will be designed to simulate long-term trends of scour and deposition in a stream channel that might result form modifying the frequency and duration of the water discharge and stage, or modifying the channel geometry. This system can be used to evaluate depositions in reservoirs, design channel contractions required to maintain navigation depths, predict the influence of dredging on the rate of deposition, estimate maximum possible scour during large flood events, and evaluate sedimentation in fixed channels.

HEC-RAS Hydraulic Model Structure

In HEC-RAS terminology, a *Project* is a set of data files associated with a particular river system. Steady flow analysis, unsteady flow analysis, and sediment transport computations may be performed as part of the project. The data files for a project are categorizes as follows: (1) plan data, (2) geometric data, (3) steady flow data, (4) unsteady flow data, (5) sediment data, and (6) hydraulic design data.

1. Plan Data – A plan represents a specific set of geometric data and flow data – the two required elements to perform a hydraulic analysis. Once the geometric and flow data are entered into the project, plans can easily be formulated by matching geometric and flow data.
2. Geometric Data – Geometric data represents the physical elements of a stream system. Included in the geometric data are the connectivity of the river, channel cross-sections, reach lengths, energy loss coefficients, stream junction information, and hydraulic structure data.
3. Steady Flow Data – Steady flow data consisting of flow regime, boundary conditions, and peak discharge information, are required to perform a steady flow analysis.
4. Unsteady Flow Data – The user is required to enter boundary conditions at all of the external boundaries of the system, as well as any desired internal locations, and set the initial flow and storage area conditions in the system at the beginning of the simulation period. The boundary conditions can be input manually by the user or imported from a HEC-DSS file.
5. Sediment Data – The sediment transport capabilities of HEC-RAS are currently under development. This feature is scheduled to be available in future releases of the program.
6. Hydraulic Design Data – This option allows the user to perform a series of channel modifications and evaluate the hydraulics of these modifications. These data can be used to determine if a channel modification will cause further scour of the channel bed and banks.

HEC GeoRas Applications

HEC-RAS has the ability to import three-dimensional river schematic and cross section data created in a GIS or CADD system. The HEC has developed an ArcView GIS extension called GeoRAS, that was designed to process geospatial data for use with HEC-RAS. The GeoRAS software allows a user to write geometric data to a file in the required format for HEC-RAS. Additionally, the users can read the HEC-RAS results into GeoRAS and perform the flood inundation mapping.

HEC-RAS Example

A trapezoidal channel is modeled to determine the head loss through a 36-inch Reinforced Concrete Pipe (RCP) at a road crossing at design flowrates of 50 and 100 cfs.

A simple HEC-RAS example schematic is shown in Fig. 38.14.

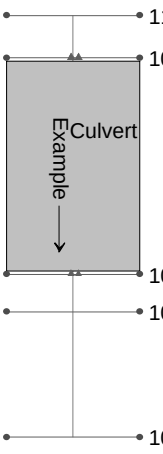

FIGURE 38.14 HEC-RAS sample schematic.

Hydraulic Input Data

Figure 38.14 shows the HEC-RAS Geometric Data for the example channel. The channel is trapezoidal and the culvert is a 36-in. RCP culvert with a length of 50 ft. The overtopping elevation of the roadway is at an elevation of 605.0 ft. The single vertical line represents the stream centerline and the horizontal lines with attached numbers represent cross-section locations that are entered into the HEC-RAS hydraulic model. The dots on the end of the cross-sections represent the channel banks. In this simple example, the channel cross-sections were not extended beyond the channel banks. The direction arrow indicates the orientation of the stream. The channel slope was assumed to be 1% and a Manning's n value of 0.027 was used for a grassed channel. The cross-section station numbers represent stream length in feet, starting from 1000 at the downstream end. However, left, right, and overbank lengths are specified at each cross-section. Manning's n values, channel bank stations, cross-section coordinates, ineffective flow areas and levees are also specified for each cross-section. The trapezoidal channel cross-section is shown in Fig. 38.15.

A culvert analysis in HEC-RAS requires four cross-sections. The first cross-section should be located sufficiently downstream of the structure so that flow is not affected by the structure. In the case of this example, the cross-section is located 40 ft downstream of the culvert opening. The second cross-section (1039) should be located immediately downstream of the culvert opening, and in this example

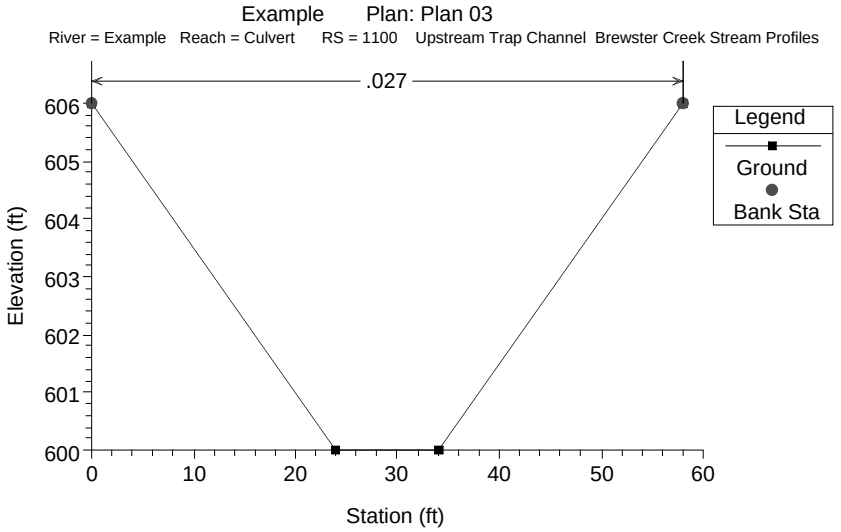

FIGURE 38.15 HEC-RAS example trapezoidal channel cross-section plot.

cross-section 1039 is located 1 ft downstream of the culvert. This cross-section should represent the effective flow area just at the culvert width. The third cross-section (1091) is located on the upstream side of the culvert, and it also should represent the effective flow area as the width of the culvert. In order to model only the effective flow areas at the second and third cross-sections, the ineffective flow area option should be used. The fourth cross-section (1100) is located upstream where the flow lines are approximately parallel and the cross-section is fully effective. These cross-section locations were arbitrarily chosen for this simple example. When using HEC-RAS to analyze bridges and culverts, special attention should be paid to the locations of these 4 cross-sections. Reference is given in the HEC-RAS User's Manual to the proper selection of cross-section locations.

The culvert cross sections with the ineffective flow areas at cross-sections 1039 and 1091 are shown in Fig. 38.16.

Once the geometry of the reach is completed, a downstream boundary condition and design flowrates must be specified. For this example, we have assumed a critical depth downstream boundary condition and a design flowrates of 100 and 50 cfs.

HEC-RAS Output

HEC-RAS allows for the output of results in both tabular and graphical formats. The tabular output for this hydraulic analysis is shown in Table 38.11.

This table shows that the head loss through the culvert for design flowrates of 100 cfs and 50 cfs is 2.75 feet and 2.16 ft, respectively. For the design flowrate of 100 cfs, the water surface elevation at the upstream cross-section (1091) is greater than the roadway elevation of 605.0 feet, which indicates that the roadway overtops for this design flowrate.

Another way to view the results in HEC-RAS is through the graphical interface. The graphical profile plot of the trapezoidal channel and culvert is shown in Fig. 38.17.

The stationing and stream length in feet from cross-section 1000 are given on the X-axis, while elevation is given on the Y-axis. The shaded area is the fill above the culvert and the opening below that is the culvert opening. The water surface profiles for the 100 cfs and 50 cfs design flowrates are given as the WS PF 4 and WS PF 2 lines in Fig. 38.18. Note that the 100 cfs water surface profile confirms that the roadway overtops at this design flowrate.

Each cross-section may also be viewed individually with resultant water surface elevations. Figure 38.18 shows cross-section 1039 with the two design flowrate elevations at this location.

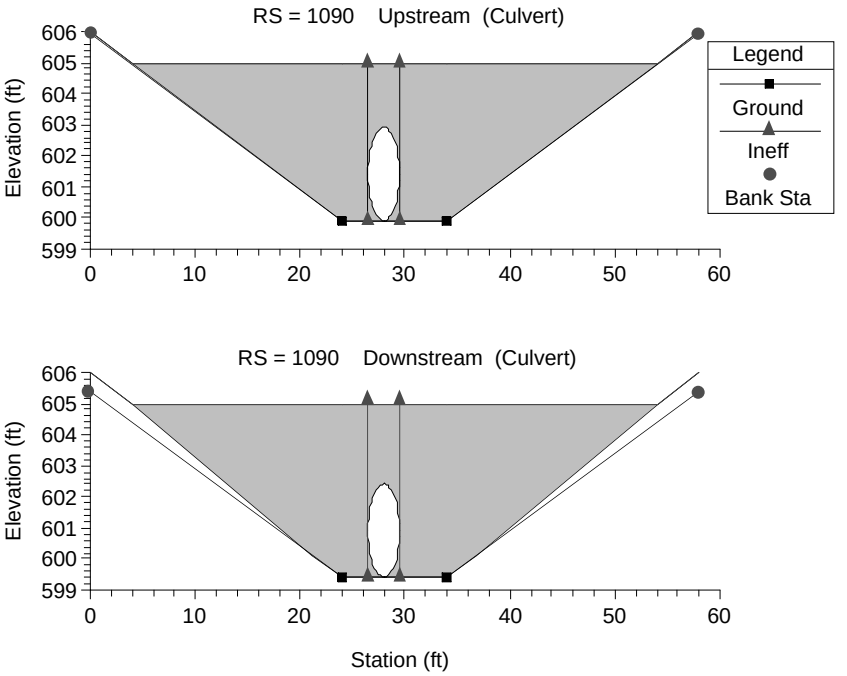

FIGURE 38.16 HEC-RAS example culvert plot.

Culvert	1039	50.00	599.40	601.45	601.45	602.48	0.008418	8.14	6.14	26.38	1.00
Culvert	1039	100.00	599.40	602.66	602.66	604.28	0.007148	10.23	9.78	36.07	1.00
Culvert	1000	50.00	599.00	599.87	599.82	600.15	0.010006	4.27	11.72	16.96	0.90
Culvert	1000	100.00	599.00	600.26	600.22	600.69	0.010010	5.25	19.04	20.11	0.95

The hatched area reflects ineffective flow areas just downstream of the culvert opening. Again, the ineffective flow areas must be determined on a case-by-case basis for each hydraulic structure. The HEC-RAS User's Manual gives a detailed description of modeling culverts and bridge openings.

38.6 XP-SWMM

Uses of XP-SWMM

Capabilities

The XP-SWMM model is comprehensive unsteady flow model that can be used for the simulation of urban runoff quantity and quality in either storm or combined sewer systems. It is a relatively sophisticated

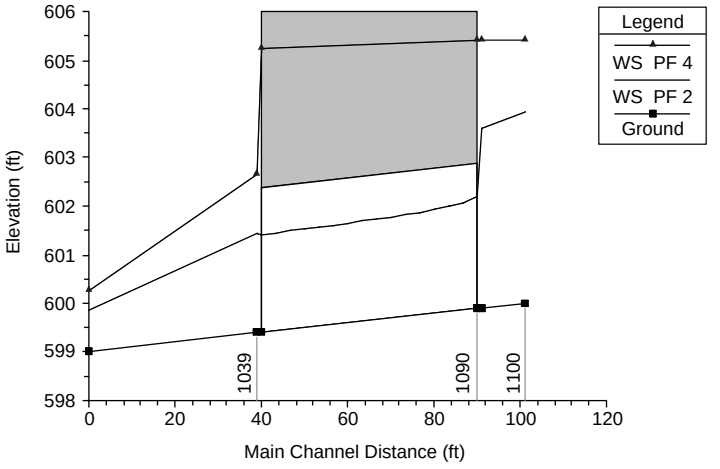

FIGURE 38.17 HEC-RAS profile graphical output.

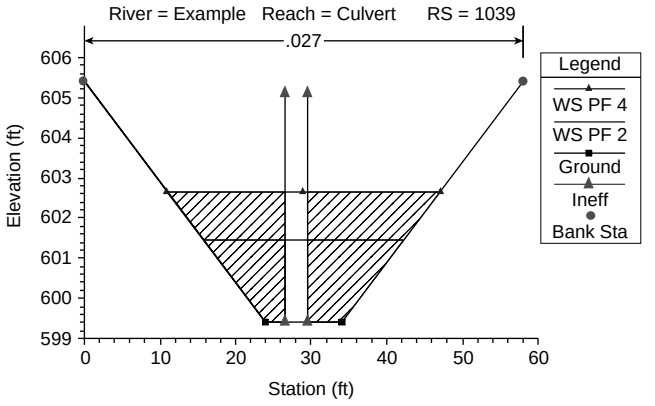

FIGURE 38.18 HEC-RAS cross section graphical Output.

hydrologic, hydraulic and water quality simulation program that utilizes the Storm Water Management Model (SWMM), developed under the sponsorship of the U.S. Environmental Protection Agency (USEPA), with an XP graphical interface. Also, many improvements to the USEPA's SWMM Version 4.3 have been incorporated into the latest version of XP-SWMM (Version 8.0). These improvements include many enhancements to the water quality capabilities of XP-SWMM, a new hydraulics solution algorithm and unsteady flow water quality routing. XP-SWMM can be used in drainage systems that are hydraulically complex, systems in which flow or stage data are available for calibration, or systems in which water quality is to be simulated.

The hydrologic simulation capabilities of XP-SWMM allow the use of historical rainfall events or design storm events, either of which may be input directly to the model or imported from programs outside of XP-SWMM. The hydraulic simulation capabilities of XP-SWMM include flow routing for both open and closed conduits in dendritic and looped networks. The model is capable of performing dynamic routing of stormwater flows through the stormwater drainage system to the outfall points of the receiving water system. Water quality characteristics of urban stormwater may also be simulated by XP-SWMM within the hydrologic and hydraulic simulation, although many applications of XP-SWMM are for water quantity purposes only.

XP-SWMM Model Structure

The XP-SWMM model is constructed of the following three "blocks" which are linked together to mathematically simulate all aspects of an urban drainage system: (1) Runoff Block, (2) Transport Block, and (3) EXTended TRANsport (EXTRAN) Block. Within the XP-SWMM graphical user interface, drainage networks are composed of links and nodes that may be dragged from the menu bar onto the screen. The nodes may represent watershed areas, manholes, level-pool reservoirs, and outfalls within the stormwater drainage system. The links may represent storm sewers of varying cross-sections, overland flow, trapezoidal or natural channels, pumps, orifices, weirs, or user-defined rating curves.

Stormwater Runoff from the drainage area is generated within the Runoff Block. The runoff may be routed through the drainage network by any of the three blocks in SWMM (Runoff, Transport, and EXTRAN), although it is recommended that routing be done in the EXTRAN Block for all drainage systems except the most simple. This text will assume that all routing of stormwater flows by the reader will be done in the EXTRAN Block. The stormwater runoff enters the EXTRAN Block at nodes shared by the Runoff Block and the EXTRAN Block. An interface file specified in each block transfers flow and water quality information between the two blocks.

The XP-SWMM model also has the ability to create and store databases of information that may be referenced within the model. This reduces data redundancy and associated problems of updating at many places when changes are made.

Runoff Block

The Runoff Block is the input source to the SWMM model. It generates surface runoff based on arbitrary rainfall and snowmelt hyetographs, antecedent moisture conditions, land use, and topography. The Runoff Block simulates the quantity and quality of the runoff from a watershed and generates hydrographs and pollutographs that may be analyzed or used as input to the EXTRAN Block. Each watershed is represented by a node in the XP-SWMM model and may be composed of up to five different subcatchments, each with unique runoff routing, rainfall hyetographs, water quality data, and infiltration characteristics.

There are several methods which may be used by the Runoff Block within XP-SWMM to compute surface runoff hydrographs. These are based on: (1) SCS Hydrology, (2) Unit Hydrograph Method, (3) Laurenson's Method, and the (4) Kinematic Wave routing methodology. Infiltration for the three latter runoff methodologies may be simulated using the Horton or Green and Ampt methodology.

EXTRAN Block

Hydrographs and pollutographs generated within the Runoff Block are transferred to the EXTRAN Block via the interface file. The EXTRAN Block performs dynamic routing of stormwater flows from the input nodes, through the major storm drainage system, and to the outfall points of the drainage network. Within the EXTRAN Block, the nodes represent level-pool reservoirs, outfall points, and junctions of the stormwater drainage system. The links may represent pipes of various cross-section, open channels, orifices, weirs, pumps, or user-defined rating curves.

The EXTRAN Block will simulate flow in branched or looped networks, backwater due to tidal conditions, free-surface flow, pressure or surcharged flow, flow reversals, flow transfers by weirs, orifices and pumping facilities, and pond or lake storage. The EXTRAN Block uses a combination of implicit and explicit finite difference formulations for solving the St. Venant equations for gradually varied one-dimensional flow. Flow conditions violating the assumptions of gradually varied flow are solved using a combination of the kinematic wave and full dynamic equations in the conduit of interest.

Water Quality Simulation

Water quality processes are represented in all three of the core blocks of XP-SWMM (Runoff Block, Transport Block, and EXTRAN Block). Up to 10 water quality constituents may be modeled, and concentrations are transferred between blocks via the interface file. For most XP-SWMM applications,

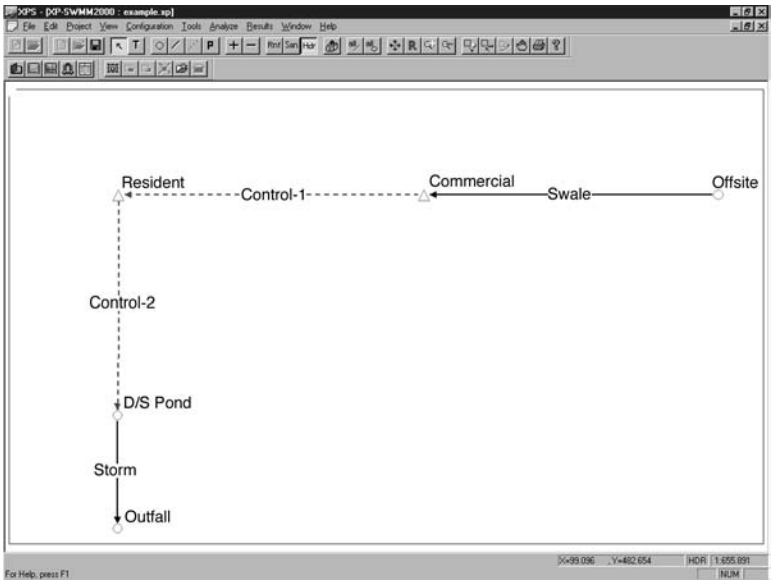

FIGURE 38.19 Sample XP-SWMM model schematic.

the Runoff Block is the origin of water quality constituents. The Runoff Block attempts to simulate the buildup of pollutants on the watershed and the overland transport of these pollutants into the drainage system. The mechanisms of urban runoff quality involve factors such as wind, erosion, traffic, atmospheric fallout, land surface activities, street cleaning, and many other complex processes. XP-SWMM attempts to consider many of these factors; however the difficulties of modeling urban runoff quality are well documented and cannot be completely overcome by XP-SWMM.

Water quality can be simulated in three different ways in the Runoff Block: (1) Buildup and Washoff, (2) Rating Curve, and (3) Event Mean Concentration. The Buildup and Washoff method simulates buildup of dust and dirt on the watershed as well as the subsequent washoff using exponential functions. The second method is the use of a rating curve of concentration vs. flow rate. The third method for simulating water quality is using the event mean concentration (EMC). The Runoff Block can also include water quality constituents in rainfall, catchbasin flushing, and erosion of solids using the Universal Soil Loss Equation.

Pollutants generated by the Runoff Block enter the drainage system as a pollutograph at the nodes, which are shared by the Runoff and EXTRAN Block (the same way hydrographs enter the system). Pollutographs may also be generated and enter the drainage system in the EXTRAN Block by simulating dry weather flow for simulation of combined sewer systems. Once in the sewer network, each pollutant is individually routed through conduits in the EXTRAN Block by assuming complete mixing within the conduit in the manner of a continually stirred tank reactor (CSTR). With this assumption, the concentration of the pollutant leaving the pipe is equal to the concentration in the pipe. All subsequent calculations are thus based on a mass balance, with pollutants being added or removed based on the concentration in the conduit. These calculations include scour, deposition, and decay of each pollutant.

XP-SWMM Example Problem

A simple XP-SWMM example watershed is shown in the following schematic (Fig. 38.19).

RUNOFF Block

The watershed will be analyzed using the National Resource Conservation Service (NRCS) TR-55 methodologies and Illinois State Water Survey (ISWS) Bulletin 70 rainfall depths and the Huff 3rd Quartile design rainfall distribution. The watershed is broken into three subbasins as shown in Table 38.12.

TABLE 38.12 Hydrologic Model Subbasin Parameters

Subbasin Name	Area (acres)	Runoff Curve Number	Time of Concentration (minutes)
Offsite	150	72	240
Commercial	20	94	15
Residential	40	83	45

This information is entered into the Runoff Block of the XP-SWMM model at the appropriate node. A hydrograph will be generated at these three "active" nodes in the Runoff Block based on this information in Table 38.12 using the NRCS methodology. In this example, the Huff 3rd Quartile design rainfall distribution and ISWS Bulletin 70 100-year 24-hour rainfall depth are entered in the Global Data database and are referenced at each node in the Runoff Block. A starting and ending date and time must be selected for a model run. For this example, the time period selected is July 18, 2001 to July 21, 2001.

EXTRAN Block

This watershed consists of farmland in the headwaters and commercial and residential development in the downstream areas. The offsite area drains via open swale to the commercial area. A cross-section, length, channel roughness, channel slope, bank stations, and upstream and downstream inverts of the swale are entered into this link to route the offsite flow to the commercial area. The commercial area drains into a stormwater detention basin, which drains to a residential area that is also served by a stormwater detention basin. The storm sewers within the commercial and residential area have been omitted from this example, for it can be reasonably assumed that all of the runoff in these areas drains to the detention basins via storm sewers and overland flow routes with little attenuation. These runoff processes can be simulated in the Runoff Block.

The stormwater detention basins for the commercial and residential areas are represented by a triangle in XP-SWMM. An elevation-area relationship is entered at the commercial and residential nodes in the EXTRAN Block. The control structure for each detention basin, represented by a dashed multi-conduit in the EXTRAN block, is composed of an orifice and an overflow weir. The relevant hydraulic properties (elevation, area, discharge coefficient, length) of the weir and orifice are explicitly entered into each multi-conduit. The residential detention basin drains into a storm sewer. Pipe size and shape, roughness, length, slope, rim, and invert elevations are entered for each storm sewer. The downstream side of this storm sewer is considered the outfall of the system. Several options exist for outfall conditions, but this example will use a critical depth assumption.

Results

XP-SWMM presents results in tabular and graphical formats. Tabular output of numerous hydrologic and hydraulic input parameters and results may be specified within XP-SWMM. This output can easily be imported into spreadsheets for further analysis or graphing. However, the graphical capabilities of XP-SWMM allow for the user to view discharge hydrographs of all links and stage hydrographs of all nodes within XP-SWMM in the EXTRAN Block. Furthermore, runoff discharge hydrographs at each node may also be viewed in the Runoff Block.

Figure 38.20 shows the discharge hydrograph of the orifice in the control structure for the residential development. The upstream elevation represents the water surface elevation in the residential stormwater detention basin. The downstream elevation represents the water surface elevation downstream of the residential stormwater detention basin control structure. In this example, the tailwater effect on the orifice from the downstream node can be clearly seen by the sharp drop in the hydrograph as the downstream water surface elevation rises.

This graph may also be exported from XP-SWMM in a tabular format that can be imported into spreadsheet programs for further analysis. XP-SWMM also produces an output file for each model run that gives details of the hydrologic and hydraulic simulation.

39.1 Introduction

Water resources planning and management engineering is concerned with conceptualizing, designing, and implementing strategies for delivering water of sufficient quality and quantity to meet societal needs in a cost-effective manner. Alternatives that can be engineered to accomplish these functions include development of new water supplies, regulation of natural sources of water, transfer of water over large distances, and treatment of degraded water so that it can be reused. The challenges for water resources engineers are: (1) to identify the essential characteristics of a given water resources problem, (2) to identify feasible alternatives for resolving the problem, (3) to systematically evaluate all feasible alternatives in terms of the goals and objectives of the decision makers, and (4) to present a clear and concise representation of the trade-offs that exist between various alternatives.

Water Resources Decision Making

Because large-scale planning, development, and management of water resource systems generally take place in the public sector, the individual responsible for making decisions about, or selecting from, a set of development alternatives is usually not the engineer(s) who perform the technical analyses related to the given problem domain. The decision-making topology is rather more like that presented in Fig. 39.1. At the top of the topology is the decision maker, usually an elected official or his or her appointee. This individual assumes the responsibility for selecting a course of action that best achieves the goals and

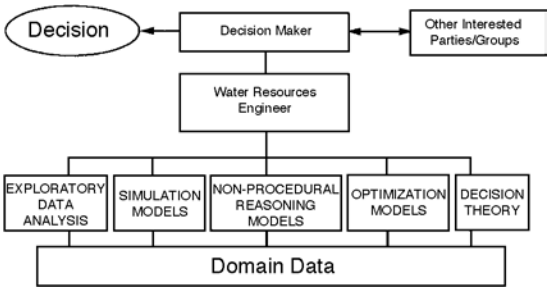

FIGURE 39.1 The water resources engineer uses a wide range of analytical tools and techniques to identify and evaluate alternative development plans and management strategies. The selection of a particular project or plan from a set of alternatives identified by the engineer is the responsibility of the decision maker.

objectives of his or her constituency. During the course of the decision-making process, the decision maker interacts with other interested parties, such as local, state, and federal government agencies; non-governmental organizations and groups; industry; and individuals.

At the bottom of the hierarchy are all data that pertain to the problem domain, including hydrologic data, economic and other cost data, demographic and historic data, and information about relevant structural and management technologies. The water resources engineer selects, from a wide range of modeling and analysis technologies, those that can best evaluate these data and provide the decision maker with information about the trade-offs that exist among and between multiple and conflicting management objectives. In addition, the water resources engineer may interact with other interested parties, including social scientists, economists, and environmentalists, to ensure a comprehensive consideration of the system and its impacts. Consequently, the water resource systems analyst must be skilled in problem identification; proficient in the use of different modeling methods and technologies; and willing and able to interact with technical, and non-technical managers and decision makers.

Comprehensive water resource, planning and management is generally conducted in several separate but related phases requiring input from a wide range of specialists including urban and regional planners, economists and financial planners, government agency personnel, citizen groups, architects, sociologists, real estate agents, civil engineers, hydrologists, and environmental specialists. The National Environmental Policy Act of 1969 (NEPA) requires the preparation of an environmental impact statement for every major federal action (program, project, on licensing action) "significantly" affecting the quality of the human environment. Most water projects fall under this legislation and most states have prepared regional guidelines for complying with NEPA. Special-purpose developments often require the assistance of specialists from disciplines such as soil scientists, agricultural specialists, crop experts, computer specialists, and legal experts. These individuals are involved in one or more of several planning and management phases

- Establishment of project goals and objectives
- Collection of relevant data
- Identification of feasible best-compromise alternative solutions
- Preliminary impact assessment
- Formulation of recommendation(s)
- Implementation (detailed structural design, construction, and/or policy implementation)
- Operation, management, and sustainment

Because most large-scale water resources projects involve many different constituencies having different goals and objectives, a multiobjective perspective through this process is essential. Consider, for example, the problem of developing an operating strategy for a large multipurpose reservoir designed to provide water for irrigated agriculture, municipal and industrial water supply, water-based recreation, and power

generation (see Chapter 37 for a comprehensive discussion of water resource structures). The reservoir may also be a critical component in a regional flood control program. The decision maker in this context might be a regional water authority which reports to a state water agency or to the state governor. Clearly, the decision maker has responsibilities to a range of constituencies that might include the citizens at large, industry special interest groups, the environment and future generations, and perhaps a present political administration. The operating strategy that best meets the needs of one interest may prove disastrous for another. (For a thorough discussion of multiple and conflicting objectives in water resources planning and management, see Cohon and Rothley, 1997; Goodman, 1984; and Linsley et al., 1992.) The selection among alternatives is thus the responsibility of the decision maker who represents these groups. The role of the engineering analyst is to develop a clear and concise documentation of feasible alternatives. The focus of this chapter is the use of analytical engineering management tools and techniques for developing these alternatives.

Water Resources Modeling

The main tool of the water resources engineer is the computer model, which can be classified by: (1) structure and function (optimization or simulation), (2) degree of uncertainty in system inputs (deterministic or stochastic), (3) level of fluctuation in economic or environmental conditions being modeled (static or dynamic), (4) distribution of model data (lumped or distributed), and (5) type of decision to be made (investment or operations/management). Each model configuration has inherent strengths and weaknesses, and each has its proper role in water resources planning. The challenge for the water resources engineer is not to determine which is better, but which is most appropriate for a particular situation given available resources including time, money, computer capability, and data.

Optimization vs. Simulation Models

A variety of water resources management and planning models can be formulated and solved as optimization models. Optimization models have the following general structure:

$$\text{Optimize } Z = f(x_1, x_2, \ldots, x_n) \tag{39.1}$$

Subject to:

$$g_1(x_1, x_2, \ldots, x_n) \le b_1 \tag{39.2}$$

$$g_2(x_1, x_2, \ldots, x_n) \le b_2 \tag{39.3}$$

$$\ldots$$

$$\ldots$$

$$g_m(x_1, x_2, \ldots, x_n) \le b_m \tag{39.4}$$

$$x_j \ge 0 \qquad j = 1, 2, \ldots, J \tag{39.5}$$

Equation (39.1) is called the objective function and is specified as a mathematical criterion for measuring the 'goodness' of any given solution. The objective function is a function of a set of non-negative variables known as decision variables ($x_1, x_2, \ldots, x_n$), which typically represent the choices available to the decision makers. The optimal solution to the optimization model is the set of values of the decision variables that provides the "best" (e.g., maximum or minimum) value for the objective function.

The quality of the solution as measured by the objective function is constrained by a set of equations, appropriately called constraint equations or constraints — Eqs. (39.2–39.4) above. The constraints

represent all the real-life restrictions on the values of the decision variables. The functions $g_1, g_2, \ldots g_m$ depend on the values of the decision variables, and are restricted to be less-than-or-equal-to a set of constants $b_1, b_2, \ldots, b_m$. This is the typical presentation of an optimization model; however, equalities and greater-than-or-equal-to inequalities in the constraints are allowed.

Finally, the optimization model typically includes the requirement that all decision variables are non-negative — Eq. (39.5). From an engineering management standpoint, decision variables represent those factors of a problem over which the engineer has control, such as the amount of resource to allocate to a particular activity the appropriate size of a component of a structure, the time at which something should begin, or cost that should be charged for a service. Clearly negative values for such things have no physical meaning. However, if there are decision variables that should be allowed to take on negative values, then this can be accommodated within an optimization model.

If a water resources planning or management model can be constructed to adhere to the rigid structure of the optimization model, a variety of solution methodologies are available to solve them [Hillier and Lieberman, 1990; Sofer and Nash, 1995]. These techniques are continuously improving in scale and efficiency with the ongoing improvements in information technology (e.g., object oriented programming, increasing computational speeds of computer processors). New techniques such as artificial neural networks, or evolutionary computing — an offshoot of artificial intelligence — are offering an even greater range of solution options (e.g., Wardlaw and Sharif, 1997).

Undoubtedly the most widely used analytical procedure employed in the area of water resources systems engineering is simulation (or descriptive) modeling. The main characteristics of this modeling methodology are: (1) problem complexities can be incorporated into the model at virtually any level of abstraction deemed appropriate by the model designer or user (in contrast to the more rigid structure required by optimization models), and (2) the model results do not inherently represent good solutions to engineering problems. These models reflect the structure and function of the system being modeled and do not attempt to suggest changes in design or configuration towards improving a given scenario.

Simulation models may be time or event sequenced. In time-sequenced simulation, time is represented as a series of discrete time steps ($t = 0, 1, 2, \ldots, N$) of an appropriate length perhaps hours, days, weeks, or months depending on the system being modeled. At the end of each time period t all model parameters would be updated (recomputed) resulting in a new system state at the beginning of time step $t + 1$. The relationships among and between model parameters may be deterministic or stochastic through this updating process, again depending on the design of the system and the level of abstraction assumed by the model. Model inputs, both initially and throughout the simulation, may follow parameter distributions as discussed in the previous section or may be input from external sources such as monitoring instrumentation or databases.

Models that simulate physical or economic water resource systems can also be event sequenced, wherein the model is designed to simulate specific events or their impacts whenever they occur. These events might be input as deterministic or stochastic events or they might be triggered by the conditions of the system. In any case, the model responds to these events as they occur regardless of their timing relative to simulated real time. Regardless of the treatment of time through the simulation process, these models can be either deterministic or stochastic.

With increasingly powerful computer technology, extremely complicated simulation models can be developed that emulate reality to increasingly high levels of accuracy. Very complicated systems can be modeled through many time steps and these models can be "exercised" heavily (can be run many times with different parameter settings and/or data inputs) to understand the system being modeled better. A number of commercial vendors market simulation systems that can be used to design and develop simulation models.

Historically, optimization models have been used as screening models in water resources planning and management analyses. The gross level of abstraction required to "fit' a particular problem to this rigid structure, coupled with the heavy computational burden required to solve these models, precluded the construction of large and accurate systems representation. Once a general solution strategy or set of alternatives was identified, simulation models could be constructed for purposes of more detailed analysis

and "what-if" -type analyses. With the advent of increasingly powerful computing capability there is a much tighter integration of these and other modeling technologies.

Deterministic vs. Stochastic Models

Water resources models can also be classified by the Ievel of uncertainty that is present in model parameters and hydrologic inputs. A model is said to be deterministic if all input parameters and expected future unregulated streamflows and other time series are assumed to be known with certainty and defined specifically within model constraint equations. If, on the other hand, only the probability distributions of these streamflows are assumed to be known within the model, the model is said to be stochastic (see Chapter 31 for a more complete discussion of statistical hydrologic analysis).

Both optimization and simulation models can be either deterministic or stochastic. Stochastic models are generally more complex than deterministic models, having more variables and constraints or limiting conditions. But deterministic models, having parameters and inputs based on average values over potentially long time periods, are usually optimistic; system benefits are usually overestimated, while costs and system losses are generally underestimated. If sufficient information and computational resources are available, stochastic models (either optimization or simulation) are generally superior (Loucks et al., 1981).

Static vs. Dynamic Models

Models vary in the manner in which changes to model parameters occur over time. In a particular watershed, for example, while actual or predicted streamflows might vary over time, the probability distribution for the streamflows may not change appreciably from one year to the next, and may thus be considered static within the corresponding model. Dynamic models, on the other hand, assume changing conditions over time and attempt to incorporate such changes into the analyses being conducted (e.g., climate change models [Lane et al., 1999; Lettenmaier et al., 1999]). Dynamic models tend to be more complex and require more computational effort to solve, but usually provide more accurate results, assuming that adequate data are available to calibrate the models appropriately; this is particularly true for investment models. Static models can be significantly larger in scope. Models may be static in terms of some factors (e.g., physical characteristics) but dynamic in terms of others (e.g., economies).

Investment vs. Operations/Management Models

Models may also be classified in terms of the time frame within which the analysis is being performed and for which the resulting decision will be made. Long-term decisions dealing with selecting investment strategies including things like physical changes to facilities (reservoir capacity expansion or hydroelectric facility development, for example) are characteristically different from short-term decisions, such as determining the appropriate reservoir release at a particular point in time. Models used to develop operating or management strategies for a water resource system can generally be more detailed than those designed to recommend longer-term investment decisions, which frequently consider actions taken over multiple time periods.

Lumped vs. Distributed Data Models

Lumped data models are those that assume single values (e.g., average monthly rainfall or average hydraulic conductivity for a 1 km^2 area) for parameters that might be represented better with a finer discretization of space or time. Distributed data models use a finer resolution of parameters through time or space (e.g., daily rainfall or hydraulic conductivity for each 100 m^2 area) to represent the same system. Clearly, distributed data models require considerably more data and probably computational effort while potentially providing a much more realistic representation of the physical system being studied. Lumped parameter models are generally much more efficient to solve and may be appropriate

in cases where insufficient or incomplete data sources are available. With the explosive growth in the use of geographic information systems and corresponding availability of spatial data, distributed data models are becoming much more popular, at least within the research arena [Maidment, 1993].

39.2 Evaluation of Management Alternatives

For any given water resources problem, an alternative may be represented as a set of investment decisions, each having a specific time-stream of costs and benefits. The level of each investment is a variable, the best value of which depends on the values of other variables and the goals and objectives of the decision maker. Hence, each alternative may have many impacts that result in numerous economic gains and losses (benefits and costs) that occur at different times, different locations, and accrue to different individuals or groups. The evaluation of the gains and losses associated with any particular alternative may be complex. However, without this analysis, the selection of the best alternative will be impossible.

The questions that must be considered systematically by the water resources engineer in providing meaningful guidance to the decision maker are: (1) how should each variable be evaluated economically? (2) what is the set of values for these variables such that the resulting alternative best satisfies a given objective? and (3) what is the best set of alternatives, and how can one be assured that there are no better alternatives? A number of proven modeling techniques are available to address these questions.

Consider a set of alternate water resources projects P consisting of individual projects $p \in P$. Each project may be specified as a set of values for a discrete number of decision variables x_p^j, $j = 1, 2, \ldots, n_p$. Each project is fully specified by a vector of these decision variables and their values, represented by X_p. A common goal of water managers is to identify that plan which maximizes net benefits (NB):

$$Maximize \sum_{p \in P} NB(Xp) \tag{39.6}$$

When the benefits (or costs) of a particular project alternative are most properly evaluated in economic terms, the value of a particular investment component of any given project depends at least in part on the timing of that particular investment. Because different water resources investment alternatives may have different useful lives, it is important that they be compared using a common framework. While a comprehensive treatment of engineering economic analysis is beyond the scope of this handbook, a brief outline of an approach to valuing alternatives is offered. Basic understanding of the time value of money, as well as finance principles, is important in an overall analysis of complex investment strategies. The interested reader is referred to Jenkins et al. [2001]; Blanchard and Fabrycky [1990]; Fabrycky and Blanchard [1991]; Grant et al. [1990]; and White et al. [1989] for additional information on performing comprehensive engineering economic analysis.

Discount factors are used to determine the value of a particular investment over time.

Let PV = the present value of an amount of money (principal)
FV = the future value of an amount (or value) of money,
i = the interest rate each period, and
n = the life (in periods) of the investment.

Given an investment at the present time, the future value of that investment n time periods into the future is given by the single-payment, compound-amount factor

$$FV = PV(1+i)^n \tag{39.7}$$

The present value of costs (or benefits) resulting from some future payment is computed using the reciprocal of this factor, which is referred to as the single-payment, present-worth factor:

$$PV = FV(1+i)^{-n} \tag{39.8}$$

Suppose that a particular investment (water resources project, for example) is anticipated to return a stream of future net benefits NB_t over T discrete time periods, $t = 1, 2, \ldots, T$. The present value of this stream of benefits is computed:

$$PV = \sum_{t=1}^{T} NB_t(1+i)^{-t} \tag{39.9}$$

It is also possible to represent the present value of net benefits (PV) of a project as an equivalent uniform or constant stream of net benefits over a horizon of T periods. Let A equal a constant amount of money each period. Then,

$$A = PV * CR \tag{39.10}$$

where CR is the capital recovery factor defined as:

$$CR = \left[i(1+i)^T\right] \Big/ \left[(1+i)^T - 1\right] \tag{39.11}$$

As a supplement to using present value of net benefits as a criterion to evaluate projects, the computation of a benefit-cost ratio — present value of benefits (PVB) divided by present value of costs (PVC) — is often used to perform preliminary screening of alternatives:

$$B/C = PVB/PVC \tag{39.12}$$

Alternatives having a benefit-cost ratio less than 1.0 should be removed from further consideration. However, because costs are typically easier to identify and estimate, care should be used in itemizing and valuing project benefits for this purpose.

For public investments, the appropriate interest rate to be used in comparing projects is a matter of public record and is based on the average yield on federal government bonds having approximately the same maturity period, the economically useful life of the project being evaluated [Water Resources Development Act of 1974 (P.L. 9302511)]. The assumption of a constant interest rate is standard practice for these types of investments. A comprehensive discussion of inflationary considerations in project evaluation is presented in Hanke et al. [1975].

39.3 Water Quantity Management Modeling

Among the largest public investments are those designed to stabilize the flow of water in rivers and streams. A stream that may carry little or no water during a significant portion of the year may experience extremely large (perhaps damaging) flows during peak periods. A storage reservoir may be employed to retain water from these peak flow periods for conservation use during low-flow periods (water supply, low-flow augmentation for environmental protection, irrigation, power production, navigation, recreation, etc.) or to contain peak flows for purposes of reducing downstream flood damage (flood control). In this section, methods for managing surface-water quantity pursuant to the development of comprehensive management alternatives are presented.

The management of a reservoir or system of reservoirs is achieved through a set of operating rules, that govern releases from the reservoir as a function of such things as inflows into the impoundment, demand for water, storage volumes, and reservoir elevations. Design of the reservoir storage volume, the spillway, and other reservoir components depends on these rules.

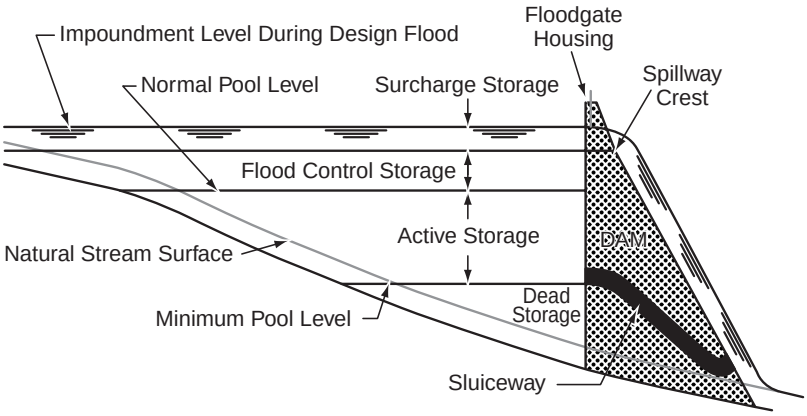

FIGURE 39.2 Schematic cross section of a typical reservoir system showing the relative location of different storage types.

Deterministic Reservoir Models

While there is always a significant amount of uncertainty in any hydrologic system, preliminary analysis of alternatives may be accomplished using deterministic models — models that do not explicitly consider uncertainty in hydrologic variables. Deterministic methods are particularly useful as screening models, which can identify alternatives for further analyses using more complete and thorough system representations.

Reservoir Storage Requirements

The factors that determine the extent to which streamflows can be stored for future use are: (1) the capacity of the impoundment, and (2) the manner in which the reservoir is operated. It is important to realize that the use of a reservoir to manage streamflows will necessarily result in a net loss of total water due to evaporation and seepage. Only if the benefits of regulation will be greater than these losses should a reservoir be utilized. Thus, the main goal of storage-reservoir design is a thorough analysis of the relationship between firm yield — the maximum quantity of flow that can be guaranteed with high reliability at a given site along a stream at all times — and reservoir capacity.

The impoundment behind a reservoir consists of three components (Fig. 39.2): (1) dead storage — that volume used for sediment control and retention of a permanent pool; (2) active storage — that volume used to meet water demands such as water supply irrigation, conservation, recreation, and power production (head); and (3) flood control storage — that volume of the reservoir reserved to contain flood flows, thereby protecting downstream assets. The determination of reservoir capacity and operating strategy should consider all three storage components with a goal of achieving a least-cost design strategy (total storage volume) that satisfies a predetermined set of operational constraints.

A variety of methods are available for performing these analyses including the mass diagram analysis [Rippl 1883; Fair et al., 1966], which finds the maximum positive cumulative difference between a sequence of specified reservoir releases and known historical (or simulated) inflows; the sequent peak procedure [Thomas and Fiering, 1963], which is a bit less cumbersome than the mass diagram method; and a variety of optimization methods [see, for example, Yeh, 1982], which can consider multiple reservoir systems.

The optimization methods incorporate mass balance constraints of the following form:

$$ST_{t+1} = ST_t + PP_t + QF_t - RR_t - EV_t \tag{39.13}$$

where ST_t = storage volume in the reservoir at the beginning of time period t
PP_t = precipitation volume on the reservoir during time period t

QF_t = reservoir inflow volume during time period t
RR_t = reservoir release volume during time period t
EV_t = evaporation volume from the reservoir during time period t

Defining K_a as the minimum active storage capacity of the reservoir for a specified firm yield release level R^* the optimization model, with variables on the left-hand-sides of the constraints and known quantities on the right-hand-sides is:

$$\text{minimize } K_a \tag{39.14}$$

subject to:

conservation of mass in each period

$$ST_{t+1} - ST_t + R_t = -R^* + PP_t + QF_t - EV_t \qquad t = 1, 2, \ldots, T \tag{39.15}$$

reservoir capacity cannot be exceeded:

$$ST_t - K_a \le 0 \qquad t = 1, 2, \ldots, T+1 \tag{39.16}$$

storage and release volumes cannot be negative.

$$\begin{aligned} ST_t &\ge 0 \qquad t = 1, 2, \ldots, T+1 \\ R_t &\ge 0 \qquad t = 1, 2, \ldots, T \end{aligned} \tag{39.17}$$

where R_t is the volume released in period t in excess of the firm release R^*.

The model can be solved to find optimal values for K_a, S_t, and R_t, and can be solved repeatedly with different values of R^* to find the relationship (trade-off) between minimum reservoir storage and firm yield. This is a deterministic model that uses a particular sequence of streamflows and the estimates of required storage volume are dependent on the adequacy of this streamflow sequence to represent the actual stochastic nature of the streamflows. In addition, because the entire sequence of streamflows is assumed to be known in advance as far as the optimization model is concerned, the results may be less conservative than expected.

Flood Control Planning

Prevention (or mitigation) of damage due to flooding may be achieved by: (1) containing excess streamflow in upstream reservoirs, or (2) confining the excess flow within a channel using levees, flood walls, or closed conduits. Flood flows generally occur during certain periods of the year and last for relatively short periods. The likelihood of a flood event of a given magnitude is described by its return period: the average interval in years between the occurrence of a flood of a specified magnitude and an equal or larger flood.

The probability that a T-year flood will be exceeded in any given year is $1/T$. Let PQ be a random annual peak flood flow and PQ_T a particular peak flood flow having a return period of T years. Then the probability of PQ equaling or exceeding PQ_T is given by:

$$\Pr\left[\text{PQ} \ge \text{PQ}_T\right] = 1/T \tag{39.18}$$

For continuous distributions

$$\Pr\left[\text{PQ} \ge \text{PQ}_T\right] = 1 - F_{PQ}\left(\text{PQ}_T\right) \tag{39.19}$$

TABLE 39.1 Reservoir Operation Priorities in HEC-5

Condition	Normal Priority	Optional Priority
During flooding at downstream location	No release for power requirements	Release for primary power
If primary power releases can be made without increasing flooding downstream	Release down to top of buffered pool	Release down to top of inactive pool (level 1)
During flooding at downstream location	No releases for minimum flow	Release minimum desired flow
If minimum desired flows can be made without increasing flooding downstream	Release minimum flow between top of conservation and top of buffered pool	Same as normal
If minimum required flows can be made without increasing flooding downstream	Release minimum flow between top of conservation and top of inactive pool	Same as normal
Diversions from reservoirs (except when diversion is a function of storage)	Divert down to top of buffered pool	Divert down to top of inactive pool (level 1)

Source: US Army Corps of Engineers, 1982.

Or

$$F_{PQ}\left(\mathrm{PQ}_T\right) = 1 - \left(1/T\right) \tag{39.20}$$

where $F_{PQ}(\mathrm{PQ}_T)$ is the cumulative distribution function of annual peak flows.

The peak flow at any potential damage site resulting from a flood of return period T will be some function of the upstream reservoir flood storage capacity K_f and the reservoir operating policy:

$$\mathrm{PQ}_T = f_T\left(K_f\right) \tag{39.21}$$

By assuming a reservoir operating policy for flood flow releases and using an appropriate flood routing simulation model, the function $f_T(K_f)$ can be defined by routing different floods through the reservoir using different storage capacities K_f. Damage functions can then be derived using field surveys at potential damage sites [James and Lee, 1971].

As an alternative to containing peak flows in upstream reservoirs in order to protect downstream sites, channel modifications at the potential damage sites can be implemented. Frequently, combinations of upstream containment and at-site improvements are considered.

In addition, a number of nonstructural measures have been adopted to reduce the impact of flooding [Johnson, 1977]. Nonstructural measures include moving people and damagable facilities out of the flood plain, thereby incurring the costs of relocation but reducing the losses of flooding.

If cost functions can be assumed for various improvement alternatives — structural and nonstructural, optimization models can be constructed to identify least-cost options for improvements or for determining optimal strategies using benefit-cost analyses [Loucks et al., 1981].

Among the most widely used reservoir simulation models is the U.S. Army Corps of Engineers Hydrologic Engineering Center HEC-5 program [U.S. Army COE 1982]. This model was developed to assist in the analysis of multipurpose, multireservoir systems, and contains routines to model flood control operation (including the computation of expected annual damages), determination of firm yield, hydropower systems simulation, multiple-purpose multiple-reservoir system operation and analysis, and simulation of pumped-storage projects. The model incorporates an operating priority as set forth in Table 39.1.

Water Supply Objectives

The model, discussed above may explicitly consider the net benefits that would result from the provision of water for domestic, commercial, and industrial water supplies, as well as supplies for irrigation and other agricultural uses. Nonagricultural water users generally base their investments on the availability of firm water yields because of the importance of the water input. A benefit function can be incorporated directly into the model (usually as an objective function in an optimization model), provided that the

expected net benefit of some specified target allocation can be assumed. Constraints are included to ensure that the allocation to meet demand in any period not exceed the available yield at that time and location. For those water uses for which economic benefit/loss data are available, constraints specifying minimum acceptable allocations can be used.

Analysis of agricultural investments is generally more activity-specific than for nonagricultural users of water and should thus consider additional input factors such as the availability of capital, labor, and seasonal availability of water. Frequently, a detailed model is used for each irrigation site within a region or watershed and may contain detailed information about soil types, cropping patterns, rainfall and runoff profiles, variation in crop yield as a function of water allocation, and perhaps market crop pricing. In cases where detailed irrigation analyses are not possible, a general benefit function may be assumed and incorporated into the planning model. A more complete discussion of the factors to be included in the analysis of water use for irrigation may be found in Chapter 14 of Linsley et al. [1992].

Power Production Objectives

The potential for power production at a reservoir site depends on the flow rate of water that can pass through generation turbines and the potential head available. Power plant capacity is the maximum power that can be generated under normal head at full flow, while firm power is the amount of power that can be sustained, available 100% of the time. Firm energy is the energy produced with the plant operating at the level of firm power. Power that is generated in excess of firm power is called secondary or interruptible power.

The problem of determining reservoir storage sufficient to produce a specified firm energy (or some surrogate benefit function) is similar to that of determining firm yield but, because firm energy, flow rate, gross head, and storage are nonlinearly related, it is more difficult to estimate. Nonlinear optimization models and, in some cases, mass curve analysis, may be used to estimate the minimum storage necessary to provide a given firm yield. More common linear optimization models may be used to analyze hydropower potential: typically, a value of head is assumed, thereby linearizing the power equations; the resulting optimization model is solved; and the actual heads are compared to the assumed values. Adjustment of the assumed values can be made if the discrepancy is too large, and the process is repeated. Simulation models may also be used to evaluate power potential, but they require an explicit specification of the operating rules for the reservoir. A more complete discussion of the use of optimization models to size and control hydropower reservoirs can be found in Major and Lenton [1979]; Loucks et al. [1981]; and Mays and Tung [1992].

Flow Augmentation and Navigation

It is often desirable to use water stored in a reservoir to augment downstream flows for instream uses such as natural habitat protection, recreation, navigation, and general water quality considerations. Not only is the volume of flow important, but the regulation of water temperature and other quality characteristics may also be of concern. Dilution of wastewater or runoff such as from agricultural sources is another potential objective of reservoir management. Assuming that appropriate target values can be established for flow augmentation during different times of the year, these considerations may readily be incorporated into simulation and optimization models used for developing reservoir-operating strategies. By constraining the appropriate streamflow yields at a specific time and location to be no less than some minimal acceptable value, it is possible to estimate the degradation in the resulting value of the objective function (or quantifiable net benefits) that would result from such a policy.

Real-Time Operations

Long-term operation, and planning models attempt to address questions such as: how large should the storage volume (reservoir) be? what type, and capacities of turbine, would be best for hydroelectric energy production? and how much freeboard should be allocated for flood control? Many long-term operations

and planning models are based on a time scale of months or seasons (and sometimes, weeks), so that any operating rules from these models serve as guides to real-time operations but do not well define the operating policy to be followed in the short term.

Real-time operations models attempt to answer the question of how best to operate a reservoir or water control system in the short term (perhaps hours or days), using the existing physical system. Real-time operations models can have all of the model characteristics already described but they typically differ because: (1) they have a short time horizon (days, or weeks compared to years); and (2) they are used repeatedly. For example, at the beginning of a particular day, the system state — current storages, anticipated flows for the next week, etc. — is input to the model; the model is solved to determine the optimal releases to be made during each of the next seven days; the recommended release for today is actually made and at the beginning of tomorrow, the whole process is repeated with the actual new system state and forecasts.

System Expansion

The water resources management models discussed thus far have assumed a single (static) planning horizon with constant parameters (demand, release targets, etc.). More typically, investments of this magnitude span many years, during which change is continuous. While these models provide reasonable solutions for a particular future time period, they are not well suited for analyses over multiple time periods or when multiple stages of development are required. When longer-term planning is required, dynamic expansion models should be considered. Two types of optimization models are used most frequently to select an investment sequence: integer programming, and dynamic programming.

The capacity expansion integer program assumes a finite set of expansion investments for each project site over a finite number of time periods, $t = 1, 2, \ldots, T$. If the present value of net benefits of each investment is known as a function of when that investment is undertaken (NB_{st} = net present value of benefits if investment at site s is undertaken in time period t), then an objective function can be written to maximize total benefits across all project, during the planning period:

$$\text{Maximize} \sum_t \sum_s NB_{st} * X_{st} \tag{39.22}$$

where $X_{st} = 1$, if investment s is undertaken in period t, and 0, otherwise.

Constraints ensuring that each investment can be undertaken only once (or that each must be undertaken exactly once), constraints on total expenditures, and constraints that enforce requirements for dependencies among investments may also be included if necessary in this capacity expansion model. This model can also be used to determine the optimal magnitude of a particular investment, such as determining the optimal net increase in storage to add to a particular reservoir. [Morin, 1973; Loucks et al., 1981].

Integer programs are relatively easy to develop but computationally expensive to solve. In contrast, dynamic programming is an alternate approach for solving capacity expansion problems, and one that has become extremely popular among water resources professionals. Dynamic programming is particularly useful for determining strategies for making decisions about a sequence of interrelated activities (investments) where nonlinearities in the objective function or constraints are present. These models tend to be more efficient to solve but, because there are only limited commercial solution packages available for dynamic programs, they may require more time and care to develop [Mays and Tung, 1992; Esogbue, 1989].

Stochastic Reservoir Modeling

The deterministic modeling approach discussed above is based on an assumed profile of system inputs (e.g., streamflows). However, the historical record of streamflows upon which these analyses are typically based may not be sufficiently representative of long-term conditions. In stochastic reservoir modeling,

available records are considered to be only a sampling of long-term hydrologic processes and are thus used to estimate the statistical properties of the underlying stochastic process. Two approaches have been developed to use the resulting stochastic model: (1) incorporate the stochastic model (e.g., a Markov model of streamflow) directly in an optimization model; and (2) use the stochastic model to generate synthetic records, which are then used as inputs for a set of deterministic models.

Consider the second option — generating synthetic records that reflect the main statistical properties of the observed historic flows (mean, standard deviations, first-order correlation coefficients, etc.). Multiple sets of these streamflow records may then be used in a variety of river basin models. (Synthetic sequences of other processes are frequently used in river basin simulation modeling, including rainfall, evaporation, temperature, and economic factors.) There are two basic approaches to synthetic streamflow generation. If a representative historic record is available, and if streamflow is believed to be a stationary stochastic process (wherein the main statistical parameters of the process do not change with time), then a statistical model can be used to generate sequences that reproduce characteristics of that historic record [Matalas and Wallis, 1976]. For river basins or watersheds that have experienced significant changes in runoff due to such factors as modified cropping practices, changing land use, urbanization, or major changes in groundwater resources (see Chapter 32), the assumption of stationarity may not be valid. In these instances, rainfall runoff models may be useful in generating streamflow sequences that can be used effectively for water resources engineering [Chow et al., 1988].

The use of synthetic sequences in simulation models is an acceptable way of dealing with uncertainty in the analysis of water resource planning and management alternatives. Recall, however, that simulation models are unable to generate optimal alternatives. The optimization modeling methodologies discussed previously can also incorporate hydrologic variability (and process uncertainties) for solution by the appropriate optimization algorithms.

The direct incorporation of the stochastic model within an optimization model permits explicit probabilistic constraints or objectives to be included [Loucks et al., 1981]. One example of this approach to the incorporation of hydrologic uncertainty into surface-water optimization models is through the use of chance constraints, which can suggest optimal reservoir size and operating strategy while enforcing prespecified levels of reliability for release and storage requirements [ReVelle et al., 1969; ReVelle, 1999; Sniedovich 1980). This technique involves the transformation of probabilistic constraints into their deterministic equivalents. Here is a probabilistic constraint on storage volumes:

$$\Pr\left[S_{\min,t} \le ST_t\right] \ge \alpha_{STt} \qquad t = 1, 2, \ldots, T \tag{39.23}$$

which ensures that the probability of the storage at the beginning of time period t being greater-than-or-equal-to a minimum storage value ($S_{\min,t}$) will be greater than or equal to some specified reliability level (α_{STt}). Similarly, for reservoir release levels:

$$\Pr\left[R_{\min,t} \le R_t \le R_{\max,t}\right] \ge \alpha_{Rt} \qquad t = 1, 2, \ldots, T \tag{39.24}$$

The result is a set of decision rules (often linear) that relate releases from the reservoir to storage, inflows, and other model decision variables [ReVelle, 1999]. This methodology can be extended to help determine strategies for planning and operating multiple reservoir systems having multiple water uses.

Water Quality Modeling

The quality of water in a stream, lake, or estuary, or the quality of groundwater is often as important as the quantity of water available. The range of pollutants of concern (e.g., heavy metals, solids, organics, heat), water quality indices (e.g., biochemical oxygen demand — BOD, temperature, total suspended solids — TSS), and specific treatment methodologies are extensive, and are described in the "Environmental Engineering" section and the "Quality of Urban Runoff" chapter of the Handbook. The impacts of these pollutants range from negligible to life-threatening.

The ability to model water quality in the natural environment has improved rapidly over the past century [see for example, Thomann, 1997]. For example, the Enhanced Stream Water Quality Model (QUAL2E) from the US Environmental Protection Agency can be used to simulate the major reactions of benthic and carbonaceous demands, atmospheric reaeration, nutrients, and algal production, and their effects on the dissolved oxygen balance in well-mixed, dendritic streams. More than a dozen water quality constituent concentrations can be modeled (www.epa.gov/docs/QUAL2E_WINDOWS). QUAL2EU is an enhancement of QUAL2E that allows uncertainty analysis to be performed.

Three-dimensional water quality models have also been developed and are in regular use. One example is the Chesapeake Bay Estuary Model (www.chesapeakebay.net/model.htm) that is three-dimensional and includes a hydrodynamics submodel as well as a water quality submodel. In addition, the estuary model is directly linked to a watershed model that predicts inputs to the estuary based on land use and other factors. It is also linked to an airshed model that predicts inputs to the estuary coming from the atmosphere. Thus, water quality models can be incorporated directly into larger and more comprehensive simulation and optimization modeling programs.

Groundwater Modeling

Comparable modeling approaches have been developed and used to solve quantity and quality problems associated with groundwater. The modeling approaches include optimization and simulation, lumped and distributed, deterministic and stochastic, and static and dynamic modeling. Further, the coupling of surface water and groundwater models to represent the actual surface and groundwater systems better is now routinely considered. For a complete description of these problems and the modeling methods used to solve them, see Freeze and Cherry [1979], Willis and Yeh [1987] and Delleur [1999].

39.4 Data Considerations

For at least four reasons there is a continuing great deal of interest in the use of spatial data as a framework for conducting water resources engineering: (1) enormous resources are being expended to collect and maintain water resources and physical attribute data within a spatial context; (2) there is a clear relationship between physical land features, which are spatially distributed, and hydrologic surface and subsurface processes [Maidment, 1993]; (3) geographic information systems (GIS) have matured to the point that they can be used to simulate hydrologic processes [Engel et al., 1993; Englund, 1993]; and (4) the integration of water resources models, spatial databases, and sophisticated user interfaces has resulted in the development of powerful (spatial) decision support systems that can be understood and used by water professionals [Fedra,1993].

Geographic information systems is a technology for storing, manipulating, and displaying geo-spatial data. While the data manipulation capabilities of GIS are still improving, the computational sophistication of these systems and the efficiency with which they can store and display data are impressive [Star and Estes, 1990]. A framework for integration of these spatial databases, traditional lumped parameter data and contextual information, with specialized water resources models is presented in Fig. 39.3. Physical, hydrologic, and possibly biological and economic data are represented as attribute maps or "layer" (A_1 - slope, A_2 - soils type, A_3 = vegetation, A_4 - depth to aquifer, etc., for example). Lumped parameter information and model parameters might be stated in a database or provided by monitoring instrumentation. The model base might include optimization screening models, or more detailed simulation models. The user would interact with the models through a graphical user interface that would allow such options as display of systems status, modification of system parameters and data sets, and display of model results.

In addition to advances in spatial data management and conventional (simulation and optimization) modeling technologies, the use of other nonprocedural modeling technologies is also being explored to improve our understanding of water resource, systems. Though simulation models have become a more important part of the technology of water resources systems engineering, many well-known and -accepted

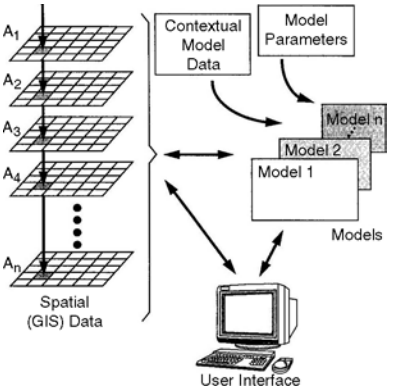

FIGURE 39.3 Functional representation of a spatial decision support system for water resources planning and management that integrates geo-referenced spatial and non-spatial data, one or more specialized models, and a custom user interface.

programs have become extremely large and complex precluding the use by inexperienced professionals. In addition, some system relationships are too poorly understood to be simulated, but may be well understood (or at least expertly managed or operated) by an individual, who possess special knowledge and expertise. Expert systems and other techniques from the field of artificial intelligence, such as artificial neural networks may be used to model water resources systems when such is the case [see, for example Bender et al., 1993; Fernandez and Naim, 2001; Davis et al., 1990].

Defining Terms

Active storage — The portion of water in a reservoir that is used to meet societal needs, such as for water supply, irrigation, etc.

Conservation — The confinement of excess flows for future societal use.

Constraints — Functional relationships that limit collective values of decision variables in optimization models.

Dead storage — The portion of water in a reservoir that is used for sediment collection and retention of a permanent pool.

Decision variable — An operational or design parameter the value of which is to be determined through formal analysis (for example reservoir capacity).

Deterministic models — Models whose inputs and parameters are assumed to be known with certainty.

Dynamic models — Models of processes the main characteristics of which are believed to change significantly over time.

Expansion model — Models that can analyze water resources investments over multiple time or planning horizons.

Firm energy — The energy produced with the plant operating at the level of firm power.

Firm power — The amount of power that can be sustained available 100% of the time.

Firm yield — The largest flow of water that can be provided continuously from a stream or reservoir.

Flood control storage — Portion of volume in a reservoir that is reserved for storing excess flow during flooding to protect downstream assets.

Future value, FV — The future value of an amount (or value) of money.

Geographic information systems, GIS — Spatial database technology used increasingly for water resources planning and management.

Gross head — The difference in elevation between the water surface immediately upstream of the reservoir structure and the elevation of the point where the water enters the turbine.

HEC-5 — A simulation model developed by the U.S. Army Corps of Engineer, designed to be used in evaluating multipurpose, multireservoir systems.

Impoundment — The volume of water stored behind a water resources reservoir.

Interest rate, i — The fraction of borrowed capital paid as a fee for the use of that resource.

Interruptible (secondary) power — Power that is generated in excess of firm power; cannot be sustained.

Optimization model — A rigid modeling structure commonly used for water resources planning and management.

N — The life (in periods) of an economic investment.

NEPA — The National Environmental Policy Act of 1969.

Net benefits, NB — The total value of benefits expected to result from some investment minus total costs.

Objective function — The function used to evaluate feasible management alternatives.

Operating rules — The policy for operation of a water resource system expressed as a set of management rules.

Optimization — A modeling procedure that determines the optimal values of the decision variables of a model.

Plant capacity — The maximum power that can be generated under normal head at full flow.

Present value, PV — The present value of an amount of money (principal).

Return period, T — The average interval in years between the occurrence of a flood of a specified magnitude and an equal or larger flood.

Rule curve — A guide to reservoir operation typically depicted as a graph showing target storage volume vs. time of the year.

Simulation — A modeling methodology that is used to describe the structure and function of a system. The model may be used to find good solution strategies for a variety of management problems.

Static models — Models of processes the major characteristics of which are assumed to not change significantly ever time.

Stochastic models — Models whose inputs and parameters are assumed to follow specified probability distributions.

Synthetic record — A streamflow sequence that is generated based an statistical properties from the historic record of streamflows.

40.1 Introduction

Concrete has been the most common building material for many years. It is expected to remain so in the coming decades. Much of the developed world has infrastructures built with various forms of concrete. Mass concrete dams, reinforced concrete buildings, prestressed concrete bridges, and precast concrete components are some typical examples. It is anticipated that the rest of the developing world will use these forms of construction in their future development of infrastructures.

In pre-historic times, some form of concrete using lime-based binder may have been used [Stanley, 1980], but modern concrete using Portland cement, which sets under water, dates back to mid-eighteenth century and more importantly, with the patent by Joseph Aspdin in 1824.

Traditionally, concrete is a composite consisting of the dispersed phase of aggregates (ranging from its maximum size coarse aggregates down to the fine sand particles) embedded in the matrix of cement paste. This is a Portland cement concrete with the four constituents of Portland cement, water, stone and sand. These basic components remain in current concrete but other constituents are now often added to modify its fresh and hardened properties. This has broadened the scope in the design and construction of concrete structures. It has also introduced factors that designers should recognize in order to realize the desired performance in terms of structural adequacy, constructability, and required service life. These are translated into strength, workability and durability in relation to properties of concrete. In addition, there is the need to satisfy these provisions at the most cost-effective price in practice.

The quality of concrete in a structure is determined not only by the proper selection of its constituents and their proportions, but also by appropriate techniques in the production, transportation, placing, compacting, finishing, and curing of the concrete of the actual structure, often at a job site. Although these processes have an impact on the actual quality of concrete achieved, they are not included under this chapter. Sources for such information include publications of concrete institutes in various countries, e.g., American Concrete Institute in the U.S. and the Concrete Society in the U.K.

The subject of concrete covers a very broad scope and a wealth of in-depth knowledge. This chapter is intended to provide a brief guide on the more important aspects for civil engineers rather than for concrete specialist in research or production of concrete. There are many textbooks and references besides those cited in this chapter from which more detailed information may be obtained. Some of these are listed under Further Information.

This chapter covers topics on the constituents and the properties of concrete. The engineer is concerned with both the properties of concrete in its fresh as well as its hardened state. The way fresh concrete is handled and the treatment of the hardened concrete at its early age have major influences on its as-built quality. These impact the resultant performance of the concrete structure as designed by the engineer.

Since the information provided in this chapter targets readers in English-speaking countries, it has selected information from two major practices, the American and the European (mainly British). This serves a wider range of users but also compares some common aspects of the two practices. An appreciation of the difference between the two practices is of importance in the coming years as more and more civil engineers practice on a global basis.

40.2 Constituents of Concrete

The constituents of modern concrete have increased from the basic four (Portland cement, water, stone, and sand) to include both chemical and mineral admixtures. These admixtures have been in use for decades, first in special circumstances, but have now been incorporated in more and more general applications for their technical, and at times economic benefits in either or both fresh and hardened properties of concrete.

Portland Cement

In the past, Portland cement is restricted to that used in ordinary concrete and is often called Ordinary Portland cement. There is a general movement towards grouping all types of Portland cement, included those blended with ground granulated slag or a pozzolan such as fly ash (also called pulverized fuel ash), and silica fume into cements of different sub-classes rather than special cements. This approach has been adopted in Europe (EN 197–1) but the American practice places them in two separate groups (American Society for Testing and Materials provides for Portland cement under ASTM C150 and blended cements under ASTM 595).

Raw materials for manufacturing Portland cement consist of basically calcareous and siliceous (generally argillaceous) material. The mixture is heated to a high temperature within a rotating kiln to produce a complex group of chemicals, collectively called cement clinker. Details of manufacturing process, the formation of these chemicals and their reactions with water are fully described in various textbooks (e.g., *Chemistry of Cement and Concrete*, 4th ed., Peter C. Hewlett, Ed). The name Portland originated from the similarity of Portland cement concrete to a well-known building stone in England found in the area called Portland. Portland cement is distinct from the ancient cement. It is termed hydraulic cement for its ability to set and harden under water.

Briefly, the chemicals present in clinker are nominally the four major potential compounds and several minor compounds (in small percentages, but not necessary of minor importance). The four major potential compounds are nominally (but actually impure varieties) termed as tricalcium silicate ($3CaO.SiO_2$), dicalcium silicate ($2CaO.SiO_2$), tricalcium aluminate ($3CaO.\ Al_2O_3$), and tetracalcium aluminoferrite ($4CaO.\ Al_2O_3.Fe_2O_3$). Cement chemists have abbreviated these chemical compounds to shorthand notations

TABLE 40.1 Listing of Cement Types (ASTM C150, ASTM 595 and EN 197–1)

European Designation		ASTM Designation	
Type	Description	Type	Description
I	Portland	I to V	Portland
II/A-S II/B-S	Portland-slag	I(SM)	Slag-modified Portland
II/A-P(Q) II/B-P(Q)	Portland-pozzolana	I(PM)	Pozzolan-modified Portland
II/A-D	Portland-silica fume	—	—
III/A III/B III/C	Blastfurnace	IS	Portland blast-furnace slag
IV/A IV/B	Pozzolanic	IP	Portland-pozzolan
V/A V/B	Composite	—	—

using C ≡ CaO; S ≡ SiO_2; A ≡ Al_2O_3; and F ≡ Fe_2O_3. Historically, because of their impure state, the compound C_3S is referred to as "Alite;" C_2S as "Belite;" C_3A as the "aluminate" phase and C_4AF as the "ferrite (or iron)" phase. In practice, two cements of the same potential compound composition may not necessarily behave in the same manner during the fresh and hardened states of concrete. The minor compounds of importance include the alkalis (sodium oxide and potassium oxide) and the amount of sulfate (mainly from added gypsum interground with clinker to prevent the violent reaction of tricalcium aluminate with the mixing water — flash set). The significance of these and other compounds in concrete is considered under the chapter on durability.

Cement may be marketed in bags (or sacks) but not necessarily of the same mass in different countries, (e.g., in U.S., a sack is of 94 lb, about 42 kg, but in U.K., a bag is of 50 kg). For ready-mixed concrete production, bulk delivery by cement tankers and pumped into plant silos is the most common practice. Hence, to avoid possible confusion, it is best to specify the amount of cement on the basis of mass, and not in number of bags, per unit volume.

Specifications for chemical and physical properties of cement are similar in most parts of the world. The approximate (not exactly equivalent) corresponding types of cement based on ASTM C150 and ASTM C595 to those based on EN 197–1 are shown in Table 40.1. For more information on the differences between the ASTM and EN standards, reference should be made to the specific standards. These include some differences in the percentages of components as well as physical and chemical properties of the cements and the details in the methods of determining these properties. Harmonizing of standards will be achieved through the development of ISO standards, a process that may take some time to be realized. The comparison provided is intended for guidance only.

The typical compositions in terms of Portland cement clinker and the other cementitious materials are shown in Tables 40.2(a) and (b). These cements are often called blended cements. The five types of Portland cement commonly used in the U.S. and their corresponding types in British standards are shown in Table 40.3.

Under ASTM, Type IA, IIA and IIIA in Table 40.2 are the corresponding cements with air entrainment capabilities. The role of entrained air is for resistance against freezing and thawing of concrete in cold climate. It is more common for air entrainment to be induced by a chemical admixture added at the time of mixing than by means of blended cements in shown in Table 40.2. By varying the dosage of air entraining agent added, the required air content in concrete is easily adjusted.

Among the five types of Portland cement, Type I is for general use with no special requirements. Type II is modified to provide moderate heat of hydration and moderate sulfate resistance. Type III has high early strength development, but currently most Type I cements have similar performance as Type III. Type IV has much lower heat of hydration but is not readily available, unless specially order where early

thermal stress is a critical factor. Type V has much lower C_3A content for better sulfate resistance. Currently, blended cements are more readily available to meet these special requirements. Details of such applications are provided in the section on blended cement and mineral admixtures.

In the specifications for Portland cements (e.g., ASTM C 150) the requirements in chemical composition are for the purpose of cement manufacturing. Civil engineers are more interested in the physical requirements in terms of fineness, strength potential and setting times. Fineness is an indication of the average size of cement grains after grinding. It is expressed in surface area per unit mass, generally in

the range of 300 to 400 m^2/kg. Fly ash is generally similar in fineness as ordinary Portland cement. Blast furnace slag may be ground finer or coarse than ordinary Portland cement. Silica fume is of very high fineness, often in the order of 20,000 m^2/kg. The higher fineness and better strength potential per unit mass of modern cements provide good early strength development and higher strength for the same water/cement ratio.

Strength potential of a cement is assessed by making mortar specimens with standard sand at a prescribed water/cement ratio and tested after curing under water at specified ages. ASTM and European standards specified different methods of making and testing of the mortar specimens. Each has it own specified grading for the standard sand, water/cement ratio, method of preparing test specimens and test methods. The specified 28-day strength of each type of cement depends on its composition. However, under EN 197–1, three different standard strength classes are specified with 28-day compressive strength of 32.5 MPa, 42.5 Mpa, and 52.5 MPa. Within each class, one with ordinary early strength (indicated by N) and another with higher early strength (indicated by R) are included. In relation to the specification requirements, strengths of modern cements are often found to be much higher than the specified values. To ensure uniformity for quality control in concrete production, some specifications have both a lower and upper limit for each strength class (e.g., EN 197–1 with a range of 20 MPa for 28-day strength).

The setting time of cement is determined using a paste of a prescribed initial stiffness. ASTM and European standards differ in the method of selecting the water/cement ratio for this stage. The subsequent testing using the "Vicat" needles is common to both. The difference between the values determined by these two approaches is not known, although the requirements on setting times are similar in cement specifications. The setting of cement as a constituent of concrete may be modified by the addition of chemical admixtures with either accelerating or retarding effects. Further information on this aspect is provided in the section of chemical admixtures below.

It is important to distinguish between the setting times determined for cement paste and those determined from wet-sieve mortar fraction of a concrete. The testing of both cement paste and for the mortar fraction of concrete is based on the principle of penetration resistance and for assessing the rate of stiffening of the respective composition, but their intended applications are very different. Cement paste testing is for production of cement; whereas in the case of concrete, it is associated with determining the change in stiffening rate of concrete due to the addition of a chemical admixture to control setting. To avoid confusion between the two cases, it may be useful to retain the term setting for cement and to refer to stiffening in the case of concrete.

Another physical property of Portland cement of interest to civil engineers is its density or specific gravity. This is determined by specified methods and does not vary much between batches from the same source of manufacture. Typical values for specific gravity of Portland cement lie within the range of 3.1 to 3.2. However, other cementitious materials, such as fly ash, slag or silica fume, generally have lower specific gravity values, in the range of 2.0 to 3.0. When blended cements are used in place of ordinary Portland cement, some minor adjustments are needed in computing the mass per cubic meter in the specified constituent proportions.

Supplementary Cementitious Materials

Supplementary cementitious materials commonly used in blended cement are fly ash, granulated blast furnace slag and silica fume besides natural pozzolans. They are also collectively called mineral admixtures, as distinct from chemical admixture (see later sections). Fly ash, also known as pulverized fuel ash (pfa), is fine particles in the flue gases after the burning of coal in power generation. There are spherical in shape and extracted by specially designed electrostatic precipitators, whereas the larger particles, which are not suitable for use as cement replacement materials, fall to the bottom of the furnace. The fineness of fly ash is of the same order as Portland cement (300 to 400 m^2/kg). Silica fume is also the fine particles collected the waste gases but is from the ferrosilicon industry. Due to its extreme fineness, (15,000 to 20,000 m^2/kg), it is densified (bulk density ranging from 130 to 430 kg/m^3) for ease of handling, hence it is often called condensed silica fume (csf). Ground granulated blastfurnace slag is a by-product of the

TABLE 40.4 Typical Composition of Cementing Materials

% by Mass	Portland Cement	Blast Furnace Slag	Low-lime Fly Ash	High-lime Fly Ash	Silica Fume
CaO	63	40	1	20	0
SiO_2	22	35	50	35	90
Al_2O_3	6	8	25	20	2
Fe_2O_3	3	0	10	5	2

production of iron in a blastfurnace. The molten slag from the furnace is rapidly cooled by water into glassy granulate form. The granulated slag is ground to fineness similar to that of normal cement, or finer for special applications. The grinding may be together with the cement clinker (intergrinding) or by separate grinding. Because slag is harder than clinker, intergrinding results in the clinker to be finer and that of slag coarser than the combined fineness. With separate grinding, both the slag and clinker may be ground to the same fineness. At times, slag is ground to a higher fineness to promote its rate of reactivity. The mineral admixtures may be blended for selected proportions in the plant as blended cement or added as an additional ingredient during batching of the materials into a mixer during concrete production. For the same combination of materials, either process produces similar resultant properties in both fresh and hardened concrete. Further details on the production of these mineral admixtures may be obtained from the publications listed under Further Information.

The specific gravity of fly ash, silica fume or slag is lower than that of Portland cement. Fly ash is normally in the range of 2.2 to 2.8 (ACI Committee 232), silica fume in the range of 2.2 to 2.3 (ACI Committee 234) and slag in the range of 2.9 to 3.0 (?) compared to 3.1 to 3.2 for Portland cement. Thus for the same mass of cementitious materials in a concrete mixture, the volume of these materials is slightly higher than for Portland cement.

The compounds found in mineral admixtures are similar to those in Portland cement but of different quantities. A comparison of typical chemical composition of the various cementing materials with Portland cement (Philleo, 1989) is shown in Table 40.4.

The hydration of the silicates in Portland cement produces calcium silicate hydrates and calcium hydroxide. When the concentration of calcium hydroxide is adequate to activate the silicates in the mineral admixtures, further calcium silicates are formed. This is known as pozzolanic reaction. In the case of blast furnace slag and high-lime fly ash there is sufficient calcium oxide in them for some degree of hydration to occur with the silicates. However, the strength developed by this self-activation process is generally too small for structural applications.

Calcium Aluminate Cement

Besides blended cements, there is another hydraulic cement used in construction. This is calcium aluminate cement, CAC (also called high alumina cement, HAC). The two major applications of CAC are as a refractory material and as a high resistance material for sewer pipe lining. In 1997, the Concrete Society reported on the study to re-assess the use of calcium aluminate cement in construction. Another recent source of information on the topic is the Proceedings of the International Conference on Calcium Aluminate Cements in 2001. Its resistance against biogenic sulfuric acid corrosion makes it most useful in sewer applications.

40.3 Aggregates

In general, aggregates in concrete have been grouped according to their sizes into fine and coarse aggregates. The separation is based on materials passing or retained on the nominally 5 mm (ASTM No. 4) sieve. It is common to refer to fine aggregate as sand and coarse aggregate as stone. Traditionally, aggregates are derived from natural sources in the form of river gravel or crushed rocks and river sand.

Fine aggregate produced by crushing rocks to sand sizes is referred as manufactured sand. Aggregates derived from special synthetic processes or as a by-product of other processes are also available. The use of such aggregates usually calls for special considerations not covered in this chapter. Similarly, lightweight or heavyweight aggregates for special applications are also not included. Some of these are listed in the "Further Information" section. This chapter considers only the ones classified as normal weight aggregates.

In most concrete mixtures, volume fraction of aggregates occupies more than double than that of the cement paste matrix. Hence, the physical properties of concrete are dependent on the corresponding properties of the aggregates. Civil engineers are more concerned with the physical, rather than the chemical or mineralogical, properties of aggregates. The only situation when mineralogical composition is of importance is treated under the chapter on durability in terms of alkali-aggregate reactions.

Although a full range of physical properties may be obtained, those of major interest to a civil engineer include specific gravity (or density), porosity and particle size distribution (or grading). Properties such as shape and surface texture of aggregates are usually stated in descriptive terms. They are not easily quantified and the semi-empirical test methods provide numerical values (e.g., elongation or flakiness index) that are limited to comparing different sources of supply in relative terms only. Others relate to thermal properties, e.g., specific heat and thermal coefficient of expansion are useful in specific applications such as mass concrete dams or thick sections. These topics are found in specialist literature. Some of these are listed in the "Further Information" section.

Each piece of aggregate may have a small amount of internal pores. These pores may be filled with water (saturated condition), partially or completely dry (oven-dry). Hence, bulk unit weight of aggregates may be expressed in the completely dry state (bulk specific gravity) or in the saturated state (bulk specific gravity, saturated-surface-dry basis). Specific test methods (e.g., ASTM C 127) are used to determine such values. They form the two extreme states of moisture in a particle of aggregate. In practice, the actual amount of moisture for aggregates stored under protection from the weather may be in between these two extremes.

When the pores of each piece of aggregate are filled with water, but without any water adhering on their surfaces, it is in its "saturated-surface-dry" (SSD) condition. The amount of water absorbed into the voids per unit mass of oven-dry aggregates is called the "absorption."

When the aggregates are placed together in bulk, there are voids between the particles. The packing of aggregates depends on their sizes and the amount of each size as well as the shape of the particles. The weight of a packing of aggregates in its dry state is called its dry-rodded unit weight when determined by ASTM C29 Method. It is an indication of the amount of cement paste needed to fill such voids. For a stockpile of sand, the particles are able to retain a significant amount of water within the voids. Thus the sand is above its saturated-surface-dry state. This additional amount of water held within the voids forms part of the water selected in mixture design. Together with the specific gravities of aggregates, they are factors of importance in mixture design.

The particle size distribution of an aggregate (often expressed as a percentage by mass of the total mass of aggregate) is called its grading. The separation into various sizes is based on a standard series of sieves of prescribed openings. In general, the successive sieve size has square openings with their sides based on the ratio of two, i.e., four times in the area of the openings.

The gradings of natural fine aggregates or sand depend on the source. The maximum size of particles is limited to those passing the 5 mm (4.75 mm in ASTM No. 4) sieve. Other than river gravels, coarse aggregates are produced in quarries by crushing of rocks. Standards usually provide overall limits on the grading of aggregates. The ideal grading is one that results in the least amount of voids when the total aggregates, both coarse and fine, are combined. The voids in the combined system have to be filled with cement paste in compacted concrete. Thus for a given set of requirements, such a combined grading leads to the most economic concrete as the cost of cement is much higher than that of aggregates. However, the best grading depends also on the shape of the particles. There is no standard approach to defining shape of aggregates although simple descriptive terms such as rounded, cubical, flaky or elongated are at times used.

The limits for fine and coarse aggregates (ASTM C33, BS 882) are shown in Table 40.5(a) and Table 40.5(b), respectively.

TABLE 40.5(a) Grading Limits of Fine Aggregate

Sieve Size		Percentage Passing		Cumulative Percentage Retained	
ASTM C33	BS 882	ASTM C33	BS 882	ASTM C33	BS 882
9.5 mm (3/8 in)	10.0 mm	100	100	0	0

150 μm (No. 100)	150 μm	2–10	0–15	98–90	100–85
			Total	338–215	401–115
			Fineness modulus	3.38–2.15	4.01–1.15

TABLE 40.5(b) Grading Limits of Coarse Aggregates

ASTM C33			BS 882		
Maximum Size	19.0 mm	12.5 mm	Maximum Size	20.0	14.0
Sieve Size	Percentage Passing		Sieve Size	Percentage Passing	
25.0 mm	100	—	37.5 mm	100	—
19.0 mm	90–100	100	20.0 mm	90–100	100
12.5 mm	—	90–100	14.0 mm	40–80	90–100
9.5 mm	20–55	40–70	10.0 mm	30–60	50–85
4.75 mm	0–10	0–15	5.0 mm	0–10	0–10
2.36 mm	0–5	0–5	2.36 mm	—	—

The maximum sizes of coarse aggregates commonly used are illustrated in Table 40.5(b). Other sizes up to 40 mm are used in mass concrete or concrete pavement.

Fineness modulus (FM) is the sum of the cumulative percentages retained on sieves (i.e., if each were the only sieve) starting from the size of 150 μm to the maximum size and divided by 100. It is often applied to fine aggregate as an indication of its fineness. It is to be noted that a fine grading has a lower value of fineness modulus. As shown in Table 40.5(a), for the upper (finest) and lower (coarsest) limits of fine aggregate, FM is 1.15 and 3.38, respectively. The same value of fineness modulus may be produced by two or more different gradings. However, a change in FM of 0.2 in fine aggregates may lead to a significant change is water demand for the same workability of a concrete mixture.

There are differences between the limits for ASTM and BS standards. In general, BS permits a wider range for grading of both fine and coarse aggregates. A grading in which one or more intermediate size fractions are missing is termed "gap graded." This is in contrast to the continuous grading commonly used. It has been found that satisfactory concrete mixtures can be obtained even for gradings that do not fall within the limits for one or more of the sieve sizes. A higher cement content and hence a higher cost is often incurred. However, this has to be compared to the cost of obtaining one of better grading from an alternate source.

Recycling of old concrete as aggregates has been much researched and some times applied. Information on such aggregates and their applications may be obtained from publications listed in the "Further Information" section.

40.4 Water

Water is needed for the hydration of cement but not all is used up for this purpose. Part of this added water is to provide workability during mixing and for placing. This latter usage can be reduced by the

introduction of chemical admixtures, e.g., plasticisers. Where possible, potable water is used. Other sources may contain impurities that introduce undesirable effects on properties of fresh and hardened concrete. A good list is given in the PCA Manual (Kosmatka and Panarese, 1988). Neville (1995) provides additional information on quality of mixing water. ASTM C94 and BS 3148 both provide guidance on acceptance criteria for water of questionable quality in terms of strength and setting time. However, the two sets of recommendations have slightly different limits. Additional, optional chemical limits using wash water from mixer washout operations are also stated in ASTM C94. The use of recycled materials is often promoted for sustainable development. Seawater should not be used as mixing water for reinforced concrete due to the presence of chloride and its effect on corrosion of steel reinforcement.

40.5 Chemical Admixtures

Unlike mineral admixtures, which may be introduced as blended cements, chemical admixtures are typically added during the mixing process of concrete production. Chemical admixtures are manufactured to specified standards, e.g., air-entraining admixtures to ASTM C260 and other types to ASTM C494. To a civil engineer, description of admixtures according to their function is more useful than based on their chemical compositions.

Air-Entraining Admixtures

Chemical admixture was first used in 1930s for entraining air into concrete to increase its frost resistance. The fine air bubbles with a close spacing provide partial relief as the liquid phase in concrete progressively freezes. Dodson (1990) clarified that air-entraining admixtures (AEA) do not generate air in the concrete. Their function is to stabilize the air present within the void system of the mixture and water as well air infolded and mechanically enveloped during mixing. Even without an AEA, concrete contains some air, which is often referred to as "entrapped" air. These air voids are typically 1 mm or more in diameter and irregular in shape. They often collect at the paste-aggregate interface. Entrained air bubbles are mainly within the paste with diameters typically between 10 μm and 1 mm. They are spherical in shape at close spacing. The spacing factor (ASTM C457 method), which is the maximum distance in the cement paste from the periphery of an air void, is usually in the range of 0.10 to 0.20 mm. The commonly recommended air content is 5 to 6% in the compacted concrete. Air bubbles promote workability but their presence reduces the strength of concrete. These factors are taken into consideration in the design of concrete mixtures.

Accelerating Admixtures

The use of accelerating admixtures is common during cold-weather concreting, as the rate of hydration of cement is decreased by lower temperatures. Their function is to increase the rate of hydration, thereby speeding up the setting time and early strength development. In the past, calcium chloride has been the most commonly used for this purpose. However, in recent years, the effect of chloride on the corrosion resistance of embedded steel reinforcement and prestressed tendons has been recognized. This has resulted in limiting the total chloride content in concrete at levels that is exceeded by the normal addition of calcium chloride as accelerating admixture. Currently, non-chloride accelerating admixtures are available, e.g., calcium nitrite (also a corrosion inhibitor). The use of calcium nitrite leads to a better strength gain at later ages than calcium chloride. However, this may not be of importance in practice as moist curing on site is limited to early ages only.

Water Reducing and Retarding Admixtures

Although each of the two functions may be obtained separately as indicated in chemical admixture standards, it is more typical to use both at the same time. This is also due to the fact that the two functions

are available in the typical materials used in their formulation, e.g., salts of lignosulfonic acids. In particular, both functions are useful in the case of hot-weather concreting.

The amount of mixing water in a typical concrete mixture is more than that needed for full hydration of the cement used. The excess water is intended to promote workability. However, when water is added to cement, there is a tendency for the cement particles to cluster together, forming into flocs. Some of the mixing water is trapped within the flocs and not available to contribute to the fluidity of the mixture.

Water reducing and retarding admixtures are surfactants and are adsorbed onto the surface of cement particles when added to the mixture. This induces a charge on to the cement particles thereby preventing their flocculation. The water so released improves the workability and the increase in surface of cement particles available for early hydration.

Water reducing admixtures provide the following potential applications:

(a) The simple addition of a dosage of the admixture to a plain concrete mixture increases its workability with only a small increase in the strength of the concrete — improving workability or plasticising action.
(b) By adding a dosage of the admixture, the mixture has the same degree of workability at lower water content and hence strength is increased if cement content remains the same — improving strength or water reducing.
(c) By adding a dosage of the admixture, the mixture may have the same degree of workability and strength by reducing both water content and cement content to retain its original water/cement ratio — saving cement. The cost of cement saved is generally more than the cost of admixture used — saving cost.

The effectiveness of a given dosage of water reducing and retarding admixture is reduced when the cement has a higher amount of alkalis or tricalcium aluminate. A higher fineness of the cement also has the same influence due to its larger surface area in adsorbing the admixture. Over a period of time, such variations in properties may occur even if it is supplied from the same cement manufacturer.

The requirements for admixtures are specified in terms of both water reducing and plasticising functions, e.g., ASTM C 494. The first generation of commercial water reducing admixtures, e.g., salts of lignosulfonic acids, provides about 10 to 15% reduction in water (minimum 5% in ASTM C 494). The second generation of water reducing admixtures enables about 15 to 20% in water reduction (minimum 12% in ASTM C494), e.g., sulfonated naphthalene formaldehyde, and is also called high range water reducing admixtures or superplasticisers. In recent years, the third generation of water reducing admixtures, e.g., carboxylate copolymers, has even higher water reducing capability as they enable the production of self-compacting concrete (no mechanical compaction required during concrete placing). The earlier types rely mainly of electrostatic repulsion of the same charge when the admixture is adsorbed on to the surfaces of cement particles. In the latest type, steric repulsion due to the long chain of the chemical plays a more important role in dispersing the cement particles. With the ability of progressive release of the chemicals by interacting with products of hydration, its high workability effect is prolonged (workability retention).

Retarding admixtures delay setting but not rate of strength development, except early strength when long retardation is provided. The effect of set retardation is assessed in terms of the time to develop a given degree of stiffness as indicated by the penetration resistance of the concrete. This is determined on the mortar fraction wet-sieved from a concrete mixture (ASTM C 403). The elapsed time after the initial contact of cement and water to reach a penetration resistance of 0.5 MPa (500 psi) is referred to as the initial setting time of concrete (not to be confused with initial set of cement by ASTM C 191). The time to reach a penetration resistance of 27.6 MPa (4000 psi) is referred to as the final setting time. A similar test method using the same principle but differing in some details in test method is specified in BS 5075 for chemical admixture tests. In addition to the 3.5 MPa penetration resistance, it includes the time to reach 0.5 MPa penetration resistance, but not for the 27.6 MPa. Although these are arbitrary limits selected for the purpose of testing chemical admixtures with specified mix proportions, they are approximately related to observed behavior in corresponding concretes as follows:

(a) Penetration resistance at 0.5 MPa (BS 5075 only) — limiting time for placing with initial workability.
(b) Penetration resistance at 3.5 MPa (BS 5075 and ASTM C 403) — limiting time for vibrating concrete without formation of cold joint (ASTM C 403 — initial set).
(c) Penetration resistance at 27.6 MPa (ASTM C 403 only) — final set or when compressive strength of standard 150mm diameter cylinder is about 0.7 MPa (100 psi).

When the above is applied to concrete mixtures in construction, their indicated significance should be taken as indicative only. The penetration resistance at an elapsed time after initial contact of water and cement is dependent on its initial stiffness (a physical factor involving mixture proportions of the mortar fraction, with or with chemical admixtures) and the change in stiffness due to cement hydration (chemical factor including the retarding effect of admixtures, if used). For example, a plain concrete with a higher water/cement ratio takes a longer time to reach the same penetration resistance than one at lower water/cement ratio even though the former tends to have a faster rate of reaction as the cement particles are more dispersed. Similarly, the test method (ASTM C 403) does not permit the use of a directly mixed mortar to simulate the mortar fraction of the concrete as this may lead to an increase in the setting times.

40.6 Hydration and Structure of Cement Paste

The chemical reactions of cement components and water are collectively called hydration. The two main types of components are the silicates and the aluminates. Under normal temperatures, the added gypsum is used up in reactions with the aluminates during the first one to two days. This can be delayed from taking place if the hydration process is subjected to high temperatures (exceeding about 70°C) during this stage (e.g., steam curing). The delayed reaction may take place at later ages causing undesirable expansion. The silicates react with water to form crystalline calcium hydroxide and a low crystalline calcium silicate hydrate called C-S-H gel. This structure has a typical gel porosity of about 26 to 28% with a very high specific surface (surface area per unit mass). The amount of water needed for full hydration of cement is about 20 to 25% by mass of cement. In addition, the gel pores also take up some of the mixing water. However, in practice, not all the mix water is used up in hydration and taken up by the gel pores. Depending on the amount of cement that has reacted, the balance of the water remains as much larger pores, often referred to as capillary pores. Gel pores, on the other hand, range from about 1 nm to about 0.1 μm. In well-hydrated cement paste, these fine pores results in extremely low permeability of the paste and a major factor for water tightness of properly cured concrete.

When water is added to cement, the first stage of reaction is very rapid but only for a short duration. The added gypsum prevents the reaction from becoming a "flash set." This is followed by a stage of very low reaction rate, called the "dormant period." This period can be extended by the used of chemical retarders (e.g., hot weather concreting) or reduced by chemical accelerators (e.g., cold weather concreting). The third stage begins with the renewed hydration of the silicates at an accelerating rate and is associated with initial set of cement (e.g., ASTM C 191). This is followed by the fourth stage during which the hydration rate slows down rapidly. The rate of hydration slows down further at the final stage which continues at a slow rate as long as the conditions enabling chemical reaction is maintained (over years with moist curing at normal temperatures).

The structure of the silicate hydrates consists of a family of silicates, called calcium silicate hydrates (C-S-H). The volume of cement, V_c and chemically combined water, V_{nw} is less than the volume of the C-S-H gel, V_g formed. However, the gel pores take up a volume of water, V_{gw}. It has been shown by Powers and Brownyard (1946/47) that the relative volume relationship is as follows:

$$V_c + V_{nw} < V_g < V_c + V_{nw} + V_g$$

For the paste to remain fully saturated, water from an external source has to fill up the difference in volume. In practice, moist curing provides this additional water to promote cement hydration at its maximum rate. If such water is not available, continuing hydration and loss of moisture to the environment reduce the internal moisture content. Hydration rate is severely reduced if the internal vapor

pressure falls below about 0.8 (relative humidity of 80%) and extremely low below about 0.3. The rate of moisture loss depends on the initial moisture content in the concrete, the exposure temperature and relative humidity and the shape and size (surface/volume ratio) of the structural member.

The reaction of cement compounds with water may be separated into two main groups. The first stage is the aluminates with water contributing to the high heat of hydration. The added gypsum goes into solution to react with tricalcium aluminate forming a product known as ettringite.

$$\text{Tricalcium Aluminates} + \text{Calcium Sulfate} \rightarrow \text{Ettringite}$$

As sulfate is depleted, ettringite is converted into monosulfate.

$$\text{Ettringite} + \text{Tricalcium Aluminate} \rightarrow \text{Calcium Monosulfate}$$

The calcium silicates react with water to for calcium silicate hydrated (C-S-H) and calcium hydroxide. This is the primary reaction in blended cements. However, as the concentration of calcium hydroxide is built up, it reactions with the silicates present in fly ash, slag or silica fume (pozzolans) to form more C-S-H gel. This second reaction is known as the pozzolanic reaction. It takes place later than the primary reaction hence in the case of blended cement concrete, a longer duration of curing is needed to ensure adequate hydration is achieved.

Primary reaction

$$\text{Calcium silicates} + \text{Water} \rightarrow \text{Calcium Silicate Hydrates} + \text{Calcium Hydroxide}$$

Pozzolanic reaction

$$\text{Calcium Hydroxide} + \text{Pozzolans} \rightarrow \text{Calcium Silicate Hydrates}$$

Another important role of this second reaction is that it takes place in the liquid phase of the concrete, i.e., in capillary pores and in zones below coarse aggregates where voids are formed due to bleeding water trapped beneath them. The zone of cement paste around an aggregate is called the interfacial zone or transition zone. Its quality is generally slightly different from the bulk of the cement paste in the matrix of concrete. These voids contribute mainly to permeability of concrete. If these voids are filled with the C-S-H gels from pozzolanic reaction, the internal structure of concrete is improved. It is often noticed that its improvement against ingress of water and chemicals from external sources is more significant than the increase in strength.

40.7 Mixture Design

Mixture design does not carry the same degree of certainty as structural design. It is more appropriately defined as a process of selecting the type of mixture constituents and their proportions. The intended properties of the mixture are usually assessed by means of a trial batch, and the mixture proportions adjusted where necessary. This type of mixture is a designed mixture. On the other hand for minor projects or where past experience provides adequate information, mixture proportions may be specified. This type of mixture is a prescribed mixture. In small projects, constituents may even be batched by volume using predetermined sizes of volume boxes. However, in general, batching by mass is the common practice, particularly with ready-mixed concrete supply.

The method of mixture design is seldom of concern to civil engineers as proper selection of materials and mixture proportions relies on past experience with the constituents at hand and their performance in mixtures previously produced. However, it is useful to be familiar with the properties of fresh and hardened concrete commonly required and how the selected mixture proportions influence these properties.

The three main requirements are compressive strength, workability and durability. For the purpose of mixture design, simplified assumptions are used on the factors influencing these properties. Water/cement ratio is the main factor for compressive strength. However, for a specified strength used in structural

design, the value is taken as the characteristic strength, i.e., the value below which a specified percentage of results is expected to fall, according to a Gaussian distribution of strength results. The mean strength for the mixture design includes a margin above this characteristic value, depending on the percentage selected. For example, for 5% defectives, the margin is 1.64 times the standard deviation. For ready-mixed concrete production, the range of standard deviation is usually between 3 to 5 MPa. For trial mix, a slightly higher margin is some times chosen. Workability is assumed to be dependent on water content (mass per cubic meter). The addition of water-reducing admixtures reduces the amount of water needed for the same workability. The likely amount of water to be reduced and the factors influencing the effectiveness of chemical admixtures have been described in earlier sections. Requirements for durability are commonly based on limiting the minimum cement content and the maximum water/cement ratio for various exposure conditions. This implicit approach is one of the most uncertain aspects in mixture design for service life prediction. Further information on durability considerations are described in later sections. Different approaches are used in the American (ACI Committee 211) and British (Department of the Environment) methods and they do not result in the same mixture proportions for the same set of requirements. It is preferred that users specify concrete by its performance requirements and for the producers of concrete to select the mixture proportions. Either from previous records or by testing, the requirements are demonstrated to be achievable before concrete is supplied to the project.

Hydrated cement paste (C-S-H gel) is the "glue" that holds the composite material together. Hence, its quality, dependent of its water/cement ratio and the degree of hydration (promoted by moist curing and indicated as strength gain) is the most important aspect of mixture design. The chemical resistance of concrete is also dependent on the type of chemical composition of cement. In particular, sulfate resistance and alkali aggregate reactions are influenced by the selection of appropriate cement type (see section on durability for more details). Another factor in the selection of cement composition relates to minimizing temperature rise in thick sections, particularly in hot weather concreting, where cement of low heat of hydration is specified. Further information on this topic is provided under hot weather concreting.

Aggregates are normally inert to chemicals in cement, except for the case of alkali-aggregate reaction. They play a significant role contributing not only to a lower cost of concrete but also to its properties. The aggregate/cement ratio is often a factor used in prescribed mixture proportions. The ease of placing and compacting concrete (part of workability requirements) is reduced by increasing amount of aggregates in the mixture. The amount of cement paste (aggregate/cement ratio) and its own fluidity (water/cement ratio) determine the workability of fresh concrete. The flow of concrete depends on the internal friction of the aggregate system and its reduction by the cement paste volume and its fluidity. The volumetric fraction of aggregates in concrete generally exceeds 60%. Hence, it is expected that to a large extent, physical properties of concrete depend on the corresponding physical properties of aggregates. These include thermal coefficient of expansion, specific heat and thermal conductivity. The deformation properties of concrete are similarly influenced, e.g., creep, shrinkage and modulus of elasticity. Further information on these topics may be obtained from the publications listed in Further Information.

The role of water in concrete is ambivalent. It is needed for chemical reaction of cement, for providing fluidity and in moisture curing. On the other hand, water not taken up for these purposes remains as capillary pores in hardened concrete. They contribute to drying shrinkage, and permeability for fluids and dissolved chemicals penetrating into concrete. These include detrimental materials such carbon dioxide and chlorides causing corrosion of embedded steel reinforcement. Sulfate attack, alkali-aggregate reactions, and delayed ettringite formation are discussed further in the section "Durability." Hence, in mixture design, the amount of water should be kept to the lowest, consistent with the mixing method. The degree of workability required is more cost-effectively provided by the addition of water-reducing admixtures.

40.8 Properties of Fresh Concrete

When concrete is freshly produced, it is plastic in behavior and is often called plastic concrete. The requirements for fresh concrete include the time available for placing it into formwork and workability. Before the advance of chemical admixtures, due to the setting of cement, the time available is often too

short for transportation from the batching plant to the work site. The extension of this setting time by addition of chemical retarders has already been described under the section on chemical admixtures.

Workability

Workability is often referred to as the ease with which a concrete can be transported, placed and consolidated without excessive bleeding or segregation. It is obvious that no single test can evaluate all these factors. In fact, most of these cannot be easily assessed even though some standard tests have been established to evaluate them under specific conditions (not always similar to that occurring on site). Thus they are more useful in comparing mixtures than for acceptance testing on site. The rheology of fresh concrete has been approximated to that of a modified Bingham body (Tattersall, 1991). This defines a linear relationship between shear stress and shear strain rate, with the intercept at the shear stress axis defined as its yield stress. The slope of the line is called its plastic viscosity. The recent development of a new generation of water reducing admixture produces a self-compacting concrete with near zero yield stress and a low plastic viscosity. The concrete is self-leveling and self-compacting, i.e., no consolidation by vibration is needed to achieve full compaction. For various types of mixtures, different methods of determining workability have been established as standard tests. They cover the range of workability commonly used in construction.

Slump

In everyday practice, slump is the most common test for workability (e.g., ASTM C 143 or BS 1881:Part 102). Minor differences in testing procedures exist between different national standards even for this simple test. The main purpose of this test is intended to detect the change in water content as indicated by a change in slump. Before the age of chemical admixtures, a higher slump is deemed to indicate higher water content and may result in lower strength due to the likely higher water/cement ratio. However, change in water content is not the only variation in the mixture constituents that can lead to a change in slump. Changes in cement composition or cement fineness as well as changes in the grading and shape of aggregates are other common factors. A high slump can also be achieved with the addition of chemical admixtures at the same or lower water content. Changes in cement composition or cement fineness often lead to a change in the effectiveness of chemical admixture resulting in a change in slump. Although the slump test is still useful in indicating any change in consistency or fluidity between batches, however, the cause of the change is not easy to detect. In practice, a tolerance on the measured slump is permitted. This may be as high as one-third of the measured value.

Additional Properties of Fresh Concrete

The other properties of fresh concrete that are of interest to civil engineers include air content (freeze-thaw durability), temperature (hot or cold weather concreting) and density (lightweight or heavy weight concrete). Additional properties that may be assessed during trial mix stage may include bleeding, segregation and stiffening time. Another property that may be determined at this stage is the rate of slump loss or the retention time for good workability needed for construction purpose. Details of test methods are provided in standards.

40.9 Properties of Hardened Concrete

As a material for construction, the main function of concrete is to enable the structure to carry its self-weight and other imposed loads. Thus the most important properties of hardened concrete are its strength and rigidity (modulus of elasticity). Concrete is stronger in compression than in tension. Hence, it is often used in the form of a composite section with steel providing the tensile resistance. In the case of prestressed concrete, a compressive stress distribution is induced into the section to counteract the tensile stress due to loading. Hence, compressive strength of concrete is the most commonly specified property

of hardened concrete. However, concrete is a brittle composite and its failure mode is dependent on its ultimate tensile strain. Even under axial compressive stress, tensile strain is generated by Poisson's effect in the lateral directions. This is evident from the failure mode when standard specimens (cubes or cylinders) are tested under an applied compressive load.

Compressive Strength

The compressive strength of hardened concrete is usually determined from standard specimens (cubes or cylinders) after they have been moist cured for 28 days. This is the historical practice, as many researchers have shown that there is no known technical basis for selecting this particular test age. Standard procedures for sampling, making, curing and testing of the test specimens are prescribed (e.g., ASTM C 39 for cylinders) so that the failure stress can be determined with better repeatability and reproducibility. The European practice (EN 206) uses cylinders or cubes as standard specimens. Standard cylinders have a length/diameter ratio of 2 but cubes have aspect ratio of unity. The ends of cylinders are capped to ensure smoothness and parallelism of the ends. Cubes are loaded against a pair of their molded sides to achieve the same requirements. Although the applied load is uniaxial compression, the friction between the test specimen and the metal bearing plates of the test machine introduces a set of biaxial state of stress at both ends of the specimen. Effectively, the end zones are under a triaxial state of stress. The influence of this end effect decreases with its distance from the contact surface. Neville (1995) suggests a distance of about 0.86d, where d is the lateral dimension of the specimen. Thus the zones of influence overlap in the case of cubes but in the case of standard cylinders (aspect ratio of 2), there is a middle zone free of the end effects. Hence, a standard cylinder fails at a lower applied load than a standard cube and reported as a lower stress when it is computed on simply load/area basis. Although the cylinder strength is closer to that due to unconfined uniaxial compression, testing of cubes do not required end preparation. The capping material for cylinders has to be stronger than that of the cylinder. This is critical for high strength concrete (80 to 100 MPa) and satisfactory end preparation is often by grinding of the ends held in special jigs. Hence, cubes are more convenient in this case. Since the main purpose of testing standard specimens is to verify the strength of concrete production, the choice of cylinders or cubes is equally satisfactory. Several researchers have reported on the relation between the strength determined from standard cylinders and standard cubes based on experimental results. EN 206 provides a table of corresponding strengths of cylinder to cube over a range of cylinder strength from 8 to 100 MPa. There is a general trend that the ratio of cube strength/cylinder strength decreases with increasing strength level (from 1.25 to 1.15 for the above range of cylinder strength).

Compressive strength of concrete is traditionally determined after 28 days of curing. This is also the concrete strength used in structural design codes. However, for the purpose of quality control in concrete production, this is no longer satisfactory for the current rate of construction. A large volume of concrete may have been built over the concrete for which the 28-day strength is just determined. The liability involved, if the test result is not in conformity with the specified value, is often unacceptable. Just as in modern manufacturing, the quality of a product should be assessed as soon as practical to provide feedback for adjustment if necessary. As designers, civil engineers are more concerned with the as-built structure even though satisfactory concrete is a pre-requisite. However, the current practice on site does not assess the concrete in the structure, but only the concrete as produced, sampled, cured and tested under standard conditions. There is a potential difference between such standard samples and the in-place concrete, which is likely to be of less compaction and much shorter period of curing than standard specimens. There is enough evidence from research and practice that in general, in-place strength of concrete is expected to be lower than that of the corresponding standard samples.

Assessment of in-place strength of concrete may be based on testing cored samples from structural members. ACI Committee 318 recommends that the concrete in the structure may be acceptable provided the strength determined from the average of three cores is at least 85% of the specified value and none of individual core is less than 75% of the specified value. BS 6089 recommends that the partial safety factor for concrete based on cores should not be less than 1.2 compared to the value of 1.5 used in design.

The designer is responsible to decide on the appropriate value for each case, taking into consideration the confidence on the estimated strength and the importance of the failure to conform. Since the standard samples in the British practice are cubes, there is a need to convert the strength determined from cylindrical cores (usually with length/diameter ratio about unity) into equivalent cube strength. The equation (BS 1881:Part 120) is based on assumed values for various factors used in the conversion (Concrete Society Technical Report No. 11).

The use of drilled cores for the purpose of assessing concrete strength in existing structures is usually limited to small number of cores. Besides the danger of cutting a reinforcement bar, the removal of concrete from critical locations is also not desirable. Hence, indirect means of assessment by non-destructive methods have been developed. Most of these do result in some degree of damage to the near surface zone of concrete. Many of these have reached the stage of standard methods and details are available in the respective testing standards. The more commonly used methods are listed below.

Method	American Practice	British Practice	Surface Damage
Rebound number	ASTM C 805	BS 1881:Part 202	Very minor
Pulse velocity	ASTM C 597	BS 1881:Part 203	Negligible
Penetration resistance	ASTM C 803	BS 1881:Part 207	Minor
Pullout strength	ASTM C 900	BS 1881:Part 207	Minor
Break-off number	ASTM C 1150	BS 1881:Part 207	Minor

None of the above methods provide a direct assessment of the compressive strength. Although the three methods with minor damage involve some aspects of strength, the volume of concrete assessed is small and only at the near surface zone. Rebound number is only a test of surface hardness. Pulse velocity measured directly through the thickness of a section provides better assessment than semi-direct or surface measurements. These two methods with minimal damage are based on the principle that compressive strength and the modulus of concrete are correlated. In all cases, a correlation curve is needed by testing companion standard specimens to provide the compressive strength. This approach is possible for new construction, where the same concrete mixture is available for preparing the specimens for both compressive strength and non-destructive measurement. For an existing structure, compressive strength is available only from testing cores taken from selected regions of the structure. The planning and interpretation of such assessment should be carried out by those who understand the principle behind the selected test method, the factors influencing the non-destructive measurement, the usefulness and limitations of the established correlation so as to provide meaningful conclusions.

Modulus of Elasticity

Modulus of elasticity is another important property in the design of concrete structures. It determines the deformation and deflection of structural members. Although the modulus of elasticity of normal weight concrete increases with concrete strength, its increase is much less, e.g., ACI 318 recommendation states that modulus of elasticity is proportional the square-root of cylinder strength of concrete. Hence, in the case of very high strength concrete, deflection limits may control the depth of section rather than concrete strength. High strength concrete is achieved with low water/cement ratio (aggregate/cement bond) and low water content (porosity arising from capillary pores). Since the conventional mixing process requires water content of at least about 150 kg/m,[3] a high cement content is often needed leading to a lower aggregate content. The paste fraction has much lower modulus of elasticity than aggregates, hence in a composite, the relative volumetric composition of these two components determine the modulus of elasticity of concrete.

Determination of modulus of elastic of concrete (ASTM C 469 or BS 1881:Part 121) is by short-term loading within the stage where the stress-strain relationship is practically linear within the sensitivity of strain measurement system used. It is called the static modulus of elasticity and is in effect the secant modulus — slope between two defined points along the stress-strain curve. Even for this short duration of

loading, some time-dependent strain (creep) occurs. There is also a dynamic modulus of elasticity, determined by means of vibration of a concrete specimen (ASTM C 215 or BS 1881:Part 209) with only a very low level of stress and short duration. With negligible creep, it is almost due to elastic effects. It is higher than static modulus and approximately equal to the initial tangent modulus of the stress-strain curve.

Volume Change

Two major types of volume change of interest to civil engineers are creep and shrinkage. Creep is the increase in strain due to sustained constant load. In most structures above ground, creep is taking place under drying conditions. Drying out of water from the interior of concrete leads to shrinkage. When creep and shrinkage occur simultaneously, it is known as drying creep. Creep without loss of moisture to the exterior is known as basic creep. Drying creep is higher than the sum of basic creep and shrinkage occurring separately. In prestressed concrete, both creep and shrinkage lead to a loss of prestressing force. Allowance for such losses have to be considered in the initial prestress applied.

Another form of shrinkage arises from the consumption of internal moisture due to continuing hydration of cement, drawing water from the capillary pores, without external supply of water (curing). This is known as autogenous shrinkage due to self-desiccation. For mixtures with water/cement ratio above 0.3, the amount of autogenous shrinkage is small compared to drying shrinkage. For low water/cement ratio mixtures, autogenous shrinkage may become the major contribution to total shrinkage.

Carbonation of concrete also induces shrinkage. This is known as carbonation shrinkage, which is accompanied by an increase in mass due to the reaction of carbon dioxide with calcium hydroxide (from hydration of silicates in cement) to form calcium carbonate.

Shrinkage is a three-dimensional change in volume, although it is generally reported as a linear strain. When shrinkage is restrained by boundary conditions, tensile stress is induced. If the magnitude of restrained shrinkage is higher than the ultimate tensile strain capacity of concrete, cracking occurs.

Permeation

Permeation relates to the ease with which fluids (liquids and gases) can penetrate into, or move through concrete. Durability of concrete is largely influenced by its permeation properties. These aspects are discussed in another chapter under "Durability of Concrete".

41.1 Introduction

Concrete is a composite with properties that change with time. During service, the quality of concrete provided by initial curing can be improved by subsequent wetting as in the cases of foundations or water-retaining structures. However, concrete can also deteriorate with time due to physical and chemical attacks. Structures are often removed when they become unsafe or uneconomical.

Lack of durability has become a major concern in construction for the past 20 to 30 years. In some developed countries, it is not uncommon to find large amount of resources, such as 30 to 50% of total infrastructure budget, applied to repair and maintenance of existing structures. As a result, many government and private developers are looking into lifecycle costs rather than first cost of construction.

Durability of concrete depends on many factors including its physical and chemical properties, the service environment and design life. As such, durability is not a fundamental property. One concrete that performs satisfactory in a severe environment may deteriorate prematurely in another situation where it is consider as moderate. This is mainly due to the differences in the failure mechanism from various exposure conditions. Physical properties of concrete are often discussed in term of permeation, the movement of aggressive agents into and out of concrete. Chemical properties refer to the quantity and type of hydration products, mainly calcium silicate hydrate, calcium aluminate hydrate, and calcium hydroxide of the set cement. Reactions of penetrating agents with these hydrates produce products that can be inert, highly soluble, or expansive. It is the nature of these reaction products that control the severity of chemical attack. Physical damage to concrete can occur due to expansion or contraction under

restraint (e.g., drying shrinkage cracking, frost action, cyclic wetting and drying), or resulting from exposure to abrasion, erosion or fire during service. It is generally considered that the surface layer or cover zone plays an important role in durability as it acts as the first line of defense against physical and chemical attacks from the environment.

Although durability is a complex topic, some of the basic fundamentals are well understood and have been documented. Many premature failures in recent years are due mainly to ignorance in design, poor specification or bad workmanship. The following discussions should be considered as a summary of commonly accepted knowledge published in various textbooks, codes of practice, and recent conference proceedings listed at the end of the chapter. These publications are useful guides for further details and information.

41.2 Permeation Properties

Permeation defines the ease with which fluids, both liquids and gases, can enter into, or move through concrete. The ability of fluids to enter into concrete is sometimes refers to as penetrability of concrete. Three fluids are relevant to durability and they are water, carbon dioxide and oxygen. Water can be detrimental in either its pure (uncontaminated) form or if it is contaminated with aggressive ions such as chlorides and sulfates.

Concrete is a porous medium with permeation properties controlled by the microstructure of its hardened cement paste, which in turn, is determined by the cementitious materials (CM) used, the water to cementitious material ratio (W/CM), the paste volume, and the extent of curing and compaction. Within this cement paste, the transition zone, i.e., the interface between the cement paste and the aggregate, is known to be more porous than the bulk of the cement paste. Thus, it is the microstructure of this transition zone that controls the permeation of concrete. As far as the ease of movement of fluids through concrete is concerned, three transport mechanisms should be distinguished and they are permeability, diffusion and sorption.

Permeability refers to the flow of water through concrete under a pressure differential. The rate of flow follows Darcy's law for laminar flow through a porous medium. It depends on the pressure gradient and size of interconnected pores in the cement paste. For flow to occur, the concrete has to be in its saturated conditions with relevant pores being continuous and greater than 120 nm. Quantitatively, this property is discussed in terms of the coefficient of permeability, commonly expressed in meters per second (m/s). Permeability is a relevant property to be measured in assessing the durability and serviceability of structures like dams, foundations, and underground structures, where they are in constant contact with water.

Diffusion is the process whereby gases (e.g., carbon dioxide or oxygen) or ions in solution (e.g., chlorides) enter concrete under a differential in concentration. The diffusion of these species can be described by Fick's law. Diffusivity or diffusion coefficient, in m^2/s, is often used to refer to the rate at which these species entering concrete. In addition to concentration gradient and sizes of capillary pores, the rate of diffusion is influenced by the type of penetrating species and the chemical properties of the concrete. Diffusion of gases is very slow in saturated concrete and is, therefore, a property relevant to concrete in aboveground structures such as buildings and bridges, where concrete is partially dry. For the durability of submerged or underground structures, the diffusion of chloride and sulfate ions should be considered.

Sorption or absorption is a result of capillary movement of liquids in the pores of the hardened cement paste under ambient conditions. Note that capillary suction occurs in dry or partially dry concrete, a condition commonly occurred in practice for aboveground structures. Sorption is relevant, particularly to coastal structures, where chloride salts carried by wind deposit on concrete surfaces. Once wetted by rain, water carrying chloride ions is absorbed into the concrete. The rate at which liquids, mainly water, absorbed into concrete is often referred to as sorptivity or absorptivity, in $m/s^{0.5}$. This parameter is highly dependent on the initial moisture content of the concrete and therefore, the test method used.

To achieve good quality concrete in practice with low permeation properties, engineers should specify concrete with low water to cementitious materials ratio, adequate initial curing and proper compaction. In testing for permeation properties, it is important to recognize the type of structure under consideration and its service environment. This helps to identify the transport mechanism and the appropriate permeation property to be measured.

41.3 Reinforcement Corrosion

Reinforcement corrosion and the subsequent spalling of the cover concrete have been major issues in construction for many years. In theory, embedded steel should not corrode. It is protected against corrosion because of the passivating film of g-ferric oxide, which is formed and maintained in the alkaline environment produced by cement hydration. Hydration products, mainly calcium hydroxide and small proportions of sodium and potassium hydroxides, give the pore solution of concrete a pH of around 13. However, aggressive agents such as carbon dioxide or chloride ions can destroy this passivating film. Once destroyed, corrosion proceeds with the formation of electrochemical cells on the steel surface. Finally, the corrosion product causes cracking and spalling of the concrete cover. Thus, the corrosion process of steel in concrete can be divided into two stages — initiation and propagation (Fig. 41.1). The initiation stage is determined by the ingress of carbon dioxide or chloride ions into the concrete cover while the propagation stage, or corrosion rate, is dependent on the availability of water and oxygen in the vicinity of the steel reinforcement. The time before repair is required, often referred to as the service life of the reinforced concrete element, is determined by the total time of these two stages.

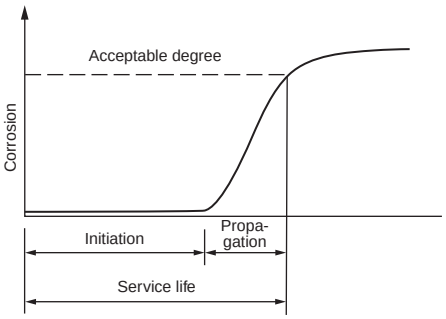

FIGURE 41.1 Schematic diagram of corrosion process of steel in concrete.

Carbonation

Carbonation is defined as the process whereby carbon dioxide in air diffuses into concrete, dissolves in the pore solution, and then reacts with the hydroxides, converting them to carbonates with a consequent drop in pH to a value less than 9. Depassivation of steel occurs as pH of the pore solution approaches 11. Carbonation continues from the concrete surface, as a penetrating front, throughout the life of the structure, with depth, d, proportional to the square root of time, t, as follows

$$d = C\ t^{0.5},$$

where C is referred to as carbonation coefficient or rate of carbonation, often expressed conveniently in mm/÷year.

In practice, the depth of carbonation can be determined by spraying a phenolphthalein solution onto a freshly broken concrete sample. This colorless solution changes to pinkish purple at pH values greater than about 9.5, indicating uncarbonated concrete.

The rate of carbonation is very much moisture dependent, i.e., the macro- and micro-climatic conditions of the exposed concrete element. Carbonation of concrete is known to be highest at RH between 40 to 70%, but negligible in dry conditions (<25% RH) due to insufficient water to promote the reaction. Negligible carbonation is also expected at high humidity (>90% RH) because water in pores of cement paste inhibits diffusion. Compared with tropical environment, concrete exposed to temperate climate are expected to have higher carbonation rates. In practice, vertical surfaces such as building facades carbonate faster than horizontally exposed surfaces like top surface of roof slabs and balconies because horizontal surfaces have a higher frequency and longer duration of wetting.

Temperature can also influence the rate of carbonation with higher rates at higher temperatures, but the influence is less significant compared to the moisture content of concrete. Carbon dioxide content is another influencing factor. In rural areas, carbon dioxide content in air is about 0.03% by volume. However, in cities, the concentration is much higher and could be in the order of 0.3% in densely populated areas. In vehicular tunnels, the concentration could reach 1% giving very fast rate of carbonation.

Note that carbonation in itself does not cause the deterioration of concrete. In fact, compared to the original concrete, carbonated elements tend to have slightly higher compressive strength and improved permeation properties due to the formation of calcium carbonate with a consequent reduction in the porosity of concrete. This reaction product is not detrimental to the durability of concrete as it does not leach out and is not expansive. Carbonation is not a concern for un-reinforced concrete elements such as roofing tiles and masonry blocks.

Carbonation affects only the length of corrosion initiation stage. For internal structural elements and due to the lack of sufficient moisture to initiate corrosion, concrete remains durable even though carbonation can be substantial. For external elements exposed to the weather, corrosion will occur once the concrete is carbonated close to the reinforcement. Thus, the quality and quantity (thickness) of the concrete cover are important in controlling the time to initiate corrosion. In normal practice and for typical run-of-the-mill concrete, it may take some 20 years or more to carbonate the concrete cover. Note that carbonation is not critical for concrete with high cementitious material content, low W/CM (<0.4) and low permeation properties, because carbonation is extremely slow in good quality concrete. The concern to practicing engineers is the concrete used for external surfaces of aboveground structures, such as buildings. This concrete is generally produced with high W/CM (>0.5) and limited initial curing.

Effects of Chloride

Soluble chlorides present in seawater, ground water or de-icing salts may enter concrete through capillary absorption or diffusion of ions in water. Chlorides may also present in chemical admixtures and contaminated aggregates or mixing water in the production of concrete. The presence of chlorides in reinforced concrete can be very serious and depending on the quality of concrete and its exposure environment, the total time of initiation can be relatively short.

Note that it is not the total chloride content that is responsible for corrosion. Part of the chlorides can be chemically bound to the hydrated cement paste, by reaction with C_3A to form calcium chloroaluminate, often referred to as Friedel's salt. Another proportion of chlorides is physically bound, being adsorbed on the surface of gel pores. The remaining part is the free chlorides, which are the only chlorides that are responsible for the initiation of steel corrosion. The distribution of these three forms of chlorides is not permanent and under special circumstances (e.g., carbonation or sulfate attack), some of the bound chlorides can be released as free chlorides. Due to various factors, the proportion of free chloride ions in concrete varies from 20% to more than 50% of the total chloride content.

For corrosion to be initiated, there has to be a minimum level of free chloride concentration at the steel surface. However, threshold values for depassivation is uncertain, with commonly quoted values between 0.1 and 0.4% of free chloride ions by mass of Portland cement. Due to the concern over the possibility of bound chlorides being released as free chlorides, the probability of corrosion has sometimes been expressed in terms of total chloride ion content. Buildings and bridges near the coast often suffer severe corrosion problems due to the co-existence of both carbonation and chloride penetration.

Propagation Stage of Corrosion

Once the embedded steel is depassivated, corrosion proceeds with the formation of electrochemical cells comprising anodic and cathodic regions on the steel surface, with electric current flowing in a loop between the two (Fig. 41.2). Corrosion occurs at the anode, where there is ionization and dissolution of the metallic iron to Fe^{++}.

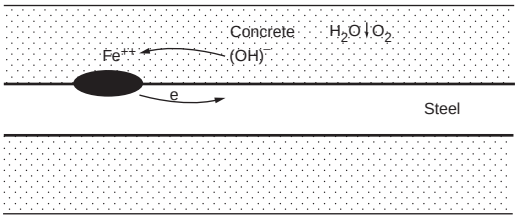

FIGURE 41.2 Schematic representation of electro-chemical reaction.

$$\text{Anode:} \qquad Fe \rightarrow Fe^{2+} + 2e^{-}$$

At the cathode, reduction of oxygen occurs. The cathodic reaction consumes electrons and leads to the formation of the OH^- ions.

$$\text{Cathode:} \qquad 0.5\,O_2 + H_2O + 2e^{-} \rightarrow 2(OH)^{-}$$

The ions formed at the cathode and anode move in the pore solution of the paste of the concrete and react chemically to produce an iron oxide near the anode, generally known as rust. It is obvious from above that for cathodic reaction, and thus corrosion, to occur, both oxygen and water are required. In dry concrete with RH less than 60% as in the case of concrete exposed indoors or protected from rain, corrosion of reinforcement may be considered negligible even though carbonation can be substantial. Corrosion may also be negligible in water-saturated concrete because of the restriction in oxygen supply. Typical examples are constantly submerged elements of offshore structures, where concrete is subjected to severe chloride attack, and due to the limited supply of oxygen, corrosion rate can be very slow. On the contrary, high corrosion rate will occur in concrete elements located in splash or tidal zones, where concrete experiences periodic wetting and drying cycles.

The deterioration of concrete due to corrosion results because the corrosion product, rust, occupies a volume two to six times larger than the original steel it replaces. This increase in volume exerts substantial pressure on the surrounding concrete, causing spalling and delamination of the concrete cover. In practice, initial concerns are cracking and rust stains on the concrete surface. Rust from outer 0.1 to 0.5 mm of steel bar is sufficient to cause cracking. However, the reduction in this diameter is generally considered too small to have practical significance on the load-carrying capacity of the reinforced concrete element. Of serious concern is the falling concrete, which may pose as a safety hazard to pedestrians and vehicles traveling below deteriorated overpasses and buildings. As corrosion continues to an advanced stage, reduction in steel cross-section will lead to a decrease in load carrying capacity of the member.

Control Strategy

To improve the service life of reinforced concrete structures, it is important to have high quality, low permeable concrete with adequate cover. Other strategies can be more complex and may require advice from specialists. These include the use of corrosion inhibitors such as nitrites of sodium and calcium, and the specification of galvanized or epoxy-coated reinforcing bars. For prestigious structures or those require high durability, expensive electro-chemical protective system such as cathodic protection is sometimes employed. This involves the application of a low-voltage direct current via an anode system to inhibit corrosion by causing the steel reinforcement to act as a cathode rather than an anode as it does when it corrodes. Other electrochemical treatments, namely re-alkalization and chloride extraction, are sometimes used as rehabilitation strategies for deteriorated structures.

41.4 Alkali-Aggregate Reaction

Certain types of rock contain reactive silica, which can react with the hydroxides in pore water derived from the alkalis (Na_2O, K_2O) in the cement causing damage to concrete. The most common is the alkali-silica reaction (ASR), which can be viewed simplistically as similar to etching of glass by strong hydroxide solutions. The visual signs of ASR damage are pop-outs or "map" cracking with gels coming through cracks on the concrete surface. Reaction rims around affected aggregate particles can also be identified from cores taken from damaged structures.

The reaction starts with the attack on the siliceous minerals in the aggregate by the alkali ions released through cement hydration with the formation of an alkali-silica gel on the surface or in the pores of aggregate particles. Gel absorbs water and causes localized swelling and cracking, which could destroy the aggregate integrity or the bond between the aggregate and the hydrated cement paste. The gel goes from solid to liquid phases as water is taken up into the concrete. Some of the liquid gel is later leached out by water and deposited in the cracks.

Damage due to ASR has caused much anxiety to property owners, particularly those from government authorities, who are responsible for the structural integrity of many civil engineering structures (dams, wharves and bridges). However, it must be emphasized that the extent to which ASR can be deleterious depends on certain critical conditions such as the nature and size of aggregates, amount of reactive silica, alkali concentration and the availability of moisture. Idorn [1997] made the following observation after reviewing some 60 years of research on ASR. "It can be concluded that ASR occurs in concrete all over the world, that the majority of available aggregate materials are alkali-reactive, and that, nevertheless the majority of ASR occurring with field concrete is harmless."

Reaction between some dolomitic limestone and the alkalis in cement, known as alkali-carbonate reaction, can also cause damage to concrete. However, reactive carbonate rocks are not very common and can usually be avoided.

Control Strategy

ASR takes place only at high pH because the solubility of the siliceous minerals increases as pH increases. The use of low alkali cement controls the alkali content and thus, the pH of the pore solution. The 'reactive' alkali content is generally expressed in terms of soda equivalent ($Na_2O + 0.65\ K_2O$) with a maximum level often quoted as 0.6% by mass of cement or 3.0 kg/m^3 of concrete. The use of blended cement is beneficial for various reasons. One is C-S-H formed by the pozzolanic reaction incorporates a certain amount of alkalis and thus lowers the pH.

The control of alkali-silica reaction can also be taken by avoiding reactive aggregates. A quick chemical test to determine the potential reactivity is prescribed by ASTM C289–94 [2000], where the amount of dissolved silica is measured from a sample of pulverized aggregate in a normal solution of NaOH. Another method to determine aggregate potential reactivity is to measure the physical expansion in the mortar bar test according to ASTM C 227–97a [2000].

The swelling of silica gel occurs only in the presence of water. However, in practice, it is practically impossible to keep water away from exposed concrete, particularly for water-retaining structures. Due to the presence of water under service conditions, structures like dams, piers and wharves are more vulnerable than buildings to ASR attack.

41.5 Sulfate Attack

Naturally occurring sulfates of sodium, potassium, calcium, or magnesium can be found in soils, seawater or ground water. Sulfates are also used extensively in industry and as fertilizers. These may cause contamination of the soil and ground water. Sources of sulfate can also be internal, released from the cement during service. Sulfate attack can take one of the following forms:

1. physical attack due to salt crystallization;
2. external chemical sulfate attack involving reactions between sulfate ions from external sources with compounds from set cement;
3. internal chemical sulfate attack due to late release of sulfate within the concrete.

In practice, sulfate attack is generally considered not a serious, or common problem or sole contributor to damage. However, damage of concrete railway ties in the 1980s in Germany and controversies over recent problems associated with floor slabs from 20 to 30 year old homes in California have caused considerable anxiety among engineers about sulfate attack mechanism. Latest information on the mechanism of sulfate attack was well summarized by Mehta [2000] and Collepardi [2000].

Physical Attack

This type of attack is likely to occur in permeable concrete with top surface exposed to the dry environment, while the bottom surface is in contact with the ground with salt-bearing solutions. Under these conditions, solutions rise to the surface by capillary action. Due to surface evaporation, and if the rate of evaporation is faster than the migration of salt solution to the surface, salt crystallization occurs beneath the top surface. The transformation of anhydrous Na_2SO_4 to its hydrated form, $Na_2SO_4 \cdot H_2O$, involves significant volume expansion. This generates pressure in the pores causing flaking, spalling and cracking. The damage is often in the form of surface scaling and loss of mass from the surface can be substantial. This damage should not generally lead to structural failure unless there is a significant reduction in the cross section of the member.

Damage of this type results in white crystalline deposits at the crack sites and should not be confused with efflorescence, where salt crystallization takes place on the concrete surface. Ettringite and gypsum are absent from mineralogical analysis of damaged samples.

External Sulfate

Normal Portland cement is the most vulnerable to chemical sulfate attack. The extent of damage depends on the quality of the concrete, the type of sulfate compounds involved and their concentrations. In permeable concrete, sulfate ions migrate from external sources and react with the products of cement hydration. The use of concrete with low permeation properties would seem to be an essential first step in limiting the penetration of sulfate ions into concrete.

With sodium sulfate, it attacks $Ca(OH)_2$ to form gypsum and NaOH. Gypsum then reacts with calcium aluminate hydrate forming ettringite ($CaO.Al_2O_3 \cdot 3CaSO_4 \cdot 32H_2O$). The formation of NaOH ensures high alkalinity in the cement system and C-S-H remains stable. As for calcium sulfate, it only attacks the calcium aluminate hydrate to form ettringite. The formation of ettringite is accompanied by volume expansion, which causes internal stresses and cracking. For concrete in contact with magnesium sulfate, the deterioration can be more serious than the damage caused by other sulfates. Magnesium sulfate attacks C-S-H as well as $Ca(OH)_2$ and calcium aluminate hydrate. The critical consequence of magnesium sulfate attack is the destruction of C-S-H resulting in loss of cohesiveness and reduction in strength.

Due to the lime-consuming pozzolanic reaction, the incorporation of mineral admixtures as a cementitious material would be beneficial in reducing the amount of calcium hydroxide and suppressing the formation of gypsum. The use of sulfate-resisting cement with a low C_3A content will minimize the damaging formation of the ettringite.

Underground structures or elements such as tunnels, foundations, pipes, and piles are vulnerable to sulfate attack. Damaged concrete often has a whitish appearance on the surface. Damage usually starts at edges and corners, eventually reducing to a friable or even soft state. Ettringite and gypsum are both present from mineralogical analysis of damaged samples.

Internal Sulfate

This is a case of chemical attack where the source of sulfates is internal. Due to late sulfate release, ettringite is formed in the hardened concrete causing expansion and cracking. This phenomenon is often

referred to as delayed ettringite formation (DEF). This phenomenon has been reported in steam-cured products using cements of high sulfate content. Ettringite is not stable at temperatures above 65ºC. Therefore, ettringite formed during the early hydration of cement decomposes when the curing temperatures exceed 65ºC. The sulfate ions released are absorbed by the C-S-H. During service, these ions are desorbed under ambient conditions with the re-formation of ettringite.

However, the above thermal decomposition mechanism on DEF has been considered by many as far too simplistic. In a holistic approach mechanism [Collipardi, 2000], three conditions must be satisfied for DEF to occur and they are (a) presence of microcracks, (b) late sulfate release and (c) exposure to water. Concrete microcracking can be promoted by steam curing process during manufacture or localized high stress in prestressed members. Alkali-silica reaction could also generated cracks around aggregates. Gypsum contaminated aggregates or sulfur-rich clinker can be sources of sulfate, which are not immediately available at early hydration, but can feed DEF later. Sulfates could also be available due to thermal decomposition of ettringite from early hydration in overheated concrete. Exposure to water facilities the migration of these sulfate and other reactant ions, followed by deposition of ettringite inside existing microcracks. Damage results from ettringite swelling or crystal growth.

Control Strategy

Highly permeable concrete exposed to sulfate-rich soils or ground water can deteriorate resulting from physical and chemical attacks. In the control of sulfate attack, it is therefore important to use high quality, low permeable concrete. The use of sulfate resisting or blended cement is an added advantage. Prestressed products produced by steam-curing process are more prone to DEF-related problems. Irrespective of the source of sulfate, the presence of interconnected microcracks and water is a necessary condition of any sulfate-related concrete. In view of the above, care should be taken in the manufacturing process of precast products to minimize the development of microcracks. During service, a good drainage or waterproofing system may be necessary to keep concrete in a relatively dry state.

41.6 Acid Attack

As with sulfates, acids can be found in soils and ground water. These may be organic in nature resulting from plant decay (e.g., humic acid) or dissolved carbon dioxide, or may be derived from industrial wastes, effluents and oxidative weathering of sulfide minerals. Liquids with pH less than 6.5 can attack concrete. The attack is considered severe at pH of 5.5 and very severe at 4.5. Concrete is held together by alkaline compounds and is therefore not resistant to attack by strong acids. They do not go into complex chemical reactions similar to those in sulfate attack, but simply dissolve the hydrated compounds of the set cement. The ultimate result of sustained attack is the disintegration and destruction of the concrete.

The mechanism of attack is the reaction between cement hydrates, mainly the calcium hydroxide and C-S-H, and the acid, resulting in the formation of calcium salts associated with the acid. The dissolution of these salts lead to further exposure of cement hydrates to attack. The rate of damage is controlled by the solubility of the calcium salt. That means more rapid deterioration occurs under conditions of flowing water, rather than static.

Acid rain, which consists of mainly sulfuric acid and nitric acid, may cause surface weathering of the exposed concrete.

The reduced content of calcium hydroxide of concrete incorporating fly ash or ground granulated blast furnace slag is generally considered to be beneficial in reducing the rate of attack. However, it appears that the permeation property of concrete is of less importance in acid attack.

Action On Sewers

This is a special case of acid attack with sulfuric acid produced by the activities of microorganisms. Domestic sewage by itself is alkaline and does not attack concrete, but severe damage can occur above

the level of flow. This occurs when anaerobic bacteria, found in the slime layer of sewer walls, convert sulfates in the sewage to hydrogen sulfide. Anaerobic bacteria become more active at higher temperatures and at slightly alkaline solutions. At high enough concentrations or due to turbulence, H_2S volatiles from the effluent and accumulates on the roof or upper part of the sewer. It then dissolves in the moisture films on the exposed concrete surfaces and undergoes oxidation by aerobic bacteria, finally producing sulfuric acid. It is this acid that attacks concrete. In localized areas, pH values can be as low as 2.

Since damage occurs only on exposed surfaces, sewers running full are not attacked. Chlorination and the injection of compressed air into rising mains have been used successfully to extend the life of sewers. Other effective measures include the removal of slime deposits, increase in flow velocities, and forced ventilation of sewers. It has also been found that the use of limestone, instead of siliceous, aggregates could greatly improve the durability of sewers.

41.7 Seawater

Concrete exposed to seawater can be subjected to both physical and chemical attacks. Seawater contains a number of dissolved salts with a total salinity of around 3.5% and pH values ranging from 7.5 to 8.4. Typical composition of seawater is sodium chloride (2.8%), magnesium chloride (0.3%), calcium chloride (0.1%), magnesium sulfate (0.2%), calcium sulfate (0.1%) and some dissolved carbon dioxide.

In terms of chemical attack, the damage from sulfates is not significant because in seawater, the deleterious expansion resulting from ettringite formation does not occur. The ettringite as well as gypsum are soluble in the presence of chlorides and can be leached out by seawater. Frost damage, abrasion due to wave actions, salt crystallization, and biological attack are other factors that may lead to the deterioration of concrete. However, the main durability concern for marine structures is the corrosion of the reinforcement resulting from chloride ingress. Of particular interest is the splash and tidal zones.

To be durable under seawater exposure conditions, concrete must have an adequate cover and low permeation properties with the appropriate choice of cementitious materials. Seawater should never be used as mixing water for the production of reinforced or prestressed concrete structures.

41.8 Physical Attrition of Concrete

Under many circumstances, concrete surfaces are subject to wear with progressive loss of mass from the concrete surface. Abrasion is a major concern to the durability of pavements or industrial floors with damage resulting from impact or wearing action by vehicular traffic. Damage may also occur due to erosion on spillways of hydraulic structures caused by water-borne solids moving at high speed, or offshore structures subjected to wave action. Another possible damage to hydraulic structures is by cavitation, which relates to the formation of vapor bubbles and their subsequent collapse due to sudden change of direction in rapidly flowing water.

Set cement paste does not have a good resistance to attrition, especially when it has a high porosity and low strength. Hard-wearing aggregates should be used for improved abrasion resistance. Heavy-duty industrial floors or pavements could be designed to have a 25 to 75 mm thick topping of low water-to-cement ratio. Small aggregates of 12.5 mm maximum size should be used to minimize the effect of aggregate pull out. To reduce the formation of a laitance or weak surface, it is often recommended to delay floating and finishing until the concrete has lost its surface bled water. In contrast to abrasion and erosion, the use of high quality concrete may not be effective in reducing damage from cavitation. The best solution appears to lie in the design by removing the causes of cavitation.

41.9 Frost Action

In cold climates, physical damage to concrete structures resulting from frost action or freeze-thaw cycles is a major concern requiring expensive repair and maintenance. The problem is common to all porous

materials but the degree of damage depends on the pore system. Set cement paste, which has large pore system and small pore diameter, represents the worst situation.

As temperature drops, some of the water in the pore system begins to freeze at about –5ºC. Water expands upon freezing and the associated 9% increase in volume generates hydraulic pressure, causing localized fracture within the cement paste. Damage can be avoided if pressure can be released by allowing the water to move out of the paste or to adjacent pores, where there is plenty of space.

Resistance of concrete to frost action can be improved by air entrainment, with air content between 3 and 6% of the volume of concrete being appropriate for most applications. The incorporation of air-entraining agent in a concrete mixture allows the distribution of free space throughout the entire cement paste in the form of tiny air bubbles. The addition of this admixture will obviously increase the yield of the fresh concrete and reduce the strength of the hardened concrete. Note that frost damage occurs mainly in saturated concrete. For partially dry concrete, many of the pores are empty and can play the role as air-entrained bubbles.

41.10 Action of Heat and Fire

In the design of residential buildings and public facilities, human safety is one of the major considerations. In general, concrete is considered to have good properties with respect to fire safety. Unlike timber, concrete is non-combustible and does not release toxic fumes on exposure to high temperatures. In practice, structural components are required to maintain their integrity over a desired length of time, often referred to as fire rating. Unlike steel, concrete is able to maintain sufficient strength at temperatures about 700 to 800ºC over several hours. This is important in terms of safety because materials with a high fire rating allow rescue operations to proceed with reduced risk of structural collapse.

Fire creates high temperature gradients and because of this, the hot surface layer tends to craze, followed by spalling from the cooler interior of the concrete member. The reinforcement may become exposed and the action of fire accelerates. The extent of damage depends on the temperature reached, loading conditions under fire, and characteristics of the concrete, which includes the quality of concrete and type of aggregates used. In general, concrete heated while under load retains a higher proportion of its original strength compared to unload concrete. Concrete of low permeability may suffer serious spalling. This occurs when vapor pressure or steam inside the concrete increases at a faster rate than the pressure relief by the release of steam to the atmosphere.

Under exposure to high temperatures, concrete made with limestone or light-weight aggregates performs better than concrete with siliceous aggregates. This could be due to the lesser difference in the coefficient of thermal expansion between the cement paste and these aggregates compared to siliceous aggregates, resulting in a stronger transition zone. In addition, at about 570ºC, siliceous aggregates containing quartz undergo deleterious expansion due to phase transformation.

Concrete made with siliceous or limestone aggregates show a color change with temperature. This provides useful information in estimating the maximum temperature reached in a fire. The color of concrete remains unchanged up to about 300ºC. Between 300 and 600ºC, it is pink to red. Then the concrete changes to grey between 600 and 900ºC, and buff above 900ºC.

As for the cement paste, when temperature reaches about 300ºC, the interlayer water and some chemically bound water from the cement hydrates are lost. At about 500ºC, decomposition of the calcium hydroxide begins. Complete decomposition of C-S-H occurs at temperatures around 900ºC. For practical purposes, approximately 600ºC is considered the limiting temperature for structural concrete.

41.11 Design for Durability

There are two approaches in the specification of concrete for durable structures and these are prescriptive and performance based specifications. Current prescriptive method focuses on important factors including service life, exposure environment, quality of concrete, and other interdependent considerations such as cover thickness, strength, curing and workmanship. An alternative approach based on performance

tests and fitness for purpose has occasionally been suggested and used [Ho and Lewis, 1988]. However, there are difficulties in its implementation. One difficulty lies in developing a commonly accepted test, which directly assesses the resistance of concrete to a particular deterioration process. Others include the establishment of relationship between the test and real performance, availability of standard sampling and test procedure, and guidance on the level of performance required under various exposure conditions. These difficulties have to be overcome before the performance approach can be implemented in general practice.

Service Life

In general construction, concrete structures and members are usually designed for a service life of 40 to 60 years. Within this design life, concrete is expected to meet all essential properties or exceed minimum acceptable values, when routinely maintained. Guidance for durability criteria for this design life is usually provided by national standards. More stringent requirements should be considered for structures requiring longer service life such as monumental or civil engineering structures (power stations, tunnels, dams, etc). For temporary structures with short service life, some relaxation of requirements may be acceptable. It is emphasized that durability is a complex topic and compliance with requirements stated in local standards may not necessary be sufficient to ensure a durable structure for an intended service life. If in doubt, specialist advice should be sought.

Exposure Environment

Exposure classifications are generally based on climatic conditions under which the concrete surfaces are exposed. Important factors include temperature, humidity, and frequency of wet-dry cycles. Compared to arid or temperate climates, tropical environment is generally considered to be more aggressive to exposed concrete. The presence of aggressive ions (sulfates and chlorides) is discussed in terms of surfaces in contact with the soil and seawater, or proximity of the structure to the coast and industrial areas. Correct interpretation of classifications and subsequent decision on the exposure class for a structure or member under consideration cannot be over-emphasized.

Concrete Quality

In the prescriptive approach, quality of concrete is specified in terms of materials selection and production process. No matter how well a mixture is selected and proportioned, inferior concrete will result from poor workmanship.

The initial step is to determine the type of cementitious material, its content, and the water-cementitious material ratio, as these are critical material properties for durability. Other factors such as aggregates and chemical admixtures are interacting factors, must be considered collectively in mixture design. For the materials and proportions required for durability, a corresponding strength will be achieved. This should be compared with the strength required for load-bearing capacity of the structure under consideration with the higher value adopted.

The next step is the specification of production process, which includes workmanship and curing. Workmanship relates to the degree of compaction and surface finish that can be achieved. The use of rigid formwork and intense vibration in the manufacture of precast products often gives better quality concrete compared to that obtained with standard consolidation (poker vibrators) on site. Curing promotes cement hydration. The duration and type of curing techniques are critical parameters and must be clearly defined. More importantly, the curing process specified has to be appropriate and can be achieved in practice for the concrete member under consideration. Note that the quality of concrete achieved with water-adding technique (e.g., water spray, wet hessian) is considered more effective than curing with water-retaining techniques (e.g., curing compound) [Ho, 1998]. However, water-adding curing techniques can be difficult to implement in many construction sites, without substantial increase in cost or delay in construction progress.

Cover Thickness

Besides quality, the quantity (thickness) of the cover determines the level of protection afforded by the concrete to the steel reinforcement against corrosion. The cover also acts as the first defense against other physical and chemical attacks. For durability, the cover thickness should be as large as possible, but this should be kept to a minimum for structural efficiency and the control of surface crack widths. The quantity and quality of the cover should be considered collectively because many codes of practice allow the reduction of cover thickness with increase in concrete quality.

42.1 Concreting in Extreme Climatic Conditions

C.T. Tam

Concrete is a commonly used construction material in most parts of the world. However, much of the current available knowledge on concrete technology has been mainly generated in the more developed parts of the world. These regions are mostly in the temperate zone. Hence, much of the standard specifications for concreting practice are based on experience in these cooler regions of the world. When concreting in climatic conditions that are different from the normal range, one should consider these to be extreme climatic conditions.

For the normal temperature range of 10 to 20°C current standard specifications developed for temperate regions are adequate. There are occasions when the ambient temperature falls way below this range. This is often referred to as cold weather concreting. On the other hand when the ambient temperature is much above this range, it is referred to as hot weather concreting. However, it is useful to differentiate between an unusually warm summer day in a temperature country from the constantly warm climate outside the temperature zones. STUVO (1982), the Netherlands representative of FIP, has classified climatic regions in the zone of hot countries around the equator into two separate main sub-groups. On the one hand,

there is a wet and tropical (hot-humid) climate and on the other, a dry and desert-type (hot-arid) climate. These three different conditions of high temperatures at the time of placing concrete require different degrees of precautions to be taken to achieve proper performance of concrete. All these three types of climatic conditions are covered by the more general description of ACI Committee 305 as follows:

> "Any combination of the following conditions that tend to impair the quality of freshly mixed or hardened concrete by accelerating the rate of moisture loss and rate of cement hydration, or otherwise resulting in detrimental results:
>
> 1. High ambient temperature
> 2. High concrete temperature
> 3. Low relative humidity
> 4. Wind velocity
> 5. Solar radiation."

This performance approach is preferred than the alternate prescriptive approach of limiting concrete temperature at time of placing. The availability of improved chemical admixtures and the increasing acceptance of mineral admixtures in blended cements offer concrete producers new opportunities to satisfy performance requirements that are not based on previous formulation of concrete mixtures. The three different conditions of high temperatures may then be provided with more appropriate and economic solutions.

Cold Climatic Condition

One of the important effects of low temperature on concrete is the reduction in the rate of hydration. It has been found that down to about 10°C below freezing, cement hydration may be extremely low. The actual temperature at which the water within concrete begins to freeze varies with the concentration and types of chemicals present. If this liquid freezes before concrete has set, cement may never set until the climate has warmed above the freezing temperature for the liquid phase. If freezing occurs after concrete has set, then the increase in volume on solidification of the liquid phase may lead to disruption of the concrete structure if the expansion exceeds the strength of concrete at this early age. The resistance to alternate freezing and thawing cycles is provided by suitable amount of air-entrainment, in the order of 5 to 7% by volume of concrete. Air-entraining agents (complex hydrocarbons) are used to entrain the air bubbles of a suitable size and spacing for this purpose. As explained by Dodson (1990), these agents do not generate air in the concrete but only stabilize the air infolded and mechanically enveloped during mixing, already dissolved in the mixing water, originally present in the intergranular spaces in the dry cement and aggregates or in the pores of the aggregates. Entrained air bubbles are typically between 10 μm and 1 mm in diameter and essentially spherical in shape. They are different from entrapped air voids, which are 1 mm or more in diameter and irregular in shape. The spacing factor, defined as the maximum distance of any point in the paste or in the cement paste fraction of mortar or concrete from the periphery of an air bubble, is usually in the range of 0.1 to 0.2 mm. However, the presence of such high percentage of air reduces the compressive strength of the mixture. A reduction in water/cement ratio to compensate for this loss of strength is taken into consideration in the design of the concrete mixture.

ACI Committee 306 defines cold weather as a period when, for more than 3 consecutive days, the following conditions exist: (a)The average daily air temperature (average of highest and lowest from midnight to midnight) is less than 5°C, and (b)The air temperature is not greater than 10°C for more than one half of any 24-hour period.

Cold weather concreting practice should aim to prevent damage to concrete due to freezing at early ages by ensuring a compressive strength of at least 3.5 MPa before the first occasion of freezing. The concrete should develop strength levels appropriate to construction stages such as removal of forms and shores as well as for taking loads during and after construction. Required concrete temperature at the time of placing may be achieved by heating the mixing water and/or aggregates. Concrete after completion of placement should be protected against freezing by insulation and heating, if required, to promote an

acceptable rate of strength development needed for the construction. Strength development may be monitored by testing specimens cured with the same temperature history as the structure or based on the concept of maturity factor (ASTM C 1074). Chemical admixtures (non-chloride based) may be added to accelerate setting and hardening. More details are available from list of publications for further information.

Hot Climatic Conditions

Three types of hot climatic conditions have been identified as follows: a hot summer day in a temperate region, hot and humid tropical conditions, hot and dry (arid) conditions.

The special issues involved due to the high ambient and high concrete temperatures are common. However, there are differences not only in the ambient relative humidity but also in the period of high ambient temperature after the placement of concrete. On the other hand, the effects of high temperature on the properties of fresh and hardened concrete are common.

Issues Relating to Properties of Fresh Concrete

The effects of both high ambient temperature and high concrete temperature on concrete and possible mitigating measures are:

1. increased water demand for a given degree of workability — 5 to 10 kg/m^3 of water for each 10^{o}C rise in temperature or a higher dosage of water-reducing admixtures to restore workability;
2. increased rate of workability loss due to more rapid rate of hydration — retarding admixtures to extend dormant period of cement hydration;
3. increased rate of setting due to more rapid rate of hydration — set retarding admixtures to prolong time before potential formation of cold joint;
4. increased tendency for plastic shrinkage cracking — reduce rate of evaporation by shielding from high wind and solar radiation and initiate curing as early as practicable after finishing;
5. increased difficulty to entrain air — higher dosage of air-entraining admixture to promote air entrainment.

Additional precautions should be taken in planning sequence of work and method of placing concrete into the form so as to minimize the need for long set retardation. Concrete has tendency to settle before setting and over retardation tends to increase potential for plastic settlement cracking.

Issues Relating to Properties of Hardened Concrete

The effects of both high ambient temperature and high concrete temperature on hardened concrete and possible mitigating measures are:

1. increased setting temperature leads to lower long-term strength — use low-heat cement and low cement content to minimise temperature rise during setting stage;
2. increased tendency for potential early age thermal cracking — use low-heat cement and low cement content to minimize temperature rise in hardened concrete and/or insulating exterior surfaces to reduce differential temperature;
3. increased early drying shrinkage due to faster rate of moisture loss from the warm concrete — longer curing period and/or applying curing compound to reduce rate of evaporation;
4. decreased durability if microcracking or surface cracks developed by one or more of the above factors — all visible cracks should be grouted to improve durability;
5. tendency to use higher water and/or cement content to provide workability aggravate the above factors — use water-reducing admixtures to compensate for loss of workability instead of increasing cement and water contents.

Additional measures include the use of blended cement when low-heat Portland cement is not readily available or not economically viable, and methods for temperature control in fresh and hardened concrete. The design of concrete mixtures with minimum water content adequate for the process of mixing results also in minimum cement content, irrespective of water-to-cement ratio required for specified strength.

Temperature Control

The need to control temperature of concrete may be divided into two stages: placing temperature of fresh concrete, and peak (maximum) temperature of hardened concrete and resultant temperature differential (potential early thermal cracking).

When a hot summer day occurs in a temperate country, the normal everyday practice of handling and placing concrete is no longer adequate. Hence, a limiting temperature for concrete at the time of placement is sometimes specified (e.g., 30°C in BS 8110). In addition, for the case of thick sections (e.g., raft foundations), when the weather has returned to cooler normal summer temperatures, the subsequent rise in temperature of the hardened concrete results in a greater thermal differential. Under such situations, specifying fresh concrete temperature at the time of placement lower than the ambient temperature of the day is beneficial. On the other hand, for the hot and humid or hot and dry climate, the daily mean temperature remains high. For such cases, cost/benefit considerations may not justify the high cost of reducing temperature of fresh concrete to below ambient temperatures. The need for this is mainly to limit the peak temperature in thick sections and also the consequential temperature differential. Other alternate approaches may provide more economic solutions. However, it is to be noted that the benefits of a lower concrete temperature include minimizing the effects listed above.

In using an initial concrete temperature below that of the ground for a thick raft foundation also reduces the temperature of the soil layer immediately below the raft. This results in a greater temperature differential with respect to the warmer interior and may be higher than that with respect to the top of the raft (exposed to ambient temperature).

Methods for minimizing the temperature rise due to heat of hydration of the cement in thick sections include:

1. select a low heat cement;
2. adopt the lowest water content for method of mixing and hence the lowest cement content for a given w/c ratio for strength;
3. use of high range water-reducing admixtures to provide workability at lowest practical water content (method (2) above);
4. partial replacement of cement with mineral admixtures (e.g., fly ash or ground granulated blast-furnace slag together with method (3) above);
5. accepting conformity of strength at a later age, instead of 28 days, to enable adopting a lower cement content for the same water content;
6. partial replacement of cement with silica fume (or micro-silica) which provides a higher strength-to-mass ratio but not significantly changing the heat of hydration per unit mass;
7. use of ice or chilled water to lower the initial concrete temperature;
8. combination of one or more of the above methods.

Tam (2000) reported on an adoption of a combination of more than one of the above methods for a 2.8m raft foundation having a specified concrete cube strength of 40 MPa. The monitored temperatures met the specified temperature control of initial concrete temperature not exceeding 30°C, peak temperature not exceeding 70°C and temperature different not more than 20°C. No insulation was needed for the top of the raft.

The potential for early thermal cracking in a structural element depends on the following factors:

1. temperature differential between the warmer interior and the cooler exterior of a thick section;
2. degree of constraint by the external boundaries
3. ultimate tensile strain capacity of the concrete mixture (depending on the thermal properties of its mix constituents) over the period where the temperature differential is significant;
4. rate of strength development over the period where the temperature differential is significant; creep relief of concrete at early ages over the period where the temperature differential is significant; drying shrinkage superimposed on thermal strain over the period where the temperature differential is significant;
5. both the space rate of change and the time rate of change of thermal strain.

Not all the above factors are independent of one another and their significance varies within the spatial location of the structural element. The whole process is complicated by the long period of time needed to place a large volume of concrete in a single continuous operation. In order to minimize the number of construction joints, each single operation often calls for a minimum volume of 2000 cubic meters. The earlier placed concrete has hardened before the final portion is placed. Even in the case of placement in a single continuous operation, the parts of the structure placed at the initial stage of placement will start their temperature history at a different time from those placed at the later stage of the placement.

In the case of hot and dry climatic conditions, the situation is more demanding than when it is only hot and humid. Some of the guidelines intended for a hot summer day in a temperate country are often not directly applicable, and appropriate adjustments should be made to take into consideration the difference in the climatic conditions. These include higher rate of evaporation reducing the stiffening time and greater potential for plastic shrinkage.

Potential Cracking in Fresh Concrete

The two main types of cracking in fresh concrete are plastic settlement cracking, and plastic shrinkage cracking.

Plastic settlement is due to the downward movement of heavier particles (particularly larger size aggregates) and the upward movement of the lighter particles (cement grout). If such movements are free to take place, the resultant segregation does not give rise to cracking. However, if such movements are hindered by top reinforcement bars, surface cracks may develop at the top surface reflecting the pattern of these bars. At local changes in cross-section, arching action may result. An internal void develops when the concrete below the arch falls away, particular for elements of a great depth, e.g., columns, walls, or deep beams. Similarly, a sudden change in depth between a slab and the ribs of a ribbed slab may give rise to a surface crack directly over the sides of a rib. A shifting of the reinforcement cage in a column may reduce the cover locally, giving rise to arching and, in general, an approximately horizontal tear develops at the side face of the column. Such cracks are formed during the first few hours before the concrete has set.

Plastic shrinkage cracks develop due to drying out of the fresh concrete. The mechanism is similar to the more familiar drying shrinkage of hardened concrete. The rate of evaporation may be estimated by the equation proposed by Uno (1998):

$$\text{Evaporation rate} = 5\left\{(\text{Tc}+18)^{2.5} - \text{R}(\text{Ta}+18)^{2.5}\right\}\{\text{V}+4\} \times 10^{-6} \ \text{kg/m}^2\text{h}$$

where Tc = concrete temperature, °C
Ta = air temperature, °C
R = relative humidity,%
V = wind velocity, km/h

The above expression points to the much more serious situation in hot and dry compared to hot and humid climatic conditions or when high wind velocity is present. Strong winds are often found along coastal regions and during placement on the high floors of a tall building. The critical rate of evaporation giving rise to cracking may be expected to vary with the type of cementitious materials used (ultimate tensile strain capacity of fresh concrete), but is often considered as 1 kg/m^{2}h in the case of commonly used Portland cement. Retardation and cohesiveness of the mixture introduce additional factors to be evaluated for their effects on potential plastic shrinkage cracking. Higher evaporation rate may be critical for mixtures with low bleeding rate or slow rate of stiffening. Evaporation of bleed water does not lead to shrinkage until the surface moisture is lost. If shrinkage occurs without any restraint, cracking may not develop. However, in practice, restraint may be due to external boundary conditions of the structural element, e.g., a slab or internal difference in moisture content within the thickness of a deep section.

Even though both types of plastic cracks may initially be very fine, subsequent drying out of the hardened concrete widens them to widths that are visible. In general, most cracks of this nature do not

significantly impair the structural behaviour, nevertheless they present a reduction in durability performance unless they are grouted or sealed.

Additional details on plastic shrinkage cracking potential may be obtained from the relevant references and publications for further information listed.

42.2 Polymer Modified Concrete

V. Sirivivatnanon

Portland cement concrete is one of the most versatile and cost-effective construction materials. Polymer-modified concrete were developed from the 1960s to overcome some of the limitations of concrete such as low tensile and flexural strength, high porosity and low resistance to certain chemicals. The relative high cost of monomers had limited the commercial viability of certain polymer-modified concrete. The advancement in chemical admixtures and mineral additives has offered alternative solutions to overcome a range of those limitations. Certain polymer cement concrete and polymer concrete remain relevant. They offer unique solutions to a range of applications.

Classifications

There are three types of polymer-modified concrete:

- *Polymer-impregnated concrete* (PIC) is a hardened cement concrete impregnated with a monomer system that is subsequently polymerised *in situ*.
- *Polymer cement concrete* (PCC) is a concrete with polymeric admixtures or a monomer system added to the fresh concrete. The monomer system is subsequently polymerised after the concrete has hardened, whereas the polymeric admixtures cure with the hardening concrete.
- *Polymer concrete* (PC) consists of an aggregate mixed with a monomer or resin that is subsequently polymerised *in situ*.

Polymer-Impregnated Concrete

The quality of porous materials such as concrete and stone can be modified vastly by the filling of the pore system. Polymer-impregnated concrete (PIC) is produced by impregnating hardened concrete with a monomer system, either by surface application or full immersion of concrete in the monomer. The amount of monomer absorbed will depend on the porosity of the concrete, the conditioning of the concrete (drying or vacuum), and the viscosity of the monomer system. The monomer is subsequently polymerized by thermal catalysis or irradiation. The polymer impregnation process enables significant improvement in both mechanical and durability properties of the concrete.

The monomer system usually involves a monomer or copolymer, a catalyst and an additive such as a surfactant. Acrylic monomer systems such as methyl methacrylate or its mixtures with acrylonitrile are preferred because they have low viscosity, high reactivity, relatively low cost and result in products with superior properties. Thermosetting monomers and prepolymers are also used to produce PIC with greatly increased thermal stability. These include epoxy prepolymers and unsaturated polyester-styrene. The concrete may be impregnated to varying depths or in the surface layer only, depending on whether increased strength and/or durability is required.

The most important feature of PIC is that a large proportion of the void volume is filled with the polymer. This results in a remarkable improvement in tensile, compressive and impact strength [Mason, 1981, Dikeou 1978], enhanced durability and reduced permeability to water and aqueous salt solutions such as sulfates and chlorides [Steinberg et al. 1968]. The compressive strength can be increased from 35 MPa to 140 MPa, the water sorption can be reduced significantly and the freeze–thaw resistance is considerably improved. The main disadvantages of PIC products are their relatively high cost, as the monomers used are expensive and the production is more complicated.

Applications of PIC include structural floors, food processing buildings, sewer pipes, storage tanks for sea water, desalination plants and distilled water plants. Partially impregnated concrete is used for the protection of bridges and concrete structures against deterioration and repair of deteriorated building structures, such as ceiling slabs, underground garage decks and bridge decks.

Kukacka [1976] reported early applications of PIC and PC as a result of their high strengths and durability. Strength increased by a factor of 4 and water absorption was reduced by more than 99%. There were also improvements in hardness and resistance to abrasion and cavitation. Two bridge decks in the USA were partially impregnated to a depth of 25.4 mm (1 in.) as a means of preventing chloride intrusion. PIC curbstones have been installed on a bridge deck as an alternative to granite, and PC patching materials are being utilized in areas where heavy traffic conditions severely limit the time during which repair work can be performed.

Polymer Cement Concrete

There are two types of polymer cement concrete (PCC). The first involves the addition of a monomer system as part of the concreting materials, and is commonly referred to as premix polymer-cement concrete (PPC). The monomer system remains in the hardening concrete and is subsequently polymerised

after the concrete has hardened. The second type involves the addition of a dispersed polymer into the mortar or concrete mix, and is usually referred to as polymer-modified cement concrete. For both types, the compatibility between the monomer or polymer and the hydrating cement system is critical to the outcome.

The monomer system and subsequent polymerisation process used in PPC are similar to those used in PIC. With limited improvements in the quality of PPC compared to conventional concrete of similar mixture proportions, and the high cost of monomer and polymerisation process, no viable commercial applications have been found for PPC.

According to Blaga and Beaudoin [1985], a range of dispersed polymer (latex: colloidal dispersion of polymer particles in water) results in greatly improved properties, at a reasonable cost. Therefore, a great variety of latexes are now available for use in PCC products and mortars. The most common latexes are based on poly (methyl methacrylate; also called acrylic latex), poly (vinyl acetate), vinyl chloride copolymers, poly (vinylidene chloride), (styrene–butadiene) copolymer, nitrile rubber and natural rubber. Each polymer produces characteristic physical properties. The acrylic latex provides a very good water-resistant bond between the modifying polymer and the concrete components, whereas use of latexes of styrene-based polymers results in a high compressive strength. Generally, PCC made with polymer latex exhibits excellent bonding to steel reinforcement and to old concrete, good ductility and resistance to penetration of water and aqueous salt solutions, and resistance to freeze–thaw damage. Its flexural strength and toughness are usually higher than those of unmodified concrete.

The drying shrinkage of PCC is generally lower than that of conventional concrete; the amount of shrinkage depends on the water-to-cement ratio, cement content, polymer content and curing conditions. It is more susceptible to higher temperatures than ordinary cement concrete. For example, creep increases with temperature to a greater extent than in ordinary cement concrete, whereas flexural strength, flexural modulus and modulus of elasticity decrease. These effects are greater in materials made with elastomeric latex (e.g., styrene–butadiene rubber) than in those made with thermoplastic polymers (e.g., acrylic). Typically, at about 45°C, PCC made with a thermoplastic latex retains only approximately 50% of its flexural strength and modulus of elasticity.

The main application of latex-containing PCC is in floor surfacing, as it is non-dusting and relatively cheap. Because of lower shrinkage, good resistance to permeation by various liquids such as water and salt solutions, and good bonding properties to old concrete, it is particularly suitable for thin (25 mm) floor toppings, concrete bridge deck overlays, anti-corrosive overlays, concrete repairs and patching.

Polymer Concrete

Polymer concrete (PC) or resin concrete is a composite containing polymer as a binder, instead of Portland cement, and inert aggregate as filler in the concrete. An epoxy or polyester is the most common polymer used. PC has higher strength, greater resistance to chemicals and corrosive agents, lower water absorption and higher freeze–thaw stability than conventional concrete. It can be produced in a similar manner to conventional concrete.

Bloomfield [1995] reported the development of PC pipes with good resistance to chemical attack from both acidic and caustic effluents inside the pipe, and from chemical attack on the outside of the pipe. Approximately 50,000 tonnes of PC pipe were manufactured by the 1960s. PC pipes made with polyester resin are reported to be corrosion resistant in continuous service with effluents ranging from a pH of 0.5 to 9.0. These pipes meet the corrosion requirements of DIN 4030, 'Assessment of Water, Soil and Gases for Their Aggressiveness to Concrete'. PC pipes can also be made with epoxy resin for a range of pH values from 0.5 to 13. In the United States, basic standards for PC pipe are being prepared by a committee on Standard Specifications for Public Works Construction, also known as the 'Green Book,' for the Los Angeles County Sanitation District.

Sewer pipes, jacking pipes, manholes, drainage system, access covers to underground services, and electrical cable jointing pits, ducting and accessories, produced with polymer concrete, are available commercially.

Schoenberner et al. [1991] compared nine general chemical family groups of polymer binders for chemically resistant concrete floor overlays. They include MMA acrylics, common epoxies, novolac epoxies, furans, polyesters, vinyl esters, potassium silicates, sulfur and urethane. It was noted that the properties were listed for average materials in the group and that the property data was obtained from manufacturers' literature on a cross-section of materials in the generic family. Vinyl ester, including vinyl ester novalacs, was reported to have better chemical resistance and to be tougher and more resilient than most polyesters. They have a lower compressive strength range and a lower coefficient of thermal expansion range, but a higher flexural and tensile strength range than polyesters. A higher full cure time of 7 days is typical for vinyl ester compared with 4 to 7 days for polyesters.

PC materials to be used in aggressive environments should be composite materials consisting of about 85% inorganic material — dry aggregate and silica (sand), which are chemically very inert and long lasting. These inorganic materials are bound together by approximately 15% of an organic matrix resin which is potentially less resistant to long-term aging in aggressive chemical environments. The vinyl ester-based matrix resin systems are known to be more chemically resistant than the polyester materials.

Limited long-term performance data on these polymer concretes are available. For unsaturated polyester concrete, an initial drop of 10% of compressive strength within the first year, followed by a period of relatively constant strength retention up to 8 years under outdoor exposure in Japan, was reported by Chandra and Ohama [1994]. It was not clear whether the concrete samples were subjected to any load during the exposure. A polyester styrene PC overlay used in the U.S. was reported by Sprinkel [1991] to provide skid resistance and protection against intrusion by chloride ions for bridge decks for 10–15 years. However, significant loss of tensile strength and bond strength, as well as elongation, were found in this polymer concrete overlay over a period of 5 to 9 years. Under accelerated deterioration tests in a weather-ometer and exposure to heat cycles, Imamura et al. [1978] found no loss in strength on a precast PC made from an unsaturated polyester resin. The concrete also exhibited good fatigue properties under bending.

For vinyl ester concrete, good resistance to water erosion, H_2SO_4, and freezing and thawing was reported. No long-term aging data were found.

Unsaturated polyester concrete is not suitable for use under severe outdoor exposure in thin section. Deterioration can occur due to photochemical reaction and hydrolysis of the ester groups in the presence of chemicals such as fuel oil (at elevated temperature) and rubber chemicals. In thicker sections, photochemical degradation could be contained in the skin, resulting in some initial drop of strength. While different degrees of degradation of polyester concrete in water were found by Imamura et al. [1978] and Mebarkia and Vipulanandan [1995], a complete recovery of the compressive strength upon drying was found by the latter.

DePuy and Selander [1978] investigated performance and durability of vinyl ester PC with initial properties of:

Compressive strength	114 MPa
Modulus of elasticity	33 GPa
Modulus of rupture	17 MPa
Flexural modulus of elasticity	35 GPa
Specific gravity	2.40

The durability of the vinyl ester PC exposed to freezing and thawing and to 5% H_2SO_4 was investigated and found to perform well. No indications of deterioration were detected after 3010 cycles of freezing and thawing, and a 0.19% weight loss was shown after 948 days of exposure to 5% H_2SO_4. The vinyl ester PC specimens were tested for creep deformation. Specimens sized 115 × 300 mm and loaded at 69.0 MPa failed within 10 to 48 days under load. This loading was about 71% of the ultimate strength for these specimens. Specimens loaded at 27.6 MPa (29% ultimate strength) and 48.1 MPa (50% ultimate strength) had creep deformation of 62.9 and 70.5 millionths/MPa respectively after 2 years. DePuy and Selander [1978] also noted that, after 2 years exposure, the experimental vinyl ester PC overlay at Shadow Mountain Dam in Colorado was in good condition, with only some minor cracking observed.

A new type of high molecular material — 3200 vinyl ester resin mortar — has been described by Lin et al. [1986], and comparison has been made with other types of polyester mortars. Vinyl ester resin,

also known as epoxy acrylic resin, is formed by a ring opening addition reaction between a low-molecular weight epoxy resin and an unsaturated carboxylic acid. The 3200 vinyl ester resin mortar is vinyl ester resin modified with a small amount of fumarate, which allows free polymerization in the presence of a peroxide initiator and can be cured at room temperature.

In 1983, 3200 vinyl ester resin mortar was used during the overhaul of the sluiceway to repair the high-velocity section of a hydropower station. At the same time, unsaturated polyester resin mortar was applied as a comparison mortar. Experience with the application of 3200 vinyl ester resin mortar showed that this type of mortar had excellent resistance to cavitation erosion, abrasion erosion, chemical corrosion and freeze–thaw cycling, with long-term durability to weathering and soaking in water. It successfully withstood three years of operation for passing water, silt and debris, and remained unaltered, while the polyester mortar exhibited signs of distress.

Okada et al. [1975] investigated the thermo-dependent properties of polyester concretes made from two types of unsaturated polyester resin. The mechanical properties of the polymer concretes were affected by atmospheric temperature. The factors influencing the thermo-dependent properties of the concrete are the type of resin and resin content, as well as the maximum size of aggregate. The strength and modulus of elasticity decrease almost linearly when temperature rises from 5°C to 60°C. Creep deformation increases remarkably above a certain temperature (about 40(c). Below about 20°C, creep deformation is almost proportional to the stress induced, and the apparent viscous flow observed is very low.
