Section I Introduction

Chapter 1 Foundations of Physiology

References

Section II Physiology of Cells and Molecules

Chapter 2 Functional Organization of the Cell

Structure of Biological Membranes

Function of Membrane Proteins

Cellular Organelles and the Cytoskeleton

Synthesis and Recycling of Membrane Proteins

Specialized Cell Types

References

Chapter 3 Signal Transduction

Mechanisms of Cellular Communication

Receptors That are Ion Channels

Receptors Coupled to G Proteins

Receptors That are Catalytic

Nuclear Receptors

References

Chapter 4 Regulation of Gene Expression

From Genes to Proteins

The Promoter and Regulatory Elements

Transcription Factors

Regulation of Inducible Gene Expression by Signal-Transduction Pathways

Epigenetic Regulation of Gene Expression

Post-Translational Regulation of Gene Expression

References

Glossary

Chapter 5 Transport of Solutes and Water

The Intracellular and Extracellular Fluids

Solute Transport Across Cell Membranes

Regulation of Intracellular Ion Concentrations

Water Transport and the Regulation of Cell Volume

Transport of Solutes and Water Across Epithelia

References

Chapter 6 Electrophysiology of the Cell Membrane

Ionic Basis of Membrane Potentials

Electrical Model of a Cell Membrane

Molecular Physiology of Ion Channels

References

Chapter 7 Electrical Excitability and Action Potentials

Mechanisms of Nerve and Muscle Action Potentials

Physiology of Voltage-Gated Channels and Their Relatives

Propagation of Action Potentials

References

Chapter 8 Synaptic Transmission and the Neuromuscular Junction

Mechanisms of Synaptic Transmission

Synaptic Transmission at the Neuromuscular Junction

Toxins and Drugs Affecting Synaptic Transmission

References

Chapter 9 Cellular Physiology of Skeletal, Cardiac, and Smooth Muscle

Skeletal Muscle

Cardiac Muscle

Smooth Muscle

Diversity among Muscles

References

Section III The Nervous System

Chapter 10 Organization of the Nervous System

Cells of the Nervous System

Development of Neurons and Glial Cells

Subdivisions of the Nervous System

References

Chapter 11 The Neuronal Microenvironment

Cerebrospinal Fluid

Brain Extracellular Space

The Blood-Brain Barrier

Glial Cells

References

Chapter 12 Physiology of Neurons

Signal Conduction in Dendrites

Control of Spiking Patterns in the Soma

Axonal Conduction

References

Chapter 13 Synaptic Transmission in the Nervous System

Neuronal Synapses

Neurotransmitter Systems of the Brain

Fast Amino Acid–Mediated Synapses in the CNS

Plasticity of Central Synapses

References

Chapter 14 The Autonomic Nervous System

Organization of the Visceral Control System

Synaptic Physiology of the Autonomic Nervous System

Central Nervous System Control of the Viscera

References

Chapter 15 Sensory Transduction

Chemoreception

Visual Transduction

Vestibular and Auditory Transduction: Hair Cells

Somatic Sensory Receptors, Proprioception, and Pain

References

Chapter 16 Circuits of the Central Nervous System

Elements of Neural Circuits

Simple, Stereotyped Responses: Spinal Reflex Circuits

Rhythmic Activity: Central Pattern Generators

Spatial Representations: Sensory and Motor Maps in the Brain

Temporal Representations: Time-Measuring Circuits

References

Section IV The Cardiovascular System

Chapter 17 Organization of the Cardiovascular System

Elements of the Cardiovascular System

Hemodynamics

How Blood Flows

Origins of Pressure in the Circulation

How to Measure Blood Pressure, Blood Flow, and Cardiac Volumes

References

Chapter 18 Blood

Blood Composition

Blood Viscosity

Hemostasis and Fibrinolysis

References

Chapter 19 Arteries and Veins

Arterial Distribution and Venous Collection Systems

Elastic Properties of Blood Vessels

References

Chapter 20 The Microcirculation

Capillary Exchange of Solutes

Capillary Exchange of Water

Lymphatics

Regulation of the Microcirculation

References

Chapter 21 Cardiac Electrophysiology and the Electrocardiogram

Electrophysiology of Cardiac Cells

The Electrocardiogram

Cardiac Arrhythmias

References

Chapter 22 The Heart as a Pump

The Cardiac Cycle

Cardiac Dynamics

From Contractile Filaments to a Regulated Pump

References

Chapter 23 Regulation of Arterial Pressure and Cardiac Output

Short-Term Regulation of Arterial Pressure

Regulation of Cardiac Output

Matching of Venous Return and Cardiac Output

Intermediate- and Long-Term Control of the Circulation

References

Chapter 24 Special Circulations

The Brain

The Heart

The Skeletal Muscle

The Splanchnic Organs

The Skin

References

Chapter 25 Integrated Control of the Cardiovascular System

Interaction among the Different Cardiovascular Control Systems

Response to Erect Posture

Responses to Acute Emotional Stress

Response to Exercise

Response to Hemorrhage

References

Section V The Respiratory System

Chapter 26 Organization of the Respiratory System

Comparative Physiology of Respiration

Organization of the Respiratory System in Humans

Lung Volumes and Capacities

References

Chapter 27 Mechanics of Ventilation

Static Properties of the Lung

Dynamic Properties of the Lung

References

Chapter 28 Acid-Base Physiology

pH and Buffers

Acid-Base Chemistry When Is the Only Buffer

Acid-Base Chemistry in the Presence of and Buffers—The Davenport Diagram

pH Regulation of Intracellular Fluid

References

Chapter 29 Transport of Oxygen and Carbon Dioxide in the Blood

Carriage of O₂

Carriage of CO₂

References

Chapter 30 Gas Exchange in the Lungs

Diffusion of Gases

Diffusion and Perfusion Limitations on Gas Transport

References

Chapter 31 Ventilation and Perfusion of the Lungs

Ventilation

Perfusion of the Lung

Matching Ventilation and Perfusion

References

Chapter 32 Control of Ventilation

Overview of the Respiratory Control System

Neurons That Control Ventilation

Generation of the Respiratory Rhythm

Chemical Control of Ventilation

Modulation of Ventilatory Control

References

Section VI The Urinary System

Chapter 33 Organization of the Urinary System

Functional Anatomy of the Kidney

Main Elements of Renal Function

Measuring Renal Clearance and Transport

The Ureters and Bladder

References

Chapter 34 Glomerular Filtration and Renal Blood Flow

Glomerular Filtration

Renal Blood Flow

Control of Renal Blood Flow and Glomerular Filtration

References

Chapter 35 Transport of Sodium and Chloride

Na^+ and Cl^- Transport by Different Segments of The Nephron

Na^+ and Cl^- , and Water Transport at the Cellular and Molecular Level

Regulation of Na^+ and Cl^- Transport

References

Chapter 36 Transport of Urea, Glucose, Phosphate, Calcium, Magnesium, and Organic Solutes

Urea

Glucose

Other Organic Solutes

Phosphate

Calcium

Magnesium

References

Chapter 37 Transport of Potassium

Potassium Balance and the Overall Renal Handling of Potassium

Potassium Transport by Different Segments of the Nephron

Potassium Transport at the Cellular and Molecular Levels

Regulation of Renal Potassium Excretion

References

Chapter 38 Urine Concentration and Dilution

- Water Balance and the Overall Renal Handling of Water
- Water Transport by Different Segments of the Nephron
- Generation of a Hyperosmotic Medulla and Urine
- Regulation by Arginine Vasopressin
- References

Chapter 39 Transport of Acids and Bases

- Acid-Base Balance and the Overall Renal Handling of Acid
- Acid-Base Transport by Different Segments of the Nephron
- Acid-Base Transport at the Cellular and Molecular Levels
- Regulation of Renal Acid Secretion
- References

Chapter 40 Integration of Salt and Water Balance

- Control of Extracellular Fluid Volume
- Control of Water Content (Extracellular Osmolality)
- References

Section VII The Gastrointestinal System

Chapter 41 Organization of the Gastrointestinal System

- Overview of Digestive Processes
- Regulation of Gastrointestinal Function
- Gastrointestinal Motility
- References

Chapter 42 Gastric Function

- Functional Anatomy of the Stomach
- Acid Secretion
- Pepsinogen Secretion
- Protection of the Gastric Surface Epithelium and Neutralization of Acid in the Duodenum
- Filling and Emptying of the Stomach

References

Chapter 43 Pancreatic and Salivary Glands

Overview of Exocrine Gland Physiology

Pancreatic Acinar Cell

Pancreatic Duct Cell

Composition, Function, and Control of Pancreatic Secretion

Salivary Acinar Cell

Salivary Duct Cell

Composition, Function, and Control of Salivary Secretion

References

Chapter 44 Intestinal Fluid and Electrolyte Movement

Functional Anatomy

Overview of Fluid and Electrolyte Movement in the Intestines

Cellular Mechanisms of Na^+ Absorption

Cellular Mechanisms of Cl^- Absorption and Secretion

Cellular Mechanisms of K^+ Absorption and Secretion

Regulation of Intestinal Ion Transport

References

Chapter 45 Nutrient Digestion and Absorption

Carbohydrate Digestion

Carbohydrate Absorption

Protein Digestion

Protein, Peptide, and Amino-Acid Absorption

Lipid Digestion

Lipid Absorption

Digestion and Absorption of Vitamins and Minerals

Nutritional Requirements

References

Chapter 46 Hepatobiliary Function

Overview of Liver Physiology

Functional Anatomy of the Liver and Biliary Tree

Uptake, Processing, and Secretion of Compounds by Hepatocytes

Bile Formation

Enterohepatic Circulation of Bile Acids

The Liver as a Metabolic Organ

References

Section VIII The Endocrine System

Chapter 47 Organization of Endocrine Control

Principles of Endocrine Function

Peptide Hormones

Amine Hormones

Steroid and Thyroid Hormones

References

Chapter 48 Endocrine Regulation of Growth and Body Mass

Growth Hormone

Growth-Promoting Hormones

Regulation of Body Mass

References

Chapter 49 The Thyroid Gland

Synthesis of Thyroid Hormones

Action of Thyroid Hormones

Hypothalamic-Pituitary-Thyroid Axis

References

Chapter 50 The Adrenal Gland

The Adrenal Cortex: Cortisol

The Adrenal Cortex: Aldosterone

The Adrenal Medulla

References

Chapter 51 The Endocrine Pancreas

Insulin

Glucagon

Somatostatin

References

Chapter 52 The Parathyroid Glands and Vitamin D

Calcium and Phosphate Balance

Physiology of Bone

Parathyroid Hormone

Vitamin D

Calcitonin and Other Hormones

References

Section IX The Reproductive System

Chapter 53 Sexual Differentiation

Genetic Aspects of Sexual Differentiation

Differentiation of the Gonads

Development of the Accessory Sex Organs

Differentiation of the External Genitalia

Endocrine and Paracrine Control of Sexual Differentiation

Puberty

References

Chapter 54 The Male Reproductive System

Hypothalamic-Pituitary-Gonadal Axis

Testosterone

Biology of Spermatogenesis and Semen

Male Sex Act

References

Chapter 55 The Female Reproductive System

Hypothalamic-Pituitary-Gonadal Axis and Control of the Menstrual Cycle

Ovarian Steroids

The Ovarian Cycle: Folliculogenesis, Ovulation, and Formation of the Corpus Luteum

The Endometrial Cycle

Female Sex Act

Menopause

References

Chapter 56 Fertilization, Pregnancy, and Lactation

Transport of Gametes and Fertilization

Implantation of the Developing Embryo

Physiology of the Placenta

The Maternal-Placental-Fetal Unit

Response of the Mother to Pregnancy

Parturition

Lactation

References

Chapter 57 Fetal and Neonatal Physiology

Biology of Fetal Growth

Development and Maturation of the Cardiopulmonary System

Cardiopulmonary Adjustments at Birth

Neonatal Physiology

References

Section X Physiology of Everyday Life

Chapter 58 Metabolism

Forms of Energy

Energy Balance

Energy Interconversion From Cycling between 6-Carbon and 3-Carbon Molecules

Energy Capture (Anabolism)

Energy Liberation (Catabolism)

Integrative Metabolism During Fasting

References

Chapter 59 Regulation of Body Temperature

Heat and Temperature: Advantages of Homeothermy

Modes of Heat Transfer

Active Regulation of Body Temperature by the Central Nervous System

Hypothermia, Hyperthermia, and Fever

References

Chapter 60 Exercise Physiology and Sports Science

Motor Units and Muscle Function

Conversion of Chemical Energy to Mechanical Work

Muscle Fatigue

Determinants of Maximal O₂ Uptake and Consumption

Sweating

Endurance (Aerobic) Training

References

Chapter 61 Environmental Physiology

The Environment

Diving Physiology

High-Altitude Physiology

Flight and Space Physiology

Preface to the Third Edition

We are delighted that the physiological community so eagerly welcomed the Second Edition of our book. The 3-fold philosophy that has guided us in the previous editions has endured as we prepared the Third Edition.

First, we combine the expertise of several authors with the consistency of a single pen. In the First Edition, we achieved this singleness of pen by sitting—shoulder to shoulder—at a computer as we rewrote the primary copy of our authors, line by line. By the time we began editing the Third Edition, one of us had moved from New Haven to Cleveland. Even so, we continued to edit jointly and in real time—monitor to monitor—using desktop-sharing software. After more than two decades, we have become so accustomed to each other's writing styles that we can literally finish each other's sentences.

Second, we still integrate physiological concepts from the level of DNA and epigenetics to the human body, and everything in between.

Third, we complete the presentation of important physiological principles by pairing them with illustrations from pathophysiology, thereby putting physiology in a clinical context.

In this Third Edition, we have updated the entire book to reflect new molecular insights. In the process, we have shortened the printed version of the book by 40 pages. The Third Edition contains 20 new or redrawn figures as well as enhancements to 125 others. Similarly, we included over 190 tables. In the First Edition, we launched the concept of online-only Notes—electronic footnotes that were available on the Student Consult website. These Notes (indicated by 📌 icons in the print version of the book) amplify concepts in the text, provide details and derivations of equations, add clinical illustrations, and include interesting facts (e.g., biographies of famous physiologists). With the increased use of online materials and eBooks, our readers may welcome our updating of the previous Notes as well as a 13% increase in the total number of Notes for the Third Edition, for a total of about 750. In the Second Edition, we provided the reader with numerous crosslinks to explanatory materials within the book by providing chapter numbers. In the Third Edition, we greatly expand the number of such crosslinks—but now refer the reader to specific pages in the print, and link the reader to specific paragraphs in the eBook. The eBook provides references to scientific literature.

In Section II (Physiology of Cells and Molecules), fresh insights led to substantial revisions in [Chapter 4](#) (*Regulation of Gene Expression*), including the subchapter on epigenetics, and another on posttranslational modifications. Moreover, advances in physiological genomics and the understanding of genetic diseases led to major expansions of two tables—one on the SLC family of transporters ([Table 5-4](#) in the chapter on *Transport of Solutes and Water*) and the other on ion channels ([Table 6-2](#) in the chapter on *Electrophysiology of the Cell Membrane*). In both tables, our updates help the reader navigate through what sometimes are multiple systems of terminology.

In Section III (The Nervous System), new molecular developments led to major changes in [Chapter 15](#) (*Sensory Transduction*), including the transduction of taste. In Section IV (The Cardiovascular System), we have improved the molecular underpinning of the ionic currents in [Chapter 21](#) (*Cardiac Electrophysiology and the Electrocardiogram*). In Section VI (The Urinary System), we welcome Peter

Aronson as a new co-author. Improved molecular insights led to major improvements in [Chapter 36](#), including the subchapters on urea, urate, phosphate, and calcium. In Section VII (The Gastrointestinal System), [Chapter 43](#) (*Pancreatic and Salivary Glands*) underwent significant modernization, including an expansion of the treatment of salivary glands. In [Chapter 45](#) (*Nutrient Digestion and Absorption*), we welcome Charles Mansbach as a new co-author. Section VIII (The Endocrine System) underwent significant updating, including the treatment of phosphate handling in [Chapter 52](#) (*The Parathyroid Glands and Vitamin D*). In Section IX (The Reproductive System), we welcome two new authors. Sam Mesiano extensively reworked [Chapters 53](#) (*Sexual Differentiation*) through [Chapter 56](#) (*Fertilization, Pregnancy, and Lactation*), and George Lister has similarly rewritten [Chapter 57](#) (*Fetal and Neonatal Physiology*). Finally, in Section X (Physiology of Everyday Life), we welcome Shaun Morrison, who extensively rewrote [Chapter 59](#) (*Regulation of Body Temperature*). [Chapter 62](#) (*The Physiology of Aging*) underwent extensive changes, including new treatments of necroptosis and frailty.

The eBook

Although you can still enjoy our book while reading the print version, you can also access the extended content at your computer via the website www.StudentConsult.com. The eBook is also available through the Inkling app on tablets and smart phones. Regardless of the platform for accessing the eBook, the student may access Notes, crosslinks, and references as noted above, and also can “follow” professors and see their highlights and annotations within the text.

Acknowledgments

A textbook is the culmination of successful collaborations among many individuals. First, we thank our chapter authors, who are listed under Contributors on pages v and vi. We also thank other colleagues who wrote WebNotes, or provided other valuable materials or input. Roberto Dominguez provided [Figure 9-5A](#), and Slavek Filipek and Kris Palczewski provided [Figure 15-12](#). Philine Wangemann made invaluable suggestions for the *Vestibular and Auditory Transduction* subchapter in [Chapter 15](#). George Dubyak responded to numerous queries. We thank all our readers who sent us their suggestions or corrections; we list them in the accompanying [NP-1](#).

At the art studio DNA Illustrations, Inc, we thank David and Alex Baker for developing new figures and updating others, while maintaining the textbook's aesthetic appeal, originally established by JB Woolsey and Associates.

At Elsevier, we are most grateful to Elyse O'Grady—Executive Content Strategist—for her trust and endurance. Marybeth Thiel—Senior Content Development Specialist—was the project's communications hub, responsible for coordinating all parties working on the textbook, and for assembling the many elements that comprised the final product. Her meticulous care was indispensable. We thank David Stein—Senior Project Manager—for overseeing production of the textbook. Striving for consistency, Elsevier did us the favor of assigning a single copyeditor—Janet E. Lincoln—to the entire project. We were especially impressed with her meticulous copyediting. Moreover, because she read the manuscript as a dedicated student, she identified several logical or scientific errors, including inconsistencies between chapters.

Finally, we thank four editorial assistants. Charleen Bertolini used every ounce of her friendly, good-

humored, and tenacious personality to keep our authors—and us—on track during the first few years as we prepared the Third Edition. Later, three students in the MS in Medical Physiology Program at Case Western Reserve University took the reins from Charleen—Evan Rotar, Alisha Bouzaher, and Anne Jessica Roe.

As we did for the first two editions, we again invite the reader to enjoy learning physiology. If you are pleased with our effort, tell others. If not, tell us.

Preface to the First Edition

We were intrigued by an idea suggested to us by W.B. Saunders: write a modern textbook of physiology that combines the expertise of a multi-author book with the consistency of a single pen. Our approach has been, first, to recruit as writers mainly professors who teach medical physiology at the Yale University School of Medicine, and then to recast the professors' manuscripts in a uniform style. After much effort, we now present our book, which we hope will bring physiology to life and at the same time be a reliable resource for students.

Target Audience

We wrote *Medical Physiology* primarily as an introductory text for medical students, although it should also be valuable for students in the allied health professions and for graduate students in the physiological sciences. The book should continue to be useful for the advanced medical student who is learning pathophysiology and clinical medicine. Finally, we hope that physicians in training, clinical fellows, and clinical faculty will find the book worthwhile for reviewing principles and becoming updated on new information pertinent for understanding the physiological basis of human disease.

Content of the Textbook

Aside from Part I, which is a brief introduction to the discipline of physiology, the book consists of nine major Parts. Part II (Physiology of Cells and Molecules) reflects that, increasingly, the underpinnings of modern physiology have become cellular and molecular. [Chapters 2, 4, and 5](#) would not be present in a traditional physiology text. [Chapter 2](#) (Functional Organization of the Cell), [Chapter 4](#) (Signal Transduction), and [Chapter 5](#) (Regulation of Gene Expression) provide the essentials of cell biology and molecular biology necessary for understanding cell and organ function. The other chapters in Part II cover the *cellular* physiology of transport, excitability, and muscle—all of which are classic topics for traditional physiology texts. In this book we have extended each of these subjects to the *molecular* level. The remainder of the book will frequently send the reader back to the principles introduced in Part II.

Parts III to IX address individual organ systems. In each case, the first chapter provides a general introduction to the system. Part III (Cellular Physiology of the Nervous System) is untraditional in that it deliberately omits those aspects of the physiology of the central nervous system that neuroscience courses generally treat and that require extensive knowledge of neuroanatomical pathways. Rather, Part III focuses on cellular neurophysiology, including synaptic transmission in the nervous system, sensory transduction, and neural circuits. In addition, Part III also treats two subjects—the autonomic nervous system and the neuronal microenvironment—that are important for understanding other physiological systems. Finally, Part X (The Physiology of Everyday Life) is an integrated, multisystem approach to metabolism, temperature regulation, exercise, and adaptations to special environments.

Emphasis of the Textbook

Some important aspects of physiology remain as fundamentally important today as when the pioneers of physiology discovered them a century or more ago. These early observations were generally phenomenological descriptions that physiologists have since been trying to understand at a mechanistic level. Where possible, a goal of this textbook is to extend this understanding all the way to the cell and molecule. Moreover, although some areas are evolving rapidly, we have tried to be as up to date as practical. To make room for the cellular and molecular bricks, we have omitted some classic experimental observations, especially when they were of a “black-box” nature.

Just as each major Part of the textbook begins with an introductory chapter, each chapter generally first describes—at the level of the whole body or organ system (e.g., the kidney)—how the body performs a certain task and/or controls a certain parameter (e.g., plasma K^+ concentration). As appropriate, our discussion then progresses in a reductionistic fashion from organ to tissue to cell and organelles, and ultimately to the molecules that underlie the physiology. Finally, most chapters include a discussion of how the body regulates the parameter of interest at all levels of integration, from molecules to the whole body.

Creating the Textbook

The first draft of each chapter was written by authors with extensive research and/or teaching experience in that field. The editors, sitting shoulder to shoulder at a computer, then largely rewrote all chapters line by line. The goal of this exercise was for the reader to recognize, throughout the entire book, a single voice—a unity provided by consistency in style, in organization, in the sequence for presenting concepts, and in terminology and notation, as well as in consistency in the expression of standard values (e.g., a cardiac output of 5 liters/min). The editors also attempted to minimize overlap among chapters by making extensive use of cross references (by page, figure, or table number) to principles introduced elsewhere in the book.

After the first round of editing, Dr. Malcolm Thaler—a practicing physician and accomplished author in his own right—improved the readability of the text and sometimes added clinical examples. Afterwards, the editors again went through the entire text line by line to decide on the material to be included in specific illustrations, and to match the main text of the book with the content of each figure. The editors then traveled to Philadelphia to visit the art studio of JB Woolsey and Associates. Over many visits, John Woolsey and the editors together developed the content and format for each of the approximately 760 full-color illustrations used in the textbook. These meetings were unique intellectual and pedagogical dialogues concerning the design of the figures. To a large extent, the figures owe their pedagogical style to the creativity of John Woolsey.

The illustrations evolved through several iterations of figure editing, based on suggestions from both the editors and authors. This evolution, as well as text changes requested by authors, led to yet a third round of editing of the entire book, often line by line. Throughout this seemingly endless process, our goal has been to achieve the proper balance among reader friendliness, depth, and accuracy.

Special Features

Compared with other major textbooks of physiology, a much larger fraction of the space in this book is devoted to illustrations. Thus, although our textbook may appear thick, it actually has fewer text words than most other leading medical physiology books. Virtually all illustrations in our book are in full color, conceived de novo, with consistent style and pedagogy. Many of the figures feature “dialogue balloons” that tell a story. The illustrations are also available in digital format on the Evolve Web site (http://evolve.elsevier.com/productPages/s_417.html) for use in the classroom.

The textbook makes considerable use of clinical boxes—highlighted on a color background—that present examples of diseases illustrating important physiological principles. The text includes over 2000 cross references that send the reader from the current page to specific pages, figures, or tables elsewhere in the book for relevant concepts or data. The text also includes hundreds of web icons, which direct the reader to our website at <http://www.wbsaunders.com/MERLIN/BandB/>. These web links provide derivations of mathematical equations, amplification of concepts, material that was deleted for the sake of brevity from earlier drafts of the textbook, and clinical illustrations not included in the clinical boxes.

The website will also contain several other features, including summaries for each subchapter, an expanded list of references (sometimes with direct links to the primary literature), other links that may be of interest to the physiology student (e.g., biographies of famous physiologists), late-breaking scientific developments that occur after publication of the book, and—alas—the correction of errors. Finally, we invite the reader to visit our website to comment on our book, to point out errors, and to make other helpful suggestions.

Acknowledgments

A textbook is the culmination of successful collaborations among many individuals. First, we would like to thank our authors. Second, we acknowledge the expert input of Dr. Malcolm Thaler, both in terms of style and clinical insight. We also thank Dr. Thaler for emphasizing the importance of telling a “good story.” The textbook's aesthetic appeal is largely attributable to JB Woolsey and Associates, particularly John Woolsey and Joel Dubin.

At W.B. Saunders, we are especially thankful to William R. Schmitt—Acquisitions Editor—for his trust and patience over the years that this book has been in gestation. At the times when the seas were rough, he steered a safe course. Melissa Dudlick—Developmental Editor at W.B. Saunders—was the project's nerve center, responsible for day-to-day communication among all parties working on the textbook, and for assembling all of the many components that went into making the final product. Her good humor and careful attention to detail greatly facilitated the creation of the textbook. We thank Frank Polizzano—Publishing Services Manager at W.B. Saunders—for overseeing production of the textbook.

Before this textbook was completed, the author of Part X (The Physiology of Everyday Life), Ethan Nadel, passed away. We are indebted to those who generously stepped up to carefully check the nearly finished manuscripts for the final four chapters: Dr. Gerald Shulman for [Chapter 57](#), Dr. John Stitt for [Chapter 58](#), the late Dr. Carl Gisolfi for [Chapter 59](#), and Dr. Arthur DuBois for [Chapter 60](#). In addition, Dr. George Lister provided expert advice for [Chapter 56](#). We are also grateful to Dr. Bruce Davis for researching the sequences of the polypeptide hormones, to Mr. Duncan Wong for expert information-technology services, and to Mrs. Leisa Strohmaier for administrative assistance.

We now invite the reader to enjoy the experience of learning physiology. If you are pleased with our effort, tell others. If not, tell us.

SECTION I

Introduction

OUTLINE

Chapter 1 Foundations of Physiology	
-------------------------------------	--

CHAPTER 1

Foundations of Physiology

Emile L. Boulpaep, Walter F. Boron

What is physiology?

Physiology is the dynamic study of life. Physiology describes the “vital” functions of living organisms and their organs, cells, and molecules. For centuries, the discipline of physiology has been closely intertwined with medicine. Although physiology is not primarily concerned with structure—as is the case for anatomy, histology, and structural biology—structure and function are inextricably linked because the living structures perform the functions.

For some, physiology is the function of the whole person (e.g., exercise physiology). For many practicing clinicians, physiology may be the function of an individual organ system, such as the cardiovascular, respiratory, or gastrointestinal system. For still others, physiology may focus on the cellular principles that are common to the function of all organs and tissues. This last field has traditionally been called *general physiology*, a term that is now supplanted by *cellular and molecular physiology*. Although one can divide physiology according to varying degrees of reductionism, it is also possible to define a branch of physiology—for example, *comparative physiology*—that focuses on differences and similarities among different species. Indeed, comparative physiology may deal with all degrees of reductionism, from molecule to whole organism. In a similar way, *medical physiology* deals with how the human body functions, which depends on how the individual organ systems function, which depends on how the component cells function, which in turn depends on the interactions among subcellular organelles and countless molecules. Thus, medical physiology takes a global view of the human body; but in doing so, it requires an integrated understanding of events at the level of molecules, cells, and organs.

Physiology is the mother of several biological sciences, having given birth to the disciplines of biochemistry, biophysics, and neuroscience, as well as their corresponding scientific societies and journals. Thus, it should come as no surprise that the boundaries of physiology are not sharply delineated. Conversely, physiology has its unique attributes. For example, physiology has evolved over the centuries from a more qualitative to a more quantitative science. Indeed, many of the leading physiologists were—and still are—trained as chemists, physicists, mathematicians, or engineers.

Physiological genomics is the link between the organ and the gene

The life of the human body requires not only that individual organ systems do their jobs but also that these organ systems work “hand in hand” with each other. They must share information. Their actions must be interdependent. The cells within an organ or a tissue often share information, and certainly the individual cells must act in concert to perform the proper function of the organ or tissue. In fact, cells in one organ must often share information with cells in another organ and make decisions that are appropriate for the health of the individual cell as well as for the health of the whole person.

In most cases, the sharing of information between organs and between cells takes place at the level of atoms or molecules. Cell-to-cell messengers or intracellular messengers may be as simple as H^+ or K^+ or Ca^{2+} . The messengers may also be more complex chemicals. A cell may release a molecule that acts on a neighboring cell or that enters the bloodstream and acts on other cells a great distance away. In other cases, a neuron may send an axon a centimeter or even a meter away and rapidly modulate, through a neurotransmitter molecule, the activity of another cell or another organ. Cells and organs must interact with one another, and the method of communication is almost always molecular.

The grand organizer—the master that controls the molecules, the cells, and the organs and the way they interact—is the genome with its epigenetic modifications. Traditionally, the discipline of physiology has, in its reductionistic journey, always stopped at about the level of cells and certain subcellular organelles as well as their component and controlling molecules. The discipline of physiology left to molecular biology and molecular genetics the business of how the cell controls itself through its DNA. The modern discipline of physiology has become closely intertwined with molecular biology, however, because DNA encodes the proteins in which physiologists are most interested. Very often, physiologists painstakingly develop elegant strategies for cloning the genes relevant to physiology. Sometimes brute-force approaches, such as the Human Genome Project in the United States, hand the physiologist a candidate gene, homologous to one of known function, on a silver platter. In still other cases, molecular biologists may clone a gene with no known function. In this case, it may be up to the physiologist to determine the *function* of the gene product; that is, to determine its *physiology*.

Physiological genomics (or functional genomics) is a new branch of physiology devoted to the understanding of the roles that genes play in physiology. Traditionally, physiologists have moved in a reductionistic direction from organ to cell to molecule to gene. One of the most fascinating aspects of physiological genomics is that it has closed the circle and linked organ physiology directly with molecular biology. Perhaps one of the most striking examples is the knockout mouse. Knocking out the gene encoding a protein that, according to conventional wisdom, is very important will sometimes have no obvious effect or sometimes unexpected effects. It is up to the physiologist, at least in part, to figure out why. It is perhaps rather sobering to consider that to truly understand the impact of a transgene or a knockout on the physiology of a mouse, one would have to carefully re-evaluate the totality of mouse physiology. To grasp the function of a gene product, the physiologist must retrace the steps up the reductionistic road and achieve an integrated understanding of that gene's function at the level of the cells, organs, and whole body. Physiology is unique among the basic medical sciences in that it is both broad in its scope (i.e., it deals with multiple systems) and integrative in its outlook.

In some cases, important physiological parameters, such as blood pressure, may be under the control of many genes. Certain polymorphisms in several of these many genes could have a cumulative effect that produces high blood pressure. How would one identify which polymorphisms of which genes may underlie high blood pressure? This sort of complex problem does not easily lend itself to a physiologist's controlled studies. One approach would be to study a population of people, or strains of experimental animals, and use statistical tools to determine which polymorphisms correlate with high blood pressure in a population. Indeed, epidemiologists use statistical tools to study group effects in populations. However, even after the identification of variants in various genes, each of which may make a small contribution to high blood pressure, the physiologist has an important role. First, the physiologist, performing controlled experiments, must determine whether a particular genetic variant does indeed have at least the potential to modulate blood pressure. Second, the physiologist must determine the mechanism of the effect.

Cells live in a highly protected milieu intérieur

In his lectures on the phenomena of life, [Claude Bernard noted in 1878](#) on the conditions of the constancy of life, which he considered a property of higher forms of life. According to Bernard, animals have two environments: the “milieu extérieur” that physically surrounds the whole organism; and the “milieu intérieur,” in which the tissues and cells of the organism live. This internal environment is neither the air nor the water in which an organism lives but rather—in the case of the human body—the well-controlled liquid environment that Bernard called “the organic liquid that circulates and bathes all the anatomic elements of the tissues, the lymph or the plasma.” In short, this internal environment is what we today call the extracellular fluid. He argued that physiological functions continue in a manner indifferent to the changing environment because the milieu intérieur isolates the organs and tissues of the body from the vagaries of the physical conditions of the environment. Indeed, Bernard described the milieu intérieur as if an organism had placed itself in a greenhouse.

According to Bernard's concept of milieu intérieur, some fluids contained within the body are not really inside the body at all. For example, the *contents* of the gastrointestinal tract, sweat ducts, and renal tubules are all outside the body. They are all continuous with the milieu extérieur.

Bernard compares a complex organism to an ensemble of anatomical elements that live together inside the milieu intérieur. Therefore, in Section II of this textbook, we examine the physiology of these cells and molecules. In [Chapter 2](#) (“Functional Organization of the Cell”), we begin our journey through physiology with a discussion of the biology of the cells that are the individual elements of the body. [Chapter 3](#) (“Signal Transduction”) discusses how cells communicate *directly* through gap junctions or *indirectly* by molecules released into the extracellular fluid. These released molecules can bind to receptors on the cell membrane and initiate signal-transduction cascades that can modify gene transcription (a genomic response) and a wide range of other cell functions (nongenomic responses). Alternatively, these released molecules can bind to receptors in the cytoplasm or nucleus and alter the transcription of genes. In [Chapter 4](#) (“Regulation of Gene Expression”), we examine the response of the nucleus. [Chapter 5](#) (“Transport of Solutes and Water”) addresses how the plasma membrane separates the cell interior from Bernard's milieu intérieur and establishes the composition of the cell interior. In the process of establishing the composition of the intracellular fluid, the plasma membrane also sets up ion and voltage gradients across itself. Excitable cells—mainly nerve and muscle cells—can exploit these gradients for the long-distance “electrical” transmission of information. The property of “excitability,” which requires both the perception of a change (a signal) and the reaction to it, is the topic of [Chapters 6 to 9](#). In Section III, we examine how the nervous system exploits excitability to process information.

Another theme developed by Bernard was that the “fixité du milieu intérieur” (the constancy of the extracellular fluid) is the condition of “free, independent life.” He explains that organ differentiation is the exclusive property of higher organisms and that each organ contributes to “compensate and equilibrate” against changes in the external environment. In that sense, each of the systems discussed in Sections IV to VIII permits the body to live within an adverse external environment because the cardiovascular system, the respiratory system, the urinary system, the gastrointestinal system, and the endocrine system create and maintain a constant internal environment. Individual cell types in various organ systems act in concert to support the constancy of the internal milieu, and the internal milieu in turn provides these cells with a culture medium in which they can thrive.

The discipline of physiology also deals with those characteristics that are the property of a living organism as opposed to a nonliving organism. Four fundamental properties distinguish the living body. First, only living organisms exchange matter and energy with the environment to continue their existence.

Several organ systems of the body participate in these exchanges. Second, only living organisms can receive signals from their environment and react accordingly. The principles of sensory perception, processing by the nervous system, and reaction are discussed in the chapters on excitability and the nervous system. Third, what distinguishes a living organism is the life cycle of growth and reproduction, as discussed in the chapters on reproduction (Section IX). Finally, the living organism is able to adapt to changing circumstances. This is a theme that is developed throughout this textbook but especially in the chapters on everyday life (Section X).

Homeostatic mechanisms—operating through sophisticated feedback control mechanisms—are responsible for maintaining the constancy of the milieu intérieur

Homeostasis is the control of a vital parameter. The body carefully controls a seemingly endless list of vital parameters. Examples of tightly controlled parameters that affect nearly the whole body are arterial pressure and blood volume. At the level of the milieu intérieur, tightly regulated parameters include body core temperature and plasma levels of oxygen, glucose, potassium ions (K^+), calcium ions (Ca^{2+}), and hydrogen ions (H^+). Homeostasis also occurs at the level of the single cell. Thus, cells regulate many of the same parameters that the body as a whole regulates: volume, the concentrations of many small inorganic ions (e.g., Na^+ , Ca^{2+} , H^+), and energy levels (e.g., ATP).

One of the most common themes in physiology is the **negative-feedback mechanism** responsible for homeostasis. Negative feedback requires at least four elements. First, the system must be able to sense the vital parameter (e.g., glucose level) or something related to it. Second, the system must be able to compare the input signal with some internal reference value called a *set-point*, thereby forming a difference signal. Third, the system must multiply the error signal by some proportionality factor (i.e., the gain) to produce some sort of output signal (e.g., release of insulin). Fourth, the output signal must be able to activate an effector mechanism (e.g., glucose uptake and metabolism) that opposes the source of the input signal and thereby brings the vital parameter closer to the set-point (e.g., decrease of blood glucose levels back to normal).  **N1-1** Sometimes the body controls a parameter, in part, by cleverly employing positive-feedback loops.

N1-1

Feedback Control

Contributed by Arthur DuBois

In proportional control, the set-point is not reached because the difference signal would disappear, and control would come to an end. Engineers devised a way around this. They took the time integral of the difference signal and used that to activate the effector mechanism to achieve integral control that would allow return to the set-point. There was another problem. Since there is a time delay in processing the input signal, there is a delay in returning to the set-point. Engineers also had a way around that. They took the time-derivative of the difference signal and added that to the corrective signal, speeding up the return toward the set-point.

Another problem turned up. If you have a heater and a cooler, each with its own thermostat, and you want the room to be 23°C to 25°C, you must set one thermostat to turn on the heater at temperatures

<23°C but to shut it off at ≥23°C. The thermostat for the cooler has to turn it on >25°C but shut it off at ≤25°C to avoid running the heater and cooler both at once. If the room is cold, the heater will warm it up to 23°C, then shut off. If the room is warm, the cooler will cool it down to 25°C, then shut off. By analogy, the body has separate systems for shivering and sweating, so both do not occur at once. One can picture that anabolic and catabolic pathways should cycle separately and not simultaneously. Many body systems such as respiratory and circulatory controls oscillate between slightly above and slightly below the desired average, hunting for it rather than sitting on a single ideal value. In a case in which the control system is less precise, the swings become wider, as they do when a drunk driver wanders back and forth across the road proceeding home.

A single feedback loop often does not operate in isolation but rather as part of a larger network of controls. Thus, a complex interplay may exist among feedback loops within single cells, within a tissue, within an organ or organ system, or at the level of the whole body. After studying these individual feedback loops in isolation, the physiologist may find that two feedback loops act either synergistically or antagonistically. For example, insulin lowers blood glucose levels, whereas epinephrine and cortisol have the opposite effect. Thus, the physiologist must determine the relative weights of feedback loops in **competition** with one another. Finally, the physiologist must also establish **hierarchy** among various feedback loops. For example, the hypothalamus controls the anterior pituitary, which controls the adrenal cortex, which releases cortisol, which helps control blood glucose levels.

Another theme of homeostasis is **redundancy**. The more vital a parameter is, the more systems the body mobilizes to regulate it. If one system should fail, others are there to help maintain homeostasis. It is probably for this reason that genetic knockouts sometimes fail to have their expected deleterious effects. The result of many homeostatic systems controlling many vital parameters is a milieu intérieur with a stable composition.

Whether at the level of the milieu intérieur or the cytoplasm of a single cell, homeostasis occurs at a price: energy. When a vital parameter (e.g., the blood glucose level) is well regulated, that parameter is not in equilibrium. **Equilibrium** is a state that does not involve energy consumption. Instead, a well-regulated parameter is generally in a **steady state**. That is, its value is constant because the body or the cell carefully matches actions that lower the parameter value with other actions that raise it. The net effect is that the vital parameter is held at a constant value.

An important principle in physiology, to which we have already alluded, is that each cell plays a specialized role in the overall function of the body. In return, the body—which is the sum of all these cells—provides the milieu intérieur appropriate for the life of each cell. As part of the bargain, each cell or organ must respect the needs of the body as a whole and not run amok for its own greedy interests. For example, during exercise, the system that controls body core temperature sheds heat by elaborating sweat for evaporation. However, the production of sweat ultimately reduces blood volume. Because the body as a whole places a higher **priority** on the control of blood volume than on the control of body core temperature, at some point the system that controls blood volume will instruct the system that controls body core temperature to reduce the production of sweat. Unfortunately, this juggling of priorities works only if the individual stops exercising; if not, the result may be heat stroke.

The **adaptability** of an organism depends on its ability to alter its response. Indeed, flexible feedback loops are at the root of many forms of physiological adaptation. For instance, at sea level, experimentally lowering the level of oxygen (the sensory stimulus) in the inspired air causes an increase in breathing (the response). However, after **acclimatization** at high altitude to low oxygen levels, the same low level of oxygen (the same sensory stimulus) causes one to breathe much faster (a greater response). Thus, the

response may depend on the previous history and therefore the “state” of the system. In addition to acclimatization, genetic factors can also contribute to the ability to respond to an environmental stress. For example, certain populations of humans who have lived for generations at high altitude withstand hypoxia better than lowlanders do, even after the lowlanders have fully acclimatized.

Medicine is the study of “physiology gone awry”

Medicine borrows its physicochemical principles from physiology. Medicine also uses physiology as a reference state: it is essential to know how organs and systems function in the healthy person to grasp which components may be malfunctioning in a patient. A large part of clinical medicine is simply dealing with the abnormal physiology brought about by a disease process. One malfunction (e.g., heart failure) can lead to a *primary* pathological effect (e.g., a decrease in cardiac output) that—in chain-reaction style—leads to a series of *secondary* effects (e.g., fluid overload) that are the appropriate responses of physiological feedback loops. Indeed, as clinician-physiologists have explored the basis of disease, they have discovered a great deal about physiology. For this reason, we have tried to illustrate physiological principles with clinical examples, some of which are displayed in clinical boxes in this text.

Physiologists have developed many tools and tests to examine normal function. A large number of functional tests—used in diagnosis of a disease, monitoring of the evolution of an illness, and evaluation of the progress of therapy—are direct transfers of technology developed in the physiology laboratory. Typical examples are cardiac monitoring, pulmonary function tests, and renal clearance tests as well as the assays used to measure plasma levels of various ions, gases, and hormones. Refinements of such technology in the hospital environment, in turn, benefit the study of physiology. Thus, the exchange of information between medicine and physiology is a two-way street. The understanding of physiology summarized in this book comes from some experiments on humans but mostly from research on other mammals and even on squids and slime molds. However, our ultimate focus is on the human body.

Functional Organization of the Cell

Michael J. Caplan

In the minds of many students, the discipline of physiology is linked inextricably to images from its past. This prejudice is not surprising because many experiments from physiology's proud history, such as those of Pavlov on his dogs, have transcended mere scientific renown and entered the realm of popular culture. Some might believe that the science of physiology devotes itself exclusively to the study of whole animals and is therefore an antique relic in this era of molecular reductionism. Nothing could be further from the truth. Physiology is and always has been the study of the homeostatic mechanisms that allow an organism to persist despite the ever-changing pressures imposed by a hostile environment. These mechanisms can be appreciated at many different levels of resolution.

Certainly it would be difficult to understand how the body operates unless one appreciates the functions of its organs and the communication between these organs that allows them to influence one another's behaviors. It would also be difficult to understand how an organ performs its particular tasks unless one is familiar with the properties of its constituent cells and molecules.

The modern treatment of physiology that is presented in this textbook is as much about the interactions of molecules in cells as it is about the interactions of organs in organisms. It is necessary, therefore, at the outset to discuss the structure and characteristics of the cell. Our discussion focuses first on the architectural and dynamic features of a generic cell. We then examine how this generic cell can be adapted to serve in diverse physiological capacities. Through adaptations at the cellular level, organs acquire the machinery necessary to perform their individual metabolic tasks.

Structure of Biological Membranes

The surface of the cell is defined by a membrane

The chemical composition of the cell interior is very different from that of its surroundings. This observation applies equally to unicellular paramecia that swim freely in a freshwater pond and to neurons that are densely packed in the cerebral cortex of the human brain. The biochemical processes involved in cell function require the maintenance of a precisely regulated intracellular environment. The cytoplasm is an extraordinarily complex solution, the constituents of which include myriad proteins, nucleic acids, nucleotides, and sugars that the cell synthesizes or accumulates at great metabolic cost. The cell also expends tremendous energy to regulate the intracellular concentrations of numerous ions. If there were no barrier surrounding the cell to prevent exchange between the intracellular and extracellular spaces, all of the cytoplasm's hard-won compositional uniqueness would be lost by diffusion in a few seconds.

The requisite barrier is provided by the **plasma membrane**, which forms the cell's outer skin. The plasma membrane is *impermeable* to large molecules such as proteins and nucleic acids, thus ensuring their retention within the cytosol. It is *selectively permeable* to small molecules such as ions and metabolites. However, the metabolic requirements of the cell demand a plasma membrane that is much more sophisticated than a simple passive barrier that allows various substances to leak through at different rates. Frequently, the concentration of a nutrient in the extracellular fluid (ECF) is several orders of magnitude lower than that required inside the cell. If the cell wishes to use such a substance, therefore, it must be able to *accumulate* it against a concentration gradient. A simple pore in the membrane cannot concentrate anything; it can only modulate the rate at which a gradient dissipates. To accomplish the more sophisticated feat of creating a concentration gradient, the membrane must be endowed with special machinery that uses metabolic energy to drive the *uphill* movements of substances—**active transport**—into or out of the cell. In addition, it would be useful to rapidly modulate the permeability properties of the plasma membrane in response to various metabolic stimuli. Active transport and the ability to control passive permeabilities underlie a wide range of physiological processes, from the electrical excitability of neurons to the resorptive and secretory functions of the kidney. In [Chapter 5](#), we will explore how cells actively transport solutes across the plasma membrane. The mechanisms through which the plasma membrane's dynamic selectivity is achieved, modified, and regulated are discussed briefly below in this chapter and in greater detail in [Chapter 7](#).

The cell membrane is composed primarily of phospholipids

Our understanding of biological membrane structure is based on studies of red blood cells, or erythrocytes, that were conducted in the early part of the 20th century. The erythrocyte lacks the nucleus and other complicated intracellular structures that are characteristic of most animal cells. It consists of a plasma membrane surrounding a cytoplasm that is rich in hemoglobin. It is possible to break open erythrocytes and release their cytoplasmic contents. The plasma membranes can then be recovered by centrifugation to provide a remarkably pure preparation of cell surface membrane. Biochemical analysis reveals that this membrane is composed of two principal constituents: lipid and protein.

Most of the lipid associated with erythrocyte plasma membranes belongs to the molecular family of **phospholipids**. In general, phospholipids share a **glycerol** backbone, two hydroxyl groups of which are esterified to various **fatty-acid** or **acyl groups** ([Fig. 2-1A](#)). These acyl groups may have different numbers

of carbon atoms and also may have double bonds between carbons. For glycerol-based phospholipids, the third glycerolic hydroxyl group is esterified to a **phosphate** group, which is in turn esterified to a small molecule referred to as a **head group**. The identity of the head group determines the name as well as many of the properties of the individual phospholipids. For instance, glycerol-based phospholipids that bear an ethanolamine molecule in the head group position are categorized as **phosphatidylethanolamines** (see Fig. 2-1A).

FIGURE 2-1 Phospholipids.

Phospholipids form complex structures in aqueous solution

The unique structure and physical chemistry of each phospholipid (see Fig. 2-1B) underlie the formation of biological membranes and explain many of their most important properties. Fatty acids are nonpolar molecules. Their long carbon chains lack the charged groups that would facilitate interactions with water, which is polar. Consequently, fatty acids dissolve poorly in water but readily in organic solvents; thus, fatty acids are **hydrophobic**. On the other hand, the head groups of most phospholipids are charged or polar. These head groups interact well with water and consequently are very water soluble. Thus, the head groups are **hydrophilic**. Because phospholipids combine hydrophilic heads with hydrophobic tails, their interaction with water is referred to as **amphipathic**.

When mixed with water, phospholipids organize themselves into structures that prevent their hydrophobic tails from making contact with water while simultaneously permitting their hydrophilic head groups to be fully dissolved. When added to water at fairly low concentrations, phospholipids form a **monolayer** (see Fig. 2-1C) on the water's surface at the air-water interface. It is energetically less costly to the system for the hydrophobic tails to stick up in the air than to interact with the solvent.

At higher concentrations, phospholipids assemble into **micelles**. The hydrophilic head groups form the surfaces of these small spheres, whereas the hydrophobic tails point toward their centers. In this geometry, the tails are protected from any contact with water and instead are able to participate in energetically favorable interactions among themselves. At still higher concentrations, phospholipids spontaneously form **bilayers** (see [Fig. 2-1D](#)). In these structures, the phospholipid molecules arrange themselves into two parallel sheets or **leaflets** that face each other tail to tail. The hydrophilic head groups form the surfaces of the bilayer; the hydrophobic tails form the center of the sandwich. The hydrophilic surfaces insulate the hydrophobic tails from contact with the solvent, leaving the tails free to associate exclusively with one another.

The physical characteristics of a lipid bilayer largely depend on the chemical composition of its constituent phospholipid molecules. For example, the width of the bilayer is determined by the length of the fatty-acid side chains. Dihexadecanoic phospholipids (whose two fatty-acid chains are each 16 carbons long) produce bilayers that are 2.47 nm wide; ditetradecanoic phospholipids (bearing 14-carbon fatty acids) generate 2.3-nm bilayers. Similarly, the nature of the head groups determines how densely packed adjacent phospholipid molecules are in each leaflet of the membrane.

Detergents can dissolve phospholipid membranes because, like the phospholipids themselves, they are amphipathic. They possess very hydrophilic head groups and hydrophobic tails and are water soluble at much higher concentrations than are the phospholipids. When mixed together in aqueous solutions, detergent and phospholipid molecules interact through their hydrophobic tails, and the resulting complexes are water soluble, either as individual dimers or in mixed micelles. Therefore, adding sufficient concentrations of detergent to phospholipid bilayer membranes disrupts the membranes and dissolves the lipids. Detergents are extremely useful tools in research into the structure and composition of lipid membranes.

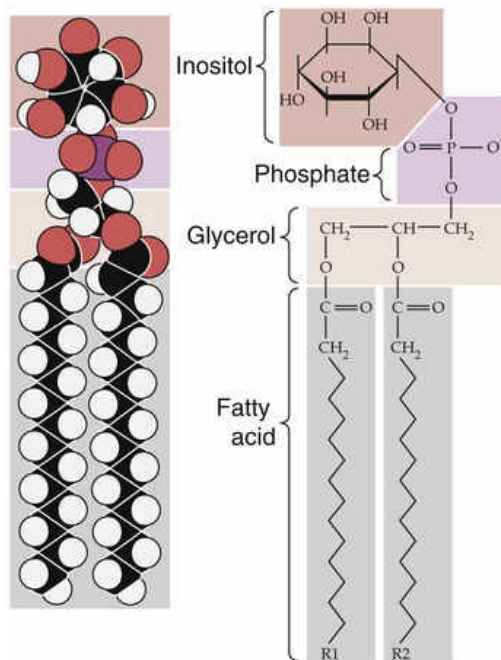

The diffusion of individual lipids within a leaflet of a bilayer is determined by the chemical makeup of its constituents

Despite its highly organized appearance, a phospholipid bilayer is a fluid structure. An individual phospholipid molecule is free to diffuse within the entire leaflet in which it resides. The rate at which this two-dimensional diffusion occurs is extremely temperature dependent. At high temperatures, the thermal energy of any given lipid molecule is greater than the interaction energy that would tend to hold adjacent lipid molecules together. Under these conditions, lateral diffusion can proceed rapidly, and the lipid is said to be in the **sol state**. At lower temperatures, interaction energies exceed the thermal energies of most individual molecules. Thus, phospholipids diffuse slowly because they lack the energy to free themselves from the embraces of their neighbors. This behavior is characteristic of the **gel state**.

The temperature at which the bilayer membrane converts from the gel to the sol phase (and vice versa) is referred to as the **transition temperature**. The transition temperature is another characteristic that depends on the chemical makeup of the phospholipids in the bilayer. Phospholipids with long, saturated fatty-acid chains can extensively interact with one another. Consequently, a fair amount of thermal energy is required to overcome these interactions and permit diffusion. Not surprisingly, such bilayers have relatively high transition temperatures. For example, the transition temperature for dioctadecanoic phosphatidylcholine (which has two 18-carbon fatty-acid chains, fully saturated) is 55.5°C. In contrast, phospholipids that have shorter fatty-acid chains or double bonds (which introduce kinks) cannot line up next to each other as well and hence do not interact as well. Considerably less energy is required to induce them to participate in diffusion. For example, if we reduce the length of the carbon chain from 18

to 14, the transition temperature falls to 23°C. If we retain 18 carbons but introduce one double bond (making the fatty-acid chains monounsaturated), the transition temperature also falls dramatically.

By mixing other types of lipid molecules into phospholipid bilayers, we can markedly alter the membrane's fluidity properties. The *glycerol-based* phospholipids, the most common membrane lipids, include the phosphatidylethanolamines described above (see [Fig. 2-1A](#)), as well as the **phosphatidylinositols** ([Fig. 2-2A](#)), **phosphatidylserines** (see [Fig. 2-2B](#)), and **phosphatidylcholines** (see [Fig. 2-2C](#)). The second major class of membrane lipids, the **sphingolipids** (derivatives of *sphingosine*), is made up of three subgroups: **sphingomyelins** (see [Fig. 2-2D](#)),  **N2-1 glycosphingolipids** such as the galactocerebrosides (see [Fig. 2-2E](#)), and **gangliosides** (not shown in figure). Cholesterol (see [Fig. 2-2F](#)) is another important membrane lipid. Because these other molecules are not shaped exactly like the glycerol-based phospholipids, they participate to different degrees in intermolecular interactions with phospholipid side chains.  **N2-2** The presence of these alternative lipids changes the strength of the interactions that prevents lipid molecules from diffusing. Consequently, the membrane has a different fluidity and a different transition temperature. This behavior is especially characteristic of the cholesterol molecule, whose rigid steroid ring binds to and partially immobilizes fatty-acid side chains. Therefore, at modest concentrations, cholesterol decreases fluidity. However, when it is present in high concentrations, cholesterol can substantially disrupt the ability of the phospholipids to interact among themselves, which increases fluidity and lowers the gel-sol transition temperature. This issue is significant because animal cell plasma membranes can contain substantial quantities of cholesterol.

A PHOSPHATIDYLINOSITOL**B PHOSPHATIDYLSERINE****C PHOSPHATIDYLCHOLINE****D SPHINGOMYELIN****E GALACTOCEREBROSIDE****F CHOLESTEROL****FIGURE 2-2** Structures of some common membrane lipids.**N2-1****Sphingomyelins***Contributed by Emile Boulpaep, Walter Boron*

The polar head group of sphingomyelins can be either phosphocholine, as shown in Figure 2-2D, or phosphoethanolamine (analogous to the phosphoethanolamine moiety in Fig. 2-1A). Note that

sphingomyelins are both (1) sphingolipids because they contain sphingosine, and (2) phospholipids because they contain a phosphate group as do the glycerol-based phospholipids shown in Figures 2-1A and 2-2A–C.

Diversity of Lipids in a Bilayer

Contributed by Michael Caplan

EFIGURE 2-1 The upper leaflet of this lipid bilayer contains, from left to right, phosphatidylinositol, phosphatidylserine, cholesterol, phosphatidylinositol, phosphatidylcholine, and cholesterol.

Bilayers composed of several different lipids do not undergo the transition from gel to sol at a single, well-defined temperature. Instead, they interconvert more gradually over a temperature range that is defined by the composition of the mixture. Within this transition range in such multicomponent bilayers, the membrane can become divided into compositionally distinct zones. The phospholipids with long-chain, saturated fatty acids will adhere to one another relatively tightly, which results in the formation of regions with gel-like properties. Phospholipids bearing short-chain, unsaturated fatty acids will be excluded from these regions and migrate to sol-like regions. Hence, “lakes” of lipids with markedly different physical properties can exist side by side in the plane of a phospholipid membrane. Thus, the same thermodynamic forces that form the elegant bilayer structure can partition distinct lipid domains within the bilayer. As discussed below, the segregation of lipid lakes in the plane of the membrane may be important for sorting membrane proteins to different parts of the cell.

Although phospholipids can diffuse in the plane of a lipid bilayer membrane, they do not diffuse between adjacent leaflets (Fig. 2-3). The rate at which phospholipids spontaneously “flip-flop” from one leaflet of a bilayer to the other is extremely low. As mentioned above, the center of a bilayer membrane

consists of the fatty-acid tails of the phospholipid molecules and is an extremely hydrophobic environment. For a phospholipid molecule to jump from one leaflet to the other, its highly hydrophilic head group would have to transit this central hydrophobic core, which would have an extremely high energy cost. This caveat does not apply to cholesterol (see Fig. 2-3), whose polar head is a single hydroxyl group. The energy cost of dragging this small polar hydroxyl group through the bilayer is relatively low, which permits relatively rapid cholesterol flip-flop.

FIGURE 2-3 Mobility of lipids within a bilayer.

Phospholipid bilayer membranes are impermeable to charged molecules

The lipid bilayer is ideally suited to separate two aqueous compartments. Its hydrophilic head groups interact well with water at both membrane surfaces, whereas the hydrophobic center ensures that the energetic cost of crossing the membrane is prohibitive for charged atoms or molecules. Pure phospholipid bilayer membranes are extremely impermeable to almost any charged water-soluble substance. Ions such as Na^+ , K^+ , Cl^- , and Ca^{2+} are insoluble in the hydrophobic membrane core and consequently cannot travel from the aqueous environment on one side of the membrane to the aqueous environment on the opposite side. The same is true of large water-soluble molecules, such as proteins, nucleic acids, sugars, and nucleotides.

Whereas phospholipid membranes are impermeable to water-soluble molecules, small *uncharged* polar molecules can cross fairly freely. This is often true for O_2 , CO_2 , NH_3 , and, remarkably, water itself. Water molecules may, at least in part, traverse the membrane through transient cracks between the hydrophobic tails of the phospholipids without having to surmount an enormous energetic barrier. The degree of permeability of water (and perhaps that of CO_2 and NH_3 as well) varies extensively with lipid composition; some phospholipids (especially those with short or kinked fatty-acid chains) permit a much greater rate of transbilayer water diffusion than others do.

The plasma membrane is a bilayer

As may be inferred from the preceding discussion, the membrane at the cell surface is, in fact, a

phospholipid bilayer. The truth of this statement was established by a remarkably straightforward experiment. In 1925, Gorter and Grendel measured the surface area of the lipids they extracted from erythrocyte plasma membranes. They used a device called a Langmuir trough in which the lipids are allowed to line up at an air-water interface (see [Fig. 2-1C](#)) and are then packed together into a continuous monolayer by a sliding bar that decreases the surface available to them. The area of the monolayer that was created by the erythrocyte lipids was exactly twice the surface area of the erythrocytes from which they were derived. Therefore, the plasma membrane must be a bilayer.

Confirmation of the bilayer structure of biological membranes has come from x-ray diffraction studies performed on the repetitive whorls of membrane that form the myelin sheaths surrounding neuronal axons (see [pp. 292–293](#)).

The membrane's bilayer structure can be visualized directly in the high-magnification electron micrograph depicted in [Figure 2-4](#). The osmium tetroxide molecule (OsO_4) with which the membrane is stained binds to the head groups of phospholipids. Thus, both surfaces of a phospholipid bilayer appear black in electron micrographs, whereas the membrane's unstained central core appears white.

FIGURE 2-4 Transmission electron micrograph of a cell membrane. The photograph shows two adjacent cells of the pancreas of a frog (original magnification $\times 43,000$). The inset is a high-magnification view (original magnification $\times 216,000$) of the plasma membranes (PM) of the cells. Note that each membrane includes two dense layers with an intermediate layer of lower density. The dense layers represent the interaction of the polar head groups of the phospholipids with the OsO_4 used to stain the preparation. E, nuclear envelope; M, mitochondrion. (From Porter KR, Bonneville MR: *Fine Structure of Cells and Tissues*, 4th ed. Philadelphia, Lea & Febiger, 1973.)

The phospholipid compositions of the two leaflets of the plasma membrane are not identical. Labeling studies performed on erythrocyte plasma membranes reveal that the surface that faces the cytoplasm contains phosphatidylethanolamine and phosphatidylserine, whereas the outward-facing leaflet is composed almost exclusively of phosphatidylcholine. As is discussed below in this chapter, this asymmetry is created during the biosynthesis of the phospholipid molecules. It is not entirely clear what advantage this distribution provides to the cell. The interactions between certain proteins and the plasma membrane may require this segregation. The lipid asymmetry may be especially important for those phospholipids that are involved in second-messenger cascades. Phosphatidylinositols, for example, give rise to phosphoinositides, which play critical roles in signaling pathways (see [pp. 58–61](#)). In addition, the phosphatidylinositol composition of the cytoplasmic face of an organelle helps to define the identity of the organelle and to govern its trafficking and targeting properties. Finally, the phospholipids that are characteristic of animal cell plasma membranes generally have one saturated and one unsaturated fatty-

acid residue. Consequently, they are less likely to partition into sol-like or gel-like lipid domains than are phospholipids that bear identical fatty-acid chains. 🍷 N2-3

Membrane Microdomains

Contributed by Michael Caplan

According to current models (see Anderson and Jacobson, 2002; Edidin, 2003), lipids and proteins are not uniformly distributed in the plane of the membranes that surround cells and organelles. Instead, certain lipids and associated proteins cluster to form microdomains that differ in composition, structure, and function from the rest of the membrane that surrounds them. These microdomains can be thought of as small islands bordered by the “lake” of lipids and proteins that constitute the bulk of the membrane. These two-dimensional structures are composed of lipids that tend to form close interactions with one another, resulting in the self-assembly of organized domains that include specific types of lipids and exclude others. The lipids that tend to be found in microdomains include sphingomyelin, cholesterol, and glycolipids. Proteins that are able to interact closely with microdomain-forming lipids can also become selectively incorporated into these microdomains. A number of different names are used to refer to these microdomains, the most common of which are caveolae and rafts.

Caveolae (see pp. 42–43) were originally identified in the electron microscope as flask-shaped invaginations of the plasma membrane. They carry a coat composed of proteins called **caveolins**, and they tend to be at least 50 to 80 nm in diameter. Caveolae have been shown to participate in endocytosis of specific subsets of proteins and are also richly endowed with signaling molecules, such as receptor tyrosine kinases.

Rafts are less well understood structures, which are defined by the biochemical behaviors of their constituents when the surrounding membrane is dissolved in nonionic detergents. Lipid microdomains rich in sphingomyelin, cholesterol, and glycolipids tend to resist solubilization in these detergents under certain conditions and can be recovered intact by density centrifugation. Once again, a number of interesting proteins involved in cell signaling and communication, including kinases, ion channels, and G proteins, tend to be concentrated in rafts, or to become associated with rafts upon the activation of specific *signal-transduction* pathways. Rafts are thought to collect signaling proteins into small, highly concentrated zones, thereby facilitating their interactions and hence their ability to activate particular pathways. Rafts are also involved in membrane trafficking processes. In polarized epithelial cells, the sorting of a number of proteins to the apical plasma membrane is dependent upon their ability to partition into lipid rafts that form in the plane of the membrane of the *trans*-Golgi network. Little is known about what lipid rafts actually look like in cell membranes in situ. It is currently thought that they are fairly small (<100 nm), although it is possible that they can be induced to coalesce into larger structures under certain circumstances. Much remains to be learned about the structures and functions of rafts and caveolae, but it is clear that they are dynamic and important entities that subdivide membrane into specialized regions that cells exploit for a wide variety of tasks.

Membrane proteins can be integrally or peripherally associated with the plasma membrane

The demonstration that the plasma membrane's lipid components form a bilayer leaves open the question of how the membrane's protein constituents are organized. Membrane proteins can belong to either of two broad classes, peripheral or integral. **Peripherally associated membrane proteins** are neither embedded within the membrane nor attached to it by covalent bonds; instead, they adhere tightly to the cytoplasmic or extracellular surfaces of the plasma membrane (Fig. 2-5A). They can be removed from the membrane, however, by mild treatments that disrupt ionic bonds (very high salt concentrations) or hydrogen bonds (very low salt concentrations).

FIGURE 2-5 Classes of membrane proteins. In E, protein is coupled via a GPI linkage.

In contrast, **integral membrane proteins** are intimately associated with the lipid bilayer. They cannot be eluted from the membrane by these high- or low-salt washes. For integral membrane proteins to be dislodged, the membrane itself must be dissolved by adding detergents. Integral membrane proteins can be associated with the lipid bilayer in any of three ways. First, some proteins actually span the lipid bilayer once or several times (see Fig. 2-5B, C) and hence are referred to as **transmembrane proteins**. Experiments performed on erythrocyte membranes reveal that these proteins can be labeled with protein-tagging reagents applied to either side of the bilayer.

The second group of integral membrane proteins is embedded in the bilayer without actually crossing it

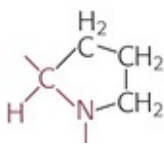

(see Fig. 2-5D). A third group of membrane-associated proteins is not actually embedded in the bilayer at all. Instead, these lipid-anchored proteins are attached to the membrane by a covalent bond that links them either to a lipid component of the membrane or to a fatty-acid derivative that intercalates into the membrane. For example, proteins can be linked to a special type of glycosylated phospholipid molecule (see Fig. 2-5E), which is most often **glycosylphosphatidylinositol (GPI)**, on the outer leaflet of the membrane. This family is referred to collectively as the **glycophospholipid-linked proteins**. Another example is a direct linkage to a fatty acid (e.g., a myristyl group) or a prenyl (e.g., farnesyl) group that intercalates into the inner leaflet of the membrane (see Fig. 2-5F).

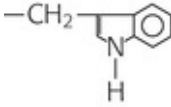

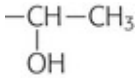

The membrane-spanning portions of transmembrane proteins are usually hydrophobic α helices

How can membrane-spanning proteins remain stably associated with the bilayer in a conformation that requires at least some portion of their amino-acid sequence to be in continuous contact with the membrane's hydrophobic central core? The answer to this question can be found in the special structures of those protein domains that actually span the membrane.

The side chains of the eight amino acids listed in the upper portion of Table 2-1 are hydrophobic. These aromatic or uncharged aliphatic groups are almost as difficult to solvate in water as are the fatty-acid side chains of the membrane phospholipids themselves. Not surprisingly, therefore, these hydrophobic side chains are quite comfortable in the hydrophobic environment of the bilayer core. Most **membrane-spanning segments**—that is, the short stretches of amino acids that pass through the membrane once—are composed mainly of these nonpolar amino acids, in concert with polar, uncharged amino acids.

TABLE 2-1
Classification of the Amino Acids Based on the Chemistry of Their Side Chains

	NAME	THREE-LETTER CODE	SINGLE-LETTER CODE	STRUCTURE OF THE SIDE CHAIN	HYDROPATHY INDEX*
Nonpolar	Alanine	Ala	A	$-\text{CH}_3$	+1.8
	Valine	Val	V	$-\text{CH}(\text{CH}_3)_2$	+4.2
	Leucine	Leu	L	$-\text{CH}_2\text{CH}(\text{CH}_3)_2$	+3.8

Polar, charged, basic	Lysine	Lys	K	$-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{NH}_3^+$	-3.9
	Arginine	Arg	R	$-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{NH}-\text{C}(=\text{NH}_2^+)-\text{NH}_2$	-4.5
	Histidine	His	H		-3.2

*Kyte and Doolittle generated these values (arbitrary scale from -4.5 to $+4.5$) by averaging two kinds of data. The first is an index of the energy that is required to transfer the side chain from the vapor phase into water. The second indicates how likely it is to find the side chain buried in (as opposed to being on the surface of) 12 globular proteins, whose structures were solved by x-ray crystallography. A positive value indicates that the side chain is hydrophobic.

Note: The portion shown in red is part of the peptide backbone.

(From Kyte J, Doolittle RF: A simple method for displaying the hydropathic character of a protein. *J Mol Biol* 157:105–132, 1982.)

The hydrophobic, membrane-spanning segments of transmembrane proteins are specially adapted to the hydrophobic milieu in which they reside. The phospholipid molecules of the membrane bilayer actually protect these portions of transmembrane proteins from energetically unfavorable interactions with the aqueous environment. Transmembrane proteins tend to be extremely insoluble in water. If we separate the membrane-spanning segments of these proteins from the amphipathic phospholipids that surround them, these hydrophobic sequences tend to interact tightly with one another rather than with water. The resulting large protein aggregates are generally insoluble and precipitate out of solution. If, however, we disrupt the phospholipid membrane by adding detergent, the amphipathic detergent molecules can substitute for the phospholipids. The hydrophobic membrane-spanning sequences remain insulated from interactions with the aqueous solvent, and the proteins remain soluble as components of **detergent micelles**. This ability of detergents to remove transmembrane proteins from the lipid bilayer—while maintaining the solubility and native architectures of these proteins—has proved important for purifying individual membrane proteins.

Transmembrane proteins can have a single membrane-spanning segment (see [Fig. 2-5B](#)) or several (see [Fig. 2-5C](#)). Those with a single transmembrane segment can be oriented with either their amino (N) or their carboxyl (C) terminus facing the extracellular space. Multispanning membrane proteins weave through the membrane like a thread through cloth. Again, the N and C termini can be exposed to either the cytoplasmic or extracellular compartments. The pattern with which the transmembrane protein weaves across the lipid bilayer defines its membrane **topology**.

The amino-acid sequences of membrane-spanning segments tend to form α helices, with ~ 3.6 amino acids per turn of the helix (see [Fig. 2-5B](#)). In this conformation, the polar atoms of the peptide backbone are maximally hydrogen bonded to one another—from one turn of the helix to the next—so they do not require the solvent to contribute hydrogen-bond partners. Hence, this structure ensures the solubility of the membrane-spanning sequence in the hydrophobic environment of the membrane. Whereas most transmembrane proteins appear to traverse the membrane with α -helical spans, it is clear that an intriguing subset of membrane polypeptides makes use of a very different structure. For example, the porin protein (see [p. 109](#)), which serves as a channel in bacterial membranes, has membrane-spanning portions arranged as a β barrel.

In the case of multispanning membrane proteins, their transmembrane helices probably pack together tightly (see [Fig. 2-5C](#)). Molecular analysis of a number of known membrane-spanning sequences has helped in the development of algorithms predicting the likelihood that a given amino-acid sequence can span the membrane. These algorithms are widely used to assess the likelihood that newly identified genes encode transmembrane proteins and to predict the number and location of membrane-spanning segments.

Many membrane proteins form tight, noncovalent associations with other membrane proteins in the plane of the bilayer. These **multimeric proteins** can be composed of a single type of polypeptide or of mixtures of two or more different proteins. The side-to-side interactions that hold these complexes

together can involve the membrane-spanning segments or regions of the proteins that protrude at either surface of the bilayer. By assembling into multimeric complexes, membrane proteins can increase their stability. They can also increase the variety and complexity of the functions that they are capable of performing.

Some membrane proteins are mobile in the plane of the bilayer

As is true for phospholipid molecules (see [Fig. 2-3](#)), some transmembrane proteins can diffuse within the surface of the membrane. In the absence of any protein-protein attachments, transmembrane proteins are free to diffuse over the entire surface of a membrane. This fact was demonstrated by [Frye and Edidin in 1970](#) ([Fig. 2-6](#)). They labeled the surface proteins of a population of *mouse* lymphocytes with a lectin (a plant protein that binds strongly to certain sugar groups attached to proteins) that was linked to the fluorescent dye fluorescein. They also tagged the surface proteins of a second population of *human* lymphocytes with a lectin that was conjugated to a different fluorescent dye, rhodamine. Because fluorescein glows green and rhodamine glows red when excited by the light of the appropriate wavelengths, these labeling molecules can be easily distinguished from one another in a fluorescence microscope. Frye and Edidin mixed the two lymphocyte populations and treated them with a reagent that caused the cells to fuse to each other. Immediately after fusion, the labeled surface proteins of the newly joined cells remained separate; half of the fused cell surface appeared red, whereas the other half appeared green. During a period of ~30 minutes, however, the green and red protein labels intermixed until the entire surface of the fused cell was covered with both labeling molecules. The rate at which this intermingling occurred increased with temperature, which is not surprising given the temperature dependence of membrane fluidity.

After about 1/2 hour,
tagged proteins spread
throughout the membrane.

FIGURE 2-6 Diffusion of membrane proteins within the plane of the cell membrane. The surface proteins of a *human* lymphocyte are tagged with a lectin conjugated to rhodamine, a fluorescent dye; the surface proteins of a *mouse* lymphocyte are tagged with a lectin linked to fluorescein, another fluorescent dye. Immediately after fusion of the two cells, the labeled surface proteins remain segregated. However, the membrane proteins intermingle during a period of ~30 minutes.

Because transmembrane proteins are large molecules, their diffusion in the plane of the membrane is much slower than that of lipids. Even the fastest proteins diffuse ~1000 times more slowly than the average phospholipid. The diffusion of many transmembrane proteins appears to be further impeded by their attachments to the cytoskeleton, just below the surface of the membrane. Tight binding to this meshwork can render proteins essentially immobile. Other transmembrane proteins appear to travel in the plane of the membrane via directed processes that are much faster and less directionally random than diffusion is. Motor proteins that are associated with the cytoplasmic cytoskeleton (discussed below) appear to grab onto certain transmembrane proteins, dragging them in the plane of the membrane like toy boats on strings. Finally, like phospholipids, proteins can diffuse only in the plane of the bilayer. They cannot flip-flop across it. The energetic barrier to dragging a transmembrane protein's hydrophilic cytoplasmic and extracellular domains across the bilayer's hydrophobic core is very difficult to surmount. Thus, a membrane protein's topology does not change over its life span.

Function of Membrane Proteins

Integral membrane proteins can serve as receptors

All communication between a cell and its environment must involve or at least pass through the plasma membrane. For the purposes of this discussion, we define communication rather broadly as the exchange of any signal between the cell and its surroundings. Except for lipid-soluble signaling molecules such as steroid hormones, essentially all communication functions served by the plasma membrane occur via membrane proteins. From an engineering perspective, membrane proteins are perfectly situated to transmit signals because they form a single, continuous link between the two compartments that are separated by the membrane.

Ligand-binding receptors comprise the group of transmembrane proteins that perhaps most clearly illustrate the concept of transmembrane signaling ([Fig. 2-7A](#)). For water-soluble hormones such as epinephrine to influence cellular behavior, their presence in the ECF compartment must be made known to the various intracellular mechanisms whose behaviors they modulate. The interaction of a hormone with the extracellular portion of the hormone receptor, which forms a high-affinity binding site, produces conformational changes within the receptor protein that extend through the membrane-spanning domain to the intracellular domain of the receptor. As a consequence, the intracellular domain either becomes enzymatically active or can interact with cytoplasmic proteins that are involved in the generation of so-called second messengers. Either mechanism completes the transmission of the hormone signal across the membrane. The transmembrane disposition of a hormone receptor thus creates a single, continuous communication medium that is capable of conveying, through its own structural modifications, information from the environment to the cellular interior. The process of transmembrane signal transduction is discussed in [Chapter 3](#).

FIGURE 2-7 Integral membrane proteins that transmit signals from the outside to the inside of a cell. **A**, The ligand may be a hormone, a growth factor, a neurotransmitter, an odorant, or another local mediator. **B**, An integrin is an adhesion molecule that attaches the cell to the extracellular matrix.

Integral membrane proteins can serve as adhesion molecules

Cells can also exploit integral membrane proteins as **adhesion molecules** that form physical contacts with the surrounding extracellular matrix (i.e., cell-matrix adhesion molecules) or with their cellular neighbors (i.e., cell-cell adhesion molecules). These attachments can be extremely important in regulating the shape, growth, and differentiation of cells. The nature and extent of these attachments must be communicated to the cell interior so that the cell can adapt appropriately to the physical constraints and cues that are provided by its immediate surroundings. Numerous classes of transmembrane proteins are involved in these communication processes. The **integrins** are examples of matrix receptors or **cell-matrix adhesion molecules**. They comprise a large family of transmembrane proteins that link cells to components of the extracellular matrix (e.g., fibronectin, laminin) at adhesion plaques (see Fig. 2-7B). These linkages produce conformational changes in the integrin molecules that are transmitted to their cytoplasmic tails. These tails, in turn, communicate the linkage events to various structural and signaling molecules that participate in formulating a cell's response to its physical environment.

In contrast to matrix receptors, which attach cells to the extracellular matrix, several enormous superfamilies of **cell-cell adhesion molecules** attach cells to each other. These cell-cell adhesion molecules include the Ca^{2+} -dependent cell adhesion molecules (cadherins) and Ca^{2+} -independent neural cell adhesion molecules (N-CAMs). The **cadherins** are glycoproteins (i.e., proteins with sugars attached) with one membrane-spanning segment and a large extracellular domain that binds Ca^{2+} . The **N-CAMs**, on the other hand, generally are members of the immunoglobulin superfamily. The two classes of cell-cell adhesion molecules mediate similar sorts of transmembrane signals that help organize the cytoplasm and

control gene expression in response to intercellular contacts. Some cell-cell adhesion molecules belong to the **GPI-linked class** of membrane proteins (see [p. 13](#)). These polypeptides lack a transmembrane and cytoplasmic tail. Interactions mediated by this unique class of adhesion molecules may be communicated to the cell interior via lateral associations with other membrane proteins.

Adhesion molecules orchestrate processes that are as diverse as the directed migration of immune cells and the guidance of axons in the developing nervous system. Loss of cell-cell and cell-matrix adhesion is a hallmark of metastatic tumor cells.

Integral membrane proteins can carry out the transmembrane movement of water-soluble substances

As noted above, a pure phospholipid bilayer does not have the permeability properties that are normally associated with animal cell plasma membranes. Pure phospholipid bilayers also lack the ability to transport substances uphill (i.e., against electrochemical gradients; [p. 105](#)). Transmembrane proteins endow biological membranes with these capabilities. Ions and other membrane-impermeable substances can cross the bilayer with the assistance of transmembrane proteins that serve as pores, channels, carriers, and pumps. **Pores** and **channels** serve as conduits that allow water, specific ions, or even very large proteins to flow passively through the bilayer. **Carriers** can either facilitate the transport of a specific molecule across the membrane or couple the transport of a molecule to that of other solutes. **Pumps** use the energy that is released through the hydrolysis of ATP to drive the transport of substances into or out of cells against energy gradients. Each of these important classes of proteins is discussed in [Chapter 5](#).

Channels, carriers, and pumps succeed in allowing hydrophilic substances to cross the membrane by creating a hydrophilic pathway in the bilayer. Previously, we asserted that membrane-spanning segments are as hydrophobic as the fatty acids that surround them. How is it possible for these *hydrophobic* membrane-spanning domains to produce the *hydrophilic* pathways that permit the passage of ions through the membrane? The solution to this puzzle appears to be that the α helices that make up these membrane-spanning segments are amphipathic. That is, they possess both hydrophobic and hydrophilic domains.

For each α helix, the helical turns produce alignments of amino acids that are spaced at regular intervals in the sequence. Thus, it is possible to align all the hydrophilic or hydrophobic amino acids along a single edge of the helix. In **amphipathic helices**, hydrophobic amino acids alternate with hydrophilic residues at regular intervals of approximately three or four amino acids (recall that there are ~ 3.6 amino acids per turn of the helix). Thus, as the helices pack together, side by side, the resultant membrane protein has distinct hydrophilic and hydrophobic surfaces. The hydrophobic surfaces of each helix will face either the membrane lipid or the hydrophobic surfaces of neighboring helices. Similarly, the hydrophilic surfaces of each helix will face a common central pore through which water-soluble substances can move. Depending on how the protein regulates access to this pore, the protein could be a channel, a carrier, or a pump. The mix of hydrophilic amino acids that line the pore presumably determines, at least in part, the nature of the substances that the pore can accommodate. In some instances, the amphipathic helices that line the pore are contributed by several distinct proteins—or subunits—that assemble into a single multimeric complex. [Figure 2-8](#) shows an example of a type of K^+ channel discussed on [page 184](#). This channel is formed by the apposition of four identical subunits, each of which has six membrane-spanning segments. The pore of this channel is created by the amphipathic helices as well as by short, hydrophilic loops (P loops) contributed by each of the four subunits.

FIGURE 2-8 Amphoteric α helices interacting to form a channel through the cell membrane. This is an example of a potassium channel.

Integral membrane proteins can also be enzymes

Ion pumps are actually enzymes. They catalyze the hydrolysis of ATP and use the energy released by that reaction to drive ion transport. Many other classes of proteins that are embedded in cell membranes function as enzymes as well. Membrane-bound enzymes are especially prevalent in the cells of the intestine, which participate in the final stages of nutrient digestion and absorption (see [pp. 916–918](#)). These enzymes—located on the side of the intestinal cells that faces the lumen of the intestine—break down small polysaccharides into single sugars, or break down polypeptides into shorter polypeptides or amino acids, so that they can be imported into the cells. By embedding these enzymes in the plasma membrane, the cell can generate the final products of digestion close to the transport proteins that mediate the uptake of these nutrient molecules. This theme is repeated in numerous other cell types. Thus, the membrane can serve as an extremely efficient two-dimensional reaction center for multistep processes that involve enzymatic reactions or transport.

Many of the GPI-linked proteins are enzymes. Several of the enzymatic activities that are classically thought of as extracellular markers of the plasma membrane, such as **alkaline phosphatase**, **5'-nucleotidase**, and carbonic anhydrase IV (see [p. 828](#)), are anchored to the external leaflet of the bilayer by covalent attachment to a GPI.

Integral membrane proteins can participate in intracellular signaling

Some integral proteins associate with the cytoplasmic surface of the plasma membrane by covalently attaching to fatty acids or prenyl groups that in turn intercalate into the lipid bilayer (see [Fig. 2-5F](#)). The fatty acids or prenyl groups act as hydrophobic tails that anchor an otherwise soluble protein to the bilayer. These proteins are all located at the *intracellular* leaflet of the membrane bilayer and often participate in intracellular signaling pathways. The family of lipid-linked proteins includes the small and heterotrimeric GTP-binding proteins, kinases, and oncogene products (see [Chapter 3](#)). Many of these proteins are involved in relaying the signals that are received at the cell surface to the effector machinery within the cell interior. Their association with the membrane, therefore, brings these proteins close to the cytoplasmic sides of receptors that transmit signals from the cell exterior across the bilayer. The medical relevance of this type of membrane association is beginning to be appreciated. For example, denying certain oncogene products their lipid modifications—and hence their membrane attachment—eliminates their ability to induce tumorigenic transformation.

Peripheral membrane proteins participate in intracellular signaling and can form a submembranous cytoskeleton

Peripheral membrane proteins attach loosely to the lipid bilayer but are not embedded within it (see [p. 13](#)). Their association with the membrane can take one of two forms. First, some proteins interact via **ionic interactions** with phospholipid head groups. Many of these head groups are positively or negatively charged and thus can participate in salt bridges with adherent proteins.

For a second group of peripheral membrane proteins, attachment is based on the direct binding of peripheral membrane proteins to the extracellular or cytoplasmic surfaces of integral membrane proteins (see [Fig. 2-5A](#)). This form of attachment is epitomized by the cytoskeleton. For instance, the cytoplasmic surface of the erythrocyte plasma membrane is in close apposition to a dense meshwork of interlocking protein strands known as the **subcortical cytoskeleton**. It consists of a long, fibrillar molecule called spectrin, short polymers of the cytoskeletal protein actin, and other proteins, including ankyrin and band 4.1 ([Fig. 2-9](#)).

FIGURE 2-9 Attachments of the cell membrane to the submembranous cytoskeleton in red blood cells. Integral membrane proteins form the bridges that link the cell membrane to the interlocking system of proteins that comprise the subcortical cytoskeleton.

Two closely related isoforms of **spectrin** (α and β) form dimers, and two of these dimers assemble head to head with one another to form spectrin heterotetramers. The tail regions of spectrin bind the globular protein **band 4.1**, which in turn can bind to actin fibrils. Each **actin** fibril can associate with more than one molecule of band 4.1 so that, together, spectrin, actin, and band 4.1 assemble into an extensive interlocking matrix. The protein known as **ankyrin** binds to spectrin as well as to the cytoplasmic domain of **band 3**, the integral membrane protein responsible for transporting Cl^- and HCO_3^- ions across the erythrocyte membrane. Thus, ankyrin is a *peripheral* membrane protein that anchors the spectrin-actin meshwork directly to an *integral* membrane protein of the erythrocyte.

The subcortical cytoskeleton provides the erythrocyte plasma membrane with strength and resilience. People who carry mutations in genes encoding components of the cytoskeleton have erythrocytes lacking the characteristic biconcave disk shape. These erythrocytes are extremely fragile and are easily torn apart by the shear stresses (see p. 415) associated with circulation through capillaries. It would appear, therefore, that the subcortical cytoskeleton forms a scaffolding of peripheral membrane proteins whose

direct attachment to transmembrane proteins enhances the bilayer's structural integrity.

The subcortical cytoskeleton is not unique to erythrocytes. Numerous cell types, including neurons and epithelial cells, have submembranous meshworks that consist of proteins very similar to those first described in the erythrocyte. In addition to band 3, transmembrane proteins found in a wide variety of cells (including ion pumps, ion channels, and cell adhesion molecules) bind ankyrin and can thus serve as focal points of cytoskeletal attachment. In polarized cells (e.g., neurons and epithelial cells), the subcortical cytoskeleton appears to play a critically important role in organizing the plasma membrane into morphologically and functionally distinct domains.

Cellular Organelles and the Cytoskeleton

The cell is composed of discrete organelles that subserve distinct functions

When a eukaryotic cell is viewed through a light microscope, a handful of recognizable intracellular structures can be discerned. The intracellular matrix, or cytoplasm, appears grainy, suggesting the presence of components that are too small to be discriminated by this technique. With the much higher magnifications available with an electron microscope, the graininess gives way to clarity that reveals the cell interior to be remarkably complex. Even the simplest nucleated animal cell possesses a wide variety of intricate structures with specific shapes and sizes. These structures are the **membrane-enclosed organelles**, the functional building blocks of cells.

[Figure 2-10](#) illustrates the interior of a typical cell. The largest organelle in this picture is the **nucleus**, which houses the cell's complement of genetic information. This structure, which is visible in the light microscope, is usually round or oblong, although in some cells it displays a complex, lobulated shape. Depending on the cell type, the nucleus can range in diameter from 2 to 20 μm . With some exceptions, including skeletal muscle and certain specialized cells of the immune system, each animal cell has a single nucleus.

FIGURE 2-10 Ultrastructure of a typical animal cell.

Surrounding the nucleus is a web of tubules or saccules known as the **endoplasmic reticulum (ER)**. This organelle can exist in either of two forms, rough or smooth. The surfaces of the rough ER tubules are studded with **ribosomes**, the major sites of protein synthesis. Ribosomes can also exist free in the cytosol. The surfaces of the smooth ER, which participates in lipid synthesis, are not similarly endowed. The ER also serves as a major reservoir for calcium ions. The ER membrane is equipped with a Ca pump that uses the energy released through ATP hydrolysis to drive the transport of Ca^{2+} from the cytoplasm into the ER lumen (see [p. 118](#)). This Ca^{2+} can be rapidly released in response to messenger molecules and plays a major role in intracellular signaling (see [p. 60](#)).

The **Golgi complex** resembles a stack of pancakes. Each pancake in the stack represents a discrete, flat saccule. The number and size of the saccules in the Golgi stack vary among cell types. The Golgi complex is a processing station that participates in protein maturation and targets newly synthesized proteins to their appropriate subcellular destinations.

Perhaps the most intriguing morphological appearance belongs to the **mitochondrion**, which is essentially a balloon within a balloon. The outer membrane and inner membrane define two distinct internal compartments: the intermembrane space and the matrix space. The surface of the inner membrane

is thrown into dramatic folds called *cristae*. This organelle is $\sim 0.2\ \mu\text{m}$ in diameter, which is at the limit of resolution of the light microscope. The mitochondrion is the power plant of the cell, a critical manufacturer of ATP. Many cellular reactions are also catalyzed within the mitochondrion.

The cell's digestive organelle is the **lysosome**. This large structure frequently contains several smaller round vesicles called **exosomes** within its internal space.

The cytoplasm contains numerous other organelles whose shapes are not quite as distinguishing, including **endosomes**, **peroxisomes**, and **transport vesicles**.

Despite their diversity, all cellular organelles are constructed from the same building blocks. Each is composed of a membrane that forms the entire extent of its surface. The membranes of the subcellular organelles are what can be visualized in electron micrographs. The biochemical and physical properties of an organelle's limiting membrane dictate many of its functional properties.

The nucleus stores, replicates, and reads the cell's genetic information

The nucleus serves as a cell's repository for its complement of chromosomal DNA. To conceive of the nucleus as simply a hermetically sealed vault for genetic information, however, is a gross oversimplification. All of the machinery necessary to maintain, to copy, and to transcribe DNA is in the nucleus, which is the focus of all of the cellular pathways that regulate gene expression and cell division. Transcriptional control is discussed in [Chapter 4](#). The focus of this section is nuclear structure.

The nucleus is surrounded by a double membrane (see [Fig. 2-10](#)). The **outer membrane** is studded with ribosomes and is continuous with the membranes of the rough ER. The **inner membrane** is smooth and faces the intranuclear space, or nucleoplasm. The space between these concentric membranes is continuous with the lumen of the rough ER. The inner and outer nuclear membranes meet at specialized structures known as **nuclear pores**, which penetrate the nuclear envelope and provide a transport pathway between the cytoplasm and the nuclear interior (see [p. 110](#)). All RNA transcripts that are produced in the nucleus must pass through nuclear pores to be translated in the cytoplasm. Similarly, all the signaling molecules that influence nuclear function as well as all proteins of the nuclear interior (which are synthesized in the cytoplasm) enter the nucleus through nuclear pores.

Nuclear pores are selective in choosing the molecules that they allow to pass. Cytoplasmic proteins destined for the nuclear interior must be endowed with a **nuclear-localization sequence** to gain entry. Several nuclear localization sequences have been characterized, and all seem to share common structural elements. For example, they all have short stretches of four to eight basic amino acids that can be located anywhere in the protein's sequence. Evidence implies that the ability of these signals to mediate nuclear localization can be modulated by phosphorylation, which suggests that the entry of proteins into the nucleus may be under the control of the cell's second-messenger systems.

The selectivity of the nuclear pore is surprising, considering its size. The outer diameter of the entire nuclear pore is $\sim 100\ \text{nm}$, considerably larger than the proteins whose passage it controls. The nuclear pore's specificity is provided by the **nuclear pore complex (NPC)**, an intricate matrix of protein that is distributed in a highly organized octagonal array. The NPC is composed of several hundred proteins, of at least 30 different types, that form a pore of variable internal diameter. In its resting state, the NPC forms an aqueous channel that is $\sim 9\ \text{nm}$ in diameter, restricting the movement of any protein larger than 60 kDa. However, when it is confronted with a protein bearing a nuclear-localization signal or a messenger RNA (mRNA) transcript, the pore complex can dilate to many times this size. The structures of the proteins lining the pore appear to be uniquely flexible, perhaps permitting the cell to regulate the pore's

permeability. The NPC acts as a barrier that prevents the random diffusion of integral membrane proteins between the outer and inner membranes of the nuclear envelope. However, newly synthesized membrane proteins destined for residence in the inner nuclear membrane appear to carry signals that allow them to diffuse from their sites of synthesis in the outer membrane to the inner membrane via the NPC. Thus, although the inner and outer nuclear membranes are continuous with one another at nuclear pores, their protein contents remain tightly controlled and distinct.

Between mitoses, the chromosomal DNA is present in the nucleus as densely packed heterochromatin and more loosely arrayed euchromatin. **Chromatin** is a complex between DNA and numerous DNA-binding proteins, which organize the chromosome into a chain of tightly folded DNA-protein assemblies called **nucleosomes** (see pp. 75–76). Interspersed within the nucleoplasm are round, dense **nucleoli**, where the transcription of ribosomal RNA and the assembly of ribosomal subunits appear to occur.

The interior surface of the inner nuclear membrane is apposed to a fibrillar protein skeleton referred to as the **nuclear lamina**. This meshwork, composed of proteins known as **lamins**, is presumably involved in providing structural support to the nuclear envelope. Mutations in the gene encoding lamin A are responsible for **progeria**, a genetic disease associated with rapid, premature aging. The nuclear lamina may also play a role in orchestrating **nuclear reassembly**. During mitosis, the nuclear envelope breaks down into small vesicles, and the contents of the nucleoplasm mix with the cytoplasm. After mitosis, these vesicles fuse with one another to regenerate the double-walled nuclear membrane. The means by which these vesicles find one another and assemble correctly is the subject of intense study. Similarly, the mechanisms involved in maintaining the compositional discreteness of the inner and outer membranes during vesiculation and reassembly have yet to be determined. After reconstitution of the nuclear envelope, the proteins of the nucleoplasm are reimported from the cytoplasm through the nuclear pores by virtue of their nuclear-localization sequences.

Lysosomes digest material derived from the interior and exterior of the cell

In the course of normal daily living, cells accumulate waste. Organelles become damaged and dysfunctional. Proteins denature and aggregate. New materials are constantly being brought into the cells from the extracellular environment through the process of endocytosis (discussed below). In specialized cells of the immune system, such as macrophages, the collection of foreign materials (in the form of pathogens) from the extracellular milieu is the cellular *raison d'être*. If this material were allowed to accumulate indefinitely, it would ultimately fill the cell and essentially choke it to death. Clearly, cells must have mechanisms for disposing of this waste material.

The lysosome is the cell's trash incinerator. It is filled with a broad assortment of degradative enzymes that can break down most forms of cellular debris. **Proton pumps** embedded within the lysosome's limiting membrane ensure that this space is an extremely acidic environment, which aids in protein hydrolysis. A rare group of inherited disorders, called lysosomal storage diseases (see Box 2-2), result from the deficiency of lysosomal enzymes that are involved in the degradation of a variety of substances.

The lysosomal membrane is specially adapted to resist digestion by the enzymes and the acid that it encapsulates, which ensures that the harsh conditions necessary for efficient degradation are effectively contained. Loss of lysosomal membrane integrity may underlie some clinically important inflammatory conditions, such as gout.

Material that has been internalized from the cell exterior by endocytosis is surrounded by the membrane of an **endocytic vesicle**. To deliver this material to the lysosome, the membranes of the endocytic vesicles

fuse with the lysosomal membrane and discharge their cargo into the lysosomal milieu.

Intracellular structures that are destined for degradation, such as fragments of organelles, are engulfed by the lysosome in a process called **autophagy**. Autophagy results in the formation of membrane-enclosed structures within the lysosomal lumen; hence, the lysosome is often referred to as a multivesicular body. Autophagy allows the cell to degrade old or damaged components. Increased metabolic needs also can stimulate autophagy, allowing the cell to recycle and “burn” its own structural components to generate energy.

The mitochondrion is the site of oxidative energy production

Oxygen-dependent ATP production—or oxidative phosphorylation—occurs in the mitochondrion. Like the nucleus, the mitochondrion (see [Fig. 2-10](#)) is a double-membrane structure. The inner mitochondrial membrane contains the proteins that constitute the electron transport chain, which generates pH and voltage gradients across this membrane. According to the “chemiosmotic” model (see [p. 118](#)), the inner membrane uses the energy in these gradients to generate ATP from ADP and inorganic phosphate.

The mitochondrion maintains and replicates its own genome. This circular DNA strand encodes **mitochondrial transfer RNAs** and (in humans) 13 **mitochondrial proteins**. Several copies of the mitochondrial genome are located in the inner mitochondrial matrix, which also has all of the machinery necessary to transcribe and to translate this DNA, including ribosomes. Whereas the proteins encoded in mitochondrial DNA contribute to the structure and function of the mitochondrion, they account for a relatively small fraction of total mitochondrial protein. Most *mitochondrial* proteins are specified by nuclear DNA and are synthesized on *cytoplasmic* ribosomes.

The two mitochondrial membranes enclose two distinct compartments: the intermembrane space and the inner mitochondrial matrix space. The **intermembrane space** lies between the two membranes; the **inner mitochondrial matrix space** is completely enclosed by the inner mitochondrial membrane. These compartments have completely different complements of soluble proteins, and the two membranes themselves have extremely different proteins.

In addition to playing a role in energy metabolism, the mitochondrion also serves as a reservoir for intracellular Ca^{2+} . The mitochondrial Ca^{2+} uniporter **MCU**, together with the regulatory protein **MICU**, mediates the uptake of Ca^{2+} across the mitochondrial inner membrane and into the matrix via facilitated diffusion. MCU exploits the mitochondrial membrane potential to drive the accumulation of very high Ca^{2+} levels. Elevated cytosolic $[\text{Ca}^{2+}]$ can lead to the release of Ca^{2+} from this reservoir and thereby amplify signaling processes. The mitochondrial Ca^{2+} stores are also released as a consequence of energy starvation, which leads to cell injury and death. Finally, the mitochondrion plays a central role in the process called **apoptosis**, or programmed cell death (see [p. 1241](#)). Certain external or internal signals can induce the cell to initiate a signaling cascade that leads ultimately to the activation of enzymes that bring about the cell's demise. One of the pathways that initiates this highly ordered form of cellular suicide depends on the participation of the mitochondrion. Apoptosis plays an extremely important role during tissue development and is also involved in the body's mechanisms for identifying and destroying cancer cells.

Mitochondriopathies—disorders of mitochondrial function—appear to play a role in several degenerative diseases (e.g., Huntington disease, dysautonomic mitochondrial myopathy).

The cytoplasm is not amorphous but is organized by the

cytoskeleton

Our discussion thus far has focused almost exclusively on the cell's membranous elements. We have treated the cytoplasm as if it were a homogeneous solution in which the organelles and vesicles carry out their functions while floating about unimpeded and at random. Rather, the cytoplasm is enormously complex with an intricate local structure and the capacity for locomotion.

The cytoplasmic **cytoskeleton** is composed of protein filaments that radiate throughout the cell, serving as the beams, struts, and stays that determine cell shape and resilience. On the basis of their appearance in the electron microscope, these filaments were initially divided into several classes ([Table 2-2](#)): thick, thin, and intermediate filaments as well as microtubules. Subsequent biochemical analysis has revealed that each of these varieties is composed of distinct polypeptides and differs with respect to its formation, stability, and biological function.

TABLE 2-2
Components of the Cytoskeleton

	SUBUNITS	DIAMETER (nm)
Intermediate filaments	Tetramer of two coiled dimers	8–10
Microtubules	Heterodimers of α and β tubulin form long protofilaments, 5 nm in diameter	25
Thin filaments	Globular or G-actin, 5 nm in diameter, arranged in a double helix to form fibrous or F-actin	5–8
Thick filaments	Assembly of myosin molecules	10

Intermediate filaments provide cells with structural support

Intermediate filaments are so named because their 8- to 10-nm diameters, as measured in the electron microscope, are intermediate between those of the actin *thin* filaments and the myosin *thick* filaments. As with all of the cytoskeletal filaments that we will discuss, intermediate filaments are polymers that are assembled from individual protein subunits. There is a very large variety of biochemically distinct subunit proteins that are all structurally related to one another and that derive from a single gene family. The expression of these subunit polypeptides can be cell-type specific or restricted to specific regions within a cell. Thus, **vimentin** is found in cells that are derived from mesenchyme, and the closely related **glial fibrillary acidic protein (GFAP)** is expressed exclusively in glial cells (see [pp. 287–288](#)). **Neurofilament proteins** are present in neuronal processes. The **keratins** are present in epithelial cells as well as in certain epithelially derived structures. The **nuclear lamins** that form the structural scaffolding of the nuclear envelope are also members of the intermediate-filament family.

Intermediate-filament monomers are themselves fibrillar in structure. They assemble to form long, intercoiled dimers that in turn assemble side to side to form the tetrameric subunits. Finally, these tetrameric subunits pack together, end to end and side to side, to form intermediate filaments. Filament assembly can be regulated by the cell and in some cases appears to be governed by phosphorylation of the subunit polypeptides. Intermediate filaments appear to radiate from and to reinforce areas of a cell subject to tensile stress. They emanate from the **adhesion plaques** that attach cells to their substrata. In epithelial cells, they insert at the **desmosomal junctions** that attach neighboring cells to one another. The toughness and resilience of the meshworks formed by these filaments is perhaps best illustrated by the keratins, the primary constituents of nails, hair, and the outer layers of skin.

Microtubules provide structural support and provide the basis

for several types of subcellular motility

Microtubules are polymers formed from heterodimers of the proteins α and β **tubulin** (Fig. 2-11A). These heterodimers assemble head to tail, creating the circumferential wall of a microtubule, which surrounds an empty lumen. Because the tubulin heterodimers assemble with a specific orientation, microtubules are polar structures, and their ends manifest distinct biochemical properties. At one tip of the tubule, designated the **plus end**, tubulin heterodimers can be added to the growing polymer at three times the rate that this process occurs at the opposite **minus end**. The relative rates of microtubule growth and depolymerization are controlled in part by an enzymatic activity that is inherent in the tubulin dimer. Tubulin dimers bind to **GTP**, and in this GTP-bound state they associate more tightly with the growing ends of microtubules. Once a tubulin dimer becomes part of the microtubule, it hydrolyzes the GTP to GDP, which lowers the binding affinity of the dimer for the tubule and helps hasten disassembly. Consequently, the microtubules can undergo rapid rounds of growth and shrinkage, a behavior termed *dynamic instability*. Various cytosolic proteins can bind to the ends of microtubules and serve as caps that prevent assembly and disassembly, and thus stabilize the structures of the microtubules. A large and diverse family of **microtubule-associated proteins** appears to modulate not only the stability of the tubules but also their capacity to interact with other intracellular components.

A MICROTUBULE AND ITS MOLECULAR MOTORS

B MICROTUBULE-ORGANIZING CENTER

C MOTILE CILIUM

FIGURE 2-11 Microtubules. **A**, Heterodimers of α and β tubulin form long protofilaments, 13 of which surround the hollow core of a microtubule. The microtubule grows more rapidly at its plus end. The molecular motor dynein moves along the microtubule in the plus-to-minus direction, whereas the molecular motor kinesin moves in the opposite direction. ATP is the fuel for each of these motors. **B**, The microtubules originate from a microtubule-organizing center or centrosome, which generally consists of two centrioles (*green cylinders*). **C**, A motile cilium can actively bend as its microtubules slide past each other. The molecular motor dynein produces this motion, fueled by ATP.

In most cells, all of the microtubules originate from the microtubule-organizing center or **centrosome**. This structure generally consists of two **centrioles**, each of which is a small ($\sim 0.5 \mu\text{m}$ long \times $0.3 \mu\text{m}$ in diameter) assembly of nine triplet microtubules that are arranged obliquely along the wall of a cylinder

(upper portion of [Fig. 2-11B](#)). The two centrioles in a centrosome are oriented at right angles to one another. The minus ends of all of a cell's microtubules are associated with proteins that surround the centrosome, whereas the rapidly growing plus ends radiate throughout the cytoplasm in a star-like arrangement (“astral” microtubules).

Microtubules participate in a multitude of cellular functions and structures. For example, microtubules project down the axon of neurons. Microtubules also provide the framework for the lacy membranes of the ER and Golgi complex. Disruption of microtubules causes these organelles to undergo dramatic morphological rearrangements and vesicularization. Microtubules also play a central role in cell division. Early in mitosis, the centrioles that make up the centrosomes replicate, forming two centrosomes at opposite poles of the dividing nucleus. Emanating from these centrosomes are the microtubules that form the **spindle fibers**, which in turn align the chromosomes (lower portion of [Fig. 2-11B](#)). Their coordinated growth and dissolution at either side of the chromosomes may provide the force for separating the genetic material during the anaphase of mitosis. A pair of centrioles remains with each daughter cell.

The architectural and mechanical capacities of microtubules are perhaps best illustrated by their role in motility. An electron microscopic cross section of a cilium demonstrates the elegance, symmetry, and intricacy of this structure (see [Fig. 2-11C](#)). Every cilium arises out of its own **basal body**, which is essentially a centriole that is situated at the ciliary root. Cilia come in two varieties—motile and nonmotile. Whereas motile cilia move and develop force, generating directional fluid flow in a number of organs, nonmotile cilia do not move on their own and instead serve sensory functions. We discuss motile cilia here and nonmotile cilia on [page 43](#).

Cilia are present on the surfaces of many types of epithelial cells, including those that line the larger pulmonary airways (see [p. 597](#)). In the airway epithelial cells, their oar-like beating motions help propel foreign bodies and pathogens toward their ultimate expulsion at the pharynx. At the center of a cilium is a structure called the **axoneme**, which is composed of a precisely defined “9 + 2” array of microtubules. Each of the 9 (which are also called outer tubules) consists of a complete microtubule with 13 tubulin monomers in cross section (the A tubule) to which is fused an incomplete microtubule with 11 tubulin monomers in cross section (the B tubule). Each of the 2, which lie at the core of the cilium, is a complete microtubule. This entire 9 + 2 structure runs the entire length of the cilium. The same array forms the core of a flagellum, the serpentine motions of which propel sperm cells (see [Fig. 56-1](#)).

Radial spokes connect the outer tubules to the central pair, and outer tubules attach to their neighbors by two types of linkages. One is composed of the protein dynein, which acts as a **molecular motor** to power ciliary and flagellar motions. 🟡 **N2-4 Dynein** is an ATPase that converts the energy released through ATP hydrolysis into a conformational change that produces a bending motion. Because dynein attached to one outer tubule interacts with a neighboring outer tubule, this bending of the dynein molecule causes the adjacent outer tubules to slide past one another. It is this sliding-filament motion that gives rise to the coordinated movements of the entire structure. To some extent, this coordination is accomplished through the action of the second linkage protein, called nexin. The **nexin** arms restrict the extent to which neighboring outer tubules can move with respect to each other and thus prevent the dynein motor from driving the dissolution of the entire complex.

N2-4

Molecular Motors

Contributed by Alisha Bouzaher

Molecular motors, a class of molecular machinery, convert chemical energy into mechanical force and motion necessary to carry out important mechanisms of translocation and organization within the cell. By harnessing chemical free energy released from the hydrolysis of ATP, molecular motors bind and translocate a substrate in a unidirectional motion along a polarized track; an example is myosin “walking” along actin filaments. The directionality of molecular motor movement along these tracks depends on track polarity and the interaction of the track with the head domain on the motor protein, the site of ATP hydrolysis. This movement is typically linear or rotational.

The families of molecular motors exhibit diverse amino-acid sequence, structure, and motile properties.

Family	Motor	Tract	Motion	Physiological Function
Cytoskeletal motors	Myosin 🔥 N2-14 (see pp. 233–234)	Actin filaments 🔥 N2-6	Linear	Muscle contraction, cell locomotion, ciliary function
	Dynein (see p. 25)	Microtubules (see p. 23–25)	Retrograde transport	Cilia, flagella movement
	Kinesin (see p. 25)	Microtubules	Anterograde transport	Intracellular transport of membrane-bound organelles, mitotic/meiotic spindle formation
Nucleic acid motors	DNA polymerase	DNA	Linear	DNA replication
	RNA polymerase (see p. 85)	DNA	Linear	DNA transcription
	Helicase	DNA	Linear	DNA transcription
	Topoisomerase	DNA	Linear	DNA transcription

Muscle Myosin

Contributed by Ed Moczydlowski

For historical reasons, the parts of the myosin II molecule in muscle often have more than one name.

- **Myosin heavy chains (MHCs)** consist of the following:
 - The N-terminal head
 - A neck or lever or linker or hinge
 - The C-terminal rod or tail
- **Essential myosin light chains** (ELCs or MLC-1) are also called *alkali chains*.
- **Regulatory myosin light chains** (RLCs or MLC-2).

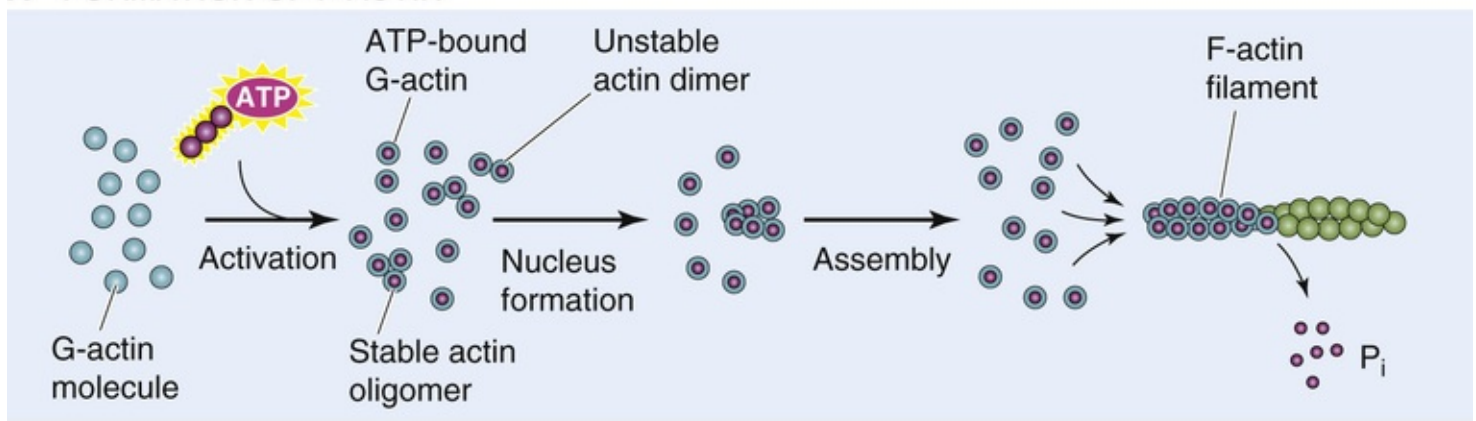

The utility of the dynein motor protein is not restricted to its function in cilia and flagella. Cytoplasmic dynein, which is a close relative of the motor molecule found in cilia, and a second family of motor proteins called kinesins provide the force necessary to move membrane-bound organelles through the cytoplasm along microtubular tracks (see [Fig. 2-11A](#)). The ability of vesicular organelles to move rapidly along microtubules was first noted in neurons, in which vesicles carrying newly synthesized proteins must be transported over extremely long distances from the cell body to the axon tip. Rather than trust this critical process to the vagaries of slow, nondirected diffusion, the neuron makes use of a kinesin motor, which links a vesicle to a microtubule. **Kinesins** hydrolyze ATP and, like dynein, convert this energy into mechanical transitions that cause kinesins to “walk” along the microtubule. Kinesins will move only along microtubules and thereby transport their vesicle cargoes in the **minus-to-plus direction (orthograde)**. Thus, in neurons, kinesin-bound vesicles move from the microtubular minus ends, originating at the centrosome in the cell body, toward the plus ends in the axons. This direction of motion is referred to as anterograde fast axonal transport. **Cytoplasmic dynein** moves in the **plus-to-minus direction (retrograde)**.

The motor-driven movement of cellular organelles along microtubular tracks is not unique to neurons. This process, involving both kinesins and cytoplasmic dynein, appears to occur in almost every cell and may control the majority of subcellular vesicular traffic.

Thin filaments (actin) and thick filaments (myosin) are present in almost every cell type

Thin filaments, also called microfilaments, are 5 to 8 nm in diameter. They are helical polymers composed of a single polypeptide called globular actin or **G-actin**. Thin filaments are functionally similar to microtubules in two respects: (1) the actin polymers are polar and grow at different rates at their two ends, and (2) actin binds and then hydrolyzes a nucleotide. However, whereas tubulin binds GTP and then hydrolyzes it to GDP, actin binds ATP and then hydrolyzes it to ADP. After G-actin binds ATP, it may interact with another ATP-bound monomer to form an unstable dimer ([Fig. 2-12A](#)). Adding a third ATP-bound monomer, however, yields a stable trimer that serves as a nucleus for assembly of the polymer of fibrous actin or **F-actin**. Once it is part of F-actin, the actin monomer hydrolyzes its bound ATP, retaining the ADP and releasing the inorganic phosphate. The ADP-bound actin monomer is more likely to disengage itself from its neighbors, just as GDP-bound tubulin dimers are more likely to disassemble from tubulin (see [p. 23](#)). Even though the length of the F-actin filament may remain more or less constant, the polymer may continually *grow* at its plus end but *disassemble* at its minus end (see [Fig. 2-12B](#)). This “treadmilling” requires the continuous input of energy (i.e., hydrolysis of ATP) and illustrates the unique dynamic properties of actin filament elongation and disassembly.

A FORMATION OF F-ACTIN

B TREADMILLING

FIGURE 2-12 Thin filaments. **A**, Single molecules of G-actin form F-actin filaments. **B**, F-actin can grow at the plus end while shrinking at the minus end, with no change in length. P_i , inorganic phosphate.

Thick filaments are composed of dimers of a remarkable force-generating protein called myosin. All **myosin** molecules have helical tails and globular head groups that hydrolyze ATP and act as motors to move along an actin filament. The energy liberated by ATP hydrolysis is invested in bending the myosin molecule around a pivot point called the hinge region, which marks the junction between the globular and tail regions. By means of this bending, myosin, like the dynein and kinesin that interact with microtubules, acts as a molecular motor that converts chemical into mechanical energy. 🟡 N2-4

In muscle, the myosin molecules are in the **myosin II** subfamily and exist as dimers with their long tails intertwined (Fig. 2-13A). In muscle, each of the two myosin II heads binds two additional protein subunits referred to as myosin **light chains**. Nonmuscle cells, in addition to myosin II, may have a variety of other, smaller myosin molecules. These other myosins, the most widely studied of which is **myosin I**, have shorter tails and, at least in some cases, act as molecular motors that move vesicles along actin filaments.

A MYOSIN

B MYOFILAMENTS

C SARCOMERE

FIGURE 2-13 Thick filaments. **A**, Myosin I is one of a large number of widely distributed myosins that have short tails. Myosin II is the myosin that participates in muscle contraction. **B**, The pivoting action of the myosin head, fueled by ATP, moves the thick filament past the thin filament. **C**, In skeletal and cardiac muscle, the sarcomere is the fundamental contractile unit. S_1 and S_2 are subfragments of heavy meromyosin.

In muscle, the myosin II dimers stack as antiparallel arrays to form a bipolar structure with a central region that contains only tails (see Fig. 2-13A). The ends of the thick filament contain the heads that bend toward the filament's central region. The pivoting action of the myosin head groups drags the neighboring thin filament (see Fig. 2-13B), which includes other molecules besides actin. This sliding-filament phenomenon underlies muscle contraction and force generation (see Fig. 2-13C).

Actin as well as an ever-growing list of myosin isoforms is present in essentially every cell type. The functions of these proteins are easy to imagine in some cases and are less obvious in many others. Many cells, including all of the fibroblast-like cells, possess actin filaments that are arranged in **stress fibers**. These linear arrays of fibers interconnect adhesion plaques to one another and to interior structures in the cell. They orient themselves along lines of tension and can, in turn, exert contractile force on the substratum that underlies the cell. Stress-fiber contractions may be involved in the macroscopic contractions that are associated with wound healing. Frequently, actin filaments in nonmuscle cells are held together in bundles by cross-linking proteins. Numerous classes of cross-linking proteins have been identified, several of which can respond to physiological changes by either stabilizing or severing filaments and filament bundles.

In motile cells, such as fibroblasts and macrophages, arrays of actin-myosin filaments are responsible for **cell locomotion**. Assembly of actin filaments can drive the directional extension of the cell membrane at the cell's leading edge, creating structures known as lamellipodia. A Ca^{2+} -stimulated myosin light chain kinase regulates the assembly of myosin and actin filaments, which produce contractile force and retraction at the cell's trailing edge. To generate directional motion, these cytoskeletal elements must be able to form transient traction-generating connections to the cell's substratum. 🍷 **N2-5** These connections are established through integrins (see p. 17).

N2-5

Cell Locomotion

Contributed by Michael Caplan

It should be noted that at least in some cases, the interactions that contribute to cellular motility are geometrically and biochemically quite distinct from those which underlie muscle contraction. For example, the amoebic cells of the bread mold *Dictyostelium discoideum* are able to continue crawling despite the elimination—by genetic deletion—of all of their myosin. Although motility in these altered cells is not normal, that it persists at all provides ample proof that the paradigms that apply to smooth and striated muscle are by no means the only schemes that nature has devised to generate actin filament-based motion.

In contrast to fibroblasts and circulating cells of the immune system, cells such as neurons and epithelial cells generally do not move much after their differentiation is complete. Despite this lack of movement, however, these cells are equipped with remarkably intricate networks of actin and myosin filaments. In some cases, these cytoskeletal elements permit the cell to extend processes to distant

locations. This is the case in neurons, in which the growth and migration of axons during development or regeneration of the nervous system bear a striking morphological resemblance to the crawling of free-living amoebae. The tip of a growing axon, known as a **growth cone**, is richly endowed with contractile fibers and is capable of the same types of crawling motions that characterize motile cells.

In **epithelial cells**, the role of the actin-myosin cytoskeleton is somewhat less obvious but still important to normal physiological function. The **microvilli** at the apical surfaces of many epithelial-cell types (e.g., those that line the renal proximal tubule and the small intestine) are supported by an intricate scaffolding of actin filaments that form their cores ([Fig. 2-14](#)). This bundle of actin fibers is held together and anchored to the overlying plasma membrane by a variety of cross-linking proteins, including various myosin isoforms. The roots of the microvillar actin filament bundles emerge from the bases of the microvilli into a dense meshwork of cytoskeletal filaments known as the **terminal web**. Included among the components of the terminal web are **fodrin** (the nonerythroid homolog of spectrin) and myosin. The myosin in the terminal web interconnects the actin filaments of neighboring microvilli. In addition, this actin-myosin complex is capable of generating contractile movements that can alter the spatial relationships among microvilli.

FIGURE 2-14 Actin filaments at the brush border of an epithelial cell.

Actin and myosin filaments also form an **adhesion belt** that encircles the cytoplasmic surface of the epithelial plasma membrane at the level of the **tight junctions** that interconnect neighboring cells. These adhesion belts are apparently capable of contraction and thus cause epithelial cells that normally form a continuous sheet to pull away from one another, temporarily loosening tight junctions and creating direct passages that connect the luminal space to the ECF compartment.

Actin and myosin also participate in processes common to most if not all cell types. The process of cytokinesis, in which the cytoplasm of a dividing cell physically separates into two daughter cells, is driven by actin and myosin filaments. Beneath the cleavage furrow that forms in the membrane of the dividing cell is a contractile ring of actin and myosin filaments. Contraction of this ring deepens the cleavage furrow; this invagination ultimately severs the cell and produces the two progeny. 🔥 **N2-6**

Contributed by Michael Caplan

In addition to having the functions discussed in the text, actin and myosin may play important roles in other processes. Actin filaments and various newly discovered isoforms of myosin may be involved in the shuttling of intracellular cargoes in much the same way that microtubules and their associated motor proteins participate in this function. Certain types of myosin appear to serve as motors that drive the movements of vesicles and other organelles along tracks composed of actin filaments. The precise role and relative importance of these movements in the physiology of the cell has yet to be fully elucidated. Despite this uncertainty, it is clear that the actin and myosin cytoskeleton subserves a multitude of functions, ranging from its classical role in the macroscopic contractions of skeletal muscles to its contributions to motility at subcellular scales.

Synthesis and Recycling of Membrane Proteins

Secretory and membrane proteins are synthesized in association with the rough ER

Transmembrane proteins are composed of hydrophobic domains that are embedded within the phospholipid bilayer and hydrophilic domains that are exposed at the intracellular and extracellular surfaces (see pp. 13–15). These proteins do not “flip” through the membrane. How, then, do intrinsic membrane proteins overcome the enormous energetic barriers that should logically prevent them from getting inserted into the membrane in the first place?

The cell has developed several schemes to address this problem. Mammalian cells have at least three different membrane insertion pathways, each associated with specific organelles. The first two are mechanisms for inserting membrane proteins into peroxisomes and mitochondria (see pp. 30–32). The third mechanism inserts membrane proteins destined for delivery to the plasma membrane and to the membranes of organelles (the endomembranous system) other than the peroxisome and mitochondrion. This same mechanism is involved in the biogenesis of essentially all proteins that mammalian cells secrete and is the focus of the following discussion.

The critical work in this field centered on studies of the rough ER. The membrane of the **rough ER** (see pp. 20–21) is notable for the presence of numerous ribosomes that are bound to its cytosol-facing surface. Although all nucleated mammalian cells have at least some rough ER, cells that produce large quantities of secretory proteins—such as the exocrine cells of the pancreas, which function as factories for digestive enzymes (see pp. 879–881)—are endowed with an abundance of rough ER. Roughly half of the cytoplasmic space in an exocrine pancreatic acinar cell is occupied by rough ER.

In early experiments exploring cell-fractionation techniques, membranes that were derived from the rough ER were separated from the other membranous and cytoplasmic components of pancreatic acinar cells. The mRNAs associated with rough ER membranes were isolated and the proteins they encoded were synthesized by in vitro translation. Analysis of the resultant polypeptides revealed that they included the cell's entire repertoire of *secretory* proteins. It is now appreciated that the mRNA associated with the ER also encodes the cell's entire repertoire of *membrane* proteins, with the exception of those destined for either the peroxisome or the mitochondrion. When the same experiment was performed with mRNAs isolated from ribosomes that are freely distributed throughout the cytoplasm, the products were not *secretory* proteins but rather the soluble *cytosolic* proteins. Later work showed that the ribosomes bound to the ER are biochemically identical to and in equilibrium with those that are free in the cytosol. Therefore, a ribosome's subcellular localization—that is, whether it is free in the cytosol or bound to the rough ER—is somehow dictated by the mRNA that the ribosome is currently translating. A ribosome that is involved in assembling a secretory or membrane protein will associate with the membrane of the rough ER, whereas the same ribosome will be free in the cytosol when it is producing cytosolic proteins. Clearly, some **localization signal** that resides in the mRNA or in the protein that is being synthesized must tell the ribosome what kind of protein is being produced and where in the cell that production should occur.

The nature of this signal was discovered in 1972 during studies of the biosynthesis of immunoglobulin light chains. Light chains synthesized in vitro, in the absence of rough ER membranes, have a 15–amino-acid extension at their amino terminus that is absent from the same light chains synthesized and secreted in

vivo by B lymphocytes. Similar **amino-terminal extensions** are present on most secretory or membrane proteins but never on the soluble proteins of the cytosol. Although they vary in length and composition, these extensions are usually α -helical and are composed of strings of hydrophobic acids that are often preceded by short stretches of basic residues. These **signal sequences**, as they have come to be known, serve as the localization devices discussed above. As it emerges from a ribosome and is freely floating in the cytosol, the signal sequence of a nascent protein (Fig. 2-15, stage 1) targets the ribosome-mRNA complex to the surface of the rough ER where the protein's biogenesis will be completed. Ribosome-mRNA complexes that lack a signal sequence complete the translation of the mRNA—which encodes neither secretory nor membrane proteins—without attaching to the rough ER. For his work on signal sequences, Günter Blobel received the 1999 Nobel Prize for Physiology or Medicine. 🍌 N2-7

Why does the cell bother to segregate the synthesis of different protein populations to different cellular locales? Proteins that are destined either to reside in a membrane or to undergo secretion are inserted into or across the membrane of the rough ER at the same time that they are translated; this is called **cotranslational translocation**. As the nascent polypeptide chain emerges from the ribosome, it traverses the rough ER membrane and ultimately appears at the ER's luminal face. There, an enzyme cleaves the amino-terminal signal sequence while the protein is still being translocated. This is why proteins that are synthesized *in vitro* in the absence of membranes are longer than the same proteins that are produced by intact cells.

Simultaneous protein synthesis and translocation through the rough ER membrane requires machinery for signal recognition and protein translocation

The information embodied within a signal sequence explains how a nascent protein can direct a cell to complete that protein's translation at the time of translocation in the rough ER. However, the signal sequence by itself is not sufficient. Two critical pieces of targeting machinery are also necessary to direct the ribosome and its attached nascent peptide to the ER. The first is a ribonucleoprotein complex called the **signal recognition particle (SRP)**, which binds to the signal sequence on the nascent peptide (see [Fig. 2-15](#), stage 2). The SRP is composed of seven distinct polypeptides and a short strand of RNA. When the SRP binds to a nascent chain, it also binds a GTP molecule. The second vital piece of targeting machinery is a transmembrane component of the rough ER, the **SRP receptor**, also called the **docking protein**. Interaction between a signal sequence and the SRP, and subsequently between the SRP–nascent peptide–ribosome complex and the docking protein, directs the nascent chain to the rough ER's translocation apparatus.

Because the membrane of the rough ER has a finite number of docking sites, the cell must coordinate the synthesis of secretory and membrane proteins with the availability of docking sites. If all docking sites were occupied, and if the synthesis of nascent secretory and membrane proteins were allowed to continue unabated, these nascent peptides would be synthesized entirely in the cytoplasm on free ribosomes. As a consequence, these newly synthesized proteins would never arrive at their proper destination. The SRP serves as a regulatory system that matches the rate of synthesis of secretory and membrane proteins to the number of unoccupied translocation sites. By associating with a nascent signal sequence, the SRP causes the ribosome to halt further protein synthesis (see [Fig. 2-15](#), stage 2). This state of **translation arrest** persists until the SRP–nascent peptide–ribosome complex finds an unoccupied docking protein with which to interact. Thus, SRP prevents secretory and membrane proteins from being translated until their cotranslational translocation can be ensured. Because SRP interacts only with nascent chains that bear signal sequences, ribosomes that synthesize proteins destined for release into the cytosol never associate with SRP, and their translation is never arrested. Thus, SRP serves as a highly specific spatial and temporal sorting machine, guaranteeing the accurate and efficient targeting of secretory and membrane proteins.

How does the cell terminate the translation arrest of the SRP–nascent peptide–ribosome complex? When this complex interacts with a docking protein (see [Fig. 2-15](#), stage 3), one of the SRP's subunits hydrolyzes the previously bound GTP, thereby releasing the SRP from a successfully targeted nascent peptide–ribosome complex. In this way, the docking protein informs the SRP that its mission has been accomplished and it can return to the cytosol to find another ribosome with a signal peptide. A second GTP hydrolysis step transfers the nascent peptide from the docking protein to the actual translocation tunnel complex. GTP hydrolysis is a common event and is involved in the transmission of numerous cellular messages (see [pp. 53](#) and [56](#)). In this case, the two separate instances of GTP hydrolysis serve a quality-control function, because the activation of the GTPase activity depends on the delivery of the nascent peptide to the appropriate component in the translocation apparatus.

Adjacent to the docking protein in the membrane of the rough ER is a protein translocator termed a **translocon** (see [Fig. 2-15](#), stage 3), which contains a tunnel through which the nascent protein will pass across the rough ER membrane. It appears that delivery of a nascent chain to the translocon causes the entrance of the translocator's tunnel, which is normally closed, to open. This opening of the translocon

also allows the flow of small ions. The electrical current carried by these ions can be measured by the patch-clamp technique (see p. 154). By “gating” the translocon so that it opens only when it is occupied by a nascent protein, the cell keeps the tunnel's entrance closed when it is not in use. This gating prevents the Ca^{2+} stored in the ER from leaking into the cytoplasm.

Because the tunnel of the translocon is an aqueous pore, the nascent secretory or membrane protein does not come into contact with the hydrophobic core of the ER membrane's lipid bilayer during cotranslational translocation. Thus, this tunnel allows hydrophilic proteins to cross the membrane. As translation and translocation continue and the nascent protein enters the lumen of the rough ER, an enzyme called **signal peptidase** cleaves the signal peptide, which remains in the membrane of the rough ER (see Fig. 2-15, stage 4). Meanwhile, translation and translocation of the protein continue (see Fig. 2-15, stage 5). In the case of **secretory proteins** (i.e., *not* membrane proteins), the peptide translocates completely through the membrane. The ribosome releases the complete protein into the lumen of the rough ER and then dissociates from the rough ER (see Fig. 2-15, stage 6).

Proper insertion of membrane proteins requires start- and stop-transfer sequences

Unlike soluble proteins, nascent *membrane proteins* do not translocate completely through the membrane of the rough ER (Fig. 2-16A, stage 1). The hydrophobic amino-acid residues that will ultimately become the transmembrane segment of a membrane protein also function as a **stop-transfer sequence** (see Fig. 2-16A, stage 2). When a stop-transfer sequence emerges from a ribosome, it causes the translocon to open laterally, releasing the hydrophobic membrane-spanning segment into the hospitable environment of the rough ER membrane's hydrophobic core (see Fig. 2-16A, stage 3). In the meantime, the ribosomal machinery continues to translate the rest of the nascent protein. If the signal peptidase cleaves the amino terminus at this time, the end result is a protein with a *single transmembrane segment*, with the amino terminus in the lumen of the rough ER and the carboxyl terminus in the cytoplasm (see Fig. 2-16A, stage 4).

A SINGLE MEMBRANE-SPANNING SEGMENT, CYTOPLASMIC C TERMINUS

B SINGLE MEMBRANE-SPANNING SEGMENT, CYTOPLASMIC C TERMINUS (ALTERNATE MECHANISM)

C SINGLE MEMBRANE-SPANNING SEGMENT, CYTOPLASMIC N TERMINUS

D MULTIPLE MEMBRANE-SPANNING SEGMENTS

FIGURE 2-16 Synthesis of integral membrane proteins. **A**, Like a secreted protein, the membrane protein can have a cleavable signal sequence. In addition, it has a stop-transfer sequence that remains in

the membrane as a membrane-spanning segment. **B**, The emerging protein lacks a signal sequence but instead has an *internal start-transfer sequence*, which is a bifunctional sequence that serves both as a signal sequence that binds SRPs and as a hydrophobic membrane-spanning segment. In this example, the positively charged region flanking the internal start-transfer sequence is on the *carboxyl* (C)–terminal end of the internal start-transfer sequence. Therefore, the C-terminal end is in the cytoplasm. **C**, The example is similar to that in **B** except that the positively charged region flanking the internal start-transfer sequence is on the *amino*- (N)–terminal end of the internal start-transfer sequence. **D**, The emerging peptide has alternating internal start-transfer and stop-transfer sequences.

There is another way of generating a protein with a single transmembrane segment. In this case, the protein lacks a signal sequence at the N terminus but instead has—somewhere in the middle of the nascent peptide—a bifunctional sequence that serves both as a signal sequence that binds SRP and as a hydrophobic membrane-spanning segment. This special sequence is called an **internal start-transfer sequence**. The SRP binds to the internal start-transfer sequence and brings the nascent protein to the rough ER, where the internal start-transfer sequence binds to the translocon in such a way that the more positively charged residues that flank the start-transfer sequence face the cytosol. Because these positively charged flanking residues can either precede or follow the hydrophobic residues of the internal start-transfer sequence, either the carboxyl (C) terminus or the N terminus can end up in the cytosol. If the more positively charged flanking residues are at the *carboxyl*-terminal end of the internal start-transfer sequence (see Fig. 2-16B), the protein will be oriented with its *carboxyl* terminus in the cytosol. If the more positively charged flanking residues are at the *amino*-terminal end of the internal start-transfer sequence (see Fig. 2-16C), the protein will be oriented with its *amino* terminus in the cytosol.

By alternating both *stop-transfer* sequences (see Fig. 2-16A) and *internal start-transfer* sequences (see Fig. 2-16B, C), the cell can fabricate membrane proteins that span the membrane more than once. Figure 2-16D shows how the cell could synthesize a multispanning protein with its N terminus in the cytosol. The process starts just as in Figure 2-16C, as the translation machinery binds to the rough ER (see Fig. 2-16D, stage 1) and the protein's first internal start-transfer sequence inserts into the translocon (see Fig. 2-16D, stage 2). However, when the first stop-transfer sequence reaches the translocon (see Fig. 2-16D, stage 3), the translocon disassembles, releasing the protein's first two membrane-spanning segments into the membrane of the rough ER. Note that the first membrane-spanning segment is the internal start-transfer sequence and the second is the stop-transfer sequence. In the meantime, an SRP binds to the second internal start-transfer sequence (see Fig. 2-16D, stage 4) and directs it to the rough ER (see Fig. 2-16D, stage 5) so that cotranslational translocation can once again continue (see Fig. 2-16D, stage 6). If there are no further stop-transfer sequences, the result will be a protein with three membrane-spanning segments.

Several points from the preceding discussion deserve special emphasis. First, translocation through the ER membrane can occur only cotranslationally. If a secretory or membrane protein were synthesized completely on a cytoplasmic ribosome, it would be unable to interact with the translocation machinery and consequently would not be inserted across or into the bilayer. As discussed below, this is not true for the insertion of either peroxisomal or mitochondrial proteins. Second, once a signal sequence emerges from a ribosome, there is only a brief period during which it is competent to mediate the ribosome's association with the ER and to initiate translocation. This time constraint is presumably due to the tendency of nascent polypeptide chains to begin to fold and acquire tertiary structure very soon after exiting the ribosome. This folding quickly buries hydrophobic residues of a signal sequence so that they cannot be recognized by the translocation machinery. Third, because the translocation channel appears to be fairly narrow, the nascent protein cannot begin to acquire tertiary structure until after it has exited at the ER's luminal face. Thus, the peptide must enter the translocation tunnel as a thin thread immediately after

emerging from the ribosome. These facts explain why translocation is cotranslational. In systems in which post-translational translocation occurs (e.g., peroxisomes and mitochondria), special adaptations keep the newly synthesized protein in an unfolded state until its translocation can be consummated.

Finally, because the protein cannot flip once it is in the membrane, the scheme just outlined results in proteins that are inserted into the rough ER membrane in their final or “mature” topology. The number and location of a membrane protein's transmembrane segments, as well as its cytoplasmic and extracytoplasmic loops, are entirely determined during the course of its cotranslational insertion into the ER membrane. The order in which signal, internal start-transfer, and stop-transfer sequences appear in a membrane protein's primary structure completely determines how that protein will be arrayed across whatever membrane it ultimately comes to occupy.

Newly synthesized secretory and membrane proteins undergo post-translational modification and folding in the lumen of the rough ER

As a newly synthesized secretory or membrane protein exits the tunnel of the translocon and enters the lumen of the rough ER, it may undergo a series of **post-translational modifications** that will help it to acquire its mature conformation. The first alteration, as discussed above, is cleavage of the signal sequence (if present) and is accomplished very soon after the signal sequence has completed its translocation. Other covalent modifications that occur as translocation continues include glycosylation and formation of intramolecular disulfide bonds. **Glycosylation** refers here to the enzymatic, en-bloc coupling of preassembled, branched oligosaccharide chains that contain 14 sugar molecules ([Fig. 2-17A](#)) to asparagine residues that appear in the sequence Asn-X-Ser or Asn-X-Thr (X can be any amino acid except proline). These **N-linked sugars** (N is the single-letter amino-acid code for asparagine) will go on to be extensively modified as the protein passes through other organellar compartments. The addition of sugar groups to proteins can serve numerous functions, which include increasing the protein's stability and endowing it with specific antigenic, adhesive, or receptor properties.

FIGURE 2-17 Post-translational modifications of integral membrane proteins. **A**, An enzyme in the ER lumen attaches a preassembled, branched, oligosaccharide chain to an asparagine (Asn or N) residue on the nascent protein. **B**, An enzyme in the ER lumen cleaves the protein and couples the protein's new terminal carboxyl group to the terminal amino group on the GPI molecule.

Disulfide bond formation is catalyzed by **protein disulfide isomerase**, an enzyme that is retained in the ER lumen through noncovalent interactions with ER membrane proteins. Because the cytoplasm is a reducing environment, disulfide bonds can form only between proteins or protein domains that have been removed from the cytosolic compartment through translocation to the ER's interior. Other, more specialized modifications also take place in the lumen of the rough ER. For example, the ER contains the enzymes responsible for the **hydroxylation** of the proline residues that are present in newly synthesized collagen chains.

The ER also catalyzes the formation of **GPI linkages** to membrane proteins (see Fig. 2-17B). GPI-linked proteins are synthesized as transmembrane polypeptides, with a typical membrane-spanning region. Shortly after their translation, however, their lumen-facing domains are cleaved from the membrane-spanning segments and covalently transferred to the GPI phospholipid. They retain this structure and orientation throughout the remainder of their journey to the cell surface. A defect in the synthesis of GPI-linked proteins underlies the human disease paroxysmal nocturnal hematuria (Box 2-1).

Box 2-1

Paroxysmal Nocturnal Hematuria

The list of proteins embedded in the plasma membrane via a GPI linkage is remarkably long and ever growing. In red blood cells, the inventory of GPI-linked proteins includes a pair of polypeptides, decay-accelerating factor (DAF) and CD59, which help protect the erythrocytes from being accidentally injured by constituents of the immune system. One of the mechanisms that the immune system uses to rid the body of invading bacteria involves the activation of the complement cascade. Complement is a complex collection of proteins that circulate in the blood plasma. The complement system recognizes antibodies that are bound to the surface of a bacterium or polysaccharides in the bacterial membrane. This recognition initiates a cascade of enzymatic cleavages that results in the assembly of a subset of complement proteins to form the membrane attack complex, which inserts itself into the membrane of the target organism and forms a large pore that allows water to rush in (see pp. 109–110). The target bacterium swells and undergoes osmotic lysis. Unfortunately, the complement system's lethal efficiency is

not matched by its capacity to discriminate between genuine targets and normal host cells. Consequently, almost every cell type in the body is equipped with surface proteins that guard against a misdirected complement attack.

DAF and CD59 are two such proteins that interfere with distinct steps in the complement activation pathway. Because GPI linkages couple both proteins to the membrane, any dysfunction of the enzymes that participate in the transfer of GPI-linked proteins from their transmembrane precursors to their GPI tails in the ER would interfere with the delivery of DAF and CD59 to their sites of functional residence at the cell surface. One of the proteins that participates in the synthesis of the GPI anchor is a sugar transferase encoded by the phosphatidylinositol glycan class A (PIG-A) gene. This gene is located on the X chromosome. Because every cell has only one working copy of the X chromosome (although female cells are genetically XX, one of the two X chromosomes is inactivated in every cell), if a spontaneous mutation occurs in the PIG-A gene in a particular cell, that cell and all of its progeny will lose the ability to synthesize GPI-linked proteins.

In **paroxysmal nocturnal hemoglobinuria** (i.e., the appearance of hemoglobin in the urine at night, with a sharp onset), a spontaneous mutation occurs in the PIG-A gene in just one of the many precursor cells that give rise to erythrocytes. All of the erythrocytes that arise from this particular precursor, therefore, are deficient in GPI-linked protein synthesis. Consequently, these cells lack DAF and CD59 expression and are susceptible to complement attack and lysis. For reasons that are largely unknown, the complement system is somewhat more active during sleep, so the hemolysis (lysis of erythrocytes) occurs more frequently at night in these patients. Some of the hemoglobin released by this lysis is excreted in the urine.

Because the PIG-A gene product is required for the synthesis of *all* GPI-linked proteins, the plasma membranes of affected red blood cells in patients with paroxysmal nocturnal hemoglobinuria are missing a number of different proteins that are found in the surface membranes of their normal counterparts. It is the lack of DAF and CD59, however, that renders the cells vulnerable to complement-mediated killing and that creates the symptoms of the disease. Paroxysmal nocturnal hemoglobinuria is an uncommon disease. Because it is the result of an acquired mutation, it is much more likely to occur in people of middle age than in children. Patients with paroxysmal nocturnal hemoglobinuria are likely to become anemic and can suffer life-threatening disorders of clotting and bone marrow function. It is a chronic condition, however, and more than half of patients survive at least 15 years after diagnosis.

Perhaps the most important maturational process for a nascent chain emerging into the ER lumen is the acquisition of **tertiary structure**. The folding of a secretory or membrane protein is determined during and immediately after its cotranslational translocation. The progress of protein folding influences—and is influenced by—the addition of sugar residues and the formation of disulfide bridges. Proteins fold into conformations that minimize their overall free energies. Their extramembranous surfaces are composed of hydrophilic residues that interact easily with the aqueous solvent. Hydrophobic residues are hidden in internal globular domains where they can be effectively isolated from contact with water or charged molecules. Left to its own devices, a linear strand of denatured protein will spontaneously fold to form a structure that reflects these thermodynamic considerations. Thus, protein folding requires no catalysis and can occur without help from any cellular machinery. However, the cell is not content to allow protein folding to follow a random course and instead orchestrates the process through the actions of molecular chaperones.

The **chaperones** constitute a large class of ATP-hydrolyzing proteins that appear to participate in a wide variety of polypeptide-folding phenomena, including the initial folding of newly synthesized

proteins as well as the refolding of proteins whose tertiary structures have been damaged by exposure to high temperature (i.e., heat shock) or other denaturing conditions. Chaperones bind to unfolded protein chains and stabilize them in an unfolded conformation, thus preventing them from spontaneously folding into what might be an energetically favorable but biologically useless arrangement. Using energy that is provided through ATP hydrolysis, the chaperones sequentially release domains of unfolded proteins and thus allow them to fold in an ordered fashion. An excess of unfolded or misfolded proteins causes **ER stress**, triggering the unfolded protein response. 🕒 **N2-8** Distinct subclasses of chaperones are present in several cell compartments, including the cytoplasm, the mitochondrion, and the lumen of the rough ER. Newly synthesized secretory and membrane proteins interact with ER chaperones as they exit from the tunnel of the translocon and subsequently disengage from the chaperones to assume their mature tertiary structure.

N2-8

Unfolded Protein Response

Contributed by D. Narayan Rao

In response to ER stress due to the accumulation of unfolded proteins in the lumen, the unfolded protein response (URP) acts to restore ER homeostasis. URP activation has three unique mechanisms that operate in parallel

1. **Feedback control:** regulating the rate of protein synthesis by temporarily halting protein translation
2. **Cell fate regulation:** recognizing and eliminating misfolded proteins
3. **Adaptive response:** ramping up production of molecular chaperones involved in protein folding

The acquisition of tertiary structure is followed quickly by the acquisition of **quaternary structure**. As noted above in this chapter, many membrane proteins assemble into oligomeric complexes in which several identical or distinct polypeptides interact with one another to form a macromolecular structure. Assembly of these multimers generally occurs in the ER. It is unknown whether the oligomeric assembly process occurs entirely spontaneously or if, like folding, it is orchestrated by specialized cellular mechanisms. Cells clearly go to great trouble to ensure that proteins inserted into or across their ER membranes are appropriately folded and oligomerized before allowing them to continue with their postsynthetic processing. As discussed below, proteins destined for secretion from the cell or for residence in plasma or organellar membranes depart the ER for further processing in the membranous stacks of the **Golgi complex**. This departure is entirely contingent on successful completion of the protein folding and assembly operations.

Misfolded or unassembled proteins are retained in the ER and ultimately degraded. The ER chaperone proteins play a critical role both in identifying proteins with incorrect tertiary or quaternary structures and in actively preventing their egress to the Golgi complex. Proteins that have not folded or assembled correctly are destroyed through a process known as **ERAD** (endoplasmic reticulum–associated degradation). The sequential covalent addition of **ubiquitin** monomers results in the formation of a branched-chain ubiquitin polymer that marks these proteins for destruction. Ubiquitin is a small protein of 76 amino-acid residues. The process known as **retrotranslocation** removes ubiquitin-tagged proteins from the ER membrane, and a large cytoplasmic complex of proteolytic enzymes—the **proteasome**—degrades the ubiquitinated proteins.

Secretory and membrane proteins follow the secretory pathway through the cell

The rough ER is the common point of origin for the cell's secretory and membrane proteins. Most of these proteins are not retained in the rough ER but depart for distribution to their sites of ultimate functional residence throughout the cell. As is true for their arrival in the rough ER, the departure of these proteins is a highly organized and regimented affair. In fact, the rough ER is the first station along the **secretory pathway**, which is the route followed (at least in part) by all secretory and membrane proteins as they undergo their post-translational modifications ([Fig. 2-18](#)).

FIGURE 2-18 The secretory pathway. After their synthesis in the rough ER, secretory and membrane proteins destined for the plasma membrane move through the Golgi stacks and secretory vesicles. In the constitutive pathway, vesicles fuse spontaneously with the plasma membrane. In the regulated pathway, the vesicles fuse only when triggered by a signal such as a hormone.

The elucidation of the secretory pathway occurred in the 1960s, mainly in the laboratory of George Palade. For his contribution, Palade was awarded the 1975 Nobel Prize in Physiology or Medicine. **N2-9** This work also exploited the unique properties of pancreatic acinar cells to illuminate the central features of the biogenesis of secretory proteins. Because ~95% of the protein that is synthesized by pancreatic acinar cells is digestive enzymes destined for secretion (see p. 882), when these cells are fed radioactively labeled amino acids, the majority of these tracer molecules are incorporated into secretory polypeptides. Within a few minutes after the tracer is added, most of the label is associated with a specialized subregion of the rough ER. Known as **transitional zones**, these membranous saccules are ribosome studded on one surface and smooth on the opposite face (see Fig. 2-18). The smooth side is directly apposed to one pole of the pancake-like membrane stacks (or cisternae) of the **Golgi complex**. Smooth-surfaced carrier vesicles crowd the narrow moat of cytoplasm that separates the transitional zone from the Golgi. These vesicles “pinch off” from the transitional zone and fuse with a Golgi stack. From this first or **cis-Golgi** stack, **carrier vesicles** ferry the newly synthesized proteins sequentially and vectorially through each Golgi stack, ultimately delivering them to the **trans**-most saccule of the Golgi. Finally, the newly synthesized secretory proteins appear in **secretory vesicles** (also called secretory granules in many tissues).

George Palade

The journey from the rough ER to the secretory vesicle takes ~45 minutes in pancreatic acinar cells and requires the expenditure of metabolic energy. Each nucleated eukaryotic cell possesses a secretory pathway that shares this same general outline, although the specific features reflect the cell's particular function. The secretory pathway of the pancreatic acinar cell, for example, is specially adapted to accommodate the controlled secretion of protein via the so-called **regulated pathway**. Instead of being released from the cell continuously as they are produced, newly synthesized secretory proteins are held in *specialized secretory vesicles* that serve as an intracellular storage depot. This type of storage occurs in several cells, including those of endocrine and exocrine secretory tissues, and neurons. When the cells receive the requisite message, the storage vesicles fuse with the plasma membrane, sometime at a specialized structure called a **porosome**, in a process known as **exocytosis**. 🍷 **N2-10** The vesicles then dump their contents into the extracellular space. In the case of the pancreatic acinar cells, the enzymes are secreted into the pancreatic ductules and then make their way to the site of digestion in the duodenum (see [p. 881](#)).

The Porosome

Contributed by Bhanu P. Jena

Porosomes are the universal secretory machinery in cells. In the past decade, this newly discovered cellular structure at the cell plasma membrane, measuring only a few nanometers, has provided a molecular understanding of the secretory process in cells. Porosomes are supramolecular lipoprotein structures at the cell plasma membrane, where membrane-bound secretory vesicles transiently dock and fuse to release intravesicular contents to the outside during cell secretion. The mouth of the porosome opening to the outside ranges in size from 150 nm in diameter in acinar cells of the exocrine pancreas to 12 nm in neurons. The mouth dilates during cell secretion, returning to its resting size following completion of the process (eFig. 2-2).

EFigure 2-2 Porosome: the secretory portal in mammalian cells. **A**, High-resolution atomic force micrograph showing a single pit with four 100- to 180-nm porosomes within (*blue arrowhead*) at the apical plasma membrane in a live pancreatic acinar cell. **B**, Electron micrograph depicting a porosome (*blue arrowhead*) close to a microvillus (MV) at the apical plasma membrane (PM) of a pancreatic acinar cell. Note the association of the porosome membrane (*yellow arrowhead*) and the zymogen granule membrane (ZGM; *red arrowhead*) of a docked zymogen granule (ZG; *inset*). Cross section of a circular complex at the mouth of the porosome is seen (*blue arrowhead*). POM, Porosome membrane. **C**, Schematic diagram of pits (*yellow arrow*) and porosomes (*blue arrow*) at the cell plasma membrane (PM). ZGs are the secretory vesicles in acinar cells of the exocrine pancreas that transiently dock and fuse at the porosome base to expel intravesicular contents during secretion. **D**, Several porosomes within a pit shown at time 0, 5 minutes, and 30 minutes (*from left to right*) following stimulation of secretion. Section analysis across three porosomes is shown, with the blue arrowhead pointing at a porosome. Note the dilation of the porosome at the 5-minute time point and its return to near resting size after 30 minutes following stimulation of secretion. **E**, Percentage of total cellular amylase release in the presence (*yellow bars*) and absence (*blue bars*) of the secretagogue Mas7. Note the increase in porosome diameter in **D**, correlating with an increase in total cellular amylase release at 5 minute following stimulation of secretion. At 30 minutes following a secretory stimulus, there is a decrease in porosome diameter (**D**) and no further increase in amylase secretion beyond that at the 5-minute time point. No significant changes in amylase secretion or porosome diameter were observed in control cells in either the presence or absence of the nonstimulatory mastoparan analog (Mas17). **F**, Electron micrograph of a porosome (*blue arrowheads*) at the nerve terminal in association with a synaptic vesicle (SV) at the presynaptic membrane (Pre-SM). Notice the central plug-like structure at the neuronal porosome opening. post-SM, postsynaptic membrane. **G**, Atomic force micrograph of a neuronal porosome in physiological buffer, also showing the central plug (*blue arrowhead*) at its opening. The central plug in the neuronal porosome complex may regulate its rapid close-open conformation during neurotransmitter release. The neuronal porosome is an order of magnitude smaller (10 to 15 nm) than the porosome in the exocrine pancreas (100 to 180 nm). Note the central plug and eight interconnected ridges within the porosome complex. **H**, Electron-density maps of negatively stained electron micrographs of isolated neuronal porosome protein complex. Note the ~12-nm complex exhibiting a circular profile and having a central plug, with eight interconnected protein densities at the rim of the complex. Bar = 5 nm. **I**, Atomic force micrograph of a pit and three porosomes within (one indicated by the *blue arrowhead*) in a pancreatic acinar cell and the specific immunolocalization of amylase-specific immunogold (*yellow spots*) demonstrating amylase secretion through the structure. **J**, Electron micrograph of a liposome-reconstituted porosome complex isolated from a pancreatic acinar cell. Note the cup-shaped, basket-like morphology of the porosome complex reconstituted in a 500-nm lipid vesicle. Bar = 100 nm. **K**, The lipid bilayer-reconstituted porosome complex is functional. Top panel shows a schematic drawing of the EPC 9 setup for making electrophysiological measurements. Isolated zymogen granules (ZG) added to the *cis* compartment of the bilayer chamber dock and fuse with the reconstituted porosomes at the bilayer and are detected as an increase in capacitance and current activity and as a concomitant time-dependent release of amylase to the *trans* compartment of the bilayer chamber as determined using immunoblot assay. (From Jena BP: Functional organization of the porosome complex and associated structures facilitating cellular secretion. *Physiology* 24:367–376, 2009.)

The past decade has witnessed the elucidation of the composition of the porosome, as well as its structure, its dynamics at nanometer resolution and in real time, and its functional reconstitution into artificial lipid membranes. Experiments have also demonstrated the molecular mechanism of secretory vesicle fusion at the porosome base as well as secretory vesicle swelling enabling expulsion of intravesicular contents. It has become clear that secretory vesicles transiently dock, fuse, partially expel their contents, and dissociate—a process that allows multiple rounds of docking-fusion-expulsion-dissociation to occur. It has been further determined that swelling of secretory vesicles is required for the expulsion of intravesicular contents during cell secretion, and the extent of swelling is directly proportional to the amount of vesicular contents expelled. These findings have led to a paradigm shift in our understanding of cell secretion, resolving the longstanding conundrum regarding the generation of partially empty vesicles as seen in electron micrographs following cell secretion.

Most cell types, however, deliver newly synthesized secretory and membrane proteins to the cell surface in a *continuous* and *unregulated* fashion, which is referred to as the **constitutive pathway**. Specialized cells that have the capacity for regulated delivery also send an important subset of their secretory and membrane protein synthetic products to the cell surface constitutively. The regulated and constitutive secretory pathways are identical except for the final station of the Golgi complex. At this point, the “regulated” proteins divert to the specialized secretory vesicles described in the previous paragraph. The “constitutive” proteins, at the *trans*-most cisterna of the Golgi complex, sort into other secretory vesicles, which move directly to the cell surface. There, the constitutive *membrane proteins* are delivered to the plasma membrane, and the constitutive *secretory proteins* are immediately exocytosed.

This section has provided a broad overview of the secretory pathway. In the following sections, we examine the details of how newly synthesized proteins move between organellar compartments of the secretory pathway, how the proteins are processed during this transit, and how they are sorted to their final destination.

Carrier vesicles control the traffic between the organelles of the secretory pathway

As the preceding discussion suggests, the secretory pathway is not a single, smooth, continuous highway but rather a series of saltatory translocations from one discrete organellar compartment to the next. Each of these steps requires some orchestration to ensure that the newly synthesized proteins arrive at their next terminus.

The cell solves the problem of moving newly synthesized proteins between membranous organelles by using membrane-enclosed carrier vesicles (or vesicular carriers). Each time proteins are to be moved from one compartment to the next, they are gathered together within or beneath specialized regions of membrane that subsequently evaginate or pinch off to produce a carrier vesicle (see [Fig. 2-18](#)). Secretory proteins reside within the lumen of the carrier vesicle, whereas membrane proteins span the vesicle's own encapsulating bilayer. On arrival at the appropriate destination, the carrier vesicle fuses with the membrane of the acceptor organelle, thus delivering its contents of *soluble* proteins to the organelle's lumen and its cargo of *membrane* proteins to the organelle's own membrane. Carrier vesicles mediate the transport of secretory and membrane proteins across the space between the ER's transition zone and the *cis*-Golgi stack and also between the rims of the Golgi stacks themselves. Often assisting the movement between one vesicular compartment and the next are the cytoskeleton and molecular motors. 🍷 **N2-4**

A few critical facts deserve emphasis. First, throughout the formation, transit, and fusion of a carrier vesicle, no mixing occurs between the vesicle lumen and cytosol. The same principle applies to the

carrier vesicle's membrane-protein passengers, which were inserted into the membrane of the rough ER with a particular topology. Those domains of a membrane protein that are exposed to the cytosol in the rough ER remain exposed to the cytosol as the protein completes its journey through the secretory pathway.

Second, the flow of vesicular membranes is not unidirectional. The rate of synthesis of new membrane lipid and protein in the ER is less than the rate at which carrier vesicles bud off of the ER that is bound for the Golgi. Because the sizes of the ER and Golgi are relatively constant, the membrane that moves to the Golgi via carrier vesicles must return to the ER. This return is again accomplished by vesicular carriers. Each discrete step of the secretory pathway must maintain vesicle-mediated backflow of membrane from the acceptor to the donor compartment so that each compartment can retain a constant size.

Finally, we have already noted that each organelle along the secretory pathway is endowed with a specific set of “resident” membrane proteins that determines the properties of the organelle. Despite the rapid forward and backward flow of carrier vesicles between successive stations of the secretory pathway, the resident membrane proteins do not get swept along in the flow. They are either actively retained in their home organelles' membranes or actively retrieved by the returning “retrograde” carrier vesicles. Thus, not only the size but also the composition of each organelle of the secretory pathway remains essentially constant despite the rapid flux of newly synthesized proteins that it constantly handles.

Specialized protein complexes, such as clathrin and coatamers, mediate the formation and fusion of vesicles in the secretory pathway

The formation of a vesicle through evagination appears to be geometrically indistinguishable from its fusion with a target membrane. In both cases, a cross-sectional view in the electron microscope reveals an “omega” profile, which is so named because the vesicle maintains a narrow opening to the organellar lumen that resembles the shape of the Greek letter omega (Ω). However, different problems are confronted during the formation and fusion of membrane vesicles.

Vesicle Formation in the Secretory Pathway

To form a spherical vesicle from a planar membrane, the mechanism that pulls the vesicle off from the larger membrane must grab onto the membrane over the entire surface of the nascent vesicle. The mechanism that achieves this makes use of a scaffold that is composed of coat proteins. The cell has at least two and probably more varieties of coat proteins. The best characterized of these is clathrin, which mediates the formation of secretory vesicles from the *trans* Golgi. Clathrin also mediates the internalization of membrane from the cell surface during the process of endocytosis, which is the reverse of exocytosis. Another major protein coat that is involved in trafficking of vesicles between the ER and Golgi, and between the stacks of the Golgi, is a protein complex known as **coatamer**. Both clathrin and coatamer proteins form the borders of a cage-like lattice.

In the case of **clathrin**, the coat proteins preassemble in the cytoplasm to form three-armed “triskelions” (Fig. 2-19A). A triskelion is not planar but resembles the three adjoining edges of a tetrahedron. As triskelions attach to one another, they produce a three-dimensional structure resembling a geodesic dome with a roughly spherical shape. A triskelion constitutes each vertex in the lattice of hexagons and pentagons that form the cage.

A FORMATION OF CLATHRIN-COATED VESICLES

B VESICLE DOCKING AND FUSION

FIGURE 2-19 Vesicle formation and fusion. **A**, Clathrin mediates the formation of secretory vesicles that bud off from the *trans* Golgi as well as the internalization of membrane from the cell surface during the process of endocytosis. **B**, A complex of proteins forms a bridge between the vesicle and the target membranes. ATP provides the fuel for fusion. The Rab appears to be a molecular switch.

The triskelions of clathrin attach indirectly to the surface of the membrane that is to be excised by binding to the cytosolic tails of membrane proteins. Mediating this binding are adapter proteins, called adaptins, that link the membrane protein tails to the triskelion scaffold. The specificity for particular membrane proteins is apparently conferred by specialized adaptins. Triskelions assemble spontaneously to form a complete cage that attaches to the underlying membrane and pulls it up into a spherical configuration. Completion of the cage occurs simultaneously with the pinching off of the evaginated

membrane from the planar surface, forming a closed sphere.

The pinching off, or fission, process involves the action of a GTP-binding protein called dynamin, which forms a collar around the neck of the forming vesicle and plays a role in severing the neck. The fission process must include an intermediate that resembles the structure depicted in [Figure 2-19A](#). According to the prevalent view, each of the lumen-facing leaflets of membrane lipids fuse, leaving only the cytoplasmic leaflets to form a continuous bridge from the vesicle to the donor membrane. This bridge then breaks, and fission is complete.

Once formed, the clathrin-coated vesicle cannot fuse with its target membrane until it loses its cage, which prevents the two membranes from achieving the close contact required to permit fusion. Because formation of the clathrin cage is spontaneous and energetically favorable, dissolution of the cage requires energy. Uncoating is accomplished by a special class of cytoplasmic enzymes that hydrolyze ATP and use the energy thus liberated to disassemble the scaffold (see [Fig. 2-19A](#)).

The function of **coatamers** is similar to that of clathrin in that coatamers form a cage around a budding membrane. However, coatamer coats differ from clathrin cages in several respects. First, coatamer coats are composed of several **coatamer proteins (COPs)**, one of which is related to the adaptins. Second, unlike the spontaneous assembly of the clathrin triskelions, assembly of the coatamer coat around the budding vesicle requires ATP. Third, a coatamer-coated vesicle retains its coat until it docks with its target membrane.

Vesicle Fusion in the Secretory Pathway

Membrane fusion occurs when the hydrophobic cores of two bilayers come into contact with one another, a process that requires the two membranes to be closely apposed. Because the cytoplasmic leaflets of most cellular membranes are predominantly composed of negatively charged phospholipids, electrostatic repulsion prevents this close apposition from occurring spontaneously. To overcome this charge barrier, and to assist in targeting as well, a multicomponent protein complex forms and acts as a bridge, linking vesicular membrane proteins to membrane proteins in the target bilayer (see [Fig. 2-19B](#)). Investigators have established the components of this complex by use of three approaches: studies of the membrane-fusion steps involved in vesicular transport between successive Golgi stacks, genetic analysis of protein secretion in yeast, and molecular dissection of the protein constituents of the synaptic vesicles of nerve terminals. In each case, the same proteins are instrumental in attaching the donor and target membranes to one another.

The central components of the bridge are proteins known as **SNAREs** (so named because they act as receptors for the SNAPs discussed in the next paragraph). There are SNAREs in both the vesicular membrane (v-SNAREs) and the membrane of the target organelle (t-SNAREs). Typical of the SNARE family members are those that participate in the fusion of neurotransmitter-containing synaptic vesicles with the plasma membrane of the axons in neurons (see [pp. 219–221](#)). In that setting, the v-SNARE is known as synaptobrevin, and proteins known as syntaxin and SNAP-25 (synaptosome-associated protein of 25 kDa) together act as t-SNAREs. The t-SNAREs and v-SNAREs bind to each other extremely tightly, pulling the vesicular and target membranes close together. This proximity alone may be sufficient to initiate fusion, although this point remains controversial. In cells that employ rapid and tightly regulated membrane fusion, such as neurons, a protein called synaptotagmin, which associates with the SNARE fusion complex, senses an increase in the cytoplasmic concentration of Ca^{2+} and triggers fusion (see [pp. 219–221](#)). Although the nature of the fusion event itself remains unclear, clues have emerged about its regulation. Fusion requires the participation of a class of small GTP-binding proteins called **Rabs** that are important for signaling. Rabs appear to act as molecular switches that assemble with the SNARE fusion

complex when they are binding GTP but dissociate from the complex after they hydrolyze the GTP to GDP. Rab-GTP appears to play a critical role in regulating the activity of the fusion complex. Numerous Rab isoforms exist, each isoform associated with a different vesicular compartment and a distinct membrane-to-membrane translocation step.

Once fusion occurs, the former vesicle generally loses its spherical shape rapidly as it becomes incorporated into the target membrane. This “flattening out” is the result of surface tension, inasmuch as the narrow radius of curvature demanded by a small spherical vesicle is energetically unfavorable. After fusion, it is also necessary to disassemble the v-SNARE/t-SNARE complex so that its components can be reused in subsequent fusion events. The dissociation step involves the activity of two additional components that participate in the SNARE complex. The first is an ATP-hydrolyzing enzyme; because it is inhibited by the alkylating agent *N*-ethylmaleimide (NEM), it was named NEM-sensitive factor (NSF). Soluble NSF attachment proteins (the SNAPs mentioned above), which target NSF to the SNARE complex, are the second. Hydrolysis of ATP by NSF causes dissociation of the SNARE complex, thus regenerating the fusion machinery. Homologs of the neuronal t-SNARE and v-SNARE proteins are found in almost every cell type in the body and are thought to participate in most if not all membrane fusion events.

Newly synthesized secretory and membrane proteins are processed during their passage through the secretory pathway

While in the rough ER, newly synthesized secretory and membrane proteins undergo the first in a series of post-translational modifications (see pp. 32–34), including glycosylation, disulfide bond formation, and the acquisition of tertiary structure. On delivery to the *cis* stack of the Golgi complex, these proteins begin a new phase in their postsynthetic maturation. For many proteins, the most visible byproduct of this second phase is the complete remodeling of their N-linked sugar chains, originally attached in the rough ER.

Of the 14 sugar residues transferred en bloc to newly synthesized proteins during N-linked glycosylation (see p. 32), nine are mannose and three are glucose (Fig. 2-20A). Enzymes called glucosidases and one called a mannosidase associate with the luminal face of the ER and remove the three glucose residues and one mannose. This trimming process is a critical step in the quality-control process through which the cell determines whether a protein is properly folded and ready to proceed to subsequent stations of the secretory pathway. An enzyme called **uridine diphosphate (UDP)–glucose glycoprotein glucosyltransferase (UGGT)** inspects proteins in the lumen of the ER. If they are not appropriately folded, UGGT adds a single glucose residue to the trimmed sugar tree. Proteins bearing this single glucose residue bind **calnexin** or **calreticulin**, ER chaperone proteins that retain misfolded proteins until they fold correctly or become targeted for degradation.

A REMODELING OF N-LINKED SUGARS

FIGURE 2-20 Modification and assembly of the sugar chains on proteins in the Golgi. **A**, Remodeling of N-linked sugars. **B**, Proteoglycans. A trisaccharide links glycosaminoglycan chains to the protein via the –OH group of a serine residue. The glycosaminoglycan is made up of n repeating disaccharide units, one of which is always an *amino* sugar.

As proteins arrive from the ER, mannosidases in the *cis* Golgi attack the N-linked sugar trees, shearing off all except two *N*-acetylglucosamine and five mannose residues. As the proteins pass from the *cis*-Golgi cisterna to the medial cisterna and ultimately to the *trans*-Golgi cisterna, another mannosidase removes two additional mannose residues, and other enzymes add sugars to the stump of the original sugar tree in a process referred to as **complex glycosylation**.

The addition of new sugars occurs one residue at a time and is accomplished by enzymes called **sugar transferases** that face the lumens of the Golgi stacks. Each sugar is transported from the cytoplasm to the Golgi lumen by a carrier protein that spans the Golgi membrane. Throughout the maturation process, the N-linked sugar chains are always exposed only to the luminal face of the Golgi. **N2-11**

The attachment of a sugar molecule to the growing N-linked sugar chain occurs in a series of four steps:

Step 1: In the cytosol, the sugar is covalently coupled to a nucleoside diphosphate (either UDP or GDP, depending on the sugar to be transported). The result of this reaction is a **sugar nucleoside diphosphate** (e.g., UDP-galactose). (An exception to this rule is sialic acid, in which the sugar is coupled to cytidine monophosphate [CMP], a nucleoside *monophosphate*, rather than a *diphosphate*.)

Step 2: A carrier protein in the membrane of the Golgi moves the sugar nucleoside diphosphate from the cytoplasm to the lumen of the Golgi.

Step 3: The sugar transferases use the **sugar nucleoside diphosphate** (e.g., UDP-galactose) as a substrate by catalyzing a reaction that couples the sugar residue (e.g., galactose) to the growing N-linked chain. As a byproduct, this reaction generates a nucleoside diphosphate (e.g., UDP), which is then converted to a nucleoside monophosphate (uridine monophosphate [UMP]) plus inorganic phosphate.

Step 4: The same carrier protein that imports the sugar nucleoside diphosphate (e.g., UDP-galactose) exports the nucleoside monophosphate (e.g., UMP) that is the byproduct of the above transferase reaction. Because the carrier protein simultaneously imports the sugar nucleoside diphosphate and exports the nucleoside monophosphate, this carrier protein is an example of an **exchanger** (see pp. 123–125).

Each cisterna of the Golgi is characterized by a different set of sugar transferases and sugar transporters. Thus, each Golgi compartment catalyzes a distinct step in the maturation of the N-linked chains. Complex glycosylation, therefore, proceeds like an assembly line from one modification station to the next. Because proteins have different shapes and sizes, however, the degree to which a sugar chain of any given polypeptide has access to each transferase can vary quite extensively. Thus, each protein emerges from the assembly line with its own particular pattern of complex glycosylation. The Golgi's *trans*-most cisterna houses the enzymes responsible for adding the terminal sugars, which cap the N-linked chain. The final residue of these terminal sugars is frequently *N*-acetylneuraminic acid, also known as sialic acid. At neutral pH, sialic acid is negatively charged. This acidic sugar residue therefore is responsible for the net negative electrostatic charge that is frequently carried by **glycoproteins**.

The Golgi's function is not limited to creating N-linked sugar tree topiaries. It oversees a number of other post-translational modifications, including the assembly of O-linked sugars. Many proteins possess **O-linked sugar chains**, which attach not to asparagine residues but to the hydroxyl groups (hence, O) of serine and threonine residues. The O-linked sugars are not preassembled for en-bloc transfer the way that the original 14-sugar tree is added in the rough ER in the case of their N-linked counterparts. Instead, the O-linked sugars are added one residue at a time by sugar transferases such as those that participate in the remodeling of complex N-linked glycosylation. O-linked chains frequently carry a great deal of negatively charged sialic acid.

Proteoglycans contain a very large number of a special class of O-linked sugar chains that are extremely long (see [Fig. 2-20B](#)). Unlike other O-linked sugars that attach to the protein core via an *N*-acetylglucosamine, the sugar chain in a proteoglycan attaches via a xylose-containing three-sugar “linker” to a serine residue on the protein backbone. One or more **glycosaminoglycan** side chains are added to this linker, one sugar at a time, to form the mature proteoglycan.

As the sugar chains grow, enzymes can add sulfate groups and greatly increase the quantity of negative charge that they carry. **Sulfated proteoglycans** that are secreted proteins become important components of the extracellular matrix and are also constituents of mucus. Proteoglycan chains can also be attached to membrane proteins that eventually reach the plasma membrane. The negatively charged sugars that are associated with the glycosaminoglycan groups, which are present both in mucus and on cell surface glycoproteins, can help form a barrier that protects cells from harsh environmental conditions such as those inside the stomach (see [p. 874](#)). In the upper portion of the respiratory tract, the mucus assists in the removal of foreign bodies (see [p. 597](#)).

Newly synthesized proteins are sorted in the *trans*-Golgi network

From their common point of origin at the rough ER, newly synthesized secretory and membrane proteins must be distributed to a wide variety of different subcellular destinations. How can a cell recognize an individual protein from among the multitudes that are inserted into or across the membranes of the rough ER and ensure its delivery to the site of its ultimate functional residence? Such a sorting operation has two prerequisites: (1) each protein to be sorted must carry some manner of address or “sorting signal” that communicates its destination, and (2) the cell must possess machinery capable of reading this sorting signal and acting on the information it embodies.

For many proteins, sorting occurs in the ***trans*-Golgi network (TGN)**. The *trans*-most cisterna of the Golgi complex is morphologically and biochemically distinct from the other Golgi stacks. Viewed in cross section, it appears as a complex web of membranous tubules and vesicles ([Fig. 2-21](#)). This structure befits the TGN's apparent function as a staging area from which carrier vesicles depart to transport their specific protein cargoes to one of many distinct subcellular locales.

FIGURE 2-21 Sorting of lysosomal enzymes.

Sorting machinery within or at the TGN appears to segregate classes of proteins—each bound for a common destination—into small discrete clusters. Each cluster is subsequently incorporated into a separate carrier vesicle, which evaginates from the TGN membrane and mediates the final stage of delivery. In the case of *secretory proteins*, this clustering happens within the lumen of the TGN. In fact, such clusters of secretory proteins can be directly visualized in the electron microscope. *Membrane proteins* gather into two-dimensional clusters in the plane of the TGN membrane. Carrier vesicles incorporate these clusters into their own bilayers. Proteins bound for different destinations co-cluster in different subdomains of the TGN. Secretory and membrane proteins that are earmarked for the same destination can cluster in the same subdomain of the TGN and can be incorporated into the same carrier vesicle. Therefore, the TGN appears to function as a cellular transportation terminal that is able to direct groups of passengers who are carrying the same tickets to a common waiting area and ultimately to load them onto a common shuttle. Ticket agents herd passengers bearing different tickets into different waiting lounges.

A mannose-6-phosphate recognition marker is required to target newly synthesized hydrolytic enzymes to lysosomes

One of the most thoroughly established sorting paradigms is the pathway for newly synthesized lysosomal enzymes. Like secretory proteins, lysosomal enzymes carry amino-terminal signal sequences that direct their cotranslational translocation across the membrane of the rough ER. Their N-linked glycosylation and folding proceed in the usual fashion, after which they join all of the other simultaneously synthesized proteins in the Golgi complex (see Fig. 2-21, stage 1).

A special sugar transferase in the *cis*-Golgi cisterna recognizes newly synthesized lysosomal enzymes and adds a unique sugar. This enzyme adds *N*-acetylglucosamine phosphate to the mannose residues at the termini of the lysosomal enzymes' N-linked sugar trees. This enzyme differs from the usual sugar transferases (see [p. 38](#)) in that it adds a *phosphosugar* group to the mannose residue, rather than just a sugar. This enzyme is also unique in recognizing specific amino-acid sequences that are exclusively in these lysosomal enzymes. A second *cis*-Golgi enzyme removes the additional *N*-acetylglucosamine sugar, leaving its phosphate group behind. As a result, the sugar trees of the lysosomal enzymes terminate in mannose-6-phosphate residues (see [Fig. 2-21](#), stage 2).

A special class of mannose-6-phosphate receptors, localized predominantly in the elements of the *trans* Golgi, recognize proteins that carry mannose-6-phosphate groups (see [Fig. 2-21](#), stage 3). This recognition step constitutes the first stage of the cosegregation and clustering process discussed above. The mannose-6-phosphate receptors are transmembrane proteins. Their luminal portions bind to the newly synthesized lysosomal enzymes, whereas their cytoplasmically facing tails possess a particular signal that allows them to interact with adaptins and hence to be incorporated into clathrin-coated vesicles. The assembly of the clathrin lattice causes the mannose-6-phosphate receptors to cluster, along with their associated lysosomal enzymes, in the plane of the TGN membrane. Completion of the clathrin cage results in the formation of a vesicle whose membrane contains the mannose-6-phosphate receptors that bind their cargo of lysosomal enzymes.

After departing the TGN, these transport vesicles lose their clathrin coats (see [Fig. 2-21](#), stage 4) and fuse with structures referred to as late endosomes or **prelysosomal endosomes**. Proton pumps in the membranes of these organelles ensure that their luminal pH is acidic (see [Fig. 2-21](#), stage 5). When exposed to this acidic environment, the mannose-6-phosphate receptors undergo a conformational change that releases the mannose-6-phosphate-bearing lysosomal enzymes (see [Fig. 2-21](#), stage 6). Consequently, the newly synthesized enzymes are dumped into the lumen of the prelysosomal endosome, which will go on to fuse with or mature into a lysosome. The empty mannose-6-phosphate receptors join vesicles that bud off from the lysosome (see [Fig. 2-21](#), stage 7) and return to the TGN (see [Fig. 2-21](#), stage 8). The luminal environment of the TGN allows the receptors to recover their affinity for mannose-6-phosphate, which permits them to participate in subsequent rounds of sorting.

Disruption of lysosomal sorting can be produced in several ways. For example, a drug called **tunicamycin** blocks the addition of N-linked sugars to newly synthesized proteins and thereby prevents attachment of the mannose-6-phosphate recognition marker. Compounds that elevate the luminal pH of the prelysosomal endosomes prevent newly synthesized enzymes from dissociating from the mannose-6-phosphate receptors and consequently block recycling of the receptor pool back to the TGN. The resulting shortage of unoccupied receptors allows mannose-6-phosphate-bearing proteins to pass through the TGN unrecognized ([Box 2-2](#)). Thus, instead of diverting to the lysosomes, these lysosomal enzymes continue along the secretory pathway and are ultimately released from the cell by constitutive secretion.

Box 2-2

Lysosomal Storage Diseases

In lysosomal storage diseases, the absence of a particular hydrolase—or group of hydrolases—from the lysosome prevents the lysosome from degrading certain substances, resulting in the formation of overstuffed lysosomes that crowd the cytoplasm and impede cell function. Indeed, a naturally occurring human disease—caused by a genetic defect in the sorting machinery—allowed the elucidation of lysosomal enzyme sorting.

In **I-cell disease**, most hydrolases are missing from the lysosomes of many cell types. As a result, lysosomes become engorged with massive quantities of undigested substrates. The enormously swollen lysosomes that characterize this disease were named inclusion bodies, and the cells that possess them were designated inclusion cells, or I cells for short. Whereas I cells lack most lysosomal enzymes, the genes that encode all of the hydrolases are completely normal. The mutation responsible for I-cell disease resides in the gene for the **phosphosugar transferase** that creates the mannose-6-phosphate recognition marker (see Fig. 2-21). Without this enzyme, the cell cannot sort any of the hydrolases to the lysosomes. Instead, the hydrolases pass through the TGN unnoticed by the mannose-6-phosphate receptors and are secreted constitutively from the affected cells.

In some other lysosomal storage diseases, *specific* hydrolases are not missorted but rather are genetically defective. For example, children who suffer from **Tay-Sachs disease** carry a homozygous mutation in the gene that encodes the lysosomal enzyme **hexosaminidase A (HEX A)**. Consequently, their lysosomes are unable to degrade substances that contain certain specific sugar linkages. Because they cannot be broken down, these substances accumulate in lysosomes. Over time, these substances fill the lysosomes, which swell and crowd the cytoplasm. The resulting derangements of cellular function are toxic to a number of cell types and ultimately underlie this disease's uniform fatality within the first few years of life. Carriers of the Tay-Sachs trait can be detected either by HEX A enzyme testing or by DNA analysis of the HEX A gene. Among the Ashkenazi Jewish population, in whom 1 in 27 individuals is a carrier, three distinct HEX A mutations account for 98% of all carrier mutations.

Cells internalize extracellular material and plasma membrane through the process of endocytosis

The same fundamental mechanisms in the secretory pathway that produce vesicles by evaginating regions of Golgi membrane can also move material in the opposite direction by inducing vesicle formation through the invagination of regions of the plasma membrane. Vesicles created in this fashion are delimited by membrane that had formerly been part of the cell surface, and their luminal contents derive from the extracellular compartment.

This internalization process, referred to as **endocytosis**, serves the cell in at least four ways. First, certain nutrients are too large to be imported from the ECF into the cytoplasm via transmembrane carrier proteins; they are instead carried into the cell by endocytosis. Second, endocytosis of hormone-receptor complexes can terminate the signaling processes that are initiated by numerous hormones. Third, endocytosis is the first step in remodeling or degrading portions of the plasma membrane. Membrane that is delivered to the surface during exocytosis must be retrieved and ultimately returned to the TGN. Fourth, proteins or pathogens that need to be cleared from the extracellular compartment are brought into the cell by endocytosis and subsequently condemned to degradation in the lysosomes. Because endocytosed material can pursue a number of different destinies, there must be sorting mechanisms in the endocytic pathway, just as in the secretory pathway, that allow the cell to direct the endocytosed material to its appropriate destination.

Fluid-phase endocytosis is the uptake of the materials that are dissolved in the ECF (Fig. 2-22, stage 1) and not specifically bound to receptors on the cell surface. This process begins when a clathrin cage starts to assemble on the cytoplasmic surface of the plasma membrane. Above we discussed the physiology of clathrin-coated vesicles in the *secretory* pathway (see Fig. 2-19). The clathrin attaches to the membrane through interactions with adaptin proteins, which in turn adhere to the cytoplasmic tail domains of certain transmembrane polypeptides. Construction of the cage causes its adherent underlying

membrane to invaginate and to form a coated pit (see Fig. 2-22, stage 2A). Completion of the cage creates a closed vesicle, which detaches from the cell surface through the process of membrane fission (see Fig. 2-22, stage 3). The resultant vesicle quickly loses its clathrin coat through the action of the uncoating ATPase and fuses with an organelle called an **endosome**.

FIGURE 2-22 Endocytosis.

Receptor-mediated endocytosis is responsible for internalizing specific proteins

Most of the proteins that a cell seeks to import via endocytosis are present in the ECF in extremely low concentrations. Furthermore, the volume of ECF that is internalized by an individual coated vesicle is very small. Consequently, the probability that any particular target molecule will enter the cell during a given round of fluid-phase endocytosis is low. To improve the efficiency of endocytosis and to ensure that the desired extracellular components are gathered in every endocytic cycle, the cell has devised a method for concentrating specific proteins at the site of endocytosis before initiating their uptake.

This concentration is achieved in a process known as **receptor-mediated endocytosis**, in which molecules to be internalized (see Fig. 2-22, stage 1) bind to cell-surface receptors with high affinity (see Fig. 2-22, stage 2B). Through this interaction, the substrates for endocytosis become physically associated with the plasma membrane, which greatly enhances the probability that they will be successfully internalized. Cells increase this probability even further by ensuring that the receptors themselves cluster in regions of the membrane destined to be endocytosed. The cytoplasmic tails of these receptors are endowed with recognition sequences that allow them to serve as binding sites for adaptins. Consequently, these receptors congregate in regions of the cell membrane where clathrin cages are

assembling and are incorporated into coated pits as they are forming. The affinity of these receptors for the endocytic machinery ensures that their ligands are internalized with maximum efficiency.

Many endocytic receptors are constitutively associated with coated pits and are endocytosed whether or not they have bound their specific ligands. The cytoplasmic tails of certain receptors, however, interact with adaptins only when the receptor is in the bound state. For example, in the absence of epidermal growth factor (EGF), the EGF receptor is excluded from regions of the membrane in which coated pits are assembling. Modifications induced by ligand binding alter these receptors' tails, which allows them to participate in coated vesicle formation and hence in endocytosis.

After the clathrin-coated vesicle forms (see [Fig. 2-22](#), stage 3), it quickly loses its clathrin coat, as described above for fluid-phase endocytosis, and fuses with an endosome. Although endosomes can be wildly pleomorphic, they frequently have an appearance like a frying pan, in which a round vesicular body is attached to a long tubular “handle” (see [Fig. 2-22](#), stage 4). The cytoplasmic surfaces of the handles are often decorated with forming clathrin lattices and are the sites of vesicular budding.

Endocytosed proteins can be targeted to lysosomes or recycled to the cell surface

In many cell types, endocytosis is so rapid that, each hour, the cell internalizes a quantity of membrane that is equivalent in area to the entire cell surface. To persist in the face of this tremendous flux of membrane, the cell must retrieve most of the endocytosed membrane components and return them to the plasma membrane. However, substances that a cell wishes to degrade must be routed to lysosomes and prevented from escaping back to the surface. The sophisticated sorting operation required to satisfy both of these conditions takes place in the endosome.

Proton pumps embedded in its membrane ensure that, like the lysosome, the endosome maintains an acidic luminal pH (see [Fig. 2-22](#), stage 4). This acidic environment initiates the separation of material that is destined for lysosomal destruction from those proteins that are to be recycled. Most endocytic receptors bind their ligands tightly at neutral pH but release them rapidly at pH values <6.0. Therefore, as soon as a surface-derived vesicle fuses with an endosome, proteins that are bound to receptors fall off and enter the endosomal lumen. The receptor proteins segregate in the membranes of the handles of the frying pan-shaped endosomes and are ultimately removed from the endosome in vesicles that shuttle them back to the cell surface (see [Fig. 2-22](#), stage 5). The soluble proteins of the endosome lumen, which include the receptors' former ligands, are ultimately delivered to the lysosome. This sorting scheme allows the receptors to avoid the fate of their cargo and ensures that the receptors are used in many rounds of endocytosis.

The **low-density lipoprotein (LDL) receptor**  **N2-12** follows this regimen precisely. On arrival of the LDL-laden receptor at the endosome, the acidic environment of the endosome induces the LDL to dissociate from its receptor, which then promptly recycles to the cell surface. The LDL travels on to the lysosome, where enzymes destroy the LDL and liberate its bound cholesterol.

N2-12

Familial Hypercholesterolemia

A Defect in Receptor-Mediated Endocytosis

The critical physiologic role played by endocytic receptors is underscored by the molecular pathogenesis of a relatively common human genetic disease. Cholesterol is carried through the bloodstream bound to binding proteins, one of which is known as **low-density lipoprotein**, or LDL. Many cells throughout the body express receptors for LDL at their plasma membranes. These cells internalize receptor-bound LDL and utilize its cargo of cholesterol for membrane synthesis and in various biochemical pathways. The imported cholesterol also serves to inhibit the cells' endogenous *de novo* synthesis of cholesterol. The disease known as **familial hypercholesterolemia (FHC)** is caused by a defect in the gene encoding the LDL receptor, resulting in the synthesis of receptors that either do not bind LDL or fail to be internalized.

In the absence of functional LDL receptors, cells are unable to import exogenous cholesterol. Even though serum cholesterol levels rise to extraordinarily high levels, cells are oblivious to its presence, inasmuch as they lack the machinery that allows them to endocytose LDL. Consequently, their cholesterol synthesis continues uninhibited. The excess cholesterol synthesis results in the buildup of cholesterol-filled lipid droplets in cells throughout the body. Accumulation of these cholesterol inclusions in the cells lining arterial walls produces atherosclerotic plaques, which can go on to occupy and occlude the lumens of the blood vessels themselves. When these plaques appear in the coronary arteries, which supply the heart (see p. 560), they impede coronary blood flow and thus prevent the heart from receiving sufficient oxygen. Not surprisingly, patients with FHC often succumb to heart disease at relatively early ages. Patients who are homozygous for defective LDL receptors usually experience their first myocardial infarction (“heart attack”) in their early teens, whereas heterozygotes (whose cells express half the normal complement of functional LDL receptor) generally experience cardiac symptoms in midlife. The heterozygous form of FHC affects ~1 in 500 people. Our current understanding of receptor-mediated endocytosis, and of the molecular interactions on which it depends, owes a tremendous amount to insights gained through the study of FHC by Brown and Goldstein, whose work earned them the 1985 Nobel Prize in Medicine or Physiology. For more information about Brown and Goldstein and the work that led to their Nobel Prize, visit <http://www.nobel.se/medicine/laureates/1985/index.html> (accessed October 2014).

A variation on this paradigm is responsible for the cellular uptake of iron. Iron circulates in the plasma bound to a protein called **transferrin**. At the mildly alkaline pH of ECF, the iron-transferrin complex binds with high affinity to a **transferrin receptor** in the plasma membranes of almost every cell type. Bound transferrin is internalized by endocytosis and delivered to endosomes. Instead of inducing *transferrin* to fall off its receptor, the acid environment of the endosome lumen causes *iron* to fall off transferrin. **Apotransferrin** (i.e., transferrin without bound iron) remains tightly bound to the transferrin receptor at an acidic pH. The released iron is transported across the endosomal membrane for use in the cytosol. The complex of apotransferrin and the transferrin receptor recycles to the cell surface, where it is again exposed to the ECF. The mildly alkaline extracellular pH causes the transferrin receptor to lose its affinity for apotransferrin and to promptly release it. Thus, the cell uses the pH-dependent sorting trick twice to ensure that both the transferrin receptor and apotransferrin recycle for subsequent rounds of iron uptake.

Certain molecules are internalized through an alternative process that involves caveolae

Clathrin-coated pits are not the only cellular structures involved in receptor-mediated internalization. Electron microscopic examination of vascular endothelial cells that line blood vessels long ago revealed the presence of clusters of small vesicles that display a characteristic appearance, in close association with the plasma membrane. These **caveolae** were thought to be involved in the transfer of large molecules across the endothelial cells, from the blood space to the tissue compartment. In fact, caveolae are present in most cell types. The caveolae are rich in cholesterol and sphingomyelin. Rather than having a clathrin lattice, they contain intrinsic membrane proteins called **caveolins**, which face the cytosol (see [Fig. 2-22](#)). In addition, caveolae appear to be rich in membrane-associated polypeptides that participate in intracellular signaling, such as the Ras-like proteins (see [p. 56](#)) as well as heterotrimeric GTP-binding proteins (see [p. 52](#)). Caveolae appear to serve as organizing centers for collections of signaling molecules, perhaps allowing them to coordinate their activities. Caveolae also participate in the endocytosis of certain substances. In vascular endothelial cells, for example, caveolae take up albumin and carry it across the cell to the opposite side in a process known as transcytosis (see [p. 467](#)). Caveolae-mediated uptake does not involve clathrin or the acidified endocytic structures of the standard endocytotic pathway.

Also enriched in caveolae is the receptor for folate, a vitamin required by several metabolic pathways (see [pp. 933–935](#)). Unlike the receptors in the plasma membrane (see [pp. 17–18](#)), the **folate receptor** has no cytoplasmic tail that might allow it to associate with coated pits. Instead, it belongs to the GPI-linked class of proteins (see [p. 17](#)) that are anchored to the membrane through covalent attachment to phospholipid molecules. It appears that caveolae mediate the internalization of folate. In fact, a large number and variety of GPI-linked proteins are embedded in the outer leaflet of the caveolar membrane that faces its lumen.

Specialized Cell Types

All cells are constructed of the same basic elements and share the same basic metabolic and biosynthetic machinery. What distinguishes one cell type from another? Certainly, cells have different shapes and molecular structures. In addition, out of an extensive repertory of molecules that cells are capable of making, each cell type chooses which molecules to express, how to organize these molecules, and how to regulate them. It is this combination of choices that endows them with specific physiological functions. These specializations are the product of cell differentiation. Each of these cell types arises from a **stem cell**. Stem cells are mitotically active and can give rise to a spectrum of cellular lineages that can range from multiple to limited. Thus, they may be *pluripotent*, *multipotent*, *oligopotent*, or *unipotent*. Clearly, the zygote is the ultimate stem cell because through its divisions, it gives rise to every cell lineage present in the complete organism and is thus *totipotent*. Specific cell types arise from stem cells by activating a differentiation-specific program of gene expression. The interplay of environmental signals, temporal cues, and transcription factors that control the processes of cellular differentiation constitutes one of the great unraveling mysteries of modern biology.

Epithelial cells form a barrier between the internal and external milieu

How can an organism tightly regulate its internal fluid environment (i.e., internal milieu) without allowing this environment to come into direct and disastrous contact with the external world (i.e., external milieu)? The body has solved these problems by arranging a sheet of cells—an **epithelium**—between these two disparate environments. Because of their unique subcellular designs and intercellular relationships, epithelial cells form a dynamic barrier that can import or expel substances, sometimes against steep concentration gradients.

Two structural features of epithelia permit them to function as useful barriers ([Fig. 2-23](#)). First, epithelial cells connect to one another via tight junctions, which constrain the free diffusion of solutes and fluids around the epithelial cells, between the internal and external compartments. Second, the tight junctions define a boundary between an apical and a basolateral domain of the plasma membrane. Each of these two domains is endowed with distinct protein and lipid components, and each subserves a distinct function. Thus, the surface membranes of epithelial cells are polarized. Beginning on [page 136](#), we discuss the mechanisms by which polarized epithelial cells exploit their unique geometry to transport salts and water from one compartment to the other. However, it is worth touching on a few of the cellular specializations that characterize polarized epithelia and permit them to perform their critical roles.

FIGURE 2-23 Epithelial cells. In an epithelial cell, the tight junction separates the cell membrane into apical and basolateral domains that have very different functional properties.

The **apical membranes** of the epithelial cells (see Fig. 2-23) face the lumen of a compartment that is often topologically continuous with the outside world. For example, in the stomach and intestine, apical membranes form the inner surface of the organs that come into contact with ingested matter. The apical membranes of many epithelial cells, including those lining kidney tubules, are endowed with a single nonmotile cilium. Known as the **central cilium**, this structure may sense the mechanical deformation associated with fluid flow. Mutations that disrupt individual components of the central cilium are associated with cystic disease of the kidney, in which the normal architecture of the kidney is replaced by a collection of large fluid-filled cysts.

The **basolateral membranes** of epithelial cells face the ECF compartment—which indirectly makes contact with the blood—and rest on a basement membrane. The **basement membrane** is composed of extracellular matrix proteins that the epithelial cells themselves secrete and include collagens, laminin, and proteoglycans. The basement membrane provides the epithelium with structural support and, most importantly, serves as an organizing foundation that helps the epithelial cells to establish their remarkable architecture.

Each epithelial cell is interconnected to its neighbors by a variety of **junctional complexes** (see Fig. 2-23). The lateral surfaces of epithelial cells participate in numerous types of cell-cell contacts, including tight junctions, adhering junctions, gap junctions, and desmosomes.

Tight Junctions

A **tight junction** (or *zonula occludens*) is a complex structure that impedes the passage of molecules and ions *between* the cells of the epithelial monolayer. This pathway between the cells is termed the **paracellular pathway**. The functional properties of tight junctions are related to their intriguing architecture (see [Fig. 2-23](#)). Viewed by transmission electron microscopy, tight junctions include regions of apparent fusion between the outer leaflets of the lipid bilayer membranes of neighboring epithelial cells. Freeze-fracture electron microscopy reveals that the tight junction comprises parallel strands of closely packed particles that represent the transmembrane proteins participating in the junction's formation. The degree of an epithelium's impermeability—or “tightness”—is roughly proportional to the number of these parallel strands. The **claudins**, a large family of proteins, are the principal structural elements of the tight junction. Interactions between the claudins present in the apposing membranes of neighboring cells form the permeability barrier (see [p. 137](#)).

Tight junctions play several roles. First, they are **barriers** in that they separate one compartment from another. In some epithelial cells, such as those of the renal thick ascending limb, the tight junctions form a boundary that blocks the flow of most ions and water between cells. In contrast, the tight junctions of the renal proximal tubule are leaky, permitting significant transepithelial movement of fluid and solutes.

Second, tight junctions can act as selective **gates** in that they permit certain solutes to flow more easily than others. Examples are the leaky tight junctions of tissues such as the proximal tubule. The permeability and selectivity of an epithelium's tight junctions are critical variables for determining that epithelium's transport characteristics (see [pp. 136–137](#)). Moreover, the permeability properties of the gate function of tight junctions can be modulated in response to various physiological stimuli. The inventory of claudins expressed by an epithelium in large measure determines the permeability properties of its tight junctions.

Third, tight junctions act as **fences** that separate the polarized surfaces of the epithelial plasma membrane into apical and basolateral domains. The presence of distinct populations of proteins and lipids in each plasma-membrane domain is absolutely essential for an epithelium to mediate transepithelial fluid and solute transport (see [pp. 137–139](#)).

Adhering Junctions

An adhering junction (or *zonula adherens*) is a belt that encircles an entire epithelial cell just below the level of the tight junction. Epithelial cells need two pieces of information to build themselves into a coherent epithelium. First, the cells must know which end is up. The extracellular matrix (see above) provides this information by defining which side will be basolateral. Second, the cells must know that there are like neighbors with which to establish cell-cell contacts. Adhering junctions provide epithelial cells with clues about the nature and proximity of their neighbors. These cell-cell contacts are mediated by the extracellular domains of members of the **cadherin** family, transmembrane proteins discussed above. Epithelial cells will organize themselves into a properly polarized epithelium—with differentiated apical and basolateral plasma membranes—only if the cadherins of neighboring cells have come into close enough apposition to form an adhering junction. Formation of these junctions initiates the assembly of a subcortical cytoskeleton, in which **anchor proteins** (e.g., vinculin, catenins, α actinin) link the cytosolic domains of cadherins to a network of **actin filaments** that is associated with the cytosolic surfaces of the lateral membranes. Conversely, the disruption of adhering junctions can lead to a loss of epithelial organization. In epithelial tumors, for example, loss of expression of the adhering-junction cadherins tends to correlate with the tumor cell's loss of controlled growth and with its ability to **metastasize**—that is, to leave the epithelial monolayer and form a new tumor at a distant site in the body. 🟡 [N2-13](#)

Role of Cell-Cell Adhesion Molecules in Development

Contributed by Michael Caplan

Formation of the first polarized epithelial cells in the developing mammalian embryo occurs when the adhesion proteins are synthesized and adhering junctions form. If these cell-cell interactions become disrupted during early embryogenesis, the embryonic cells separate from one another, preventing further development.

Gap Junctions

The channels that interconnect the cytosols of neighboring cells are called gap junctions (see pp. 158–159). They allow small molecules (less than ~1 kDa) to diffuse freely between cells. In some organs, epithelial cells are interconnected by an enormous number of gap junctions, which organize into paracrystalline hexagonal arrays. Because ions can flow through gap junctions, cells that communicate through gap junctions are electrically coupled. The permeability of gap junctions, and hence the extent to which the cytoplasmic compartments of neighboring cells are coupled, can be regulated in response to a variety of physiological stimuli.

Desmosomes

A desmosome (or *macula adherens*) holds adjacent cells together tightly at a single, round spot. Desmosomes are easily recognized in thin-section electron micrographs by the characteristic dense plaques of intermediate filaments (see p. 23). The extracellular domains of desmoglein or desmocollin, which are transmembrane proteins in the **cadherin** family (see p. 17) mediate the interaction of adjacent cells. **Anchor proteins** link the cytosolic domains of the cadherins to **intermediate filaments** that radiate into the cytoplasm from the point of intercellular contact (see Fig. 2-23). These filaments interact with and organize the cytoplasmic intermediate filaments, thus coupling the structurally stabilizing elements of neighboring cells to one another. Epithelial cells are often coupled to adjacent cells by numerous desmosomes, especially in regions where the epithelium is subject to physical stress.

Epithelial cells are polarized

In many epithelia, the apical surface area is amplified by the presence of a **brush border** that is composed of hundreds of finger-like microvillar projections (see Fig. 2-23). In the case of the small intestine and the renal proximal tubule, the membrane covering each microvillus is richly endowed with enzymes that digest sugars and proteins as well as with transporters that carry the products of these digestions into the cells. The presence of a microvillar brush border can amplify the apical surface area of a polarized epithelial cell by as much as 20-fold, thus greatly enhancing its capacity to interact with, to modify, and to transport substances present in the luminal fluid.

The basolateral surface area of certain epithelial cells is amplified by the presence of **lateral interdigitations** and **basal infoldings** (see Fig. 2-23). Although they are not as elegantly constructed as microvilli, these structures can greatly increase the basolateral surface area. In epithelial cells that are involved in large volumes of transport—or in transport against steep gradients—amplifying the basolateral membrane can greatly increase the number of Na-K pumps that a single cell can place at its

basolateral membrane.

Although the morphological differences between apical and basolateral membranes can be dramatic, the most important distinction between these surfaces is their protein composition. As noted above, the “fence” function of the tight junction separates completely different rosters of membrane proteins between the apical and basolateral membranes. For example, the Na-K pump is restricted to the basolateral membrane in almost all epithelial cells, and the membrane-bound enzymes that hydrolyze complex sugars and peptides are restricted to apical membranes in intestinal epithelial cells. The polarized distribution of transport proteins is absolutely necessary for the directed movement of solutes and water across epithelia. Furthermore, the restriction of certain enzymes to the apical domain limits their actions to the lumen of the epithelium and therefore offers the advantage of not wasting energy putting enzymes where they are not needed. The polarity of epithelial membrane proteins also plays a critical role in detecting antigens present in the external milieu and in transmitting signals between the external and internal compartments.

The maintenance of epithelial polarity involves complex intermolecular interactions. When tight junctions are disrupted, diffusion in the plane of the membrane leads to intermingling of apical and basolateral membrane components and thus a loss of polarity. The subcortical cytoskeleton beneath the basolateral surface may play a similar role in maintaining polarity by physically restraining a subset of membrane proteins at the basolateral surface.

However, such mechanisms for stabilizing the polarized distributions of membrane proteins do not explain how newly synthesized proteins come to be distributed at the appropriate plasma membrane. We give two examples of mechanisms that cells can use to direct membrane proteins to either the basolateral or apical membrane. The first example focuses on protein-protein interactions. As noted during our discussion of the secretory protein pathway, the sorting operation that separates apically from basolaterally directed proteins apparently occurs in the TGN (see [p. 39](#)). Some proteins destined for the basolateral membrane have special amino-acid motifs that act as sorting signals. Some of these motifs are similar to those that allow membrane proteins to participate in endocytosis. Members of the adaptin family recognize these motifs during the formation of clathrin-coated vesicles at the TGN and segregate the basolateral proteins into a vesicle destined for the basolateral membrane.

Another example of mechanisms that cells use to generate a polarized distribution of membrane proteins focuses on lipid-lipid interactions. In many epithelia, GPI-linked proteins are concentrated exclusively at the apical surface. It appears that the phospholipid components of GPI-linked proteins are unusual in that they cluster into complexes of fairly immobile gel-phase lipids during their passage through the Golgi apparatus. We saw above how lakes of phospholipids with different physical properties may segregate within a membrane (see [p. 10](#)). The “glycolipid rafts” of GPI-linked proteins incorporate into apically directed vesicles so that sorting can occur through lipid-lipid interactions in the plane of the membrane rather than through protein-protein interactions at the cytoplasmic surface of the Golgi membrane. From these two examples, it should be clear that a number of different mechanisms may contribute to protein sorting and the maintenance of epithelial polarity.

CHAPTER 3

Signal Transduction

Lloyd Cantley

Even single-cell organisms must respond to environmental challenges, which necessitated the development of signal-transduction mechanisms. The evolution of multicellular organisms required the evolution of **cell-to-cell communication** within the organism to coordinate between cells activities ranging from the induction of embryonic development to the integration of physiological responses.

All cells receive and process information. External **signals** such as odorants, metabolites, ions, hormones, growth factors, and neurotransmitters can all serve as **chemical messengers** linking neighboring or distant cells. Even external signals that are not considered chemical in nature (e.g., light and mechanical or thermal stimuli) may ultimately be transduced into a chemical messenger. Most chemical messengers interact with specific **cell-surface receptors** and trigger a cascade of secondary events, including the activation of intracellular **second-messenger systems** that mediate the cell's response to that stimulus. However, hydrophobic messengers, such as steroid hormones and some vitamins, can diffuse across the plasma membrane and interact with **cytosolic or nuclear receptors**. Indeed, cells use a number of intersecting intracellular signaling pathways to ensure that the cell's response to a stimulus is tightly controlled.

Mechanisms of Cellular Communication

Cells can communicate with one another via chemical signals

Cells secrete chemical signals that can induce a physiological response in any (or all) of three ways (Fig. 3-1): by entering the circulation and acting on distant tissues (**endocrine**), by acting on a neighboring cell in the same tissue (**paracrine**), or by stimulating the same cell that released the chemical (**autocrine**).

Secreted factors that are produced by cells of one organ and enter the circulation to induce a response in a separate organ are called **hormones**, and the organs that secrete them—such as the pituitary, adrenal, and thyroid glands—are parts of the **endocrine system**. However, many other cells and tissues not classically thought of as endocrine in nature also produce hormones. For example, the kidney produces 1,25-dihydroxyvitamin D₃, and the salivary gland synthesizes nerve growth factor. Finally, physical contact between one cell and another, or between a cell and the matrix secreted by another cell, can transmit a signal (**juxtacrine**).

FIGURE 3-1 Modes of intercellular communication.

For paracrine and autocrine signals to be delivered to their proper targets, their diffusion must be limited. This restriction can be accomplished by rapid endocytosis of the chemical signal by neighboring cells, its destruction by extracellular enzymes, or its immobilization by the extracellular matrix. The events that take place at the neuromuscular junction are excellent examples of paracrine signaling. When an electrical impulse travels down an axon and reaches the nerve terminal (Fig. 3-2), it stimulates release of the neurotransmitter acetylcholine (ACh). In turn, ACh transiently activates a ligand-gated cation channel on the muscle cell membrane. The resultant transient influx of Na⁺ causes the membrane potential (V_m) to shift locally in a positive direction (i.e., depolarization), initiating events that result in propagation of an action potential along the muscle cell. The ACh signal is rapidly terminated by the action of acetylcholinesterase, which is present in the synaptic cleft. This enzyme degrades the ACh that is released by the neuron.

FIGURE 3-2 Example of paracrine signaling. The release of ACh at the neuromuscular junction is a form of paracrine signaling because the nerve terminal releases a chemical (i.e., ACh) that acts on a neighboring cell (i.e., the muscle).

Soluble chemical signals interact with target cells via binding to surface or intracellular receptors

Four types of chemicals can serve as extracellular signaling molecules:

1. **Amines**, such as epinephrine
2. **Peptides and proteins**, such as angiotensin II and insulin
3. **Steroids**, including aldosterone, estrogens, and retinoic acid
4. **Other small molecules**, such as amino acids, nucleotides, ions (e.g., Ca^{2+}), and gases (e.g., nitric oxide)

For a molecule to act as a signal, it must bind to a **receptor**. Most receptors are proteins on the cell surface or within the cell that specifically bind a signaling molecule (the ligand) and induce a cellular response by interacting with an effector. In some cases, the receptor is itself the effector, as in ligand-gated ion channels that alter transmembrane ion conductance in response to an extracellular signal. In most cases, however, interaction of the ligand with its receptor results in association of the receptor with one or more intracellular effector molecules that in turn initiate the cellular response. Effectors include enzymes, channels, transport proteins, contractile elements, and transcription factors. The ability of a cell or tissue to respond to a specific signal is dictated by the complement of receptors it possesses and by the

chain of intracellular reactions that are initiated by the binding of any one ligand to its receptor. Receptors can be divided into five categories on the basis of their mechanisms of signal transduction ([Table 3-1](#)).

1. **Ligand-gated ion channels.** Integral membrane proteins, these hybrid receptors/channels are involved in signaling between electrically excitable cells. The binding of a neurotransmitter such as ACh to its receptor—which in fact is merely part of the channel—results in transient opening of the channel and thus alters the ion permeability of the cell.
2. **G protein-coupled receptors.** These integral plasma-membrane proteins work indirectly—through multiple intermediaries—to activate or inactivate downstream effectors, such as membrane-associated enzymes or channels. This group of receptors is named for the initial intermediary, which is a heterotrimeric GTP-binding complex called a G protein.
3. **Catalytic receptors.** When activated by a ligand, these integral plasma-membrane proteins are either enzymes themselves or part of an enzymatic complex. In many cases, these receptors are either **kinases** that add phosphate groups to their substrates or **phosphatases** that remove substrate phosphate groups.
4. **Nuclear receptors.** These proteins, located in the cytosol or nucleus, are ligand-activated transcription factors. These receptors link extracellular signals to gene transcription.
5. **Receptors that undergo cleavage.** In response to ligand binding, some transmembrane proteins undergo **regulated intramembranous proteolysis (RIP; see pp. 87–88)**, 🍷 **N3-1** which liberates one or more fragments of their cytosolic domain that signal a cellular response by entering the nucleus to modulate gene expression.

TABLE 3-1

Classification of Receptors and Associated Signal-Transduction Pathways

CLASS OF RECEPTOR	SUBUNIT COMPOSITION OF RECEPTOR	LIGAND	SIGNAL-TRANSDUCTION PATHWAY DOWNSTREAM FROM RECEPTOR
Ligand-gated ion channels (ionotropic receptors)	Heteromeric or homomeric oligomers	<i>Extracellular</i>	<i>Ion current</i>
		GABA	$\text{Cl}^- > \text{HCO}_3^-$
		Glycine	$\text{Cl}^- > \text{HCO}_3^-$
		ACh: muscle	$\text{Na}^+, \text{K}^+, \text{Ca}^{2+}$
		ACh: nerve	$\text{Na}^+, \text{K}^+, \text{Ca}^{2+}$
		5-HT	Na^+, K^+
		Glutamate: non-NMDA	$\text{Na}^+, \text{K}^+, \text{Ca}^{2+}$
		Glutamate: NMDA	$\text{Na}^+, \text{K}^+, \text{Ca}^{2+}$
		ATP (opening)	$\text{Ca}^{2+}, \text{Na}^+, \text{Mg}^{2+}$
		<i>Intracellular</i>	
		cGMP (vision)	Na^+, K^+
		cAMP (olfaction)	Na^+, K^+
		ATP (closes channel)	K^+
		IP_3	Ca^{2+}
		Ca^{2+} or ryanodine	Ca^{2+}
Receptors coupled to heterotrimeric ($\alpha\beta\gamma$) G proteins	Single polypeptide that crosses the membrane seven times	<i>Small transmitter molecules</i> ACh Norepinephrine <i>Peptides</i> Oxytocin PTH NPY Gastrin CCK <i>Odorants</i> <i>Certain cytokines, lipids, and related molecules</i>	<i>$\beta\gamma$ directly activates downstream effector</i> Muscarinic AChR activates atrial K^+ channel <i>α activates an enzyme</i> Cyclases that make cyclic nucleotides (cAMP, cGMP) Phospholipases that generate IP_3 and diacylglycerols Phospholipases that generate AA and its metabolites
Catalytic receptors	Single polypeptide that crosses the membrane once	ANP TGF- β	Receptor guanylyl cyclase Receptor serine/threonine kinases
	May be dimeric or may dimerize after activation	NGF, EGF, PDGF, FGF, insulin, IGF-1	Receptor tyrosine kinase
		IL-3, IL-5, IL-6, EPO, LIF, CNTF, GH, IFN- α , IFN- β , IFN- γ , GM-CSF	Tyrosine kinase-associated receptor
		CD45	Receptor tyrosine phosphatase
Intracellular (or nuclear) receptors	Homodimers of polypeptides, each with multiple functional domains	<i>Steroid hormones</i> Mineralocorticoids Glucocorticoids Androgens Estrogens Progestins	Bind to regulatory DNA sequences and directly or indirectly increase or decrease the transcription of specific genes
		<i>Others</i> Thyroid hormones Retinoic acid Vitamin D Prostaglandin	
	Heterodimers of polypeptides, each with multiple functional domains		
Cleavage-activated receptors	Single polypeptide that crosses the membrane once	Jagged Delta	After receptor cleavage, cytosolic domain of receptor translocates to nucleus and regulates gene transcription

CCK, cholecystokinin; NMDA, N-methyl-D-aspartate; NPY, neuropeptide Y; PTH, parathyroid hormone.

N3-1

Examples of RIP

Contributed by Peter Igarashi

In addition to sterol regulatory element-binding protein (SREBP) noted in the text on pp. 87–88, other proteins that undergo RIP are Notch and APP—all span the membrane at least once.

Notch is a plasma-membrane receptor whose cytoplasmic domain is released in response to Delta, a membrane-bound ligand that regulates cell fate during development.

Amyloid precursor protein (APP) is a protein of unknown function that is cleaved in the membrane to

produce the extracellular amyloid β peptide implicated in **Alzheimer disease**. For Notch and APP, the intramembrane cleavage does not take place until a primary cleavage event removes the bulk of the protein on the extracytoplasmic face. Although the cleaved sites differ in these proteins, the net effect of the first step is to shorten the extracytoplasmic domain to <30 amino acids, which allows the second cleavage to release a portion of the cytoplasmic domain.

The **epithelial Na^+ channel ENaC**—a heterotrimer that consists of α , β , and γ subunits—also undergoes intramembrane proteolysis. While the ENaC is still in the vesicular subcompartment of the secretory pathway, the protease **furin** cleaves the extracellular domain of the α subunit twice (after consensus RXXR motifs), releasing a peptide of 26 amino acids. By itself, this modification increases the open probability of ENaC to ~ 0.30 . Furin also cleaves the γ subunit, but only once. A variety of extracellular proteases—including prostatic, elastase, and plasmin—can make a second cut after the protein has reached the plasma membrane. The result of the γ -subunit cleavages is to increase the open probability to nearly 1.0. Thus, both examples of proteolysis greatly increase the activity of the channel.

Hughey RP, Carattino MD, Kleyman TR. Role of proteolysis in the activation of epithelial sodium channels. *Curr Opin Nephrol Hypertens*. 2007;16:444–450.

Signaling events initiated by membrane-associated receptors can generally be divided into six steps:

Step 1: Recognition of the signal by its receptor. The same signaling molecule can sometimes bind to more than one kind of receptor. For example, ACh can bind to both ligand-gated channels and G protein-coupled receptors. Binding of a ligand to its receptor involves the same three types of weak, noncovalent interactions that characterize substrate-enzyme interactions. *Ionic bonds* are formed between groups of opposite charge. In *van der Waals* interactions, a transient dipole in one atom generates the opposite dipole in an adjacent atom and thereby creates an electrostatic interaction. *Hydrophobic interactions* occur between nonpolar groups.

Step 2: Transduction of the extracellular message into an intracellular signal or second messenger. Ligand binding causes a conformational change in the receptor that triggers the catalytic activities intrinsic to the receptor or causes the receptor to interact with membrane or cytoplasmic enzymes. The final consequence is the generation of a **second messenger** or the activation of a catalytic cascade.

Step 3: Transmission of the second messenger's signal to the appropriate effector. The second messenger can be amplified and transmitted to distant regions within the cell by myriad events, such as activation of intracellular kinases and phosphatases that alter the activity of other enzymes and proteins, release or sequestration of intracellular ions, or regulation of metabolic pathways that generate ATP.

Step 4: Modulation of the effector. These effectors represent a diverse array of molecules, such as enzymes, ion channels, cytoskeletal components, and transcription factors. The second message can modulate their expression or activity as well as alter their location or substrate availability.

Step 5: Response of the cell to the initial stimulus. This collection of actions represents the summation and integration of input from multiple signaling pathways.

Step 6: Termination of the response by feedback mechanisms at any or all levels of the signaling pathway.

Cells can also communicate by direct interactions—juxtacrine signaling

Gap Junctions

Neighboring cells can be electrically and metabolically coupled by means of gap junctions formed by the interaction of connexins in two closely apposed cell membranes (see pp. 158–159). These water-filled channels facilitate the passage of inorganic ions and small molecules, such as Ca^{2+} and cyclic 3',5'-adenosine monophosphate (cAMP), from the cytoplasm of one cell into the cytoplasm of an adjacent cell. Mammalian gap junctions permit the passage of molecules that are less than ~1200 Da but restrict the movement of molecules that are greater than ~2000 Da. Gap junctions are also excellent pathways for the flow of electrical current between adjacent cells, playing a critical role in cardiac and smooth muscle.

The permeability of gap junctions can be rapidly regulated by changes in cytosolic concentrations of Ca^{2+} , cAMP, and H^+ as well as by the voltage across the cell membrane or V_m . This type of modulation is physiologically important for cell-to-cell communication. For example, if a cell's plasma membrane is damaged, Ca^{2+} passively moves into the cell and raises $[\text{Ca}^{2+}]_i$ to toxic levels. Elevated intracellular $[\text{Ca}^{2+}]$ in the damaged cell triggers closure of the gap junctions, which prevents the flow of excessive amounts of Ca^{2+} into the adjacent cell.

Adhering and Tight Junctions

Adhering junctions form as the result of the Ca^{2+} -dependent interactions of the extracellular domains of transmembrane proteins called **cadherins** (see p. 17). The clustering of cadherins at the site of interaction with an adjacent cell causes secondary clustering of intracellular proteins known as **catenins**, which in turn serve as sites of attachment for the intracellular **actin cytoskeleton**. Thus, adhering junctions provide important clues for the maintenance of normal cell architecture as well as the organization of groups of cells into tissues.

In addition to playing a homeostatic role, adhering junctions can serve a signaling role during organ development and remodeling. In a cell that is stably associated with its neighbors, a catenin known as **β -catenin** is mainly sequestered at the adhering junctions, so that the concentration of free β -catenin is minimized. However, disruption of adhering junctions following stimulation by certain growth factors, for example, causes β -catenin to disassociate from cadherin. The resulting rise in free β -catenin levels promotes the translocation of β -catenin to the nucleus. There, β -catenin regulates the transcription of multiple genes, including ones that promote cell proliferation and migration. 🕯️ **N3-2**

N3-2

β -Catenins

Contributed by Lloyd Cantley

The concentration of free β -catenin in the cytoplasm is regulated by a cluster of cytosolic proteins (including the adenomatous polyposis coli [APC] protein that is mutated in some colon cancers) that bind and phosphorylate β -catenin, targeting it for degradation. Thus, inhibition of this regulatory pathway, such as occurs following activation of Wnt signaling during organ development, will increase β -catenin levels

and enhance nuclear localization and transcriptional regulation.

Similar to adhering junctions, **tight junctions** (see pp. 43–44) comprise transmembrane proteins that link with their counterparts on adjacent cells as well as intracellular proteins that both stabilize the complex and have a signaling role. The transmembrane proteins—including claudins, occludin, and junctional adhesion molecule (JAM)—and their extracellular domains create the diffusion barrier of the tight junction. One of the integral cytoplasmic proteins in tight junctions, zonula occludin 1 (ZO-1), colocalizes with a serine/threonine kinase known as WNK1,  **N3-3** which is found in certain renal tubule epithelial cells that reabsorb Na^+ and Cl^- from the tubule lumen. By phosphorylating specific claudins in the tight-junction complex, WNK1 determines the paracellular Cl^- permeability and thereby helps regulate NaCl uptake from the glomerular filtrate. Mutations in WNK1 that increase the movement of Cl^- through the tight junctions (see pp. 754–755) cause increased salt reabsorption by the kidney and lead to hypertension.

N3-3

WNK Kinases

Contributed by Lloyd Cantley

WNK kinases are serine/threonine kinases that are unique in that they lack an otherwise highly conserved lysine residue in the catalytic domain (specifically, subdomain II) of the enzyme. Hence, they are kinases “with no *K*”—that is, no lysine residue (the single-letter code for lysine is *K*). These kinases have emerged as highly important regulators of epithelial ion transport in the kidney, predominantly via phosphorylation-dependent changes in ion channel surface localization and activity.

Membrane-Associated Ligands

Another mechanism by which cells can directly communicate is the interaction of a receptor in the plasma membrane with a ligand that is itself a membrane protein on an adjacent cell. Such membrane-associated ligands can provide spatial clues in migrating cells. For example, an **ephrin** ligand expressed on the surface of one cell can interact with an Eph receptor on a nearby cell. The resulting activation of the Eph receptor can in turn provide signals for regulating such developmental events as axonal guidance in the nervous system and endothelial-cell guidance in the vasculature.

Ligands in the Extracellular Matrix

Cells also receive input from their extracellular environment via cell-surface receptors that interact with the extracellular matrix. These receptors, called **integrins** (see p. 17), have an extracellular domain that interacts with amino-acid sequences that are specific to certain matrix components, such as collagen, fibronectin, and laminin. This ligand-receptor interaction results in a conformational change in the integrin that promotes the accumulation of a cluster of signaling molecules—called a **focal adhesion**—on the cytosolic side of the membrane. The focal adhesion includes small GTP-binding proteins (see p. 56) such as Rac and Rho that regulate actin cytoskeletal anchoring and turnover, as well as intracellular kinases such as focal-adhesion kinase (FAK) and Src that control such diverse processes as cell proliferation, cell migration, and cell differentiation. Thus, by sensing a change in the matrix composition, cells can activate migratory responses needed for organ repair or can undergo terminal differentiation during organ

development.

Second-messenger systems amplify signals and integrate responses among cell types

Once a signal has been received at the cell surface, it is typically amplified and transmitted to specific sites within the cells via second messengers. For a molecule to function as a second messenger, its concentration, activation, and location must be finely regulated. The cell achieves this control by rapidly producing or activating the second messenger and then inactivating or degrading it. To ensure that the system returns to a resting state when the stimulus is removed, counterbalancing activities function at each step of the cascade.

The involvement of second messengers in catalytic cascades provides numerous opportunities to **amplify** a signal. For example, the binding of a ligand to its receptor can generate hundreds of second-messenger molecules, which can in turn alter the activity of thousands of downstream effectors. This modulation usually involves the conversion of an inactive species into an active molecule or vice versa. An example of *creating* an active species would be G proteins that elicit the formation of the second messenger **cAMP** (see pp. 56–57), whereas an example of *destroying* an active species would be G proteins that elicit the breakdown of a related second messenger, cGMP; (see p. 58).

Second-messenger systems also allow both **specificity** and **diversity**. Distinct ligand-receptor combinations that activate the same intracellular signaling pathways often produce the same cellular response. For example, epinephrine, adrenocorticotrophic hormone (ACTH), glucagon, and thyroid-stimulating hormone (TSH) all signal via cAMP to induce triacylglycerol breakdown. In contrast, a single signaling molecule can produce distinct responses in different cells, depending on the complement of receptors and signal-transduction pathways that are available in the cell as well as the specialized function that the cell carries out in the organism. For example, ACh stimulates contraction of skeletal muscle cells, inhibits contraction of heart muscle cells, and facilitates the exocytosis of secretory granules by pancreatic acinar cells. This signaling molecule achieves these different end points by interacting with distinct receptors on each cell. Finally, even within a single cell, a second messenger such as cAMP can act within microdomains to target a specific set of effector molecules, thereby conferring spatially based specificity. 🍎 N3-4

N3-4

Compartmentalization of Second-Messenger Effects

Contributed by Laurie Roman

In the textbook, we referred only to whole-cell levels of intracellular second messengers (e.g., cAMP), as if these messengers were uniformly distributed throughout the cell. However, some cell physiologists and cell biologists believe that *local effects* of intracellular second messengers may be extremely important in governing how signal-transduction processes work. One piece of evidence for such local effects is that the receptors for hormones and other extracellular agonists often are a part of macromolecular clusters of proteins that share a common physiological role. For example, a hormone receptor, its downstream heterotrimeric G protein, an amplifying enzyme (e.g., adenylyl cyclase) that generates the intracellular second messenger (e.g. cAMP), other proteins (e.g., the A kinase anchoring protein [or AKAP]), and the effector molecule (e.g., protein kinase A) may all reside in a microdomain

at the cell membrane. Thus, it is possible that a particular hormone could act by locally raising $[cAMP]_i$ to levels much higher than in neighboring areas, so that—of all the cellular proteins potentially sensitive to cAMP—only a local subset of these targets may be activated by the newly formed cAMP.

A second piece of evidence for the local effects of cAMP is the wide distribution of phosphodiesterases, which would be expected to break down cAMP and limit its ability to spread throughout the cell.

The diversity and specialization of second-messenger systems are important to a multicellular organism, as can be seen in the coordinated response of an organism to a stressful situation. Under these conditions, the adrenal gland releases epinephrine. Different organ systems respond to epinephrine in a distinct manner, such as activation of glycogen breakdown in the liver, constriction of the blood vessels of the skin, dilation of the blood vessels in skeletal muscle, dilation of airways in the lung, and increased rate and force of heart contraction. The overall effect is an **integrated response** that readies the organism for attack, defense, or escape. In contrast, complex cell behaviors, such as proliferation and differentiation, are generally stimulated by combinations of signals rather than by a single signal. Integration of these stimuli requires **crosstalk** among the various signaling cascades.

As discussed below, most signal-transduction pathways use elaborate cascades of signaling proteins to relay information from the cell surface to effectors in the cell membrane, the cytoplasm, or the nucleus. In [Chapter 4](#), we discuss how signal-transduction pathways that lead to the nucleus can affect the cell by modulating gene transcription. These are **genomic** effects. Signal-transduction systems that project to the cell membrane or to the cytoplasm produce **nongenomic** effects, the focus of this chapter.

Receptors That are Ion Channels

Ligand-gated ion channels transduce a chemical signal into an electrical signal

The property that defines the ligand-gated ion channel class of multisubunit membrane-spanning receptors is that the signaling molecule itself controls the opening and closing of an ion channel by binding to a site on the receptor. Thus, these receptors are also called **ionotropic receptors** to distinguish them from the metabotropic receptors, which act via “metabolic” pathways. One superfamily of ligand-gated channels includes the ionotropic receptors for ACh, serotonin, gamma-aminobutyric acid (GABA), and glycine. Most structural and functional information for ionotropic receptors comes from the *nicotinic* ACh receptor (AChR) present in skeletal muscle (see [Fig. 8-7](#)). The *nicotinic* AChR is a cation channel that consists of four membrane-spanning subunits, α , β , γ or ϵ , and δ , in a stoichiometry of 2 : 1 : 1 : 1. This receptor is called *nicotinic* because the nicotine contained in tobacco can activate or open the channel and thereby alter V_m . Note that the nicotinic AChR is very different from the *muscarinic* AChR discussed below, which is not a ligand-gated channel. Additional examples of ligand-gated channels are the inositol 1,4,5-trisphosphate (IP_3) receptor and the Ca^{2+} -release channel (also known as the ryanodine receptor). Both receptors are tetrameric Ca^{2+} channels located in the membranes of intracellular organelles.

Receptors Coupled to G Proteins

G protein–coupled receptors (GPCRs) constitute the largest family of receptors on the cell surface, with >1000 members either known or predicted from genome sequences. GPCRs mediate cellular responses to a diverse array of signaling molecules, such as hormones, neurotransmitters, vasoactive peptides, odorants, tastants, and other local mediators. Despite the chemical diversity of their ligands, most receptors of this class have a similar structure (Fig. 3-3). They consist of a single polypeptide chain with seven membrane-spanning α -helical segments, an extracellular N terminus that is glycosylated, a large cytoplasmic loop that is composed mainly of hydrophilic amino acids between helices 5 and 6, and a hydrophilic domain at the cytoplasmic C terminus. Most small ligands (e.g., epinephrine) bind in the plane of the membrane at a site that involves several membrane-spanning segments. In the case of larger protein ligands, a portion of the extracellular N terminus also participates in ligand binding. The 5,6-cytoplasmic loop appears to be the major site of interaction with the intracellular G protein, although the 3,4-cytoplasmic loop and the cytoplasmic C terminus also contribute to binding in some cases. Binding of the GPCR to its extracellular ligand regulates this interaction between the receptor and the G proteins, thus transmitting a signal to downstream effectors. In the next four sections of this subchapter, we discuss the general principles of how G proteins function and then consider three major second-messenger systems that G proteins trigger.

FIGURE 3-3 G protein–coupled receptor.

General Properties of G Proteins

G proteins are heterotrimers that exist in many combinations of different α , β , and γ subunits

G proteins are members of a superfamily of **GTP-binding proteins**. This superfamily includes the classic heterotrimeric G proteins that bind to GPCRs as well as the so-called small GTP-binding proteins, such

as Ras. Both the heterotrimeric and small G proteins can hydrolyze GTP and switch between an active GTP-bound state and an inactive GDP-bound state.

Heterotrimeric G proteins are composed of three subunits, α , β , and γ . At least 16 different α subunits (~42 to 50 kDa), 5 β subunits (~33 to 35 kDa), and 11 γ subunits (~8 to 10 kDa) are present in mammalian tissue. The α subunit binds and hydrolyzes GTP and also interacts with “downstream” effector proteins such as adenylyl cyclase. Historically, the α subunits were thought to provide the principal specificity to each type of G protein, with the $\beta\gamma$ complex functioning to anchor the trimeric complex to the membrane. However, it is now clear that the $\beta\gamma$ complex also functions in signal transduction by interacting with effector molecules distinct from those regulated by the α subunits. Moreover, both the α and γ subunits are involved in anchoring the complex to the membrane. The α subunit is held to the membrane by either a myristyl or a palmitoyl group, whereas the γ subunit is held via a prenyl group.

The multiple α , β , and γ subunits demonstrate distinct tissue distributions and interact with different receptors and effectors (Table 3-2). Because of the potential for several hundred combinations of the known α , β , and γ subunits, G proteins are ideally suited to link a diversity of receptors to a diversity of effectors. The many classes of G proteins, in conjunction with the presence of several receptor types for a single ligand, provide a mechanism whereby a common signal can elicit the appropriate physiological response in different tissues. For example, when epinephrine binds β_1 adrenergic receptors in the heart, it stimulates adenylyl cyclase, which increases heart rate and the force of contraction. However, in the periphery, epinephrine acts on α_2 adrenergic receptors coupled to a G protein that inhibits adenylyl cyclase, thereby increasing peripheral vascular resistance and consequently increasing venous return and blood pressure.

TABLE 3-2
Families of G Proteins

FAMILY/SUBUNIT	% IDENTITY	TO XIN	DISTRIBUTION	RECEPTOR	EFFECTOR/ROLE
C _s (α_s)					
$\alpha_{s(s)}$	100	CTX	Ubiquitous	β adrenergic, TSH, glucagon, others	↑ Adenylyl cyclase
$\alpha_{s(l)}$					↑ Ca ²⁺ channel
α_{olf}	88	CTX	Olfactory epithelium	Odorant	↑ Adenylyl cyclase Open K ⁺ channel
G _i (α_i)					
α_{i1}	100	PTX	~Ubiquitous	M ₂ , α_2 adrenergic, others	↑ IP ₃ , DAG, Ca ²⁺ , and AA, ↓ adenylyl cyclase

α_{13}	67		Ubiquitous		

CTX, cholera toxin; PTX, pertussis toxin.

Among the first effectors found to be sensitive to G proteins was the enzyme adenylyl cyclase. The

heterotrimeric G protein known as G_s was so named because it stimulates adenylyl cyclase. A separate class of G proteins was given the name G_i because it is responsible for the ligand-dependent inhibition of adenylyl cyclase. Identification of these classes of G proteins was greatly facilitated by the observation that the α subunits of individual G proteins are substrates for ADP ribosylation catalyzed by bacterial toxins. The toxin from *Vibrio cholerae* activates G_s , whereas the toxin from *Bordetella pertussis* inactivates the cyclase-inhibiting G_i (Box 3-1).

Box 3-1

Action of Toxins on Heterotrimeric G Proteins

Infectious diarrheal disease has a multitude of causes. **Cholera toxin**, a secretory product of the bacterium *Vibrio cholerae*, is responsible in part for the devastating characteristics of cholera. The toxin is an oligomeric protein composed of one A subunit and five B subunits (AB_5). After cholera toxin enters intestinal epithelial cells, the A subunit separates from the B subunits and becomes activated by proteolytic cleavage. The resulting active A1 fragment catalyzes the ADP ribosylation of $G\alpha_s$. This ribosylation, which involves transfer of the ADP-ribose moiety from the oxidized form of nicotinamide adenine dinucleotide (NAD^+) to the α subunit, inhibits the GTPase activity of $G\alpha_s$. As a result of this modification, $G\alpha_s$ remains in its activated, GTP-bound form and can activate adenylyl cyclase. In intestinal epithelial cells, the constitutively activated $G\alpha_s$ elevates levels of cAMP, which causes an increase in Cl^- conductance and water flow and thereby contributes to the large fluid loss characteristic of this disease.

A related bacterial product is **pertussis toxin**, which is also an AB_5 protein. It is produced by *Bordetella pertussis*, the causative agent of whooping cough. Pertussis toxin ADP-ribosylates $G\alpha_i$. This ADP-ribosylated $G\alpha_i$ cannot exchange its GDP (inactive state) for GTP. Thus, α_i remains in its GDP-bound inactive state. As a result, receptor occupancy can no longer release the active α_i -GTP, so adenylyl cyclase cannot be inhibited. Thus, both cholera toxin and pertussis toxin increase the generation of cAMP.

For their work in identifying G proteins and elucidating the physiological role of these proteins, Alfred Gilman and Martin Rodbell received the 1994 Nobel Prize in Physiology or Medicine. 🏆 **N3-5**

G-protein activation follows a cycle

N3-5

Alfred Gilman and Martin Rodbell

For more information about Alfred Gilman and Martin Rodbell and the work that led to their Nobel Prize, visit <http://www.nobel.se/medicine/laureates/1994/index.html> (accessed October 2014).

In their inactive state, heterotrimeric G proteins are a complex of α , β , and γ subunits in which GDP occupies the guanine nucleotide-binding site of the α subunit. After ligand binding to the GPCR (Fig. 3-4, step 1), a conformational change in the receptor–G protein complex facilitates the release of bound GDP

and simultaneous binding of GTP to the α subunit (see Fig. 3-4, step 2). This GDP-GTP exchange stimulates dissociation of the complex from the receptor (see Fig. 3-4, step 3) and causes disassembly of the trimer into a free GTP-bound α subunit and separate $\beta\gamma$ complex (see Fig. 3-4, step 4). The GTP-bound α subunit interacts in the plane of the membrane with downstream effectors such as adenylyl cyclase and phospholipases (see Fig. 3-4, step 5), or cleavage of its myristoyl or palmitoyl group can release the α subunit from the membrane. Similarly, the $\beta\gamma$ subunit can activate ion channels or other effectors.

The α subunit is itself an enzyme that catalyzes the hydrolysis of GTP to GDP and inorganic phosphate (P_i). The result is an *inactive* α -GDP complex that dissociates from its downstream effector and reassociates with a $\beta\gamma$ subunit (see Fig. 3-4, step 6); this reassociation terminates signaling and brings the system back to resting state (see Fig. 3-4, step 1). The $\beta\gamma$ subunit stabilizes α -GDP and thereby substantially slows the rate of GDP-GTP exchange (see Fig. 3-4, step 2) and dampens signal transmission

in the resting state.

The **RGS** (for “regulation of G-protein signaling”) family of proteins appears to enhance the intrinsic **GTPase** activity of some but not all α subunits. Investigators have identified at least 19 mammalian RGS proteins and shown that they interact with specific α subunits. RGS proteins promote GTP hydrolysis and thus the termination of signaling.

Activated α subunits couple to a variety of downstream effectors, including enzymes and ion channels

Activated α subunits can couple to a variety of enzymes. A major enzyme that acts as an effector downstream of activated α subunits is **adenylyl cyclase** (Fig. 3-5A), which catalyzes the conversion of ATP to cAMP. This enzyme can be either activated or inhibited by G-protein signaling, depending on whether it associates with the GTP-bound form of $G\alpha_s$ (stimulatory) or $G\alpha_i$ (inhibitory). Thus, different ligands—acting through different combinations of GPCRs and G proteins—can have opposing effects on the same intracellular signaling pathway. 🍷 **N3-4**

A G PROTEINS ACTING VIA ADENYLYL CYCLASE

B G PROTEIN ACTING VIA A PHOSPHODIESTERASE

C G PROTEIN ACTING VIA A PHOSPHOLIPASE

FIGURE 3-5 Downstream effects of activated G-protein α subunits. **A**, When a ligand binds to a receptor coupled to α_s , adenylyl cyclase (AC) is activated, whereas when a ligand binds to a receptor coupled to α_i , the enzyme is inhibited. The activated enzyme converts ATP to cAMP, which then can activate PKA. **B**, In phototransduction, a photon interacts with the receptor and activates the G protein transducin. The α_t activates phosphodiesterase (PDE), which in turn hydrolyzes cGMP; this lowers the intracellular concentrations of cGMP and therefore closes the cGMP-activated channels. **C**, In this example, the ligand binds to a receptor that is coupled to α_q , which activates PLC. This enzyme converts PIP_2 to IP_3 and DAG. The IP_3 leads to the release of Ca^{2+} from intracellular stores, whereas the DAG activates PKC.

G proteins can also activate enzymes that break down cyclic nucleotides. For example, the G protein called **transducin** contains an α_t subunit that activates the **cGMP phosphodiesterase**, which in turn catalyzes the breakdown of cGMP to GMP (see Fig. 3-5B). This pathway plays a key role in phototransduction in the retina (see p. 368).

G proteins can also couple to **phospholipases**. These enzymes catabolize phospholipids, as discussed in detail below in the section on G-protein second messengers. This superfamily of phospholipases can be grouped into phospholipases A_2 , C, or D on the basis of the site at which the enzyme cleaves the phospholipid. G proteins that include the α_q subunit activate **phospholipase C**, which breaks phosphatidylinositol 4,5-bisphosphate into two intracellular messengers, membrane-associated diacylglycerol and cytosolic IP_3 (see Fig. 3-5C). Diacylglycerol stimulates protein kinase C, whereas IP_3 binds to a receptor on the endoplasmic reticulum (ER) membrane and triggers the release of Ca^{2+} from intracellular stores.

Some G proteins interact with **ion channels**. Agonists that bind to the β adrenergic receptor activate the L-type Ca^{2+} channel (see pp. 190–193) in the heart and skeletal muscle. The α subunit of the G protein G_s binds to and directly stimulates L-type Ca^{2+} channels and also indirectly stimulates this channel via a signal-transduction cascade that involves cAMP-dependent phosphorylation of the channel.

$\beta\gamma$ subunits can activate downstream effectors

Following activation and disassociation of the heterotrimeric G protein, $\beta\gamma$ subunits can also interact with downstream effectors. The neurotransmitter ACh released from the vagus nerve reduces the rate and strength of heart contraction. This action in the atria of the heart is mediated by *muscarinic* M_2 AChRs, members of the GPCR family (see p. 341). These receptors can be activated by muscarine, an alkaloid found in certain poisonous mushrooms. *Muscarinic* AChRs are very different from the *nicotinic* AChRs discussed above, which are ligand-gated ion channels. Binding of ACh to the muscarinic M_2 receptor in the atria activates a heterotrimeric G protein, which results in the generation of both activated $G\alpha_i$ as well as a free $\beta\gamma$ subunit complex. The $\beta\gamma$ complex then interacts with a particular class of K^+ channels, increasing their permeability. This increase in K^+ permeability keeps the membrane potential relatively negative and thus renders the cell more resistant to excitation. The $\beta\gamma$ subunit complex also modulates the activity of adenylyl cyclase and phospholipase C and stimulates phospholipase A_2 . Such effects of $\beta\gamma$ can be independent of, synergize with, or antagonize the action of the α subunit. For example, studies using various isoforms of adenylyl cyclase have demonstrated that purified $\beta\gamma$ stimulates some isoforms, inhibits others, and has no effect on still others. Different combinations of $\beta\gamma$ isoforms may have different activities. For example, $\beta_1\gamma_1$ is one tenth as efficient at stimulating type II adenylyl cyclase as is $\beta_1\gamma_2$.

Some $\beta\gamma$ complexes can bind to a special protein kinase called the **β adrenergic receptor kinase (β ARK)**. As a result of this interaction, β ARK translocates to the plasma membrane, where it phosphorylates the ligand-receptor complex (but not the unbound receptor). This phosphorylation results

in the recruitment of **β -arrestin** to the GPCR, which in turn mediates disassociation of the receptor-ligand complex and thus attenuates the activity of the same β adrenergic receptors that gave rise to the $\beta\gamma$ complex in the first place. This action is an example of **receptor desensitization**. These phosphorylated receptors eventually undergo endocytosis, which transiently reduces the number of receptors that are available on the cell surface. This endocytosis is an important step in **resensitization** of the receptor system.

Small GTP-binding proteins are involved in a vast number of cellular processes

A distinct group of proteins that are structurally related to the α subunit of the heterotrimeric G proteins are the **small GTP-binding proteins**. More than 100 of these have been identified to date, and they have been divided into five groups: Ras, Rho, Rab, Arf, and Ran families. These 21-kDa proteins can be membrane associated (e.g., Ras) or may translocate between the membrane and the cytosol (e.g., Rho).

The three isoforms of Ras (NRas, HRas, and KRas) relay signals from the plasma membrane to the nucleus via an elaborate kinase cascade (see pp. 89–90), thereby regulating gene transcription. In some tumors, mutation of the genes encoding Ras proteins results in constitutively active Ras. These mutated genes are called **oncogenes** because the altered Ras gene product promotes the malignant transformation of a cell and can contribute to the development of cancer (oncogenesis). In contrast, Rho family members are primarily involved in rearrangement of the actin cytoskeleton. Rab and Arf regulate vesicle trafficking, whereas Ran regulates nucleocytoplasmic transport.

Similarly to the α subunit of heterotrimeric G proteins, the small GTP-binding proteins switch between an inactive GDP-bound form and an active GTP-bound form. Two classes of regulatory proteins modulate the activity of these small GTP-binding proteins. The first of these includes the **GTPase-activating proteins (GAPs)** and neurofibromin (a product of the neurofibromatosis type 1 gene). GAPs increase the rate at which small GTP-binding proteins hydrolyze bound GTP and thus result in more rapid inactivation. Counteracting the activity of GAPs are **guanine nucleotide exchange factors (GEFs)** such as “son of sevenless” or SOS (see p. 69), which promote the conversion of inactive Ras-GDP to active Ras-GTP. Interestingly, cAMP directly activates several GEFs, such as Epac (exchange protein activated by cAMP); this demonstrates crosstalk between a classical heterotrimeric G-protein signaling pathway and the small Ras-like G proteins.

G-Protein Second Messengers: Cyclic Nucleotides

cAMP usually exerts its effect by increasing the activity of protein kinase A

Activation of G_s -coupled receptors results in the stimulation of **adenylyl cyclase**, which can cause $[cAMP]_i$ to rise 5-fold in ~5 seconds (see Fig. 3-5A). This sudden rise is counteracted by cAMP breakdown to AMP by **cAMP phosphodiesterase**. The downstream effects of this increase in $[cAMP]_i$ depend on the cellular microdomains in which $[cAMP]_i$ rises as well as the specialized functions that the responding cell carries out in the organism. For example, in the adrenal cortex, ACTH stimulation of cAMP production results in the secretion of aldosterone and cortisol (see p. 1023); in the kidney, a vasopressin-induced rise in cAMP levels facilitates water reabsorption (see p. 818). Excess cAMP is also responsible for certain pathological conditions, such as **cholera** (see Box 3-1). Another pathological process associated with excess cAMP is **McCune-Albright syndrome**, characterized by a triad of (1) variable hyperfunction of multiple endocrine glands, including precocious puberty in girls; (2) bone

lesions; and (3) pigmented skin lesions (café au lait spots). This disorder is caused by a somatic mutation during development that constitutively activates the G-protein α_s subunit in a mosaic pattern.

cAMP exerts many of its effects through **cAMP-dependent protein kinase A (PKA)**. This enzyme catalyzes transfer of the terminal phosphate of ATP to specific **serine or threonine residues** on substrate proteins. PKA phosphorylation sites are present in a multitude of intracellular proteins, including ion channels, receptors, metabolic enzymes, and signaling pathway proteins. Phosphorylation of these sites can influence either the localization or the activity of the substrate. For example, phosphorylation of the β_2 adrenergic receptor by PKA causes receptor desensitization in neurons, whereas phosphorylation of the cystic fibrosis transmembrane conductance regulator (CFTR) increases its Cl^- channel activity.

To enhance regulation of phosphorylation events, the cell tightly controls the activity of PKA so that the enzyme can respond to subtle—and local—variations in cAMP levels. One important control mechanism is the use of **regulatory subunits** that constitutively inhibit PKA. In the absence of cAMP, two catalytic subunits of PKA associate with two of these regulatory subunits; the result is a heterotetrameric protein complex that has a low level of catalytic activity (Fig. 3-6). Binding of cAMP to the regulatory subunits induces a conformational change that diminishes their affinity for the catalytic subunits, and the subsequent dissociation of the complex results in activation of kinase activity. Not only can PKA activation have the short-term effects noted above, but the free catalytic subunit of PKA can also enter the nucleus, where substrate phosphorylation can activate the transcription of specific PKA-dependent genes (see p. 89). Although most cells use the same catalytic subunit, different regulatory subunits are found in different cell types.

FIGURE 3-6 Activation of PKA by cAMP.

Another mechanism that contributes to regulation of PKA is the targeting of the enzyme to specific subcellular locations. Such targeting promotes the preferential phosphorylation of substrates that are

confined to precise locations within the cell. PKA targeting is achieved by the association of a PKA regulatory subunit with an **A kinase anchoring protein (AKAP)**, which in turn binds to cytoskeletal elements or to components of cellular subcompartments. More than 35 AKAPs are known. The specificity of PKA targeting is highlighted by the observation that, in neurons, PKA is localized to postsynaptic densities through its association with AKAP79. This anchoring protein also targets calcineurin—a protein phosphatase—to the same site. This targeting of both PKA and calcineurin to the same postsynaptic site makes it possible for the cell to tightly regulate the phosphorylation state of important neuronal substrates.

The cAMP generated by adenylyl cyclase can interact with effectors other than PKA. For example, olfactory receptors (see pp. 358–359) activate a member of the G_s family called G_{olf} . The subsequent rise in $[cAMP]_i$ activates a **cyclic nucleotide-gated (CNG) ion channel** (see Table 6-2, family No. 4). Na^+ influx through this channel leads to membrane depolarization and the initiation of a nerve impulse.

For his work in elucidating the role played by cAMP as a second messenger in regulating glycogen metabolism (see Fig. 58-9), Earl Sutherland received the 1971 Nobel Prize in Physiology or Medicine.  **N3-6** In 1992, Edmond Fischer and Edwin Krebs shared the prize for their part in demonstrating the role of protein phosphorylation in the signal-transduction process.  **N3-7**

This coordinated set of phosphorylation and dephosphorylation reactions has several physiological advantages. First, it allows a single molecule (e.g., cAMP) to regulate a range of enzymatic reactions. Second, it affords a large amplification to a small signal. The concentration of epinephrine needed to stimulate glycogenolysis in muscle is $\sim 10^{-10}$ M. This subnanomolar level of hormone can raise $[cAMP]_i$ to $\sim 10^{-6}$ M. Thus, the catalytic cascades amplify the hormone signal 10,000-fold, which results in the liberation of enough glucose to raise blood glucose levels from ~ 5 to ~ 8 mM. Although the effects of cAMP on the synthesis and degradation of glycogen are confined to muscle and liver, a wide variety of cells use cAMP-mediated activation cascades in the response to a wide variety of hormones.

Protein phosphatases reverse the action of kinases

As discussed above, one way that the cell can terminate a cAMP signal is to use a phosphodiesterase to degrade cAMP. In this way, the subsequent steps along the signaling pathway can also be terminated. However, because the downstream effects of cAMP often involve phosphorylation of effector proteins at serine and threonine residues by kinases such as PKA, another powerful way to terminate the action of cAMP is to dephosphorylate these effector proteins. Such dephosphorylation events are mediated by

enzymes called serine/threonine phosphoprotein phosphatases.

Four groups of **serine/threonine phosphoprotein phosphatases (PPs)** are known: 1, 2a, 2b, and 2c. These enzymes themselves are regulated by phosphorylation at their serine, threonine, and tyrosine residues. The balance between kinase and phosphatase activity plays a major role in the control of signaling events.

PP1 dephosphorylates many proteins phosphorylated by PKA, including those phosphorylated in response to epinephrine (see Fig. 58-9). Another protein, **phosphoprotein phosphatase inhibitor 1 (I-1)**, can bind to and inhibit PP1. Interestingly, PKA phosphorylates and induces I-1 binding to PP1 (Fig. 3-7), thereby inhibiting PP1 and preserving the phosphate groups added by PKA in the first place.

FIGURE 3-7 Inactivation of PP1 by PKA.

PP2a, which is less specific than PP1, appears to be the main phosphatase responsible for reversing the action of other protein serine/threonine kinases. The Ca^{2+} -dependent **PP2b**, also known as **calcineurin**, is prevalent in the brain, muscle, and immune cells and is also the pharmacological target of the immunosuppressive reagents FK-506 (tacrolimus) and cyclosporine.

The substrates for **PP2c** include the DNA checkpoint regulators Chk1 and Chk2, which normally sense DNA damage in the setting of organ injury and temporarily stop cell proliferation. Dephosphorylation of these kinases by PP2c inactivates them and allows the cell to re-enter the cell cycle during the repair process.

In addition to serine/threonine kinases such as PKA, a second group of kinases involved in regulating signaling pathways (discussed beginning on pp. 68–70) are **tyrosine kinases** that phosphorylate their substrate proteins on tyrosine residues. The enzymes that remove phosphates from these tyrosine residues—**phosphotyrosine phosphatases (PTPs)**—are much more variable than the serine and threonine

phosphatases. The first PTP to be characterized was the *cytosolic* enzyme **PTP1B** from human placenta. PTP1B has a high degree of homology with **CD45**, a *membrane protein* that is both a receptor and a tyrosine phosphatase. The large family of PTPs can be divided into two classes: membrane-spanning receptor-like proteins such as CD45 and cytosolic tyrosine phosphatases such as PTP1B. A number of intracellular PTPs contain **Src homology 2 (SH2) domains**, a peptide sequence or motif that interacts with phosphorylated tyrosine groups and thus acts to recruit the phosphatase to its target substrate. Many of the PTPs are themselves regulated by phosphorylation.

cGMP exerts its effect by stimulating a nonselective cation channel in the retina

cGMP is another cyclic nucleotide that is involved in G-protein signaling events. In the outer segments of rods and cones in the visual system, the G protein does not couple to an enzyme that *generates* cGMP but, as noted above, couples to an enzyme that breaks it down. As discussed beginning on [page 367](#), light activates a GPCR called **rhodopsin**, which activates the G protein **transducin** (see [p. 368](#)), which in turn activates the **cGMP phosphodiesterase** (see [p. 368](#)) that lowers $[cGMP]_i$. The fall in $[cGMP]_i$ closes cGMP-gated nonselective cation channels that are members of the same family of CNG ion channels that cAMP activates in olfactory signaling (see [pp. 358–359](#)).

G-Protein Second Messengers: Products of Phosphoinositide Breakdown

Many messengers bind to receptors that activate phosphoinositide breakdown

Although the **phosphatidylinositols (PIs)** are minor constituents of cell membranes, they are largely distributed in the internal leaflet of the membrane and play an important role in signal transduction. The inositol sugar moiety of PI molecules (see [Fig. 2-2A](#)) can be phosphorylated to yield two major phosphoinositides involved in signal transduction: **phosphatidylinositol 4,5-bisphosphate (PI(4,5)P₂ or PIP₂)** and **phosphatidylinositol 3,4,5-trisphosphate (PI(3,4,5)P₃ or PIP₃)**; see [p. 69](#)). 📖 N3-8

N3-8

Acyl Groups

Contributed by Emile Boulpaep, Walter Boron

As noted in the text, phosphatidylinositols (PIs) (see [p. 10](#)) and phosphatidylcholines (PCs) (see [p. 10](#)) can each contain a variety of acyl groups. Therefore, the phosphoinositides derived from them can also contain a variety of acyl groups.

A **phosphoinositide** is a PI derivative containing one, two, or three additional phosphate groups. Because there are three possible attachment sites (at sites 3, 4, or 5), there are a total of seven combinations possible.

Seven Combinations

- Three monophosphates:

- PI3P
- PI4P
- PI5P
- Three bisphosphates called PIP_2
 - $\text{PI}(3,4)\text{P}_2$
 - $\text{PI}(4,5)\text{P}_2$
 - $\text{PI}(3,5)\text{P}_2$
- One trisphosphate called PIP_3
 - $\text{PI}(3,4,5)\text{P}_3$

Certain membrane-associated receptors act through G proteins (e.g., G_q) that stimulate phospholipase C (PLC) to cleave PIP_2 into inositol 1,4,5-trisphosphate (or IP_3) and diacylglycerol (DAG), as shown in [Figure 3-8A](#). PLCs are classified into three families (β , γ , δ) that differ in their catalytic properties, cell-type-specific expression, and modes of activation. $\text{PLC}\beta$ is typically activated downstream of certain G proteins (e.g., G_q), whereas $\text{PLC}\gamma$ contains an SH2 domain and is activated downstream of certain tyrosine kinases. Stimulation of $\text{PLC}\beta$ results in a rapid increase in cytosolic IP_3 levels as well as an *early* peak in DAG levels (see [Fig. 3-8B](#)). Both products are second messengers. The water-soluble IP_3 travels through the cytosol to stimulate Ca^{2+} release from intracellular stores (see next section). DAG remains in the plane of the membrane to activate protein kinase C, which migrates from the cytosol and binds to DAG in the membrane (see [pp. 60–61](#)).

B TIME COURSE OF IP₃ AND DAG LEVELS

C BREAKDOWN OF PHOSPHATIDYLCHOLINE BY PLC AND PLD

Phosphatidylcholines (PCs), which—unlike PI—are an abundant phospholipid in the cell membrane, are also a source of DAG. The cell can produce DAG from PC by either of two mechanisms (see Fig. 3-8C). First, PLC can directly convert PC to phosphocholine and DAG. Second, **phospholipase D (PLD)**, by cleaving the phosphoester bond on the other side of the phosphate, can convert PC to choline and phosphatidic acid (PA; also phospho-DAG). This PA can then be converted to DAG via PA-phosphohydrolase. Production of DAG from PC, either directly (via PLC) or indirectly (via PLD), produces the *slow* wave of increasing cytosolic DAG shown in Figure 3-8B. Thus, in some systems, the formation of DAG is biphasic and consists of an early peak that is transient and parallels the formation of IP₃, followed by a late phase that is slow in onset but sustained for several minutes.

IP₃ liberates Ca²⁺ from intracellular stores

As discussed on page 126, three major transport mechanisms keep free intracellular Ca²⁺ ([Ca²⁺]_i) below ~100 nM. Increases in [Ca²⁺]_i from this extremely low baseline allow Ca²⁺ to function as an important second messenger. IP₃ generated by the metabolism of membrane phospholipids travels through the cytosol and binds to the IP₃ receptor, a ligand-gated Ca²⁺ channel located in the membrane of the *endoplasmic* reticulum (see Fig. 3-8A). The result is a release of Ca²⁺ from intracellular stores and a rise in [Ca²⁺]_i. Indeed, it was within this system that Ca²⁺ was first identified as a messenger mediating the stimulus-response coupling of endocrine cells. The **IP₃ receptor (ITPR)** is a tetramer composed of subunits of ~260 kDa. At least three genes encode the subunits of the receptor. These genes are subject to alternative splicing, which further increases the potential for receptor diversity. The receptor is a substrate for phosphorylation by protein kinases A and C as well as calcium-calmodulin (Ca²⁺-CaM)–dependent protein kinases. 🍎 N3-9

N3-9

IP₃ Receptor Diversity

Contributed by Laurie Roman

As noted in the text, the IP₃ receptor (IPTR) is a tetramer composed of subunits of ~260 kDa, and at least four different genes encode the receptor subunits. These genes are subject to alternative splicing, further increasing the potential for receptor diversity. IP₃ receptors bind their ligand with high affinity (the dissociation constant $K_D = 2\text{--}10$ nM) or low affinity ($K_D = 40$ nM). However, the extent to which these different affinities correlate with particular forms of the receptor has not been established.

Interaction of IP₃ with its receptor results in passive efflux of Ca²⁺ from the ER and thus a rapid rise in the free cytosolic Ca²⁺ concentration. The IP₃-induced changes in [Ca²⁺]_i exhibit complex temporal and spatial patterns. The rise in [Ca²⁺]_i, which can be brief or persistent, can oscillate repetitively or spread across groups of cells coupled by gap junctions. In at least some systems, the frequency of [Ca²⁺]_i oscillations seems to be physiologically important. For example, in isolated pancreatic acinar cells, graded increases in the concentration of ACh produce graded increases in the *frequency*—but not the

magnitude—of repetitive $[Ca^{2+}]_i$ spikes. The mechanisms responsible for $[Ca^{2+}]_i$ oscillations and waves are complex. It appears that both propagation and oscillation depend on *positive*-feedback mechanisms, in which high $[Ca^{2+}]_i$ facilitates Ca^{2+} release, as well as on *negative*-feedback mechanisms, in which high $[Ca^{2+}]_i$ inhibits further Ca^{2+} release.

Structurally related to ITPRs are the Ca^{2+} -release channels known as **ryanodine receptors (RYRs)** (see p. 230). Because cytosolic Ca^{2+} activates RYRs, these channels play an important role in elevating $[Ca^{2+}]_i$ in certain cells by a process known as **calcium-induced Ca^{2+} release (CICR)** (see pp. 242–243)—an example of the positive feedback noted above. For example, RYRs are responsible for releasing Ca^{2+} from the *sarcoplasmic* reticulum of muscle and thereby switching on muscle contraction (see pp. 229–230). Moreover, **cyclic ADP ribose (cADPR)**, the product of ADP-ribosylcyclases, increases the sensitivity of RYR to cytosolic Ca^{2+} , thereby augmenting CICR.

$[Ca^{2+}]_i$ can increase as the result not only of Ca^{2+} release from intracellular stores, but also of enhanced influx through Ca^{2+} channels in the plasma membrane. By whatever mechanism, increased $[Ca^{2+}]_i$ exerts its effects by binding to cellular proteins and changing their activity, as discussed in the next two sections. Some Ca^{2+} -dependent signaling events are so sensitive to Ca^{2+} that a $[Ca^{2+}]_i$ increase of as little as 100 nM can trigger a vast array of cellular responses. These responses include secretion of digestive enzymes by pancreatic acinar cells, release of insulin by β cells, contraction of vascular smooth muscle, conversion of glycogen to glucose in the liver, release of histamine by mast cells, aggregation of platelets, and DNA synthesis and cell division in fibroblasts.

The same mechanisms that normally keep $[Ca^{2+}]_i$ at extremely low levels (see p. 126) are also responsible for reversing the increases in $[Ca^{2+}]_i$ that occur during signaling events. Increases in $[Ca^{2+}]_i$ activate an ATP-fueled Ca pump (SERCA; see p. 118) that begins pumping Ca^{2+} back into the ER. In addition, a Ca pump (see p. 118) and Na-Ca exchanger (see pp. 123–124) at the plasma membrane extrude excess Ca^{2+} from the cell. These processes are much slower than Ca^{2+} release, so $[Ca^{2+}]_i$ remains high until IP_3 is dephosphorylated, terminating Ca^{2+} release via ITPR and thereby allowing the transporters to restore $[Ca^{2+}]_i$ to basal levels.

Calcium activates calmodulin-dependent protein kinases

How does an increase in $[Ca^{2+}]_i$ lead to downstream responses in the signal-transduction cascade? The effects of changes in $[Ca^{2+}]_i$ are mediated by Ca^{2+} -binding proteins, the most important of which is **calmodulin (CaM)**. CaM is a high-affinity cytoplasmic Ca^{2+} -binding protein of 148 amino acids. Each molecule of CaM cooperatively binds four calcium ions. Ca^{2+} binding induces a major conformational change in CaM that allows it to bind to other proteins (Fig. 3-9). Although CaM does not have intrinsic enzymatic activity, it forms a complex with a number of enzymes and thereby confers a Ca^{2+} dependence on their activity. For example, binding of the Ca^{2+} -CaM complex activates the enzyme that degrades cAMP, cAMP phosphodiesterase.

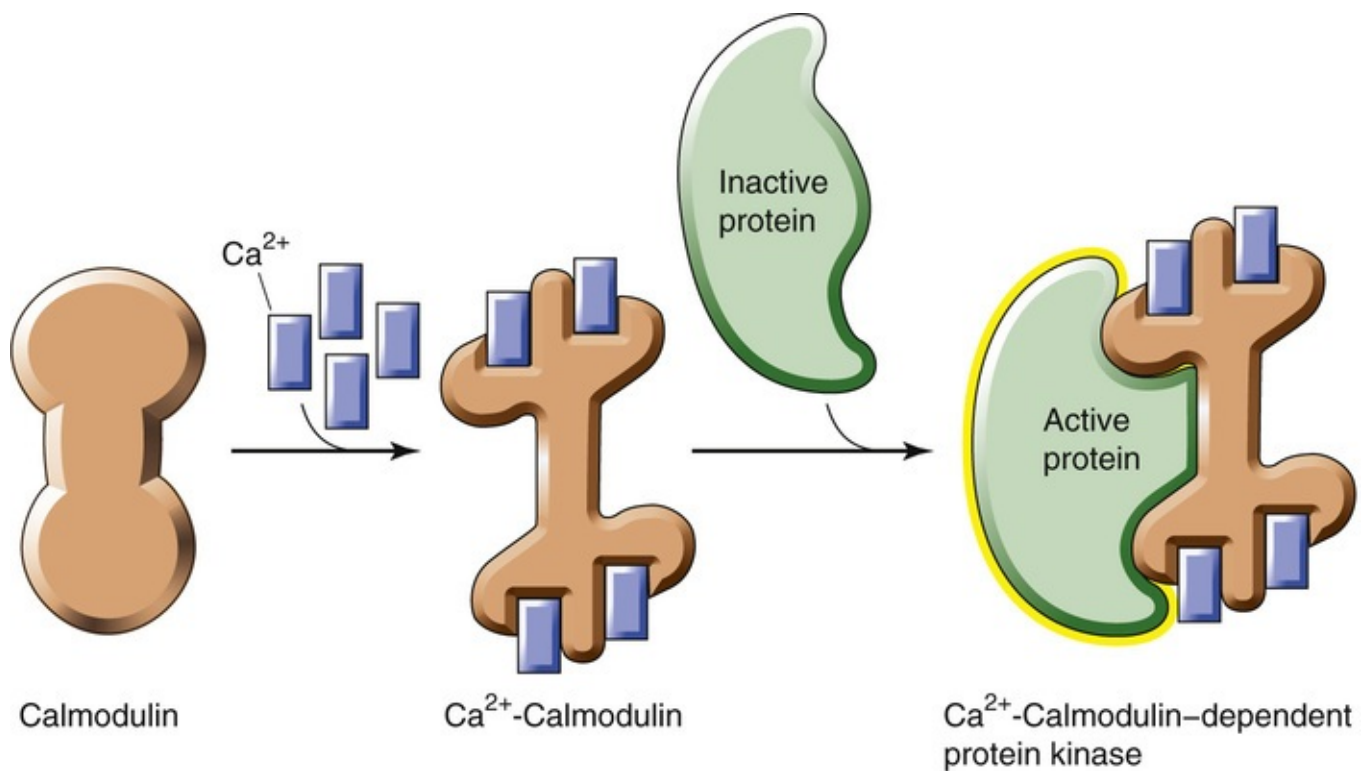

FIGURE 3-9 CaM. After four intracellular Ca²⁺ ions bind to CaM, the Ca²⁺-CaM complex can bind to and activate another protein. In this example, the activated protein is a Ca²⁺-CaM-dependent kinase.

Many of the effects of CaM occur as the Ca²⁺-CaM complex binds to and activates a family of Ca²⁺-CaM-dependent kinases known as **CaM kinases (CaMKs)**. These kinases phosphorylate specific serine and threonine residues of a variety of proteins. An important CaMK in smooth-muscle cells is myosin light-chain kinase (MLCK) (see p. 247). Another CaMK is glycogen phosphorylase kinase (PK), which plays a role in glycogen degradation (see p. 1182).

MLCK, PK, and some other CaMKs have a rather narrow substrate specificity. The ubiquitous CaM kinase II (CaMKII), on the other hand, has a broad substrate specificity. Especially high levels of this multifunctional enzyme are present at the synaptic terminals of neurons. One of the actions of CaMKII is to phosphorylate and thereby activate the rate-limiting enzyme (tyrosine hydroxylase; see Fig. 13-8) in the synthesis of catecholamine neurotransmitters. CaMKII can also phosphorylate itself, which allows it to remain active in the absence of Ca²⁺.

DAGs and Ca²⁺ activate protein kinase C

As noted above, hydrolysis of PIP₂ by PLC yields not only the IP₃ that leads to Ca²⁺ release from internal stores but also DAG (see Fig. 3-8A). The most important function of DAG is to activate **protein kinase C (PKC)**, an intracellular serine/threonine kinase. In mammals, the PKC family comprises at least 10 members that differ in their tissue and cellular localization. This family is further subdivided into three groups that all require membrane-associated phosphatidylserine but have different requirements for Ca²⁺ and DAG. The *classical* PKC family members PKCα, PKCβ, and PKCγ require both DAG and Ca²⁺ for activation, whereas the *novel* PKCs (such as PKCδ, PKCε, and PKCη) require DAG but are independent of Ca²⁺, and the *atypical* PKCs (PKCζ and PKCλ) appear to be independent of both DAG and Ca²⁺. As a consequence, the signals generated by the PKC pathway depend on the isoforms of the enzyme that a cell expresses as well as on the levels of Ca²⁺ and DAG at specific locations at the cell membrane. Moreover, proteins such as receptor for activated C-kinase (RACK) and receptor for inactivated C-kinase (RICK) can target specific PKC isoforms to specific cellular compartments.

In its basal state, PKC α is an inactive, soluble cytosolic protein. When a GPCR activates PLC, both DAG (generated in the inner leaflet of the plasma membrane) and Ca²⁺ (released in response to IP₃) bind to the PKC regulatory domain; this results in translocation of PKC α to the membrane and activation of the PKC kinase domain. Even though the initial Ca²⁺ signal is transient, PKC α activation can be sustained, resulting in activation of physiological responses, such as proliferation and differentiation. Elevated levels of active PKC α are maintained by a slow wave of elevated DAG (see Fig. 3-8B), which is due to the hydrolysis of PC by PLC and PLD.

Physiological stimulation of the classical and novel PKCs by DAG can be mimicked by the exogenous application of a class of tumor promoters called **phorbol esters**. These plant products bind to the regulatory domain of PKCs and thus specifically activate them even in the absence of DAG.

Among the major substrates of PKC are the myristoylated, alanine-rich C-kinase substrate proteins, known as **MARCKS proteins**. These acidic proteins contain consensus sites for PKC phosphorylation as well as CaM- and actin-binding sites. MARCKS proteins cross-link actin filaments and thus appear to play a role in translating extracellular signals into actin plasticity and changes in cell shape. Unphosphorylated MARCKS proteins are associated with the plasma membrane, and they cross-link actin. Phosphorylation of the MARCKS proteins causes them to translocate into the cytosol, where they are no longer able to cross-link actin. Thus, mitogenic growth factors that activate PKC may produce morphological changes and anchorage-independent cell proliferation in part by modifying the activity of MARCKS proteins.

PKC can also directly or indirectly modulate transcription factors and thereby enhance the transcription of specific genes (see p. 86). Such genomic actions of PKC explain why phorbol esters are tumor promoters.

G-Protein Second Messengers: Arachidonic Acid Metabolites

In addition to DAG, other hydrolysis products of membrane phospholipids can act as signaling molecules. **N3-10** The best characterized of these hydrolysis products is **arachidonic acid (AA)**, which is attached by an ester bond to the second carbon of the glycerol backbone of membrane phospholipids (Fig. 3-10). Phospholipase A₂ initiates the cellular actions of AA by releasing this fatty acid from glycerol-based phospholipids. **N3-11** A series of enzymes subsequently convert AA into a family of biologically active metabolites that are collectively called **eicosanoids** (from the Greek *eikosi* [20]) because, like AA, they all have 20 carbon atoms. Three major pathways can convert AA into these eicosanoids (Fig. 3-11). In the first pathway, cyclooxygenase (COX) enzymes produce *thromboxanes* (TXs), *prostaglandins* (PGs), and *prostacyclins*. In the second pathway, 5-lipoxygenase enzymes produce *leukotrienes* (LTs) and some *hydroxyeicosatetraenoic acid* (HETE) compounds. In the third pathway, the epoxygenase enzymes, which are members of the cytochrome P-450 class, produce other HETE compounds as well as *cis-epoxyeicosatrienoic acid* (EET) compounds. These three enzymes catalyze the stereospecific insertion of molecular O₂ into various positions in AA. The cyclooxygenases, lipoxygenases, and epoxygenases are selectively distributed in different cell types, which further increases the complexity of eicosanoid biology. Eicosanoids have powerful biological activities, including effects on allergic and inflammatory processes, platelet aggregation, vascular smooth muscle, and gastric acid secretion.

Eicosanoid Nomenclature

The nomenclature of the eicosanoids is not as arcane as it might first appear. The numerical subscript 2 (as in PGH_2) or 4 (as in LTA_4) refers to the number of double bonds in the eicosanoid backbone. For example, AA has four double bonds, as do the leukotrienes.

For the cyclooxygenase metabolites, the letter (A to I) immediately preceding the 2 refers to the structure of the 5-carbon ring that is formed about halfway along the 20-carbon chain of the eicosanoid. For the leukotrienes, the letters A and B that immediately precede the 4 refer to differences in the eicosanoid backbone. For the cysteinyl leukotrienes, the letter C refers to the full glutathione conjugate (see Fig. 46-8). Removal of glutamate from LTC_4 yields LTD_4 , and removal of glycine from LTD_4 yields LTE_4 , leaving behind only cysteine.

For 5-HPETE and 5-HETE, the fifth carbon atom (counting the carboxyl group as number 1) is derivatized with a hydroperoxy or hydroxy group, respectively.

FIGURE 3-10 Release of AA from membrane phospholipids by PLA₂. AA is esterified to membrane

phospholipids at the second carbon of the glycerol backbone. PLA₂ cleaves the phospholipid at the indicated position and releases AA as well as a lysophospholipid.

FIGURE 3-11 AA signaling pathways. In the direct pathway, an agonist binds to a receptor that activates PLA₂, which releases AA from a membrane phospholipid (see [Fig. 3-10](#)). In one of three indirect pathways, an agonist binds to a different receptor that activates PLC and thereby leads to the formation of DAG and IP₃, as in [Figure 3-8](#); DAG lipase then releases the AA from DAG. In a second indirect pathway, the IP₃ releases Ca²⁺ from internal stores, which leads to the activation of PLA₂ (see the direct pathway). In a third indirect pathway (not shown), MAPK stimulates PLA₂. Regardless of its source, the AA may follow any of three pathways to form a wide array of eicosanoids. The cyclooxygenase pathway produces

thromboxanes (TXA₂ and TXB₂), prostacyclin (i.e., PGI₂), and prostaglandins. The 5-lipoxygenase pathway produces 5-HETE and the leukotrienes. The epoxigenase pathway leads to the production of other HETEs and EETs. AACoA, arachidonic-Acid-coenzyme A; ASA, acetylsalicylic acid.

N3-10

Platelet-Activating Factor

Contributed by Ed Moczydlowski

Although it is not a member of the arachidonic acid (AA) family, platelet-activating factor (PAF) is an important lipid signaling molecule. PAF is an *ether* lipid that the cell synthesizes either de novo or by remodeling of a membrane-bound precursor. PAF occurs in a wide variety of organisms and mediates many biological activities. In mammals, PAF is a potent inducer of platelet aggregation and stimulates the chemotaxis and degranulation of neutrophils, thereby facilitating the release of LTB₄ and 5-HETE. PAF is involved in several aspects of allergic reactions; for example, it stimulates histamine release and enhances the secretion of immunoglobulin E, immunoglobulin A, and tumor necrosis factor. Endothelial cells are also an important target of PAF; PAF causes a negative shift of V_m in these cells by activating Ca²⁺-dependent K⁺ channels. PAF also enhances vascular permeability and the adhesion of neutrophils and platelets to endothelial cells.

PAF exerts its effects by binding to a specific receptor on the plasma membrane. A major consequence of PAF binding to its GPCR is formation of IP₃ and stimulation of a group of MAPKs. PAF acetylhydrolase terminates the action of this signaling lipid.

N3-11

Phospholipase A₂

Contributed by Laurie Roman

Phospholipase A₂ (PLA₂) catalyzes the hydrolytic cleavage of glycerol-based phospholipids (see Fig. 2-2A–C) at the second carbon of the glycerol backbone, yielding AA and a lysophospholipid (see Fig. 3-10). Some of the cytosolic PLA₂ enzymes require Ca²⁺ for activity. In addition, raising [Ca²⁺]_i from the physiological level of ~100 nM to ~300 nM facilitates the association of cytoplasmic PLA₂ with cell membranes, where the PLA₂ can be activated by specific G proteins.

Phospholipase A₂ is the primary enzyme responsible for releasing AA

The first step in the **phospholipase A₂ (PLA₂)** signal-transduction cascade is binding of an extracellular agonist to a membrane receptor (see Fig. 3-11). These receptors include those for serotonin (5-HT₂ receptors), glutamate (mGLUR1 receptors), fibroblast growth factor-β, interferon-α (IFN-α), IFN-β, and IFN-γ. Once the receptor is occupied by its agonist, it can activate a G protein that belongs to the G_i/G_o family. The mechanism by which this activated G protein stimulates PLA₂ is not well understood. It does not appear that a G-protein α subunit is involved. The G-protein βγ dimer may stimulate PLA₂ either directly or via **mitogen-activated protein kinases (MAPKs)** (see p. 69), which phosphorylates PLA₂ at

a serine residue. The result is rapid hydrolysis of phospholipids that contain AA.

In contrast to the *direct* pathway just mentioned, agonists acting on other receptors may promote AA release indirectly. First, a ligand may bind to a receptor coupled to PLC, which would lead to the release of DAG (see Fig. 3-11). As noted above, DAG lipase can cleave DAG to yield AA and a monoacylglycerol (MAG). Agonists that act via this pathway include dopamine (D2 receptors), adenosine (A_1 receptors), norepinephrine (α_2 adrenergic receptors), and serotonin (5-HT₁ receptors). Second, any agonist that raises $[Ca^{2+}]_i$ can promote AA formation because Ca^{2+} can stimulate some cytosolic forms of PLA₂. Third, any signal-transduction pathway that activates MAPK can also enhance AA release because MAPK phosphorylates PLA₂.

Cyclooxygenases, lipoxygenases, and epoxygenases mediate the formation of biologically active eicosanoids

Once it is released from the membrane, AA can diffuse out of the cell, be reincorporated into membrane phospholipids, or be metabolized (see Fig. 3-11).

In the first pathway of AA metabolism (see Fig. 3-11), **cyclooxygenases**  **N3-12** catalyze the stepwise conversion of AA into the intermediates prostaglandin G₂ (PGG₂) and prostaglandin H₂ (PGH₂). PGH₂ is the precursor of the other **prostaglandins**, the **prostacyclins** and the **thromboxanes**. As noted in Box 3-3, cyclooxygenase exists in two predominant isoforms, cyclooxygenase 1 (COX-1) and COX-2, as well as the COX-1b splice variant of COX-1. In many cells, COX-1 is expressed in a constitutive fashion, whereas COX-2 levels can be induced by specific stimuli. For example, in monocytes stimulated by inflammatory agents such as interleukin-1 β (IL-1 β), only levels of COX-2 increase. These observations have led to the concept that expression of COX-1 is important for homeostatic prostaglandin functions such as platelet aggregation and regulation of vascular tone, whereas upregulation of COX-2 is primarily important for mediating prostaglandin-dependent inflammatory responses. However, as selective inhibitors of COX-2 have become available, it has become clear that this is an oversimplification.

Box 3-3

Therapeutic Inhibition of Cyclooxygenase Isoforms

Cyclooxygenase is a bifunctional enzyme that first oxidizes AA to PGG₂ through its *cyclooxygenase* activity and then *peroxidizes* this compound to PGH₂. X-ray crystallographic studies of **COX-1** reveal that the sites for the two enzymatic activities (i.e., cyclooxygenase and peroxidase) are adjacent but spatially distinct. The cyclooxygenase site is a long hydrophobic channel. **Aspirin** (acetylsalicylic acid) irreversibly inhibits COX-1 by acetylating a serine residue at the top of this channel. Several of the other **NSAIDs** interact, via their carboxyl groups, with other amino acids in the same region.

COX-1 activation plays an important role in intravascular thrombosis because it leads to **TXA₂** synthesis by platelets. Inhibition of this process by low-dose aspirin is a mainstay for prevention of coronary thrombosis in patients with atherosclerotic coronary artery disease. However, COX-1 activation is also important for producing the cytoprotective prostanoids PGE₂ (a prostaglandin) and PGI₂ (a prostacyclin) in the gastric mucosa. It is the loss of these compounds that can lead to the unwanted side effect of gastrointestinal bleeding after long-term aspirin use.  **N3-15**

Side Effects of Cyclooxygenase Inhibitors

Contributed by Emile Boulpaep, Walter Boron

Both COX-1 and COX-2 appear to be required for production of PGE₂ in the renal glomerulus, a process that is important in maintaining normal glomerular perfusion in the event of decreased renal blood flow. Thus, another risk of cyclooxygenase inhibitors is diminished renal function in patients with heart failure or volume depletion.

Similar to the nonselective cyclooxygenase inhibitors, COX-2 inhibitors have been shown to decrease renal perfusion and increase the risk of hemodynamic acute renal failure in susceptible individuals.

Reference

Schnermann J, Chou C-L, Ma T, et al. Defective proximal tubular fluid reabsorption in transgenic aquaporin-1 null mice. *Proc Natl Acad Sci U S A*. 1998;95:9660–9664.

Inflammatory stimuli induce **COX-2** in a number of cell types, and it is inhibition of COX-2 that provides the anti-inflammatory actions of high-dose aspirin (a weak COX-2 inhibitor) and other nonselective cyclooxygenase inhibitors such as **ibuprofen**. Because the two enzymes are only 60% homologous, pharmaceutical companies have now generated compounds that specifically inhibit COX-2, such as **celecoxib**. COX-2 inhibitors work well as anti-inflammatory agents and have a reduced likelihood of causing gastrointestinal bleeding because they do not inhibit COX-1–dependent prostacyclin production. COX-2 inhibitors have been reported to increase the risk of thrombotic cardiovascular events when they are taken for long periods.

Cyclooxygenase

Contributed by Laurie Roman

Cyclooxygenase catalyzes the stepwise conversion of AA into the intermediates PGG₂ and PGH₂. Thus, this enzyme is also referred to as prostaglandin H synthetase (PGHS). As noted in Box 3-3, it is the same enzyme that catalyzes both reactions. Cyclooxygenase exists in three isoforms, COX-1 (a transcript of 2.8 kilobases [kb]), COX-2 (a 4.1-kb transcript), and COX-3 (a splice variant of COX-1 that is also known as COX-1b).

In the second pathway of AA metabolism, **5-lipoxygenase** initiates the conversion of AA into biologically active **leukotrienes**. For example, in myeloid cells, 5-lipoxygenase converts AA to 5-hydroperoxyeicosatetraenoic acid (5-HPETE),  **N3-13** which is short-lived and rapidly degraded by a peroxidase to the corresponding alcohol 5-HETE. Alternatively, a dehydrase can convert 5-HPETE to an unstable epoxide, leukotriene A₄ (LTA₄), which can be either further metabolized by LTA₄ hydrolase to LTB₄ or coupled (“conjugated”) by LTC₄ synthase to the tripeptide glutathione (see [p. 955](#)). This conjugation—via the cysteine residue of glutathione—yields LTC₄. Enzymes sequentially remove portions

of the glutathione moiety to produce LTD₄ and LTE₄. LTC₄, LTD₄, and LTE₄ are the “cysteinyl” leukotrienes; they participate in allergic and inflammatory responses and make up the mixture previously described as the **slow-reacting substance of anaphylaxis**.

N3-13

Names of Arachidonic Acid Metabolites

Contributed by Emile Boulpaep, Walter Boron

5-HPETE = 5-*S*-hydroperoxy-6-8-*trans*-11,14-*cis*-eicosatetraenoic acid

5-HETE = 5-hydroxyeicosatetraenoic acid

EET = *cis*-epoxyeicosatrienoic acid

The third pathway of AA metabolism begins with the transformation of AA by **epoxygenase** (a cytochrome P-450 oxidase). 🟡 N3-14 Molecular O₂ is a substrate in this reaction. The epoxygenase pathway converts AA into two major products, **HETEs** and **EETs**. Members of both groups display a diverse array of biological activities. Moreover, the cells of different tissues (e.g., liver, kidney, eye, and pituitary) use different biosynthetic pathways to generate different epoxygenase products.

N3-14

Epoxygenase

Contributed by Emile Boulpaep, Walter Boron

As shown in Figure 3-11, one pathway of arachidonic-acid (AA) metabolism begins with the transformation of AA by **epoxygenase** (a cytochrome P-450 oxidase) to two major products: **HETEs** and **EETs**. Epoxygenase requires molecular oxygen (i.e., it is an oxidase) and has several required cofactors, including cytochrome P-450 reductase, NADPH/NADP⁺ (reduced/oxidized forms of nicotinamide adenine dinucleotide phosphate), or NADH/NAD⁺ (reduced/oxidized forms of nicotinamide adenine dinucleotide).

Prostaglandins, prostacyclins, and thromboxanes (cyclooxygenase products) are vasoactive, regulate platelet action, and modulate ion transport 🟡 N3-16

The metabolism of PGH₂ to generate selected prostanoid derivatives is cell specific. For example, platelets convert PGH₂ to **thromboxane A₂ (TXA₂)**, a short-lived compound that can aggregate platelets, bring about the platelet release reaction, and constrict small blood vessels. In contrast, endothelial cells convert PGH₂ to **prostacyclin I₂ (PGI₂)**, which *inhibits* platelet aggregation and *dilates* blood vessels. Many cell types convert PGH₂ to prostaglandins. Acting locally in a paracrine or autocrine fashion, **prostaglandins** are involved in such processes as platelet aggregation, airway constriction, renin release, and inflammation. 🟡 N3-16 Prostaglandin synthesis has also been implicated in the pathophysiological

mechanism of cardiovascular disease, cancer, and inflammatory diseases. **Nonsteroidal anti-inflammatory drugs (NSAIDs)** such as aspirin, acetaminophen, ibuprofen, indomethacin, and naproxen directly target cyclooxygenase. NSAID inhibition of cyclooxygenase is a useful tool in the treatment of inflammation and fever and, at least in the case of aspirin, in the prevention of heart disease.

N3-16

Actions of Prostanoids

Contributed by Laurie Roman

The prostanoids may participate in regulation of the Na-K pump, which plays a central role in salt and water transport in the kidney and the maintenance of ion gradients in all cell types. For example, the inhibition of the Na-K pump produced by IL-1 appears to be mediated by the formation of PGE₂. Indeed, IL-1 stimulates the formation of PGE₂, and application of exogenous PGE₂ inhibits Na-K pump activity directly. Moreover, cyclooxygenase blockers prevent the Na-K pump inhibition induced by IL-1. This action on the Na-K pump is not limited to the kidney; AA metabolites also inhibit the pump in the brain.

Prostaglandins also are vasoactive and are important in the regulation of renal blood flow.

The diverse cellular responses to prostanoids are mediated by a family of G protein–coupled **prostanoid receptors**. This family currently has nine proposed members, including receptors for thromboxane/PGH₂ (TP), PGI₂ (IP), PGE₂ (EP₁ to EP₄), PGD₂ (DP and CRTH2), and PGF_{2α} (FP). These prostanoid receptors signal via G_q, G_i, or G_s, depending on cell type. These in turn regulate intracellular adenylyl cyclase (see p. 53) and phospholipases (see p. 58).

The leukotrienes (5-lipoxygenase products) play a major role in inflammatory responses

Many lipoxygenase metabolites of AA have a role in allergic and inflammatory diseases (Table 3-3). **N3-17** LTB₄ is produced by inflammatory cells such as neutrophils and macrophages. The cysteinyl leukotrienes including LTC₄ and LTE₄ are synthesized by mast cells, basophils, and eosinophils, cells that are commonly associated with allergic inflammatory responses such as **asthma** and **urticaria**.

Box 3-4

Role of Leukotrienes in Disease

Since the original description of the slow-reacting substance of anaphylaxis, which is generated during antigenic challenge of a sensitized lung, leukotrienes have been presumed to play a part in allergic disease of the airways (see Table 3-3). The involvement of cells (mast cells, basophils, and eosinophils) that produce cysteinyl leukotrienes (LTC₄ through LTF₄) in these pathobiological processes supports this concept. In addition, the levels of LTC₄, LTD₄, and LTE₄ are increased in lavage fluid from the nares of patients with allergic rhinitis after the application of specific antigens to the nasal airways. Introducing LTC₄ or LTD₄ into the airways as an aerosol (nebulizer concentration of only 10 μM) causes maximal expiratory airflow (a rough measure of airway resistance; see p. 602) to decline by ~30%. This bronchoconstrictor effect is 1000-fold more potent than that of histamine, the “reference” agonist.

Leukotrienes affect both large and small airways; histamine affects relatively smaller airways. Activation of the cysLT1 receptor in mast cells and eosinophils results in the chemotaxis of these cells to sites of inflammation. Because antagonists of the cysLT1 receptor (e.g., **montelukast sodium**) can partially block these bronchoconstrictive and proinflammatory effects, these agents are useful in the treatment of allergen-induced asthma and rhinitis.

In addition to being involved in allergic disease, several of the leukotrienes are associated with other inflammatory disorders. Synovial fluid from patients with **rheumatoid arthritis** contains 5-lipoxygenase products. Another example is the skin disease **psoriasis**. In patients with active psoriasis, LTB₄, LTC₄, and LTD₄ have been recovered from skin chambers overlying abraded lesions. Leukotrienes also appear to be involved in inflammatory bowel disease. LTB₄ and other leukotrienes are generated and released in vitro from intestinal mucosa obtained from patients with **ulcerative colitis** or **Crohn disease**.

TABLE 3-3
Involvement of Leukotrienes in Human Disease

DISEASE	EVIDENCE
Asthma	Bronchoconstriction from inhaled LTE ₄ ; identification of LTC ₄ , LTD ₄ , and LTE ₄ in serum or urine or both
Psoriasis	Detection of LTB ₄ and LTE ₂ in fluids from psoriatic lesions
Adult respiratory distress syndrome (ARDS)	Elevated levels of LTB ₄ in plasma
Allergic rhinitis	Elevated levels of LTB ₄ in nasal fluids
Gout	Detection of LTB ₄ in joint fluid
Rheumatoid arthritis	Elevated levels of LTB ₄ in joint fluids and serum
Inflammatory bowel disease (ulcerative colitis and Crohn disease)	Identification of LTB ₄ in gastrointestinal fluids and LTE ₄ in urine

N3-17

Actions of Leukotrienes

Contributed by Laurie Roman

LTC₄, LTD₄, LTE₄, and LTF₄ are often referred to as the “cysteinyl leukotrienes” or sometimes as the “peptidyl leukotrienes.” As summarized in Figure 3-11, the enzyme **glutathione-S-transferase** (GST) conjugates LTA₄, which is unstable, to the sulfhydryl group of the cysteine in glutathione (glutathione, also abbreviated GSH, is the branched tripeptide Glu-Cys-Gly) to produce LTC₄. (See page 955 to learn how the liver uses GSH for conjugation reactions.) The enzyme **γ-glutamyl transferase** clips off the glutamate residue of LTC₄ to produce LTD₄ (which is conjugated to -Cys-Gly). A **dipeptidase** clips the dipeptide bond between Cys and Gly to release the terminal Gly as well as LTE₄ (which is conjugated to only the -Cys).

Leukotrienes have multiple effects on the vascular endothelium during inflammation. Various regulatory processes may interact at the level of the small blood vessels to increase the margination (i.e., the attachment to the vessel wall) of subgroups of leukocytes, increase the permeability at the postcapillary venule, and evoke diapedesis (i.e., the migration of the cell through the endothelium) of the adherent leukocytes to create a focus of interstitial inflammation. Each of these steps can be affected by leukotrienes as well as other agents.

The infiltration of leukocytes begins when the cells adhere to the endothelium of the postcapillary venule. Mediators that can increase the adhesiveness of leukocytes include LTB₄ and several of the

cysteinyl leukotrienes. Increased vascular permeability, influenced by the pulling apart of adjacent endothelial cells, can occur in response to LTC₄, LTD₄, and LTE₄. After adherent leukocytes accumulate—and the size of the interendothelial cell pores increases—a stimulus for diapedesis produces an influx of leukocytes into the interstitial space. Once in the interstitial space, the leukocytes come under the influence of LTB₄, a potent chemotactic factor (i.e., chemical attractant) for neutrophils (a type of white blood cell that phagocytoses invading organisms) and less so for eosinophils (another type of white blood cell). LTB₄ is also chemokinetic (i.e., speeds up chemotaxis) for eosinophils.

In the lungs, the cysteinyl leukotrienes appear to stimulate the secretion of mucus by the bronchial mucosa. Nanomolar concentrations of LTC₄ and LTD₄ stimulate the contraction of the smooth muscles of bronchi as well as smaller airways.

Both LTB₄ (generated by a hydrolase from the unstable LTA₄) and the cysteinyl leukotrienes (i.e., LTC₄, LTD₄, and LTE₄) act as growth or differentiation factors for a number of cell types in vitro. LTB₄ stimulates myelopoiesis (formation of white blood cells) in human bone marrow, whereas LTC₄ and LTD₄ stimulate the proliferation of glomerular epithelial cells in the kidney. Picomolar concentrations of LTB₄ stimulate the differentiation of a particular type of T lymphocytes referred to as competent suppressor or CD8⁺ lymphocytes. Additional immunological regulatory functions that may be subserved by LTB₄ include the stimulation of IFN-γ and IL-2 production by T cells.

The **cysteinyl leukotriene receptors** cysLT1 and cysLT2 are GPCRs found on airway smooth-muscle cells as well as on eosinophils, mast cells, and lymphocytes. CysLT1, which couples to both pertussis toxin-sensitive and pertussis toxin-insensitive G proteins, mediates phospholipase-dependent increases in [Ca²⁺]_i. In the airways, these events produce a potent bronchoconstriction, whereas activation of the receptor in mast cells and eosinophils causes release of the proinflammatory cytokines histamine and tumor necrosis factor-α (TNF-α).

In addition to playing a role in the inflammatory response, the lipoxygenase metabolites can also influence the activity of many ion channels, either directly or by regulating protein kinases. For example, in synaptic nerve endings, lipoxygenase metabolites decrease the excitability of cells by activating K⁺ channels. Lipoxygenase products may also regulate secretion. In pancreatic islet cells, free AA generated in response to glucose appears to be part of a negative-feedback loop that prevents excess insulin secretion by inhibiting CaM kinase II.

The HETEs and EETs (epoxygenase products) tend to enhance Ca²⁺ release from intracellular stores and to enhance cell proliferation

The epoxygenase pathway leads to the production of HETEs other than 5-HETE as well as EETs. HETEs and EETs have been implicated in a wide variety of processes, some of which are summarized in [Table 3-4](#). For example, in stimulated mononuclear leukocytes, **HETEs** enhance Ca²⁺ release from intracellular stores and promote cell proliferation. In smooth-muscle cells, HETEs increase proliferation and migration; these AA metabolites may be one of the primary factors involved in the formation of atherosclerotic plaque. In blood vessels, HETEs can be potent vasoconstrictors. **EETs** enhance the release of Ca²⁺ from intracellular stores, increase Na-H exchange, and stimulate cell proliferation. In blood vessels, EETs primarily induce vasodilation and angiogenesis, although they have vasoconstrictive properties in the smaller pulmonary blood vessels.

TABLE 3-4
Actions of Epoxygenase Products

	CELL/TISSUE	ACTION
HETEs	Stimulated mononuclear leukocytes	↑ Cell proliferation ↑ Ca ²⁺ release from intracellular stores ↓ TNFα production
	β cells of pancreatic islets	Implicated in the destruction of these cells in type 1 (juvenile-onset) diabetes mellitus
	Endothelial cells	↓ Release of fibrinolytic factors ↓ Binding of antithrombin
	Vascular smooth-muscle cells	↑ Cell proliferation ↑ Migration Formation of atherosclerotic plaque?
	Blood vessels	Potent vasoconstrictors “Myogenic” vasoconstrictive response of renal and cerebral arteries
EETs	Cells, general	↑ Ca ²⁺ release from intracellular stores ↑ Na-H exchange ↑ Cell proliferation ↓ Cyclooxygenase activity
	Endocrine cells	↓ Release of somatostatin, insulin, glucagon
	Toad bladder	↓ Vasopressin-stimulated H ₂ O permeability ↓ Renin release
	Blood vessels	Vasodilation Angiogenesis
	Endothelium	↑ Tumor cell adhesion
	Platelets	↓ Aggregation

Degradation of the eicosanoids terminates their activity

Inactivation of the products of eicosanoids is an important mechanism for terminating their biological action. In the case of COX products, the enzyme 15-hydroxyprostaglandin dehydrogenase catalyzes the initial reactions that convert biologically active prostaglandins into their inactive 15-keto metabolites. This enzyme also appears to be active in the catabolism of thromboxanes.

As far as the 5-lipoxygenase products are concerned, the specificity and cellular distribution of the enzymes that metabolize leukotrienes parallel the diversity of the enzymes involved in their synthesis. For example, 20-hydrolase-LTB₄, a member of the P-450 family, catalyzes the ω-oxidation of LTB₄, thereby terminating its biological activity. LTC₄ is metabolized through two pathways. One oxidizes the LTC₄. The other pathway first removes the glutamic acid residue of the conjugated glutathione, which yields LTD₄, and then removes the glycine residue, which yields LTE₄; the latter is readily excreted into the urine.

The metabolic breakdown of the HETE and EET products of epoxygenase (cytochrome P-450) is rapid and complex. The predominant pathway of inactivation appears to be hydrolysis via soluble epoxide hydrolase to form dihydroxyeicosatrienoic acids (DHETs), which themselves can induce biological responses, such as vasodilation. Once formed, DHETs can be excreted intact in the urine or can form conjugates with reduced glutathione (GSH). In addition, both EETs and DHETs can undergo β-oxidation to form epoxy fatty acids or can be metabolized by cyclooxygenase to generate various prostaglandin analogs.

Receptors That are Catalytic

A number of hormones and growth factors bind to cell-surface proteins that have—or are associated with—enzymatic activity on the cytoplasmic side of the membrane. Here we discuss five classes of such catalytic receptors (Fig. 3-12):

1. **Receptor guanylyl cyclases** catalyze the generation of cGMP from GTP.
2. **Receptor serine/threonine kinases** phosphorylate serine or threonine residues on cellular proteins
3. **Receptor tyrosine kinases (RTKs)** phosphorylate tyrosine residues on themselves and other proteins.
4. **Tyrosine kinase–associated receptors** interact with cytosolic (i.e., not membrane-bound) tyrosine kinases.
5. **Receptor tyrosine phosphatases** cleave phosphate groups from tyrosine groups of cellular proteins.

FIGURE 3-12 Catalytic receptors. **A**, Receptor guanylyl cyclases have an extracellular ligand-binding domain. **B**, Receptor serine/threonine kinases have two subunits. The ligand binds only to the type II subunit. **C**, RTKs similar to the NGF receptor dimerize on binding a ligand. **D**, Tyrosine kinase–associated receptors have no intrinsic enzyme activity but associate noncovalently with soluble nonreceptor tyrosine kinases. **E**, Receptor tyrosine phosphatases have intrinsic tyrosine phosphatase activity.

The receptor guanylyl cyclase transduces the activity of atrial natriuretic peptide, whereas a soluble guanylyl cyclase transduces the activity of nitric oxide

Receptor (Membrane-Bound) Guanylyl Cyclase

Some of the best-characterized examples of a transmembrane protein with guanylyl cyclase activity (see Fig. 3-12A) are the receptors for the natriuretic peptides. **N3-18** These ligands are a family of related small proteins (~28 amino acids) including **atrial natriuretic peptide (ANP)**, B-type or brain natriuretic peptide (BNP), and C-type natriuretic peptide (CNP). For example, in response to atrial and ventricular stretch that occur with intravascular volume expansion, cardiac myocytes release ANP and BNP, which act through receptor guanylyl cyclases. Their action is to relax vascular smooth muscle and dilate blood vessels (see ANP in Table 20-7, and p. 553) as well as to enhance Na⁺ excretion into urine (natriuresis; see p. 843). Both activities contribute to lowering of effective circulating blood volume and thus blood pressure (see pp. 554–555).

N3-18

Atrial Natriuretic Peptide

Contributed by Emile Boulpaep

Granular inclusions in atrial myocytes, called Palade bodies, contain pro-ANP, the precursor of **atrial natriuretic peptide (ANP)**; also called atrial natriuretic factor, ANF). Pro-ANP, comprising 126 amino acids, is derived from the precursor known as prepro-ANP (151 residues in the human). The converting enzyme **corin**—a cardiac transmembrane serine protease—cleaves the pro-ANP during or after release from the atria, which yields the inactive N-terminal fragment of 98 residues and the active C-terminal 28-amino-acid peptide called **ANP**. Release is primarily caused by stretch of the atrial myocytes. Hormones such as angiotensin, endothelins, arginine vasopressin, and glucocorticoid modulate ANP expression and release. It is noteworthy that expression of corin is reduced in heart failure, which blunts the release of ANP in the failing heart. This blunting might contribute to the inappropriate increase of extracellular fluid volume in heart failure.

ANP is a member of the NP (natriuretic peptide) family of peptides. The biological effects of ANP are potent vasodilation, diuresis, natriuresis, and kaliuresis, as well as inhibition of the renin-angiotensin-aldosterone system.

At least three types of **natriuretic peptide receptors (NPRs)** exist: NPRA (also called GC-A—GC for guanylyl cyclase), NPRB (also called GC-B), and NPR-C. **NPRA** and **NPRB** are receptors with a single transmembrane domain coupled to a cytosolic guanylyl cyclase (see p. 66). Activation of NPRA or NPRB leads to the intracellular generation of cGMP. In smooth muscle, intracellular cGMP activates the cGMP-dependent protein kinase that phosphorylates MLCK. Phosphorylation of MLCK inactivates MLCK; this leads to the dephosphorylation of myosin light chains, which allows muscle relaxation.

The ANP C-type receptor **NPRC** is not coupled to a messenger system but serves mainly to clear the natriuretic peptides from the circulation.

The heart, brain, pituitary, and lung synthesize an ANP-like compound termed **BNP**, originally known as **brain natriuretic peptide** (32 residues in the human). The biological actions of BNP are similar to those of ANP.

The hypothalamus, pituitary, and kidney synthesize **C-type natriuretic peptide** or **CNP**, which is highly homologous to ANP and BNP. CNP binds only to NPRB and is only a weak natriuretic but a strong vasodilator.

The kidney also synthesizes an ANP-like natriuretic compound known as **urodilatin** or **URO**. URO has four additional amino acids compared to ANP and also binds to the ANP A-type receptor. Its biological effect in the target tissue is also transduced by cGMP.

Natriuretic peptide receptors NPRA and NPRB are membrane proteins with an extracellular ligand-binding domain and a single membrane-spanning segment (see Fig. 3-12A). The intracellular domain has two consensus catalytic domains for guanylyl cyclase activity. Binding of a natriuretic peptide induces a conformational change in the receptor that causes receptor dimerization and activation. Thus, binding of ANP to its receptor causes the conversion of GTP to cGMP and raises intracellular levels of cGMP. In turn, cGMP activates a **cGMP-dependent kinase** (PKG or cGK) that phosphorylates proteins at certain serine and threonine residues. In the renal medullary collecting duct, the cGMP generated in response to ANP may act not only via PKG but also by directly modulating ion channels (see p. 768).

Soluble Guanylyl Cyclase

In contrast to the receptor guanylyl cyclase, which is activated by ANP, the cytosolic soluble guanylyl cyclase (sGC) is activated by **nitric oxide (NO)**. This sGC is unrelated to the receptor guanylyl cyclase and contains a heme moiety that binds NO.

NO is a highly reactive, short-lived free radical. This dissolved gas arises from a family of **NO synthase (NOS)** enzymes that catalyze the reaction

Here, NADPH and NADP⁺ are the reduced and oxidized forms of nicotinamide adenine dinucleotide phosphate, respectively. Tetrahydrobiopterin is a cofactor. The NOS family includes neuronal or nNOS (NOS1), inducible or iNOS (NOS2), and endothelial or eNOS (NOS3). nNOS and iNOS are soluble enzymes, whereas eNOS is linked to the plasma membrane. The activation of NOS begins as an extracellular agonist (e.g., ACh) binds to a plasma-membrane receptor, triggering the entry of Ca²⁺, which binds to cytosolic CaM and then stimulates NOS. In smooth muscle, NO stimulates the sGC, which then converts GTP to cGMP, activating PKG, which leads to smooth-muscle relaxation.

Why NO is so ubiquitous and when its release is important are not known. However, abnormalities of the NO system are involved in the pathophysiological processes of adult respiratory distress syndrome, high-altitude pulmonary edema, stroke, and other diseases. For example, the importance of NO in the control of blood flow had long been exploited unwittingly to treat **angina pectoris**. Angina is the classic chest pain that accompanies inadequate blood flow to the heart muscle, usually as a result of coronary artery atherosclerosis. Nitroglycerin relieves this pain by spontaneously breaking down and releasing NO, which relaxes the smooth muscles of peripheral arterioles, thereby reducing the work of the heart and relieving the associated pain. Understanding the physiological and pathophysiological roles of NO has led to the introduction of clinical treatments that modulate the NO system. In addition to the use of NO generators for treatment of angina, examples include the use of gaseous NO for treatment of pulmonary

edema and inhibitors of cGMP phosphodiesterase (see p. 53) such as sildenafil (Viagra) for treatment of erectile dysfunction.

In addition to acting as a chemical signal in blood vessels, NO generated by iNOS appears to play an important role in the destruction of invading organisms by macrophages and neutrophils. NO generated by nNOS also serves as a neurotransmitter (see pp. 315–317) and may play a role in learning and memory.

The importance of the NO signaling pathway was recognized by the awarding of the 1998 Nobel Prize for Physiology or Medicine to R.F. Furchgott, L.J. Ignarro, and F. Murad for their discoveries concerning NO as a signaling molecule in the cardiovascular system. 🍷 **N3-18A**

Robert F. Furchgott, Louis J. Ignarro, and Ferid Murad

For more information about Robert F. Furchgott, Louis J. Ignarro, and Ferid Murad and the work that led to their Nobel Prize, visit http://www.nobelprize.org/nobel_prizes/medicine/laureates/1998/ (Accessed March 2015).

Some catalytic receptors are serine/threonine kinases

We have already discussed how activation of various G protein–linked receptors can initiate a cascade that eventually activates kinases (e.g., PKA, PKC) that phosphorylate proteins at serine and threonine residues. In addition, some receptors are *themselves* serine/threonine kinases—such as the one for transforming growth factor- β (TGF- β)—and are thus catalytic receptors.

The TGF- β superfamily includes a large group of cytokines, including five TGF- β s, antimüllerian hormone (see p. 1080), as well as the inhibins and activins (see p. 1113), bone morphogenic proteins, and other glycoproteins, all of which control cell growth and differentiation. Members of this family participate in embryogenesis, suppress epithelial-cell growth, promote wound repair, and influence immune and endocrine functions. Unchecked TGF- β signaling is important in progressive fibrotic disorders (e.g., liver cirrhosis, idiopathic pulmonary fibrosis) that result in replacement of normal organ tissue by deposits of collagen and other matrix components.

The receptors for TGF- β and related factors are glycoproteins with a single membrane-spanning segment and intrinsic serine/threonine-kinase activity. Receptor types I and II (see Fig. 3-12B) are required for ligand binding and catalytic activity. The **type II receptor** first binds the ligand, and this binding is followed by the formation of a stable ternary complex of ligand, type II receptor, and type I receptor. After recruitment of the **type I receptor** into the complex, the type II receptor phosphorylates the type I receptor, thereby activating the serine/threonine kinase activity of the type I receptor. The principal targets of this kinase activity are SMAD proteins, which fall into three groups. 🍷 **N3-19** The largest group is the receptor-activated SMADs (SMADs 1, 2, 3, 5, and 8), which—after phosphorylation by activated type I receptors—association with SMAD4, the only member of the second group. This heterodimeric complex translocates to the nucleus, where it regulates transcription of target genes. The third group (SMAD6, SMAD7) is the inhibitory SMADs, which can bind to type I receptors and prevent the phosphorylation of the receptor-activated SMADs.

N3-19

SMADs

The largest group of SMAD proteins is the receptor-activated SMADs (SMADs 1, 2, 3, 5, and 8), which have a type I receptor-interacting domain that is phosphorylated by the activated type I receptor; this phosphorylation results in their disassociation from the receptor and subsequent association with the regulatory SMAD, SMAD4. This heterodimeric complex translocates to the nucleus where it can regulate transcription of target genes by both direct and indirect mechanisms.

The signaling specificity of this system comes from two mechanisms. First, distinct members of the receptor-activated SMAD group interact with specific type I receptors. For example SMAD2 and SMAD3 associate with the TGF- β type I receptor ALK-5, whereas SMAD1 associates with bone morphogenic protein (BMP) type I receptors such as ALK-2 and ALK-3. Second, the receptor-activated SMAD/SMAD4 heterodimer regulates not only downstream effector gene expression but also the expression of a third group of SMADs, the inhibitory SMADs. These proteins (SMAD6, SMAD7), once expressed, can bind to type I receptors and prevent the association and activation of receptor-activated SMADs.

RTKs produce phosphotyrosine motifs recognized by SH2 and phosphotyrosine-binding domains of downstream effectors

In addition to the class of receptors with intrinsic *serine/threonine* kinase activity, other plasma-membrane receptors have intrinsic *tyrosine* kinase activity. All **RTKs** discovered to date phosphorylate themselves in addition to other cellular proteins. Epidermal growth factor (EGF), platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), insulin and insulin-like growth factor type 1 (IGF-1), fibroblast growth factor (FGF), and nerve growth factor (NGF) can all bind to receptors that possess intrinsic tyrosine kinase activity.

Creation of Phosphotyrosine Motifs

Most RTKs are single-pass transmembrane proteins that have an extracellular ligand-binding domain and a single intracellular kinase domain (see [Fig. 3-12C](#)). Binding of a ligand, such as NGF, facilitates the formation of receptor dimers that in turn promote the direct association and trans-phosphorylation of the adjacent kinase domains; the result is activation of the receptor complex. The activated receptors then catalyze the addition of phosphate to tyrosine (Y) residues on the receptor itself as well as specific membrane-associated and cytoplasmic proteins. The resulting **phosphotyrosine (pY) motifs** serve as high-affinity binding sites for the recruitment of a number of intracellular signaling molecules, discussed in the next paragraph. These interactions lead to the formation of a signaling complex and the activation of downstream effectors. Some RTKs, such as the **insulin** and **IGF-1 receptors**,  [N3-20](#) exist as dimers even before ligand binding but undergo a conformational change that promotes autophosphorylation and activation of the kinase domains (see [pp. 1041–1042](#)).

[N3-20](#)

Insulin and IGF-1 Receptors

Contributed by Emile Boulpaep, Walter Boron

The **insulin** receptor (see [Fig. 51-5](#)) and the **IGF-1** receptor are activated by somewhat different

mechanisms, as we discuss on pages 1041–1042 for the insulin receptor and on page 996 for the IGF-1 receptor. In brief, these receptors are tetrameric; they are composed of two α and two β subunits. The α subunit contains a cysteine-rich region and functions in ligand binding. The β subunit is a single-pass transmembrane protein with a cytoplasmic tyrosine kinase domain. The α and β subunits are held together by disulfide bonds (as are the two α subunits), forming a heterotetramer. Ligand binding produces conformational changes that appear to cause allosteric interactions between the two α and β pairs, as opposed to the dimerization characteristic of the first class of RTKs (see Fig. 3-12C). Thus, insulin binding results in the autophosphorylation of tyrosine residues in the catalytic domains of the β subunits. The activated insulin receptor also phosphorylates cytoplasmic substrates such as **IRS-1** (insulin-receptor substrate 1; see Fig. 51-6), which, once phosphorylated, serves as a docking site for additional signaling proteins.

Recognition of pY Motifs by SH2 and Phosphotyrosine-Binding Domains

The pY motifs created by tyrosine kinases serve as high-affinity binding sites for the recruitment of cytoplasmic or membrane-associated proteins that contain either an **SH2 domain** or **PTB (phosphotyrosine-binding) domain**. SH2 domains are ~100 amino acids in length. They are composed of relatively well conserved residues that form the binding pocket for pY motifs as well as more variable residues that are implicated in binding specificity. These residues that confer binding specificity primarily recognize the three amino acids located on the C-terminal side of the phosphotyrosine. For example, the activated PDGF receptor has five such pY motifs ([Table 3-5](#)), each of which interacts with a specific SH2-containing protein.

TABLE 3-5
Tyrosine Phosphopeptides of the PDGF Receptor That Are Recognized by SH2 Domains on Various Proteins

TYROSINE (Y) THAT IS PHOSPHORYLATED IN PDGF RECEPTOR	pY MOTIF RECOGNIZED BY SH2-CONTAINING PROTEIN	SH2-CONTAINING PROTEIN
Y579	pYIYVD	Src family kinases
Y708	pYMDMS	p85
Y719	pYVPML	p85
Y739	pYNAPY	GTPase-activating protein
Y1021	pYIIPY	PLC γ

In contrast to SH2 and PTB domains, which interact with highly regulated pY motifs, **Src homology 3 (SH3)** domains interact constitutively with proline-rich regions in other proteins in a manner that does not require phosphorylation of the motif. However, phosphorylation at distant sites can change the conformation near the proline-rich region and thereby regulate the interaction. Like SH2 interactions, SH3 interactions appear to be responsible for targeting of signaling molecules to specific subcellular locations. SH2- or SH3-containing proteins include growth factor receptor-bound protein 2 (GRB2), PLC γ , and the p85 subunit of the phosphatidylinositol-3-kinase.

The MAPK Pathway

A common pathway by which activated RTKs transduce their signal to cytosol and even to the nucleus is a cascade of events that increase the activity of the small GTP-binding protein Ras. This **Ras-dependent signaling pathway** involves the following steps ([Fig. 3-13](#)):

Step 1: A ligand binds to the extracellular domain of a specific **RTK**, thus causing receptor dimerization.

Step 2: The now-activated RTK phosphorylates itself on tyrosine residues of the cytoplasmic domain (autophosphorylation).

Step 3: **GRB2**, an SH2-containing protein, recognizes pY residues on the activated receptor.

Step 4: Because GRB2 constitutively associates with the guanine nucleotide exchange factor **SOS** (son of sevenless), via an SH3-proline interaction, the recruitment of GRB2 automatically results in the recruitment of SOS as well.

Step 5: SOS activates the small G protein **Ras** by catalyzing the replacement of GDP with GTP.

Step 6: The activated GTP-Ras complex activates other proteins by physically recruiting them to the plasma membrane. In particular, active GTP-Ras interacts with the N-terminal portion of the cytosolic serine/threonine kinase **Raf-1** (also known as **MAP kinase kinase kinase** or MAPKKK or MAP3K), which is the first in a series of sequentially activated protein kinases that ultimately transmits the activation signal.

Step 7: Raf-1 phosphorylates and activates a protein kinase called **MEK** (also known as **MAP kinase kinase** or MAPKK). MEK is a multifunctional protein kinase that phosphorylates substrates on *both* tyrosine and serine/threonine residues.

Step 8: MEK phosphorylates **MAPKs**, cytosolic serine/threonine kinases also called extracellular signal-regulated kinases (ERK1, ERK2). Activation of MAPK requires dual phosphorylation on neighboring serine and tyrosine residues. Raf, MEK, and MAPK typically assemble on a scaffolding protein at the inner side of the cell membrane to facilitate interaction/phosphorylation during the activation process.

Step 9: MAPK is an important effector molecule in Ras-dependent signaling to the cytoskeleton. MAPK phosphorylates multiple proteins involved in actin cytoskeletal assembly and cell-matrix interactions; this phosphorylation leads to Ras-dependent changes in cell morphology and cell migration.

Step 10: Once activated, MAPK disassociates from the scaffold and translocates primarily to the nucleus, where it phosphorylates a number of nuclear proteins that are transcription factors. The result is either enhancement or repression of the DNA binding and transcriptional activity of these nuclear proteins. 🍌

N3-21

N3-21

Transcription Factors Phosphorylated by MAPK

Contributed by Peter Igarashi

The following table summarizes some transcription factors that MAPK phosphorylates, together with the site of phosphorylation on the transcription factor and the effect.

Transcription Factor	Site	Effect
c-Myc	Ser-62	Stabilizes protein
c-Jun	Ser-243 (Ser-63/Ser-73 in the activation domain are phosphorylated by a distinct Ras-dependent kinase)	Inhibits DNA binding
c-Fos	Ser-374 (direct) Ser-362 (indirect via ribosomal S6 kinase, which is activated by MAPK)	Stimulates transrepression
p62TCF = Elk-1	Multiple	Stimulates transactivation and possibly also DNA binding
C/EBPβ = LAP or NF-IL-6	Thr-235	Stimulates transactivation
ATF-2	Thr-69 and Thr-71 (via p38 and JNK MAPK)	Stimulates transactivation

ATF-2, activating transcription factor 2; C/EBPβ, CCAAT/enhancer-binding protein β; JNK, c-Jun N-terminal kinases.

Two other signal-transduction pathways (cAMP and Ca^{2+}) can modulate the activity of some of the protein intermediates in this MAPK cascade, which suggests multiple points of integration for the various signaling systems.

The Phosphatidylinositol-3-Kinase Pathway

The phosphatidylinositol-3-kinase (**PI3K**) is an SH2 domain-containing protein that commonly signals downstream of RTKs. PI3K is a heterodimer consisting of a p85 regulatory subunit and p110 catalytic subunit. p85 has an SH2 domain for targeting the complex to activated receptors and an SH3 domain that mediates constitutive association with p110. p110 is a lipid kinase that phosphorylates PIP₂ (see [p. 58](#)) on the 3 position of the inositol ring to form **PIP₃**. PIP₂ is a relatively common lipid in the inner leaflet of the cell membrane, whereas PIP₃ constitutes <1% of membrane lipids in a quiescent cell.

Following RTK activation, the newly recruited PI3K produces PIP₃ locally in the membrane, where it serves as a binding site for proteins such as 3-phosphoinositide-dependent kinase 1 (PDK1), PKC (see [pp. 60–61](#)), and the guanine nucleotide exchange factor Vav. 🍷 [N3-22](#) The events downstream of the insulin receptor are a good example of PDK1 signaling (see [Fig. 51-6](#)). As PDK1 binds to PIP₃, its kinase activity leads to phosphorylation and activation of the downstream target Akt (also known as protein kinase B or PKB). Akt is itself a serine/threonine kinase that regulates multiple downstream targets, inhibiting glycogen synthase kinase 3-β (GSK-3β), activating the mTOR pathway via phosphorylation and inhibition of tuberin 🍷 [N3-23](#) and inhibiting the proapoptotic proteins BAD and caspase-9 (see [Fig. 62-6](#)).

N3-22

PIP₃-Binding Domains

Contributed by Ed Moczydlowski

Proteins that bind PIP₃ contain either a pleckstrin homology domain, PTB domain, or FYVE domain that binds to the membrane-associated PIP₃.

N3-23

Tuberous Sclerosis

Contributed by Ed Moczydlowski

Tuberous sclerosis is a result of the mutation of the gene *TSC1* or *TSC2*.

Tyrosine kinase-associated receptors activate cytosolic tyrosine kinases such as Src and JAK

Some of the receptors for cytokines and growth factors that regulate cell proliferation and differentiation do not themselves have *intrinsic* tyrosine kinase activity but can associate with nonreceptor tyrosine kinases (see [Fig. 3-12D](#)). Receptors in this class include those for several cytokines, including IL-2, IL-3, IL-4, IL-5, IL-6, leukemia inhibitory factor (LIF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and erythropoietin (EPO). The family also includes receptors for growth hormone (GH), prolactin (PRL), leptin, ciliary neurotrophin factor (CNTF), oncostatin M, and IFN-α, IFN-β, and IFN-γ.

The **tyrosine kinase-associated receptors** typically comprise multiple subunits that form homodimers (αα), heterodimers (αβ), or heterotrimers (αβγ). For example, the IL-3 and the GM-CSF receptors are heterodimers (αβ) that share common β subunits with transducing activity. 🍷 [N3-24](#) However, none of the cytoplasmic portions of the receptor subunits contains kinase domains or other sequences with

recognized catalytic function. Instead, tyrosine kinases of the Src family and Janus family (JAK or Janus kinases) associate noncovalently with the cytoplasmic domains of these receptors. Thus, these are **receptor-associated tyrosine kinases**. Ligand binding to these receptors results in receptor dimerization and activation of the associated tyrosine kinase. The activated kinase then phosphorylates tyrosines on both itself and the receptor. Thus, tyrosine kinase–associated receptors, together with their tyrosine kinases, function much like the RTKs discussed in the previous section. A key difference is that for the tyrosine kinase–*associated* receptors, the receptors and kinases are encoded by separate genes and the proteins are only loosely associated with one another.

N3-24

Multimeric Composition of Tyrosine Kinase–Associated Receptors

Contributed by Laurie Roman

In the text, we pointed out that the IL-3 and GM-CSF receptors are heterodimers ($\alpha\beta$) that share a common β subunit that has transducing activity. A similar example is the group of three receptors for **IL-6**, **oncostatin M** (OncM), and **IL-11**. These three receptors use a common transducer subunit called gp130 as well as a unique subunit for ligand binding.

The **Src family** of receptor-associated tyrosine kinases includes at least nine members. Alternative initiation codons and tissue-specific splicing result in at least 14 related gene products.

The conserved regions of Src-related proteins can be divided into five domains: (1) an N-terminal myristylation site, through which the kinase is tethered to the membrane; (2) an SH3 domain, which binds to proline-rich regions of the kinase itself or to other cytosolic proteins; (3) an SH2 domain, which binds phosphorylated tyrosines; (4) the catalytic domain, which has tyrosine kinase activity; and (5) a noncatalytic C terminus. Members of this family are kept in the inactive state by tyrosine phosphorylation at a conserved residue in the C terminus that causes the pY to bind to the N-terminal SH2 domain of the same molecule. The result is a masking of the intervening kinase domain. Dephosphorylation of the pY residue after the activation of such phosphatases as receptor protein tyrosine phosphatase α (RPTP α) or the cytosolic SHP2 releases this inhibition, and the kinase domain can then phosphorylate its intracellular substrates.

Many of the Src family members were first identified in transformed cells or tumors because of mutations that caused them to be constitutively active. When these mutations result in malignant transformation of the cell, the gene in question is designated an **oncogene**; the normal, unaltered physiological counterpart of an oncogene is called a **proto-oncogene**.

Box 3-5

Oncogenes

The ability of certain viral proteins (**oncogenes**) to transform a cell from a normal to a malignant phenotype was initially thought to occur because these viral proteins acted as transcriptional activators or repressors. However, during the last 20 years, only a few of these viral proteins have been found to work in this manner. The majority of oncogenes harbor mutations that transform them into constitutively

active forms of normal cellular signaling proteins called **proto-oncogenes**. Most of these aberrant proteins (i.e., the oncogenes) encode proteins important in a key signal-transduction pathway. For example, expression of the viral protein v-erb B is involved in fibrosarcomas, and both v-erb A and v-erb B are associated with leukemias. **v-erb B** resembles a constitutively activated RTK (EGF receptor), and the retroviral **v-erb A** is derived from a cellular gene encoding a thyroid hormone receptor. Other receptors and signaling molecules implicated in cell transformation include Src, Ras, and PDGF receptor. A mutation in protein tyrosine phosphatase 1C results in abnormal hematopoiesis and an increased incidence of lymphoreticular tumors.

The **Janus family** of receptor-associated tyrosine kinases in mammals includes **JAK1, JAK2, and Tyk2**. JAK originally stood for “just another kinase.” Major downstream targets of the JAKs include one or more members of the STAT (signal transducers and activators of transcription) family. When phosphorylated, STATs interact with other STAT family members to form a complex that translocates to the nucleus (see p. 90). There, the complex facilitates the transcription of specific genes that are specialized for a rapid response, such as those that are characterized by the **acute-phase response** of inflammation (see p. 1202). For example, IL-6 binding to the heterodimeric IL6R/GP130 receptor on hepatocytes activates JAK/STAT, which enhances transcription of the **acute-phase proteins**. During inflammation, these acute-phase proteins function to limit tissue damage by inhibiting the proteases that attack healthy cells as well as diseased ones. The *pattern* of STAT activation provides a mechanism for cytokine individuality. For example, EPO activates STAT5a and STAT5b as part of the early events in erythropoiesis, whereas IL-4 or IL-12 activates STAT4 and STAT6.

Attenuation of the cytokine JAK-STAT signaling cascade involves the production of **inhibitors** that suppress tyrosine phosphorylation and activation of the STATs. For example, IL-6 and LIF both induce expression of the inhibitor SST-1, which contains an SH2 domain and prevents JAK2 or Tyk2 from activating STAT3 in M1 myeloid leukemia cells.

Receptor tyrosine phosphatases are required for lymphocyte activation

Tyrosine residues that are phosphorylated by the tyrosine kinases described in the preceding two sections are *dephosphorylated* by PTPs, which can be either cytosolic or membrane spanning (i.e., the receptor tyrosine phosphatases). We discussed the cytosolic PTPs above. Both classes of *tyrosine* phosphatases have structures very different from the ones that dephosphorylate *serine* and *threonine* residues. Because the tyrosine phosphatases are highly active, pY groups tend to have a short half-life and are relatively few in number in unstimulated cells.

The **CD45** protein, found at the cell surface of T and B lymphocytes, is an example of a receptor tyrosine phosphatase. CD45 makes a single pass through the membrane. Its glycosylated extracellular domain functions as a receptor for antibodies, whereas its cytoplasmic domain has tyrosine phosphatase activity (see Fig. 3-12E). During their maturation, lymphocytes express several variants of CD45 characterized by different patterns of alternative splicing and glycosylation. CD45 plays a critical role in signal transduction in lymphocytes. For instance, CD45 dephosphorylates and thereby activates Lck and Fyn (two receptor-associated tyrosine kinases of the Src family) and triggers the phosphorylation of other proteins downstream in the signal-transduction cascade. This interaction between receptor tyrosine phosphatases and tyrosine kinase-associated receptors is another example of crosstalk between signaling pathways.

Nuclear Receptors

Steroid and thyroid hormones enter the cell and bind to members of the nuclear receptor superfamily in the cytoplasm or nucleus

A number of important signaling molecules produce their effects not by binding to receptors on the cell membrane but by binding to **nuclear receptors (NRs)**—also called intracellular receptors—that can act as transcription regulators, a concept that we will discuss in more depth beginning on [p. 81](#). This family includes receptors for steroid hormones, prostaglandins, vitamin D, thyroid hormones, and retinoic acid ([Table 3-6](#)). In addition, this family includes related receptors, known as orphan receptors, whose ligands have yet to be identified. Steroid hormones, vitamin D, and retinoic acid appear to enter the cell by diffusing through the lipid phase of the cell membrane. Thyroid hormones, which are charged amino-acid derivatives, may cross the cell membrane either by diffusion or by carrier-mediated transport. Once inside the cell, these substances bind to intracellular receptors. The ligand-bound receptors are activated **transcription factors** that regulate the expression of target genes by binding to specific DNA sequences. In addition, steroid hormones can have nongenomic effects (see [p. 989](#)). 🍷 [N3-25](#)

TABLE 3-6
Nuclear Receptors

RECEPTOR	FULL NAME	DIMERIC ARRANGEMENT
GR	Glucocorticoid receptor	GR/GR
MR	Mineralocorticoid receptor	MR/MR
PR	Progesterone receptor	PR/PR
ER α , ER β	Estrogen receptors	ER/ER
AR	Androgen receptor	AR/AR
VDR	Vitamin D receptor	VDR/RXR
TR	Thyroid hormone receptor	TR/RXR
RAR	Retinoic acid receptor	RAR/RXR
PPAR α , PPAR γ , PPAR δ	Peroxisome proliferation–activated receptors α , γ , δ	PPAR/RXR
FXR	Bile acid receptor	FXR/RXR
LXR	Liver X receptor	LXR/RXR
SXR (or PXR)	Steroid and xenobiotic receptor (pregnane X receptor)	SXR/RXR
CAR	Constitutive androstane receptor	CAR/RXR

RXR, retinoid X receptor.

N3-25

Nongenomic Effects of Steroid Hormones

Contributed by Emile Boulpaep, Walter Boron

A theme that is developing in the literature is that certain steroid hormones, when applied to cells in culture, produce biological effects that are too rapid to be mediated by altered gene expression. An example is aldosterone, which—in several cell lines—can cause $[Ca^{2+}]_i$ to decrease so rapidly that the effect simply could not be due to altered protein synthesis. Moreover, treatments that block protein synthesis fail to inhibit the ability of aldosterone to lower $[Ca^{2+}]_i$. It is not clear how such rapid, nongenomic effects of steroid hormones may occur. One possibility is that the aldosterone interacts with an alternate receptor (i.e., not the mineralocorticoid receptor that it would normally bind to in the

cytoplasm). Another possibility is that aldosterone might bind to the mineralocorticoid receptor, which could have a rapid effect in addition to the traditional, slower genomic effect. Finally, it is possible that the aldosterone nonspecifically interacts with elements of another signaling cascade. Regardless of the mechanism, the rapid action of aldosterone is an exception to the general rule that all of the actions of steroid-type hormones occur by modulation of transcription.

The family of nuclear receptors contains at least 48 genes and has been classically divided into two subfamilies based on structural homology. One subfamily consists of receptors for **steroid hormones**, including the glucocorticoids (see pp. 1018–1026), mineralocorticoids (see pp. 1026–1030), and androgens (see pp. 1097–1100), as well as estrogens and progesterone (see pp. 1116–1120). These receptors function primarily as *homodimers* (see Table 3-6). The other group includes receptors for **retinoic acid**, **thyroid hormone** (see pp. 1006–1010), and **vitamin D** (see pp. 1063–1067). These receptors appear to act as *heterodimers* (see Table 3-6). As we will see on page 956, other nuclear receptors recognize a wide range of **xenobiotics** and metabolites, and thereby modulate the expression of genes that encode transporters and enzymes involved in drug metabolism.

The intracellular localization of the different unoccupied receptors varies. The glucocorticoid (GR) and mineralocorticoid (MR) receptors are mainly cytoplasmic, the estrogen (ER) and progesterone (PR) receptors are primarily nuclear, and the thyroid hormone (TR) and retinoic acid (RAR) receptors are bound to DNA in the nucleus. Cytoplasmic receptors are frequently complexed to chaperone (or “heat shock”) proteins. Hormone binding induces a conformational change in these receptors that causes dissociation from the cytoplasmic chaperone and unmasks a nuclear transport signal that allows the hormone-receptor complex to translocate into the nucleus.

Nuclear receptors contain five to six functionally distinct domains (Fig. 3-14) that are differentially conserved among the various members of the family. The N-terminal A/B region differs most widely among receptors and contains the first of two transactivation domains. **Transactivation** is the process by which a ligand-induced conformational change of the receptor results in a change in conformation of the DNA and thus initiates transcription. The C region, the most highly conserved among receptor types, contains the DNA-binding domain and is also involved in **dimerization** (see Table 3-6). It is composed of two “zinc finger” structures (see p. 82). The D, or hinge, region contains the “nuclear localization signal” and may also contain transactivation sequences. The E domain is responsible for hormone binding. Like the C region, it is involved in dimerization via its “basic zipper” region (see p. 83). Finally, like the A/B region, the E region contains a transactivation domain. The small C-terminal F domain is present in only some nuclear receptors and is of unknown function.

FIGURE 3-14 Modular construction of intracellular (or nuclear) receptors. Members of this family exist in the cytoplasm or nucleus and include receptors for several ligands, including retinoic acid, vitamin D, thyroid hormones, and steroid hormones. These receptors have modular construction, with up to six elements. The percentages listed inside the A/B, C, and E domains refer to the degrees of amino-acid identity, referenced to the glucocorticoid receptor. Thus, the DNA-binding or C domain of the retinoic acid receptor is 45% identical to the corresponding domain on the glucocorticoid receptor.

Activated nuclear receptors bind to sequence elements in the regulatory region of responsive genes and either activate or repress DNA transcription

One of the remarkable features of nuclear receptors is that they bind very specifically to short DNA sequences—called **hormone response elements**—in the regulatory region of responsive genes. The various nuclear receptors display specific cell and tissue distributions. Thus, the battery of genes affected by a particular ligand depends on the complement of receptors in the cell, the ability of these receptors to form homodimers or heterodimers, and the affinity of these receptor-ligand complexes for a particular response element on the DNA.

In addition to affecting transcription by directly binding to specific regulatory elements, several nuclear receptors modulate gene expression by acting as transcriptional repressors (see [p. 92](#)). For example, the glucocorticoids, acting via their receptor, can attenuate components of the inflammatory response by suppressing the transcriptional activity of other transcription factors such as activator protein 1 (AP-1; see [Table 4-1](#)) and nuclear factor κ B (NF- κ B; see [pp. 86–87](#)).

CHAPTER 4

Regulation of Gene Expression

Peter Igarashi

In this chapter, we discuss general principles of gene structure and expression as well as mechanisms underlying the regulation of tissue-specific and inducible gene expression. We will see that proteins (transcription factors) control gene transcription by interacting with regulatory elements in DNA (e.g., promoters and enhancers). Because many transcription factors are effector molecules in signal-transduction pathways, these transcription factors can coordinately regulate gene expression in response to physiological stimuli. Finally, we describe the important roles of epigenetic and post-transcriptional regulation of gene expression. Because many of the proteins and DNA sequences are known by abbreviations, the Glossary at the end of the chapter identifies these entities.

From Genes to Proteins

Gene expression differs among tissues and—in any tissue—may vary in response to external stimuli

The haploid human genome contains 20,000 to 30,000 distinct genes, but only about one third of these genes are actively translated into proteins in any individual cell. Cells from different tissues have distinct morphological appearances and functions and respond differently to external stimuli, even though their DNA content is identical. For example, although all cells of the body contain an albumin gene, only liver cells (hepatocytes) can synthesize and secrete albumin into the bloodstream. Conversely, hepatocytes cannot synthesize insulin, which pancreatic β cells produce. The explanation for these observations is that expression of genes is regulated so that some genes are active in hepatocytes and others are silent. In pancreatic β cells, a different set of genes is active; others, such as those expressed only in the liver, are silent. How does the organism program one cell type to express liver-specific genes, and another to express a set of genes appropriate for the pancreas? This phenomenon is called **tissue-specific gene expression**.

A second issue is that genes in individual cells are generally not expressed at constant, unchanging levels (constitutive expression). Rather, their expression levels often vary widely in response to environmental stimuli. For example, when blood glucose levels decrease, α cells in the pancreas secrete the hormone glucagon (see pp. 1050–1053). Glucagon circulates in the blood until it reaches the liver, where it causes a 15-fold increase in expression of the gene that encodes phosphoenolpyruvate carboxykinase (PEPCK), an enzyme that catalyzes the rate-limiting step in gluconeogenesis (see pp. 1051). Increased gluconeogenesis then contributes to restoration of blood glucose levels toward normal. This simple regulatory loop, which necessitates that the liver cells perceive the presence of glucagon and stimulate PEPCK gene expression, illustrates the phenomenon of **inducible gene expression**.

Genetic information flows from DNA to proteins

The “central dogma of molecular biology” states that genetic information flows unidirectionally from DNA to proteins. DNA is a polymer of nucleotides, each containing a nitrogenous base (adenine, A; guanine, G; cytosine, C; or thymine, T) attached to deoxyribose 5'-phosphate. The polymerized nucleotides form a polynucleotide strand in which the sequence of the nitrogenous bases constitutes the genetic information. With few exceptions, all cells in the body share the same genetic information. Hydrogen-bond formation between bases (A and T, or G and C) on the two complementary strands of DNA produces a double-helical structure.

DNA has two functions. The first is to serve as a self-renewing data repository that maintains a constant source of genetic information for the cell. This role is achieved by DNA replication, which ensures that when cells divide, the progeny cells receive exact copies of the DNA. The second purpose of DNA is to serve as a template for the translation of genetic information into proteins, which are the functional units of the cell. This second purpose is broadly defined as **gene expression**.

Gene expression involves two major processes (Fig. 4-1). The first process—**transcription**—is the synthesis of RNA from a DNA template, mediated by an enzyme called RNA polymerase II. The resultant RNA molecule is identical in sequence to one of the strands of the DNA template except that the base uracil (U) replaces thymine (T). The second process—**translation**—is the synthesis of protein from RNA.

During translation, the genetic code in the sequence of RNA is “read” by transfer RNA (tRNA), and then amino acids carried by the tRNA are covalently linked together to form a polypeptide chain. In eukaryotic cells, transcription occurs in the nucleus, whereas translation occurs on ribosomes located in the cytoplasm. Therefore, an intermediary RNA, called **messenger RNA (mRNA)**, is required to transport the genetic information from the nucleus to the cytoplasm. The complete process, proceeding from DNA in the nucleus to protein in the cytoplasm, constitutes gene expression.

FIGURE 4-1 Pathway from genes to proteins. Gene expression involves two major processes. First, the DNA is transcribed into RNA by RNA polymerase. Second, the RNA is translated into protein on the ribosomes.

Although the **central dogma of molecular biology** applies to most protein-coding genes, exceptions exist. For example, RNA viruses (such as the human immunodeficiency virus [HIV] that causes acquired immunodeficiency syndrome) contain their genetic information in the sequence of an RNA genome. Upon infection with HIV, the cell “reverse transcribes” the RNA genome into double-stranded DNA that then integrates into the host DNA genome. Transcription of the virally encoded DNA by the host transcriptional machinery produces RNA molecules that become part of new HIV particles. Cells transcribe some genes into RNAs that do not encode proteins. So-called noncoding RNAs include ribosomal RNAs (rRNAs) and transfer RNA (tRNA) that participate in protein translation, small nuclear RNAs (snRNAs) that are involved in RNA splicing, and microRNAs (miRNAs) that regulate mRNA abundance and translation (see pp. 99–100).

The gene consists of a transcription unit

Figure 4-2 depicts the structure of a typical eukaryotic protein-coding gene. The **gene** consists of a segment of DNA that is transcribed into RNA. It extends from the site of transcription initiation to the site of transcription termination. The region of DNA that is immediately adjacent to and upstream (i.e., in the 5' direction) from the transcription initiation site is called the **5' flanking region**. The corresponding domain that is downstream (3') to the transcription termination site is called the **3' flanking region**. (Recall that DNA strands have directionality because of the 5' to 3' orientation of the phosphodiester bonds in the sugar-phosphate backbone of DNA. By convention, the DNA strand that has the same sequence as the RNA is called the coding strand, and the complementary strand is called the noncoding strand. The 5' to 3' orientation refers to the coding strand.) Although the 5' and 3' flanking regions are not transcribed into RNA, they frequently contain DNA sequences, called **regulatory elements**, that control gene transcription. The site where transcription of the gene begins, sometimes called the cap site, may have a variant of the nucleotide sequence 5'-ACTT(T/C)TG-3' (called the cap sequence), where T/C means T *or* C. The A is the **transcription initiation site**. Transcription proceeds to the **transcription termination site**, which has a less defined sequence and location in eukaryotic genes. Slightly upstream from the termination site is another sequence called the **polyadenylation signal**, which often has the sequence 5'-AATAAA-3'.

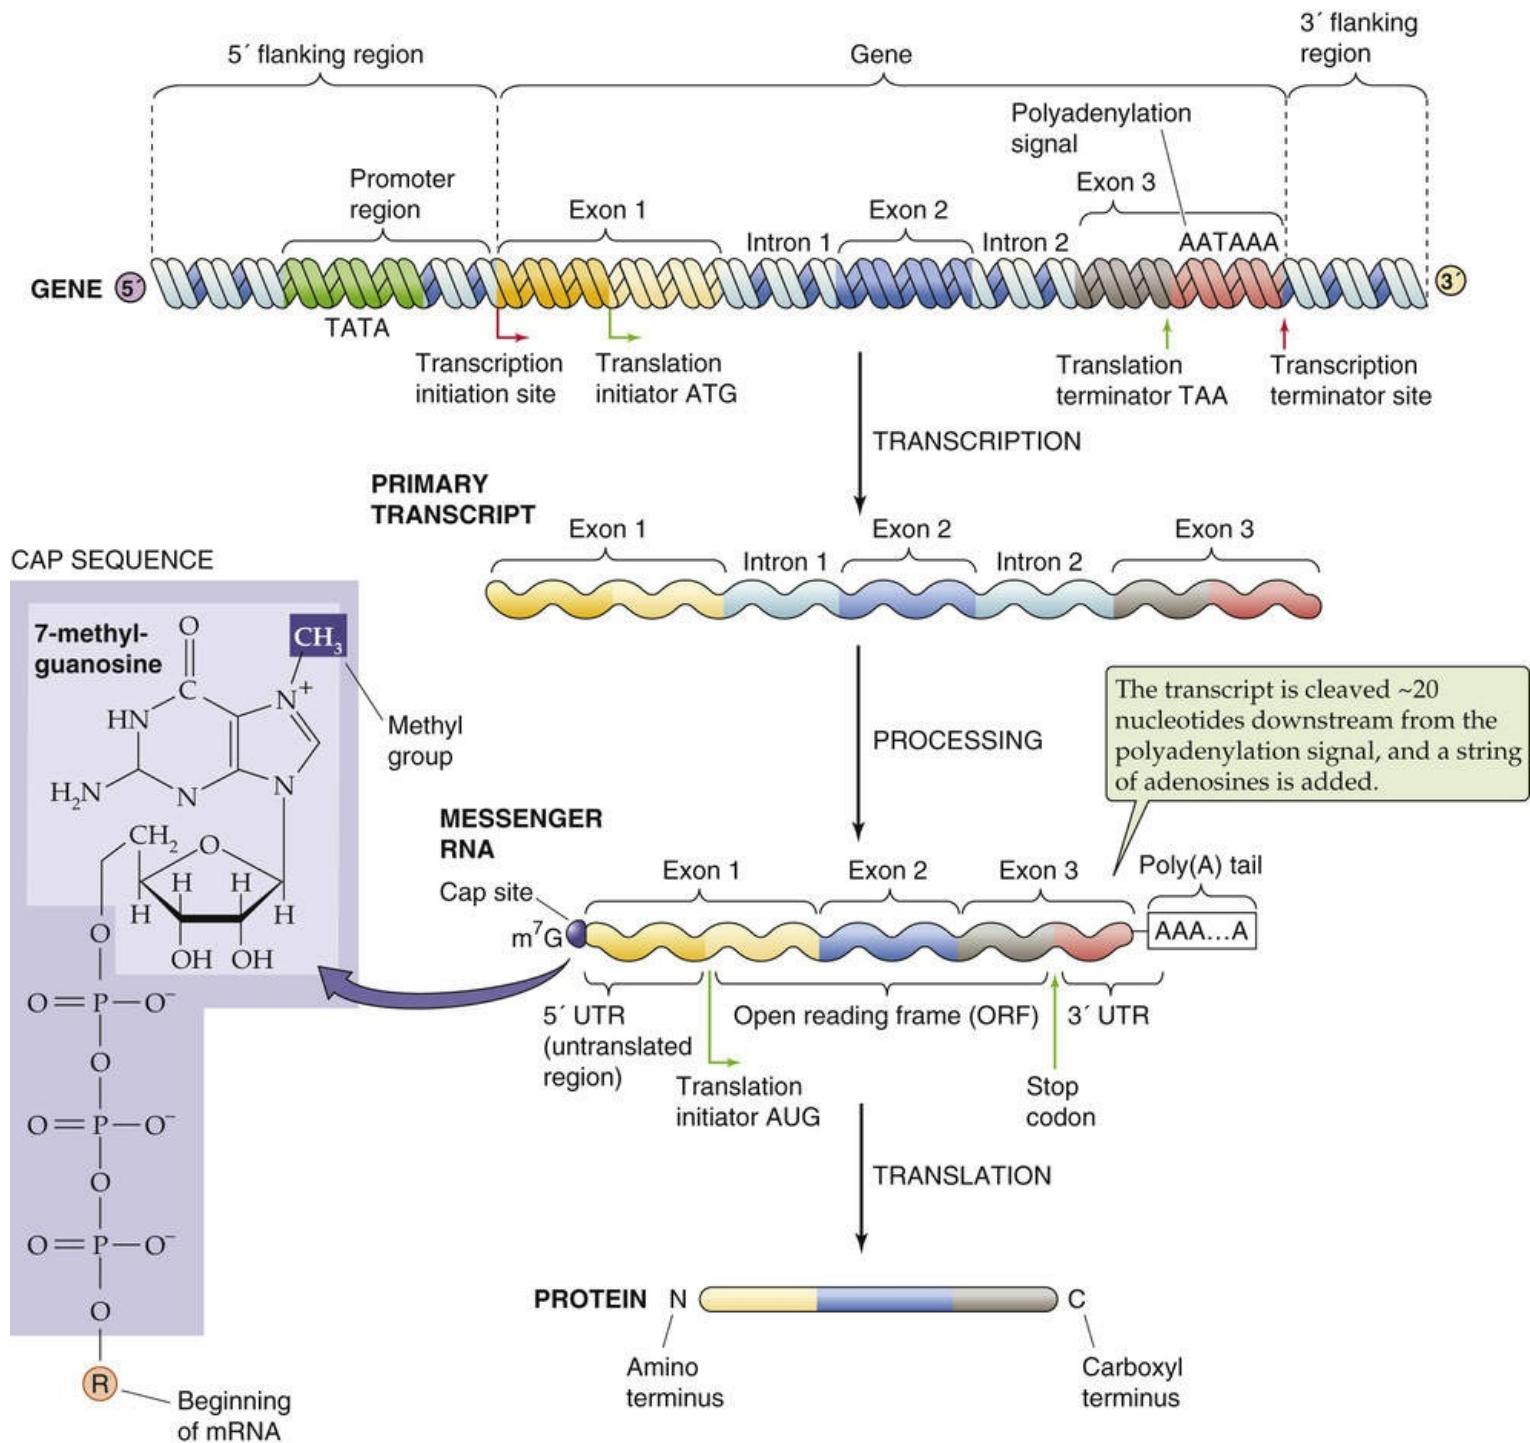

FIGURE 4-2 Structure of a eukaryotic gene and its products. The figure depicts a gene, a primary RNA transcript, the mature mRNA, and the resulting protein. The 5' and 3' numbering of the gene refers to the coding strand. ATG, AATAAA, and the like, are nucleotide sequences. m⁷G, 7-methyl guanosine.

The RNA that is initially transcribed from a gene is called the **primary transcript** (see Fig. 4-2) or precursor mRNA (pre-mRNA). Before it can be translated into protein, the primary transcript must be processed into a mature mRNA in the nucleus. Most eukaryotic genes contain **exons**, DNA sequences that are present in the mature mRNA, alternating with **introns**, which are not present in the mRNA. The primary transcript is colinear with the coding strand of the gene and contains the sequences of both the exons and the introns. To produce a mature mRNA that can be translated into protein, the cell must process the primary transcript in four steps.

First, the cell adds an unusual guanosine base, which is methylated at the 7 position, via a 5'-5' phosphodiester bond to the 5' end of the transcript. The result is a 5' methyl **cap**. The presence of the 5' methyl cap is required for export of the mRNA from the nucleus to the cytoplasm as well as for translation

of the mRNA.

Second, the cell removes the sequences of the introns from the primary transcript via a process called **pre-mRNA splicing**. Splicing involves the joining of the sequences of the exons in the RNA transcript and the removal of the intervening introns. As a result, **mature mRNA** (see [Fig. 4-2](#)) is shorter and not colinear with the coding strand of the DNA template.

The third processing step is cleavage of the RNA transcript about 20 nucleotides downstream from the polyadenylation signal, near the 3' end of the transcript.

The fourth step is the addition of a string of 100 to 200 adenine bases at the site of the cleavage to form a **poly(A) tail**. This tail contributes to mRNA stability.

The mature mRNA produced by RNA processing not only contains a coding region—the open-reading frame—that encodes protein but also sequences at the 5' and 3' ends that are not translated into protein—the 5' and 3' untranslated regions (UTRs), respectively. Translation of the mRNA on ribosomes always begins at the codon AUG, which encodes methionine, and proceeds until the ribosome encounters one of the three stop codons (UAG, UAA, or UGA). Thus, the 5' end of the mRNA is the first to be translated and provides the N terminus of the protein; the 3' end is the last to be translated and contributes the C terminus.

DNA is packaged into chromatin

Although DNA is commonly depicted as linear, chromosomal DNA in the nucleus is actually organized into a higher-order structure called chromatin. This packaging is required to fit DNA with a total length of ~ 1 m into a nucleus with a diameter of 10^{-5} m. **Chromatin** consists of DNA associated with **histones** and other nuclear proteins. The basic building block of chromatin is the **nucleosome** ([Fig. 4-3](#)), each of which consists of a protein core and 147 base pairs (bp) of associated DNA. The protein core is an octamer of the histones H2A, H2B, H3, and H4. DNA wraps twice around the core histones to form a solenoid-like structure. A linker histone, H1, associates with segments of DNA between nucleosomes. Regular arrays of nucleosomes have a beads-on-a-string appearance and constitute the so-called 11-nm fiber of chromatin, which can condense to form the 30-nm fiber.

FIGURE 4-3 Chromatin structure.

Chromatin exists in two general forms that can be distinguished cytologically by their different degrees of condensation. **Heterochromatin** is a highly condensed form of chromatin that is transcriptionally inactive. In general, highly organized chromatin structure is associated with *repression* of gene transcription. Heterochromatin contains mostly repetitive DNA sequences and relatively few genes. **Euchromatin** has a more open structure and contains genes that are actively transcribed. Even in the transcriptionally active "open" euchromatin, local chromatin structure may influence the activity of individual genes.

Gene expression may be regulated at multiple steps

Gene expression involves eight steps (Fig. 4-4):

Step 1: Chromatin remodeling. Before a gene can be transcribed, some local alteration in chromatin structure must occur so that the enzymes that mediate transcription can gain access to the genomic DNA. The alteration in chromatin structure is called chromatin remodeling, which may involve loosening of the interaction between histones and DNA, repositioning of nucleosomes, or local depletion of histones.

Step 2: Initiation of transcription. In this step, RNA polymerase is recruited to the gene promoter and begins to synthesize RNA that is complementary in sequence to one of the strands of the template DNA. For most eukaryotic genes, initiation of transcription is the critical, rate-limiting step in gene

expression.

Step 3: Transcript elongation. During transcript elongation, RNA polymerase proceeds down the DNA strand and sequentially adds ribonucleotides to the elongating strand of RNA. 🍷N4-1

N4-1

Role of Tat in Transcript Elongation

Contributed by Peter Igarashi

Regulation of elongation appears to be critical for the expression of certain genes, such as some genes of HIV-1, the causative agent of acquired immunodeficiency syndrome (AIDS). HIV-1 is a retrovirus (RNA virus) that preferentially infects cells of the immune system. After infection, the RNA viral genome is “reverse” transcribed into double-stranded DNA, which integrates into the host genome. A viral promoter that is located in the long terminal repeat of the viral genome then drives expression of the viral genes. Immediately downstream from the promoter—and within the 5′ untranslated region—is a regulatory element known as the **trans-activation response element (TAR)**. Unlike the regulatory elements that we have discussed above, this element is active in *transcribed RNA*. The sequence of TAR contains an inverted repeat, and a stretch of nucleotides on one part of the TAR pairs with nucleotides on the other part to create a hairpin structure in this viral transcript (eFig. 4-1). Because the inverted repeat is imperfect, the hairpin contains a “bulge.” Elongation of transcription cannot occur unless a virally encoded protein called **Tat** binds to this bulge in the TAR portion of the RNA transcript. In the absence of Tat, transcription initiates but elongation does not proceed past the TAR; the resulting truncated transcripts do not encode proteins. In the presence of Tat, Pol II can read through the TAR and elongation proceeds normally, producing full-length RNA. It appears that the function of TAR is to recruit Tat to the promoter. Tat, in turn, associates with P-TEFb, a kinase that phosphorylates the CTD of Pol II (see p. 85 and Fig. 4-10) and stimulates transcription elongation.

FIGURE 4-1 Role of Tat in transcript elongation. **A**, The TAR (*trans*-activation response element) of the newly transcribed RNA forms a hairpin loop with a bulge. In the absence of Tat, transcription terminates prematurely and releases a short strand of RNA. **B**, Tat binds to the bulge and recruits a coactivator that allows transcript elongation to form full-length RNAs.

Step 4: Termination of transcription. After producing a full-length RNA, the enzyme halts elongation.

Step 5: RNA processing. As noted before, RNA processing involves (a) addition of a 5' methylguanosine cap, (b) pre-mRNA splicing, (c) cleavage of the RNA strand, and (d) polyadenylation.

Step 6: Nucleocytoplasmic transport. The next step in gene expression is the export of the mature mRNA through pores in the nuclear envelope (see [p. 21](#)) into the cytoplasm. Nucleocytoplasmic transport is a regulated process that is important for mRNA quality control.

Step 7: Translation. The mRNA is translated into proteins on ribosomes. During translation, the genetic code on the mRNA is read by tRNA, and then amino acids carried by the tRNA are added to the nascent polypeptide chain.

Step 8: mRNA degradation. Finally, the mRNA is degraded in the cytoplasm by a combination of endonucleases and exonucleases.

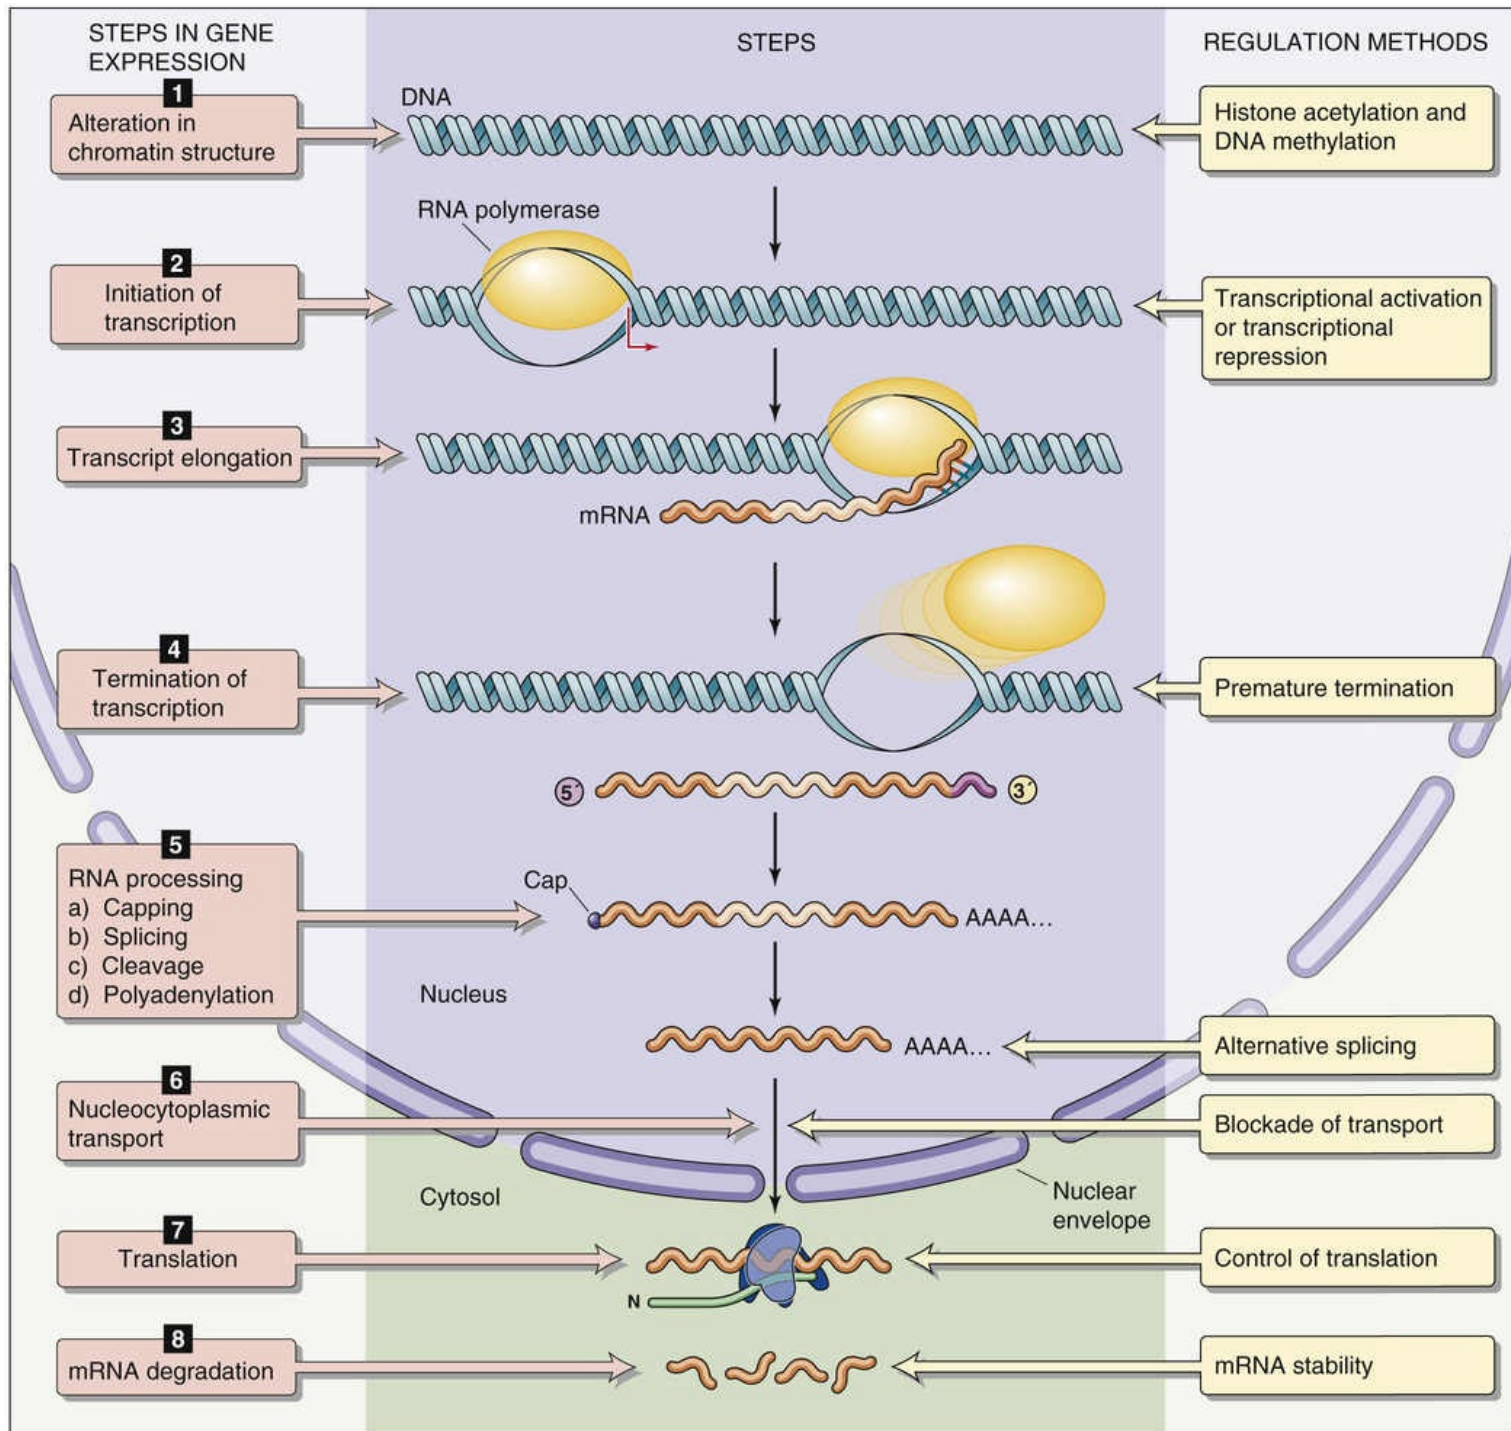

FIGURE 4-4 Steps in gene expression. Nearly all of the eight steps in gene expression are potential targets for regulation.

Each of these steps is potentially a target for regulation (see Fig. 4-4, right panel):

1. Gene expression may be regulated by global as well as by local alterations in chromatin structure.
2. An important related alteration in chromatin structure is the state of methylation of the DNA.
3. Initiation of transcription can be regulated by transcriptional activators and transcriptional repressors.
4. Transcript elongation may be regulated by premature termination in which the polymerase falls off (or is displaced from) the template DNA strand; such termination results in the synthesis of truncated transcripts.

5. Pre-mRNA splicing may be regulated by alternative splicing, which generates different mRNA species from the same primary transcript.
6. At the step of nucleocytoplasmic transport, the cell prevents expression of aberrant transcripts, such as those with defects in mRNA processing. In addition, mutant transcripts containing premature stop codons may be degraded in the nucleus through a process called nonsense-mediated decay.
7. Control of translation of mRNA is a regulated step in the expression of certain genes, such as the transferrin receptor gene.
8. Control of mRNA stability contributes to steady-state levels of mRNA in the cytoplasm and is important for the overall expression of many genes.

Although any of these steps may be critical for regulating a particular gene, transcription initiation is the most frequently regulated (step 2) and is the focus of this chapter. At the end of the chapter, we describe examples of epigenetic regulation of gene expression and regulation at steps that are subsequent to the initiation of transcription—post-transcriptional regulation.

Transcription factors are proteins that regulate gene transcription

A general principle is that gene transcription is regulated by interactions of specific proteins with specific DNA sequences. The proteins that regulate gene transcription are called **transcription factors**. Many transcription factors recognize and bind to specific sequences in DNA. The binding sites for these transcription factors are called **regulatory elements**. Because they are located on the same piece of DNA as the genes that they regulate, these regulatory elements are sometimes referred to as **cis-acting** factors.

[Figure 4-5](#) illustrates the overall scheme for the regulation of gene expression. Transcription requires proteins (transcription factors) that bind to specific DNA sequences (regulatory elements) located near the genes they regulate (target genes). Once the proteins bind to DNA, they stimulate (or inhibit) transcription of the target gene. A particular transcription factor can regulate the transcription of multiple target genes. In general, regulation of gene expression can occur at the level of either transcription factors or regulatory elements. Examples of regulation at the level of transcription factors include variations in the abundance of transcription factors, their DNA-binding activities, and their ability to stimulate (or to inhibit) transcription. Examples of regulation at the level of regulatory elements include alterations in chromatin structure (which influences accessibility to transcription factors) and covalent modifications of DNA, especially methylation.

FIGURE 4-5 Regulation of transcription. Protein A, a transcription factor that is encoded by gene A (not shown), regulates another gene, gene B. Protein A binds to a DNA sequence (a regulatory element) that is upstream from gene B; this DNA sequence is a *cis*-acting element because it is located on the same DNA as gene B. In this example, protein A stimulates (transactivates) the transcription of gene B. Transcription factors also can inhibit transcription.

The Promoter and Regulatory Elements

The basal transcriptional machinery mediates gene transcription

Protein-coding genes are transcribed by an enzyme called **RNA polymerase II (Pol II)**, which catalyzes the synthesis of RNA that is complementary in sequence to a DNA template. Pol II is a large protein (molecular mass of 600 kDa) comprising 10 to 12 subunits. Although Pol II catalyzes mRNA synthesis, by itself it is incapable of binding to DNA and initiating transcription at specific sites. The recruitment of Pol II and initiation of transcription requires an assembly of proteins called **general transcription factors**. Six general transcription factors are known—TFIIA, TFIIB, TFIID, TFIIE, TFIIIF, and TFIIH—each of which contains multiple subunits. **N4-2** These general transcription factors are essential for the transcription of all protein-coding genes, which distinguishes them from the transcription factors discussed below that are involved in the transcription of specific genes. Together with Pol II, the general transcription factors constitute the **basal transcriptional machinery**, which is also known as the **RNA polymerase holoenzyme** or **preinitiation complex** because its assembly is required before transcription can begin. The basal transcriptional machinery assembles at a region of DNA that is immediately upstream from the gene and includes the transcription initiation site. This region is called the **gene promoter** (Fig. 4-6).

FIGURE 4-6 Promoter and DNA regulatory elements. The basal transcriptional machinery assembles on the promoter. Transcriptional activators bind to enhancers, and repressors bind to negative regulatory elements.

Sequential Assembly of General Transcription Factors

Contributed by Peter Igarashi

In vitro, the general transcription factors and Pol II assemble in a stepwise, ordered fashion on DNA. The first protein that binds to DNA is **TFIID**, which induces a bend in the DNA and forms a platform for the assembly of the remaining factors. Once TFIID binds to DNA, the other components of the basal transcriptional machinery assemble spontaneously by protein-protein interactions. The next general transcription factor that binds is **TFIIA**, which stabilizes the interaction of TFIID with DNA. Assembly of TFIIA is followed by assembly of **TFIIB**, which interacts with TFIID and also binds DNA. TFIIB then recruits a preassembled complex of **Pol II** and **TFIIF**. Entry of the Pol II–TFIIF complex into the basal transcriptional machinery is followed by binding of **TFIIE** and **TFIIH**. TFIIF and TFIIH may assist in the transition from basal transcriptional machinery to an elongation complex, which may involve unwinding of the DNA that is mediated by the helicase activity of TFIIH. Although this stepwise assembly of Pol II and general transcription factors occurs in vitro, the situation in vivo may be different. In vivo, Pol II has been observed in a multiprotein complex containing general transcription factors and other proteins. This preformed complex may be recruited to DNA to initiate transcription.

The promoter determines the initiation site and direction of transcription

The promoter is a *cis*-acting regulatory element that is required for expression of the gene. In addition to locating the *site* for initiation of transcription, the promoter also determines the *direction* of transcription. Perhaps somewhat surprisingly, no unique sequence defines the gene promoter. Instead, the promoter consists of modules of simple sequences (DNA elements).  **N4-3** A common DNA element in many promoters is the Goldberg-Hogness **TATA box**. The TATA box has the consensus sequence 5'-GNGTATA(A/T)A(A/T)-3', where N is any nucleotide. The TATA box is usually located ~30 bp upstream (5') from the site of transcription initiation. The general transcription factor TFIID—a component of the basal transcriptional machinery—recognizes the TATA box, which is thus believed to determine the site of transcription initiation. TFIID itself is composed of **TATA-binding protein (TBP)** and at least 10 **TBP-associated factors (TAFs)**. The TBP subunit is a sequence-specific DNA-binding protein that binds to the TATA box. TAFs are involved in the activation of gene transcription (more on this below).

N4-3

Binding of Specific Transcription Factors to Promoter Elements on DNA

Contributed by Peter Igarashi

FIGURE 4-3 In this example, specific transcription factors bind to enhancer elements on the DNA and interact with the basal transcriptional machinery to increase the efficiency of gene transcription.

Some promoters do not contain a TATA box. Instead, these promoters contain other elements—for example, the **initiator (Inr)**—that bind general transcription factors. In addition to the TATA box and Inr, gene promoters contain other DNA elements that are necessary for initiating transcription. These elements consist of short DNA sequences and are sometimes called **promoter-proximal sequences** because they are located within ~100 bp upstream from the transcription initiation site. Promoter-proximal sequences are a type of regulatory element that is required for the transcription of specific genes. Well-characterized examples include the GC box (5'-GGGCGG-3') and the CCAAT box (5'-CCAAT-3'), **N4-4** as well as the CACCC box and octamer motif (5'-ATGCAAAT-3'). These DNA elements function as binding sites for additional proteins (transcription factors) that are necessary for initiating transcription of particular genes. The proteins that bind to these sites help recruit the basal transcriptional machinery to the promoter. Examples include the transcription factor NF-Y, which recognizes the CCAAT box, and Sp1 (stimulating protein 1), which recognizes the GC box. The CCAAT box is often located ~50 bp upstream from the TATA box, whereas multiple GC boxes are frequently found in TATA-less gene promoters. Some promoter-proximal sequences are present in genes that are active only in certain cell types. For example, the CACCC box found in gene promoters of β -globin (see pp. 80–81) is recognized by the erythroid-specific transcription factor EKLF (erythroid Kruppel-like factor).

EFIGURE 4-4 Typical eukaryotic gene promoters. A promoter consists of modules of simple DNA sequences or “elements.”

Positive and negative regulatory elements modulate gene transcription

Although the promoter is the site where the basal transcriptional machinery binds and initiates transcription, the promoter alone is not generally sufficient to initiate transcription at a physiologically significant rate. High-level gene expression generally requires activation of the basal transcriptional machinery by specific transcription factors, which bind to additional regulatory elements located near the target gene. Two general types of regulatory elements are recognized. First, **positive regulatory elements** or **enhancers** represent DNA-binding sites for proteins that activate transcription; the proteins that bind to these DNA elements are called **activators**. Second, **negative regulatory elements (NREs)** or **silencers** are DNA binding sites for proteins that inhibit transcription; the proteins that bind to these DNA elements are called **repressors** (see Fig. 4-6).

A general property of enhancers and silencers is that they consist of modules of relatively short sequences of DNA, generally 6 to 12 bp. Regulatory elements are generally located in the vicinity of the genes that they regulate. Typically, regulatory elements reside in the 5' flanking region that is upstream from the promoter. However, enhancers and silencers may be located downstream from the transcription initiation site or a considerable distance from the gene promoter, many hundreds or thousands of base pairs away. Moreover, the distance between the enhancer or silencer and the promoter can often be varied experimentally without substantially affecting transcriptional activity. In addition, many regulatory elements work equally well if their orientation is inverted. Thus, in contrast to the gene promoter,

enhancers and silencers exhibit position independence and orientation independence. Another property of regulatory elements is that they are active on heterologous promoters; that is, if enhancers and silencers from one gene are placed near a promoter for a different gene, they can stimulate or inhibit transcription of the second gene.

After transcription factors (activators or repressors) bind to regulatory elements (enhancers or silencers), they may interact with the basal transcriptional machinery to alter gene transcription. How do transcription factors that bind to regulatory elements physically distant from the promoter interact with components of the basal transcriptional machinery? Regulatory elements may be located hundreds of base pairs from the promoter. This distance is much too great to permit proteins that are bound at the regulatory element and promoter to come into contact along a two-dimensional linear strand of DNA. Rather, **DNA looping** explains these long-range effects, whereby the transcription factor binds to the regulatory element, and the basal transcriptional machinery assembles on the gene promoter. Looping out of the intervening DNA permits physical interaction between the transcription factor and the basal transcriptional machinery, which subsequently leads to alterations in gene transcription.

Locus control regions and insulator elements influence transcription within multigene chromosomal domains

In addition to enhancers and silencers, which regulate the expression of *individual* genes, some *cis*-acting regulatory elements are involved in the regulation of chromosomal domains containing multiple genes.

The first of this type of element to be discovered was the **locus control region (LCR)**, also called the locus-activating region or dominant control region. The LCR is a dominant, positive-acting *cis* element that regulates the expression of several genes within a chromosomal domain. LCRs were first identified at the β -globin gene locus, which encodes the β -type subunits of hemoglobin. Together with α -type subunits, these β -globin-like subunits form embryonic, fetal, and adult hemoglobin (see [Box 29-1](#)). The β -globin gene locus consists of a cluster of five genes (ϵ , γ_G , γ_A , δ , β) that are distributed over 90 kilobases (kb) on chromosome 11.  **N4-5** During ontogeny, the genes exhibit highly regulated patterns of expression in which they are transcribed only in certain tissues and only at precise developmental stages. Thus, embryonic globin (ϵ) is expressed in the yolk sac, fetal globins (γ_G , γ_A) are expressed in fetal liver, and adult globins (δ , β) are expressed in adult bone marrow. This tightly regulated expression pattern requires a regulatory region that is located far from the structural genes. This region, designated the LCR, extends from 6 to 18 kb upstream from the ϵ -globin gene. The LCR is essential for high-level expression of the β -globin-like genes within red blood cell precursors because the promoters and enhancers near the individual genes permit only low-level expression.

B TIME COURSE OF EXPRESSION OF β -GLOBIN-LIKE GENE PRODUCTS

EFIGURE 4-5 Locus control region for the β -globin gene family. **A**, The β -globin gene LCR lies upstream from the genes that encode the ϵ -, γ_G -, γ_A -, δ -, and β -globin subunits. The five vertical arrows indicate sites at which the DNA is unusually sensitive to degradation by deoxyribonuclease (DNase). **B**, The LCR ensures that the genes are expressed in a temporally colinear manner, with ϵ and γ expressed early during development and δ and β expressed later.

The β -globin LCR contains five sites, each with an enhancer-like structure that consists of modules of simple sequence elements that are binding sites for the erythrocyte-specific transcription factors GATA-1 and NF-E2. It is believed that the LCRs perform two functions: one is to alter the chromatin structure of the β -globin gene locus so that it is more accessible to transcription factors, and the second is to serve as a powerful enhancer of transcription of the individual genes. In one model, temporally dependent expression of β -type globin genes is achieved by sequential interactions involving activator proteins that bind to the LCR and promoters of individual genes (Fig. 4-7).

FIGURE 4-7 *Cis*-acting elements that regulate gene transcription. This model shows a loop of chromatin that contains genes A, B, and C. The matrix-attachment region (MAR) is an insulator element on the DNA. Matrix-attachment regions attach to the chromosome scaffold and thus isolate this loop of chromatin from other chromosomal domains. Contained within this loop are several *cis*-acting elements (i.e., DNA sequences that regulate genes on the same piece of DNA), including promoters, enhancers, negative regulatory elements, and the LCR.

Box 4-1

Abnormalities of Regulatory Elements in β -Thalassemias

The best-characterized mutations affecting DNA regulatory elements occur at the gene cluster encoding the β -globin-like chains of hemoglobin. Some of these mutations result in thalassemia, whereas others cause hereditary persistence of fetal hemoglobin. The **β -thalassemias** are a heterogeneous group of disorders characterized by anemia caused by a deficiency in production of the β chain of hemoglobin. The anemia can be mild and inconsequential or severe and life-threatening. The thalassemias were among the first diseases to be characterized at the molecular level. As noted on page 80, the β -globin gene locus consists of five β -globin-like genes that are exclusively expressed in hematopoietic cells and exhibit temporal colinearity. **ON4-5** As expected, many patients with β -thalassemia have mutations or deletions that affect the coding region of the β -globin gene. These patients presumably have thalassemia because the β -globin gene product is functionally abnormal or absent. In addition, some patients have a deficiency in β -globin as a result of inadequate levels of expression of the gene. Of particular interest are patients with the Hispanic and Dutch forms of β -thalassemia. These patients have deletions of portions of chromosome 11. However, the deletions do not extend to include the β -globin gene itself. Why, then, do these patients have β -globin deficiency? It turns out that the deletions involve the region 50 to 65 kb upstream from the β -globin gene, which contains the LCR. In these cases, deletion of the LCR results in failure of expression of the β -globin gene, even though the *structural gene* and its *promoter* are completely normal. These results underscore the essential role that the LCR plays in β -globin gene expression.

Transcription Factors

DNA-binding transcription factors recognize specific DNA sequences

The preceding discussion has emphasized the structure of the gene and the *cis*-acting elements that regulate gene expression. We now turn to the proteins that interact with these DNA elements and thus regulate gene transcription. Because the basal transcriptional machinery—Pol II and the general transcription factors—is incapable of efficient gene transcription alone, additional proteins are required to stimulate the activity of the enzyme complex. The additional proteins include transcription factors that recognize and bind to specific DNA sequences (enhancers) located near their target genes, as well as others (see pp. 83–84) that do not bind to DNA.

Examples of **DNA-binding transcription factors** are shown in Table 4-1. The general mechanism of action of a specific transcription factor is depicted in Figure 4-6. After the basal transcriptional machinery assembles on the gene promoter, it can interact with a transcription factor that binds to a specific DNA element, the enhancer (or silencer). Looping out of the intervening DNA permits physical interaction between the activator (or repressor) and the basal transcriptional machinery, which subsequently leads to stimulation (or inhibition) of gene transcription. The specificity with which transcription factors bind to DNA depends on the interactions between the amino-acid side chains of the transcription factor and the purine and pyrimidine bases in DNA. Most of these interactions consist of noncovalent hydrogen bonds between amino acids and DNA bases. A peptide capable of a specific pattern of hydrogen bonding can recognize and bind to the reciprocal pattern in the major (and to a lesser extent the minor) groove of DNA. Interaction with the DNA backbone may also occur and involves electrostatic interactions (salt bridge formation) with anionic phosphate groups. The site that a transcription factor recognizes (see Table 4-1) is generally short, usually less than a dozen or so base pairs.

TABLE 4-1
DNA-Binding Transcription Factors and the DNA Sequences They Recognize

NAME	TYPE	RECOGNITION SITE*	BINDS AS
Sp1	Zinc finger	5'-GGGCGG-3'	Monomer
AP-1	bZIP	5'-TGASTCA-3'	Dimer
C/EBP	bZIP	5'-ATTGCGCAAT-3'	Dimer
Heat shock factor	bZIP	5'-NGAAN-3'	Trimer
ATF/CREB	bZIP	5'-TGACGTCA-3'	Dimer
c-Myc	bHLH	5'-CACGTG-3'	Dimer
Oct-1	HTH	5'-ATGCAAAT-3'	Monomer
NF-1	Novel	5'-TTGCN ₅ GCCAA-3'	Dimer

*N indicates any nucleotide; S indicates G or C.
ATF, activating transcription factor; NF-1, nuclear factor 1.

DNA-binding transcription factors do not recognize single, unique DNA sequences; rather, they recognize a *family* of closely related sequences. For example, the transcription factor AP-1 (activator protein 1) recognizes the sequences

5'-TGAC**TC**A-3'

5'-TGAGTC A-3'

5'-TGAGTC T-3'

and so on, as well as each of the complementary sequences. That is, some *redundancy* is usually built into the recognition sequence for a transcription factor. An important consequence of these properties is that the recognition site for a transcription factor may occur many times in the genome. For example, if a transcription factor recognizes a 6-bp sequence, the sequence would be expected to occur once every 4^6 (or 4096) base pairs, that is, 7×10^5 times in the human genome. If redundancy is permitted, recognition sites will occur even more frequently. Of course, most of these sites will not be relevant to gene regulation but will instead have occurred simply by chance. This high frequency of recognition sites leads to an important concept: *transcription factors act in combination*. Thus, high-level expression of a gene requires that a combination of multiple transcription factors bind to multiple regulatory elements. Although it is complicated, this system ensures that transcription activation occurs only at appropriate locations. Moreover, this system permits greater fine-tuning of the system, inasmuch as the activity of individual transcription factors can be altered to modulate the overall level of transcription of a gene.

An important general feature of DNA-binding transcription factors is their **modular** construction (Fig. 4-8A). Transcription factors may be divided into discrete domains that bind DNA (**DNA-binding domains**) and domains that activate transcription (**transactivation domains**).  **N4-6** This property was first directly demonstrated for a yeast transcription factor known as GAL4, which activates certain genes when yeast grows in galactose-containing media. GAL4 has two domains. One is a so-called zinc finger (see p. 82) that mediates sequence-specific binding to DNA. The other domain is enriched in acidic amino acids (i.e., glutamate and aspartate) and is necessary for transcriptional activation. This “acidic blob” domain of GAL4 can be removed and replaced with the transactivation domain from a different transcription factor VP16 (see Fig. 4-8B). The resulting GAL4-VP16 chimera binds to the same DNA sequence as normal GAL4 but mediates transcriptional activation via the VP16 transactivation domain. This type of “domain-swapping” experiment indicates that transcription factors have a modular construction in which physically distinct domains mediate binding to DNA and transcriptional activation (or repression).

A DNA-BINDING AND TRANSACTIVATION DOMAINS

B CHIMERIC TRANSCRIPTION FACTOR

FIGURE 4-8 Modular design of specific transcription factors. **A**, DNA-binding transcription factors have independent domains for binding to DNA regulatory sequences and for activating transcription. In this example, amino acids 1 through 147 of the GAL4 yeast transcription factor bind to DNA, whereas amino acids 768 through 881 activate transcription. **B**, Replacement of the transactivation domain of GAL4 with that of VP16 results in a chimera that is a functional transcription factor.

N4-6

Grouping of Transcription Factors According to Transactivation Domain

Contributed by Peter Igarashi

The following table groups some of the transcription factors (described in the text) on the basis of the type of transactivation domain (i.e., the domain that activates transcription).

Type of Transactivation Domain	Transcription Factors with This Domain
Acidic blob (rich in negatively charged amino acids—aspartate and glutamate)	GAL4 (a yeast transcription factor) VP16 (a herpesvirus transcription factor)
Proline rich	CTF (a family of CCAAT-box-binding transcription factor; also known as NF-1) NF-1 (nuclear factor 1)
Glutamine rich	Sp1 (stimulating protein 1)
Serine/threonine rich	GHF-1/Pit-1 (growth hormone factor 1, which is the same as pituitary-specific transcription factor 1; an HTH-type transcription factor)

Transcription factors that bind to DNA can be grouped into families based on tertiary structure

On the basis of sequence conservation as well as structural determinations from x-ray crystallography and nuclear magnetic resonance spectroscopy, DNA-binding transcription factors have been grouped into families. Members of the same family use common structural motifs for binding DNA (see [Table 4-1](#)). These structures include the zinc finger, basic zipper, basic helix-loop-helix, helix-turn-helix, and β sheet. Each of these motifs consists of a particular tertiary protein structure in which a component, usually an α helix, interacts with DNA, especially the major groove of the DNA.

Zinc Finger

The term **zinc finger** describes a loop of protein held together at its base by a zinc ion that tetrahedrally

coordinates to either two histidine residues and two cysteine residues or four cysteine residues. Sometimes two zinc ions coordinate to six cysteine groups. [Figure 4-9A](#) shows a zinc finger in which Zn^{2+} coordinates to two residues on an α helix and two residues on a β sheet of the protein. The loop (or finger) of protein can protrude into the major groove of DNA, where amino-acid side chains can interact with the base pairs and thereby confer the capacity for sequence-specific DNA binding. Zinc fingers consist of 30 amino acids with the consensus sequences $\text{Cys-X}_{2-4}\text{-Cys-X}_{12}\text{-His-X}_{3-5}\text{-His}$, where X can be any amino acid. Transcription factors of this family contain at least two zinc fingers and may contain dozens. Three amino-acid residues at the tips of each zinc finger contact a DNA subsite that consists of three bases in the major groove of DNA; these residues are responsible for site recognition and binding (see [Table 4-1](#)). Zinc fingers are found in many mammalian transcription factors, including several that we discuss in this chapter—Egr-1, Wilms tumor protein (WT-1), and Sp1 (see [Table 4-1](#))—as well as the steroid-hormone receptors (see [p. 71](#)).

A ZINC FINGER

B BASIC ZIPPER

C BASIC HELIX-LOOP-HELIX

D HELIX-TURN-HELIX

Basic Zipper

Also known as the leucine zipper family, the basic zipper (bZIP) family consists of transcription factors that bind to DNA as dimers (see Fig. 4-9B). Members include C/EBP β (CCAAT/enhancer-binding protein- β), c-Fos, c-Jun, and CREB. Each monomer consists of two domains, a basic region that contacts DNA and a leucine zipper region that mediates dimerization. The basic region contains about 30 amino acids and is enriched in arginine and lysine residues. This region is responsible for sequence-specific binding to DNA via an α helix that inserts into the major groove of DNA. The leucine zipper consists of a region of about 30 amino acids in which every seventh residue is a leucine. Because of this spacing, the leucine residues align on a common face every second turn of an α helix. Two protein subunits that both contain leucine zippers can associate because of hydrophobic interactions between the leucine side chains; they form a tertiary structure called a *coiled coil*. Proteins of this family interact with DNA as *homodimers* or as structurally related *heterodimers*. Dimerization is essential for transcriptional activity because mutations of the leucine residues abolish both dimer formation and the ability to bind DNA and activate transcription. The crystal structure reveals that these transcription factors resemble scissors in which the blades represent the leucine zipper domains and the handles represent the DNA-binding domains (see Fig. 4-9B).

Basic Helix-Loop-Helix

Similar to the bZIP family, members of the basic helix-loop-helix (bHLH) family of transcription factors also bind to DNA as dimers. Each monomer has an extended α -helical segment containing the basic region that contacts DNA, linked by a loop to a second α helix that mediates dimer formation (see Fig. 4-9C). Thus, the bHLH transcription factor forms by association of four amphipathic α helices (two from each monomer) into a bundle. The basic domains of each monomer protrude into the major grooves on opposite sides of the DNA. bHLH proteins include the MyoD family, which is involved in muscle differentiation, and E proteins (E12 and E47). MyoD and an E protein generally bind to DNA as heterodimers.  N4-7

N4-7

Dimerization of bHLH Transcription Factors

Contributed by Peter Igarashi

The MyoD family of transcription factors includes **MyoD** itself as well as **myogenin**, **myf5**, and **MRF4**. All are involved in controlling the differentiation of muscle. MyoD and an E protein generally bind to DNA as heterodimers.

Some bHLH transcription factors contain additional domains—located immediately adjacent to the HLH domain—that mediate protein dimerization. A leucine zipper motif is contained in bHLH-Zip proteins such as c-Myc and SREBP, and a PAS domain is contained in bHLH-PAS proteins such as HIF-1 α .

Helix-Turn-Helix

Homeodomain proteins that regulate embryonic development are members of the helix-turn-helix (HTH)

family (see [Fig. 4-9D](#)). The homeodomain consists of a 60–amino-acid sequence that forms three α helices. Helices 1 and 2 lie adjacent to one another, and helix 3 is perpendicular and forms the DNA-recognition helix. Particular amino acids protrude from the recognition helix and contact bases in the major groove of the DNA. Examples of homeodomain proteins include the Hox proteins, which are involved in mammalian pattern formation; engrailed homologs, which are important in nervous system development; and the POU family members Pit-1, Oct-1, and unc-86.  [N4-8](#)

N4-8

Novel Families of Transcription Factors

Contributed by Peter Igarashi

On pages 82–83 we describe four families of transcription factors: zinc finger, bZIP, bHLH, and HTH. In each case, an α helix in the transcription factor binds in the major groove of the DNA. Some transcription factors use an antiparallel **β -pleated sheet** for DNA binding. The β sheet fills the major groove of DNA, and amino-acid side chains that are exposed on the face of the β sheet contact the DNA bases.

In addition to transcription factors that bind to DNA via β -pleated sheets, there are several other transcription factors that do not appear to fall into one of the four structural families listed on pages 82–83. Thus, it seems likely that other structural motifs can also mediate DNA binding. One example is the forkhead domain. It is also important to note that some transcription factors bind to DNA through more than one domain. Examples include the POU family, in which the POU-specific domain is required in addition to the POU homeodomain for DNA binding.

Coactivators and corepressors are transcription factors that do not bind to DNA

Some transcription factors that are required for the activation of gene transcription do not directly bind to DNA. These proteins are called **coactivators**. Coactivators work in concert with DNA-binding transcriptional activators to stimulate gene transcription. They function as adapters or protein intermediaries that form protein-protein interactions between activators bound to enhancers and the basal transcriptional machinery assembled on the gene promoter (see [Fig. 4-6](#)). Coactivators often contain distinct domains, one that interacts with the transactivation domain of an activator and a second that interacts with components of the basal transcriptional machinery. Transcription factors that interact with repressors and play an analogous role in transcriptional repression are called **corepressors**.

One of the first coactivators found in eukaryotes was the VP16 herpesvirus protein discussed above (see [Fig. 4-8B](#)). VP16 has two domains. The first is a transactivation domain that contains a region of acidic amino acids that in turn interacts with two components of the basal transcriptional machinery, general transcription factors TFIIB and TFIID. The other domain of VP16 interacts with the ubiquitous activator Oct-1, which recognizes a DNA sequence called the octamer motif (see [Table 4-1](#)). Thus, VP16 activates transcription by bridging an activator and the basal transcriptional machinery.

Some coactivators play a general role in the activation of transcription. One example is **Mediator**, a multiprotein complex consisting of 28 to 30 subunits, which is not required for basal transcription but is essential for transcriptional activation by most activator proteins. Consistent with its essential role, Mediator is present in the basal transcriptional machinery or preinitiation complex.

Another type of coactivator is involved in transcriptional activation by specific transcription factors.

This type of coactivator is not a component of the basal transcriptional machinery. Rather, these coactivators are recruited by a DNA-binding transcriptional activator through protein-protein interactions. An example is the coactivator **CBP (CREB-binding protein)**, which interacts with a DNA-binding transcription factor called CREB (see [Table 4-1](#)).

Transcriptional activators stimulate transcription by three mechanisms

Once transcriptional activators bind to enhancers (i.e., positive regulatory elements on the DNA) and recruit coactivators, how do they stimulate gene transcription? We discuss three mechanisms by which transactivation might be achieved. These mechanisms are not mutually exclusive, and more than one mechanism may be involved in the transcription of a particular gene.

Recruitment of the Basal Transcriptional Machinery

We have already introduced the concept by which looping out of DNA (see [pp. 79–80](#)) permits proteins that are bound to distant DNA enhancer elements to become physically juxtaposed to proteins that are bound to the gene promoter ([Fig. 4-10](#), pathway 1). The interaction between the DNA-binding transcription factor and general transcription factors, perhaps with coactivators as protein intermediaries, enhances the recruitment of the basal transcriptional machinery to the promoter. Two general transcription factors, TFIID and TFIIB, are targets for recruitment by transcriptional activators. For example, the acidic transactivation domain of VP16 binds to TFIIB, and mutations that prevent the interaction between VP16 and TFIIB also abolish transcriptional activation. Conversely, mutations of TFIIB that eliminate the interaction with an acidic activator also abolish transactivation but have little effect on *basal* transcription.

FIGURE 4-10 Mechanisms of transcriptional activation. The transcriptional activator binds to the enhancer and directly or indirectly (via coactivators) activates transcription by recruiting RNA polymerase to the promoter (1), recruiting HATs that remodel chromatin (2), or stimulating the phosphorylation of the CTD of RNA polymerase (3).

Chromatin Remodeling

A second mechanism by which transcriptional activators may function is alteration of chromatin structure. Gene transcription first requires local disruption of the regular nucleosome structure of chromatin (see [p. 76](#)) so that the basal transcriptional machinery can access the promoter and initiate RNA synthesis. One mechanism of chromatin remodeling involves **histone acetylation**. Acetylation of lysine residues in histones (see [p. 88](#)) weakens the electrostatic interaction between histones and the negatively charged DNA. **Histone acetyltransferases (HATs)** are enzymes that acetylate histones and thus produce local alterations in chromatin structure that are more favorable for transcription. Transcriptional activators may recruit HATs either directly or indirectly through coactivators (see [Fig. 4-10](#), pathway 2). Alternatively, some coactivator proteins that mediate transcriptional activation possess intrinsic histone acetylase activity.

Another mechanism of chromatin remodeling involves the **SWI/SNF family** of proteins. SWI/SNF (switching mating type/sucrose nonfermenting) are large multiprotein complexes, initially identified in yeast but evolutionarily conserved in all animals. SWI/SNF chromatin-remodeling complexes can inhibit the association between DNA and histones by using the energy of ATP to peel the DNA away from the histones and thereby make this DNA more accessible to transcription factors. Some transcriptional activators promote chromatin remodeling by binding and recruiting subunits of the SWI/SNF complex.

Stimulation of Pol II

A third mechanism by which transcriptional activators function is by stimulating RNA polymerase II (see [Fig. 4-10](#), pathway 3). The C-terminal domain (CTD) of the largest subunit of Pol II contains 52 repeats

of the sequence Tyr-Ser-Pro-Thr-Ser-Pro-Ser, which can be phosphorylated at multiple serine and threonine residues. A cyclin-dependent kinase called positive transcription elongation factor b (P-TEFb) phosphorylates the CTD.  **N4-9** Phosphorylation of the CTD occurs coincident with initiation of transcription and is required for chain elongation. Thus, transcriptional activators that interact with P-TEFb may stimulate the conversion of the Pol II holoenzyme from an initiation complex into an **elongation complex**.

N4-9

Phosphorylation of the CTD

Contributed by Peter Igarashi

The CTD of the largest subunit of Pol II can be phosphorylated in vitro by TFIIH and by cdc2 kinase (a regulatory component of the cell cycle). However, the identity of the kinase that is responsible for phosphorylation of the CTD in vivo remains uncertain. There is some evidence that phosphorylation of the CTD may mediate responses to viral transcriptional activators, such as VP16.

Taken together, these three mechanisms of interaction lead to the following model for activation of transcription. A transcription factor that is bound to an enhancer presents a functional domain (e.g., an acidic domain) that either directly or via coactivators interacts with chromatin-remodeling enzymes and components of the basal transcriptional machinery. These interactions facilitate the assembly of the basal transcriptional machinery on the gene promoter and thereby stimulate the initial transcription of RNA. Subsequent interactions—with the CTD of Pol II, for example—may promote elongation of the nascent RNA transcript.

Transcriptional activators act in combination

Two or more activators may increase the rate of transcription by an amount that is greater than the sum of the amounts for each of the activators alone. Almost all naturally occurring promoters contain more than one site for binding of transcriptional activators. A promoter region that contains only a single copy of an enhancer element shows only weak stimulation, whereas a promoter containing multiple copies of an enhancer exhibits substantial activation ([Fig. 4-11](#)). Two mechanisms for synergy have been proposed.

FIGURE 4-11 Synergism of transcriptional activators. The promoter contains three DNA enhancer elements A, B, and C. Binding of a transcription factor to only one of the enhancer elements (A, B, or C) causes a modest activation of transcription. Simultaneous binding of different transcription factors to each of the three enhancer elements can produce a supra-additive increase in transcription (i.e., synergy).

In the first, synergy may reflect **cooperative binding to DNA**; that is, binding of one transcription factor to its recognition site enhances binding of a second transcription factor to a different site. This phenomenon occurs with the glucocorticoid receptor (GR), which binds to a site on DNA known as the **glucocorticoid response element (GRE)**. Binding of GRs to the multiple GREs is cooperative in that binding of the first receptor promotes binding of additional receptors. Thus, the presence of multiple copies of the GRE greatly stimulates gene expression in comparison to a single copy of the GRE.

In the second case, synergy reflects **cooperative protein-protein interactions** between transcription factors and multiple sites on the basal transcriptional machinery. For example, a transcriptional activator that recruits TFIID could synergize with another activator that recruits TFIIB. Similarly, a transcriptional activator that interacts with a HAT could synergize with another activator that interacts with components of the basal transcriptional machinery. Here, the effect on transcription depends on the cumulative effects of multiple transcription factors, each bound to its cognate recognition site and interacting with chromatin-remodeling proteins and the basal transcriptional machinery.

Transcription factors may act in combination by binding to DNA as **homodimers** or **heterodimers**. This synergism is particularly true for members of the bZIP and bHLH families but also for steroid and thyroid hormone receptors. Often, different combinations of monomers have different DNA-binding *affinities*. For example, the thyroid hormone receptor (TR) can bind to DNA as a homodimer, but the heterodimer formed from the TR and the retinoid X receptor (TR/RXR) has much higher binding affinity.

The transcription factor MyoD (see [p. 83](#)), which is involved in muscle differentiation, requires heterodimerization with a ubiquitous E protein (e.g., E12 or E47) for maximal DNA binding. Different combinations of monomers may also have different DNA-binding *specificities* and thus be targeted to different sites on the DNA. Finally, different combinations of monomers may have different *transactivational properties*. For example, the c-Myc protein can bind to DNA as a homodimer or as a heterodimer with Max, but c-Myc/Max heterodimers have greater transcriptional activity.

Transcriptional repressors act by competition, quenching, or active repression

Cells can regulate transcription not only *positively* via transcriptional activators but also *negatively* via transcriptional repressors. 🍷**N4-10** Repression of transcription is important for tissue specificity in that it allows cells to silence certain genes where they should not be expressed. Repression is also important for regulating inducible gene expression by rapidly turning off transcription after removal of the inducing stimulus.

N4-10

Modes of Action of Transcriptional Repression

Contributed by Peter Igarashi

EFIGURE 4-6 Transcriptional repressor modes of action.

Transcriptional repressors may act by three mechanisms. First, some repressors inhibit the binding of transcriptional activators because they **compete** for DNA-binding sites that are identical to, or overlap with, those for activators. An example is the CCAAT displacement protein (CDP), which binds to the CAAT box in the promoter of the γ -globin gene and thereby prevents binding of the transcriptional activator CP1. This action helps prevent inappropriate expression of the fetal globin gene in adults.

Second, some repressors inhibit the activity of transcriptional activators not by interference with DNA binding but by a direct protein-protein interaction with activators. This form of repression is termed **quenching**. A classic example in yeast is the GAL80 repressor, which inhibits transcriptional activation by GAL4. By binding to the transactivation domain of GAL4, GAL80 blocks transcriptional activation. Dissociation of GAL80 (which occurs in the presence of galactose) relieves the inhibition of GAL4, which can then induce expression of galactose-metabolizing genes. Transcriptional repression can also be

mediated by proteins that prevent transcriptional activators from entering the nucleus. For example, the heat shock protein hsp90 binds to GR and prevents this transcriptional activator from entering the nucleus.

A third class of repressors binds to a silencer (or NRE) and then directly inhibits transcription. This mechanism is referred to as **active repression**. The opposite of transcriptional activators, these proteins contain domains that mediate repression. Repression domains may directly interact with and inhibit the assembly or activity of the basal transcriptional machinery. Alternatively, transcriptional repressors may inhibit transcription through protein-protein interactions with corepressors. We have previously seen that transcriptional activators may function by recruiting histone acetylases (HATs) that remodel chromatin and facilitate the initiation of RNA synthesis. Conversely, **histone deacetylases (HDACs)** are enzymes that remove the acetyl groups from histones, which leads to tighter binding to DNA and inhibition of transcription. Some transcriptional corepressors, such as the N-CoR adapter protein that mediates repression by steroid hormone receptors, can interact with HDAC.

The activity of transcription factors may be regulated by post-translational modifications

Cells can regulate the activity of transcription factors by controlling the amount of transcription factor they synthesize. In addition, cells can modulate the activity of preformed transcription factors by three general mechanisms of post-translational modification ([Table 4-2](#)).

TABLE 4-2
Post-Translational Modifications of Transcription Factors

MODIFICATION	MODIFYING GROUP	MODIFIED AMINO ACID	TRANSCRIPTION FACTOR (EXAMPLES)	EFFECTS (EXAMPLE)
Phosphorylation	–PO ₄	Ser/Thr, Tyr	p53, HIF-1α, GR, Sp1, PPARα, β-catenin, STAT1, CREB, NFAT	Altered affinity for coactivators, promotion of ubiquitination, altered protein-protein or protein-DNA interactions
Site-specific proteolysis	None	None	SREBP-1, Notch, NF-κB, ATF-6	Generation of an active transcription factor from an inactive precursor
Acetylation	–COCH ₃	Lys	Sp3, p53, MEF2, STAT3	Regulation of protein stability, DNA binding, protein-protein interactions
Methylation	–CH ₃	Arg, Lys	PGC-1α, STAT1, CBP	Inhibition of protein-protein interactions
Glycosylation	GlcNAc	Ser/Thr	Elf-1, c-Myc, Sp1, ER	Stimulation of transcriptional activity, nuclear transport, protein stability
Ubiquitination	Ubiquitin	Lys	SREBP-1, c-Myc, VP16, β-catenin, p53, SMAD2	Targeting for proteasomal degradation (polyubiquitination). Transcriptional activation (monoubiquitination)
Sumoylation	SUMO	Lys	ER, SF-1, AR	Inhibition of transcriptional activity
Hydroxylation	–OH	Pro, Asn	HIF-1α	Altered affinity for coactivators, altered protein-protein interactions
Nitrosylation	–NO	Cys	NF-κB, Sp1, HIF-1α	Inhibition of DNA binding or protein degradation

ATF-6, activating transcription factor 6; GlcNAc, *N*-acetylglucosamine; MEF2, myocyte enhancer factor; NFAT, nuclear factor of activated T cell; PGC-1α, peroxisome proliferator-activated receptor-γ cofactor 1α; SF-1, steroidogenic factor 1.

Phosphorylation

The best-studied post-translational modification affecting transcription factor activity is phosphorylation, which increases or decreases (1) transport of the transcription factor from the cytoplasm into the nucleus, (2) the affinity with which the transcription factor binds to DNA, and (3) transcriptional activation.

For transcription factors that reside in the cytoplasm under basal conditions, migration from the cytoplasm into the nucleus is a necessary step. Many proteins that are transported into the nucleus contain a sequence that is relatively enriched in basic amino-acid residues (i.e., arginine and lysine). This sequence, the **nuclear localization signal**, is required for transport of the protein into the nucleus. Phosphorylation at sites within or near the nuclear localization signal can dramatically change the rate of

nuclear translocation. Phosphorylation can also modulate import into the nucleus by regulating the binding of transcription factors to cytoplasmic anchors. In the case of the transcription factor nuclear factor κ B (NF- κ B; Fig. 4-12A), binding to a cytoplasmic anchor called inhibitor of κ B (I κ B) conceals the nuclear localization signal on the p50 and p65 subunits of NF- κ B from the nuclear translocation machinery. Only after these two other subunits dissociate from the phosphorylated I κ B is the transcription factor dimer free to enter the nucleus.

FIGURE 4-12 Regulation of transcription factors by post-translational modification. **A**, The phosphorylation of the cytoplasmic anchor I κ B releases the p50 and p65 subunits of NF- κ B, which allows them to translocate into the nucleus. **B**, Proteolytic cleavage of a 105-kDa precursor releases the p50 subunit of NF- κ B. Together with the p65 subunit, the p50 subunit can now translocate to the nucleus.

Phosphorylation can also regulate transcription factor activity by altering the *affinity* of the transcription factor for its target recognition sequences on DNA. As a result, phosphorylation increases or decreases DNA-binding activity. For example, phosphorylation of SRF (serum response factor), a transcription factor that activates the *c-fos* gene in response to growth factors, enhances DNA binding. In contrast, phosphorylation of the transcription factor c-Jun by casein kinase II inhibits binding to DNA.

Phosphorylation can greatly influence the *transactivation properties* of transcription factors. c-Jun is an example of a transcription factor whose transcriptional activity is increased by the phosphorylation of serine residues located within the transactivation domain near the N terminus of the protein. Phosphorylation of a transcriptional activator may stimulate its activity by increasing its binding affinity

for a coactivator. Phosphorylation can also *inhibit* transcriptional activation by reducing transcriptional activation or stimulating active transcriptional repression.

Effects of phosphorylation on nuclear translocation, DNA binding, and transactivation are not mutually exclusive. Moreover, not only phosphorylation by protein kinases but also dephosphorylation by protein phosphatases may regulate transcriptional activity.

Site-Specific Proteolysis

Many transcription factors undergo proteolytic cleavage at specific amino-acid residues, particularly in response to exogenous signals. Site-specific proteolysis often converts an inactive precursor protein into an active transcriptional regulator. One example is NF- κ B. Although phosphorylation can regulate NF- κ B by controlling its binding to I κ B (see Fig. 4-12A), proteolysis can also regulate NF- κ B (see Fig. 4-12B). A 105-kDa precursor of the 50-kDa subunit of NF- κ B (p50), which we mentioned above, binds to and thereby retains the 65-kDa subunit of NF- κ B (p65) in the cytoplasm. Proteolysis of this larger precursor yields the 50-kDa subunit that together with the 65-kDa subunit constitutes the active NF- κ B transcription factor.

Another form of site-specific proteolysis, which creates active transcription factors from inactive membrane-tethered precursors, is called **regulated intramembranous proteolysis (RIP)**. One example is the **sterol regulatory element-binding protein (SREBP)**, a membrane protein that normally resides in the endoplasmic reticulum. In response to depletion of cellular cholesterol, SREBP undergoes RIP, which releases an N-terminal fragment containing a bHLH motif. The proteolytic fragment translocates to the nucleus, where it binds to DNA and activates transcription of genes that encode enzymes involved in cholesterol biosynthesis and the LDL (low-density lipoprotein) receptor (see p. 42).  **N4-11**

N4-11

Examples of RIP

Contributed by Peter Igarashi

In addition to SREBP noted in the text, other proteins that undergo RIP are Notch and APP—all span the membrane at least once.

Notch is a plasma membrane receptor whose cytoplasmic domain is released in response to Delta, a membrane-bound ligand that regulates cell fate during development.

Amyloid precursor protein (APP) is a protein of unknown function that is cleaved in the membrane to produce the extracellular amyloid β peptide implicated in **Alzheimer disease**. For Notch and APP, the intramembrane cleavage does not take place until a primary cleavage event removes the bulk of the protein on the extracytoplasmic face. Although the cleaved sites differ in these proteins, the net effect of the first step is to shorten the extracytoplasmic domain to <30 amino acids, which allows the second cleavage to release a portion of the cytoplasmic domain.

The **epithelial Na⁺ channel ENaC**—a heterotrimer that consists of α , β , and γ subunits—also undergoes intramembrane proteolysis. While the ENaC is still in the vesicular subcompartment of the secretory pathway, the protease **furin** cleaves the extracellular domain of the α subunit twice (after consensus RXXR motifs), releasing a peptide of 26 amino acids. By itself, this modification increases the open probability of ENaC to ~ 0.30 . Furin also cleaves the γ subunit, but only once. A variety of extracellular proteases—including prostatic, elastase, and plasmin—can make a second cut after the protein has reached the plasma membrane. The result of the γ -subunit cleavages is to increase the open

probability to nearly 1.0. Thus, both examples of proteolysis greatly increase the activity of the channel.

Other Post-Translational Modifications

In addition to phosphate groups, a variety of other covalent attachments can affect the activity of transcription factors (Table 4-3). These small molecules—such as acetyl groups, methyl groups, sugars or peptides, hydroxyl groups, or nitro groups—attach to specific amino-acid residues in the transcription factor. Post-translational modifications of transcription factors can affect their stability, intracellular localization, dimerization, DNA-binding properties, or interactions with coactivators. For example, **acetylation** of lysine residues in the p53 transcription factor increases binding to DNA and inhibits degradation. **Methylation** of an arginine residue in the coactivator CBP inhibits its interaction with the transcription factor CREB. **O-linked glycosylation**, a covalent modification in which sugar groups attach to serine or threonine residues, stimulates NF-κB. **Ubiquitin** is a small peptide that is covalently attached to lysine groups in proteins. Addition of multiple ubiquitin groups (polyubiquitination) frequently results in degradation of the protein via the proteasome (see pp. 33–34). However, addition of a single ubiquitin group (monoubiquitination) may stimulate the activity of a transcription factor, perhaps by increasing its affinity for transcriptional elongation factors. Conversely, **sumoylation**, covalent modification of lysine residues with small ubiquitin-like modifiers (SUMOs), may inhibit activity by altering the localization of a transcription factor within the nucleus. As we will see in the next section, extracellular signals often trigger post-translational modifications to regulate the activity of transcription factors.

TABLE 4-3
Examples of Transcription Factors That Regulate Gene Expression in Response to Physiological Stimuli

PHYSIOLOGICAL STIMULUS	TRANSCRIPTION FACTOR	EXAMPLES OF PROTEINS ENCODED BY TARGETED GENE
Hypoxia	HIF-1α	VEGF, erythropoietin, glycolytic enzymes
DNA damage	p53	CIP1, GADD45, PCNA, MDM2
Cholesterol depletion	SREBP-1	HMG-CoA reductase, fatty-acid synthase, LDLl receptor
Viruses, oxidants	NF-κB	Tumor necrosis factor-α, interleukin-1β, interleukin-2, granulocyte colony-stimulating factor, inducible nitric oxide synthase, intercellular cell adhesion molecule
Heat stress	HSF1	Heat shock proteins, αB-crystallin
Fatty acids	PPARα	Lipoprotein lipase, fatty-acid transport protein, acyl-CoA synthetase, carnitine palmitoyltransferase I

CIP1, CDK (cyclin-dependent kinase)-interacting protein 1; GADD45, growth arrest and DNA damage 5; HSF1, heat shock factor protein 1; MDM2, mouse double minute 2 homolog (an E3 ubiquitin-protein ligase); PCNA, proliferating cell nuclear antigen.

The expression of some transcription factors is tissue specific

Some transcription factors are ubiquitous, either because these transcription factors regulate the transcription of genes that are expressed in many different tissues or because they are required for the transcription of many different genes. Examples of ubiquitous transcription factors are the DNA-binding transcription factors Sp1 and NF-Y, which bind to regulatory elements (i.e., GC boxes and CCAAT boxes,

respectively—see [p. 79](#)) that are present in many gene promoters. Other transcription factors are present only in certain tissues or cell types; these transcription factors are involved in the regulation of tissue-specific gene expression.

Tissue-specific activators bind to enhancers present in the promoters and regulatory regions of genes that are expressed in a tissue-specific manner. Conversely, tissue-specific repressors bind to silencers that prevent transcription of a gene in nonexpressing tissues. Each tissue-specific transcription factor can regulate the expression of multiple genes. Because the short sequences of enhancers and silencers may occur by chance, the combined effect of multiple transcription factors—each binding to distinct regulatory elements near the gene—prevents illegitimate transcription in nonexpressing tissues. In addition to being activated by transcriptional activators, tissue-specific gene expression may also be regulated by transcriptional repression. In this case, transcriptional repressors prevent transcription of a gene in nonexpressing tissues. Tissue-specific expression probably also involves permanent silencing of nonexpressed genes through epigenetic modifications, such as DNA methylation (see [pp. 95–96](#)).

Pit-1 is an HTH-type tissue-specific transcription factor that regulates the pituitary-specific expression of genes encoding growth hormone, thyroid-stimulating hormone, and prolactin. MyoD and myogenin are bHLH-type transcription factors that bind to the E-box sequence CANNTG of promoters and enhancers of many genes expressed in skeletal muscle, such as myosin heavy chain and muscle creatine kinase. EKLF as well as GATA-1 and NF-E2 mediate the erythroid-specific expression of β -globin genes. The combined effects of HNF-1, HNF-3, HNF-4, C/EBP, and other transcription factors—each of which may individually be present in *several* tissues—mediate the *liver*-specific expression of genes such as albumin and α_1 -antitrypsin. Many tissue-specific transcription factors play important roles in embryonic development. For example, myogenin is required for skeletal muscle differentiation, and GATA-1 is required for the development of erythroid cells.

Regulation of Inducible Gene Expression by Signal-Transduction Pathways

How do cells activate previously quiescent genes in response to environmental cues? How are such external signals transduced to the cell nucleus to stimulate the transcription of specific genes?

Transcription factors may be thought of as effector molecules in signal-transduction pathways (see [Chapter 3](#)) that modulate gene expression. Several such signaling pathways have been defined. Lipid-soluble steroid and thyroid hormones can enter the cell and interact with specific receptors that are themselves transcription factors. However, most cytokines, hormones, and mitogens cannot diffuse into the cell interior and instead bind to specific receptors that are located on the cell surface. First, we consider three pathways for transducing signals from cell-surface receptors into the nucleus: a cAMP-dependent pathway, a Ras-dependent pathway, and the JAK-STAT pathway. Next, we examine the mechanisms by which steroid or thyroid hormones act via nuclear receptors. Finally, we discuss how transcription factors coordinate gene expression in response to physiological stimuli.

cAMP regulates transcription via the transcription factors CREB and CBP

cAMP is an important second messenger (see [p. 57](#)) in the response to agonists binding to specific cell-surface receptors. Increases in $[cAMP]_i$ stimulate the transcription of certain genes, including those that encode a variety of hormones, such as somatostatin (see [pp. 993–994](#)), the enkephalins (see [p. 315](#)), glucagon (see [pp. 1050–1053](#)), and vasoactive intestinal peptide (see [Table 41-1](#)). Many genes that are activated in response to cAMP contain within their regulatory regions a common DNA element called **CRE (cAMP response element)** that has the consensus sequence 5'-TGACGTCA-3'. Several different transcription factors bind to CRE, among them **CREB (cAMP response element-binding protein)**, a 43-kDa member of the bZIP family. As shown in [Figure 4-13](#), increases in $[cAMP]_i$ stimulate protein kinase A (PKA) by causing dissociation of the PKA regulatory subunit. The catalytic subunit of PKA then translocates into the nucleus, where it phosphorylates CREB and other proteins. Activation of CREB is rapid (30 minutes) and declines gradually during a 24-hour period. This phosphorylation greatly increases the affinity of CREB for the coactivator **CBP**, which is a 245-kDa protein containing two domains, one that binds to phosphorylated CREB and another that activates components of the basal transcriptional machinery. Thus, CBP serves as a “bridge” protein that communicates the transcriptional activation signal from CREB to the basal transcriptional machinery. In addition, because CBP has intrinsic HAT activity (see [p. 84](#)), its recruitment by CREB also results in chromatin remodeling that facilitates gene transcription. The result of phosphorylation of CREB is a 10- to 20-fold stimulation of CREB's ability to induce the transcription of genes containing a CRE.

FIGURE 4-13 Regulation of gene transcription by cAMP. Phosphorylated CREB binds CBP, which has a transactivation domain that stimulates the basal transcriptional machinery. In parallel, phosphorylation activates phosphoprotein phosphatase 1 (PP1), which dephosphorylates CREB, terminating the activation of transcription. R, regulatory subunit of protein kinase A.

How is the transcriptional signal terminated? When $[cAMP]_i$ is high, PKA phosphorylates and activates phosphoprotein phosphatase 1 in the nucleus. When cAMP levels fall, the still-active phosphatase

dephosphorylates CREB.

Receptor tyrosine kinases regulate transcription via a Ras-dependent cascade of protein kinases

Many growth factors bind to cell-surface receptors that, when activated by the ligand, have tyrosine kinase activity (see pp. 70–71). Examples of growth factors that act through such receptor tyrosine kinases (RTKs) are epidermal growth factor (EGF), platelet-derived growth factor (PDGF), insulin, insulin-like growth factor type 1 (IGF-1), fibroblast growth factor (FGF), and nerve growth factor (NGF). The common pathway by which activation of RTKs is transduced into the nucleus is a cascade of events that increase the activity of the small GTP-binding protein Ras (see pp. 68). This **Ras-dependent signaling pathway** culminates in the activation of mitogen-activated protein kinase (MAPK), which translocates to the nucleus, where it phosphorylates a number of nuclear proteins that are transcription factors. Phosphorylation of a transcription factor by MAPK can enhance or inhibit binding to DNA and can stimulate either transactivation or transrepression. **N4-12** Transcription factors that are regulated by the Ras-dependent pathway include c-Myc, c-Jun, c-Fos, and Elk-1. Many of these transcription factors regulate the expression of genes that promote cell proliferation.

N4-12

Transcription Factors Phosphorylated by MAPK

Contributed by Peter Igarashi

The following table summarizes some transcription factors that MAPK phosphorylates, together with the site of phosphorylation on the transcription factor, and the effect.

Transcription Factor	Site	Effect
c-Myc	Ser-62	Stabilizes protein
c-Jun	Ser-243 (Ser-63/Ser-73 in the activation domain are phosphorylated by a distinct Ras-dependent kinase)	Inhibits DNA binding
c-Fos	Ser-374 (direct) Ser-362 (indirect via ribosomal S6 kinase, which is activated by MAPK)	Stimulates transrepression
p62TCF = Elk-1	Multiple	Stimulates transactivation and possibly also DNA binding
C/EBPβ = LAP or NF-IL-6	Thr-235	Stimulates transactivation
ATF-2	Thr-69 and Thr-71 (via p38 and JNK MAPK)	Stimulates transactivation

ATF-2, activating transcription factor 2; C/EBPβ, CCAAT/enhancer-binding protein β; JNK, c-Jun N-terminal kinases.

Tyrosine kinase–associated receptors can regulate transcription via JAK-STAT

A group of cell-surface receptors termed tyrosine kinase–associated receptors lack *intrinsic* tyrosine kinase activity (see pp. 70–71). The ligands that bind to these receptors include several cytokines, growth hormone, prolactin, and interferons (IFN-α, IFN-β, and IFN-γ). Although the receptors themselves lack catalytic activity, their cytoplasmic domains are associated with the **Janus kinase (JAK) family** of protein tyrosine kinases.

Binding of ligand to certain tyrosine kinase–associated receptors activates a member of the JAK family, which results in phosphorylation of cytoplasmic proteins, among which are believed to be latent

cytoplasmic transcription factors called signal transducers and activators of transcription (STATs). When phosphorylated on tyrosine residues, the STAT proteins dimerize and thereby become competent to enter the nucleus and induce transcription.

A well-characterized example of the JAK-STAT pathway is the activation of **interferon-responsive genes** by IFN- α and IFN- γ . IFN- α activates the JAK1 and Tyk2 kinases that are associated with its receptor ([Fig. 4-14A](#)). Subsequent phosphorylation of two different STAT monomers causes the monomers to dimerize. This STAT heterodimer enters the nucleus, where it combines with a third 48-kDa protein to form a transcription factor that binds to a DNA sequence called the IFN-stimulated response element (ISRE). In the case of IFN- γ (see [Fig. 4-14B](#)), the receptor associates with the JAK1 and JAK2 (rather than Tyk2) kinases, and subsequent phosphorylation of a *single* kind of STAT monomer causes these monomers to dimerize. These STAT homodimers also enter the nucleus, where they bind to the DNA at IFN- γ response elements called IFN- γ activation sites (GASs), without requiring the 48-kDa protein.

FIGURE 4-14 JAK-STAT pathway. **A**, Binding of a ligand such as IFN-α to a tyrosine kinase–associated receptor causes JAK1 and Tyk2 to phosphorylate themselves, the receptor, and two different STAT monomers. The phosphorylation of the STAT monomers leads to the formation of a *heterodimer*, which translocates to the nucleus and combines with a third protein (p48). The complex binds to ISRE and activates gene transcription. **B**, Binding of a ligand such as IFN-γ to a tyrosine kinase–associated receptor causes JAK1 and JAK2 to phosphorylate themselves, the receptor, and two identical STAT monomers. The phosphorylation of the STAT monomers leads to the formation of a *homodimer*, which translocates to the nucleus. The complex binds to the GAS response element and activates gene transcription.

Nuclear receptors are transcription factors

Steroid and thyroid hormones are examples of ligands that activate gene expression by binding to cellular receptors that are themselves transcription factors. Members of the steroid and thyroid hormone receptor superfamily, also called the nuclear receptor superfamily, are grouped together because they are structurally similar and have similar mechanisms of action. After these hormones enter the cell, they bind to receptors in the cytoplasm or nucleus. Ligand binding converts the receptors into active transcription factors. The transcription factors bind to specific regulatory elements on the DNA, called **hormone response elements**, and activate the transcription of *cis*-linked genes. The family of nuclear receptors includes receptors that bind glucocorticoids (GR), mineralocorticoids (MR), estrogens (ER), progesterone (PR), androgens (AR), thyroid hormone (TR), vitamin D (VDR), retinoic acid (RAR), lipids (peroxisome proliferator–activated receptor, PPAR), and 9-*cis*-retinoic acid (retinoid X receptor, RXR) as well as bile acids (bile acid receptor, FXR; see [p. 964](#)) and xenobiotics (steroid and xenobiotic receptor, SXR; constitutive androstane receptor, CAR; see [p. 956](#)).

With the exception of the thyroid hormones, the hormones that bind to these receptors are lipophilic molecules that enter cells by diffusion and do not require interaction with cell-surface receptors. The thyroid hormones differ in that they are electrically charged and may cross the cell membrane via transporters.

Modular Construction

The nuclear receptors have a modular construction consisting of an N-terminal transactivation domain, a DNA-binding domain, and a C-terminal ligand-binding domain (see [pp. 71–72](#)). These receptors bind to specific DNA sequences through two *zinc fingers* (see [p. 82](#)), each of which contains four cysteine residues rather than the two histidines and two cysteines that are typical of many other zinc finger proteins (see [Fig. 4-9A](#)). Particularly important for DNA recognition is the P-box motif in the hormone receptor, a sequence of six amino acids at the C-terminal end of each finger. These P boxes make base pair contacts in the major groove of DNA and determine the DNA-binding specificities of the zinc finger.

Dimerization

GR, MR, PR, ER, and AR bind to DNA as **homodimers** (see [Table 3-6](#)). The recognition sites for these receptors (except for ER) consist of two 6-bp DNA sequences that are separated by three other base pairs. The 6-bp DNA sequences, commonly called **half-sites**, represent binding sites for each zinc-finger monomer.

In contrast, other nuclear receptors preferentially bind to DNA as **heterodimers** formed with RXR, the receptor for 9-*cis*-retinoic acid. Examples of such heterodimers are VDR/RXR, TR/RXR, RAR/RXR, and PPAR/RXR (see [Table 3-6](#)). Interestingly, these heterodimers work even in the absence of the ligand of RXR (i.e., 9-*cis*-retinoic acid). Only the non-RXR part of the dimer needs to be occupied by its hormone ligand. These heterodimers recognize a family of DNA sites containing a DNA sequence such as 5'-AGGTCA-3', followed by a DNA spacer and then by a direct repeat of the previous 6-bp DNA sequence. Moreover, because VDR/RXR, TR/RXR, and RAR/RXR may each recognize the *same* 6-bp sequences, binding specificity also depends on the length of the spacer between the direct repeats. The VDR/RXR, TR/RXR, and RAR/RXR heterodimers preferentially recognize separations of 3 bp, 4 bp, and 5 bp, respectively, between the repeats of 5'-AGGTCA-3'. This relationship forms the basis for the so-called **3-4-5 rule**.

Activation of Transcription

Ligand binding activates nuclear receptors through two main mechanisms: regulation of subcellular localization and interactions with coactivators. Some nuclear receptors, such as GR, are normally located in the cytoplasm and are maintained in an inactive state by association with a cytoplasmic anchoring protein ([Fig. 4-15A](#)). The protein that retains GR in the cytoplasm is a **molecular chaperone**, the 90-kDa heat shock protein **hsp90**. GR must bind to hsp90 to have a high affinity for a glucocorticoid hormone. When glucocorticoids bind to the GR, hsp90 dissociates from the GR and exposes a nuclear localization signal that permits the transport of GR into the nucleus. The receptor must remain hormone bound for receptor dimerization, which is a prerequisite for binding to the GRE on the DNA. Other receptors, such as TR, are normally already present in the nucleus before binding the hormone (see [Fig. 4-15B](#)). For these receptors, binding of hormone is evidently not essential for dimerization or binding to DNA. However, ligand binding is necessary at a subsequent step for transactivation.

FIGURE 4-15 Transcriptional activation by glucocorticoid and thyroid hormones. **A**, The binding of a glucocorticoid hormone to a cytoplasmic receptor causes the receptor to dissociate from the chaperone hsp90 (90-kDa heat shock protein). The free hormone-receptor complex can then translocate to the nucleus, where dimerization leads to transactivation. **B**, The binding of thyroid hormone to a receptor in the nucleus leads to transactivation. The active transcription factor is a heterodimer of the TR and the RXR.

Although nuclear receptors may stimulate gene expression by interacting directly with components of the basal transcriptional machinery, full transcriptional activation requires **coactivators** that interact with the receptor in a ligand-dependent manner. More than 200 coactivators may interact directly or indirectly with nuclear receptors via mechanisms that include the following:

1. Recruitment of basal transcriptional machinery. Coactivators that belong to the **SRC (steroid receptor coactivator)/p160** family bind only to the ligand-bound form of the receptor. On binding to the nuclear receptor, SRC/p160 coactivators recruit a second coactivator, CBP (see p. 84), which then promotes recruitment of the basal transcriptional machinery. Nuclear receptors also bind in a ligand-dependent manner to the coactivator TRAP220, a component of Mediator (see p. 84), which is part of the

basal transcriptional machinery.

- 2. Binding to a chromatin-remodeling complex.** Nuclear receptors also interact with Brg1 (Brahma-related gene 1), the central motor component of the chromatin-remodeling complex SWI/SNF (see [p. 84](#)).
- 3. Histone acetylation.** Several coactivators have enzymatic activities that mediate chromatin remodeling. Both SRC-1 and CBP have intrinsic HAT activity.
- 4. Histone methylation.** The coactivator CARM1 is a methyltransferase that methylates specific arginine residues in histones, thereby enhancing transcriptional activation.
- 5. Ubiquitination.** Nuclear receptors recruit components of the ubiquitin-proteasome pathway (see [pp. 33–34 and 88](#)) to the promoter region of nuclear receptor target genes. Ubiquitination appears to promote transcript elongation.

Repression of Transcription

Nuclear receptors sometimes function as active repressors, perhaps acting by alternative mechanisms. First, a receptor may form inactive heterodimers with other members of the nuclear receptor family. Second, a receptor may compete with other transcription factors for DNA-binding sites. For example, when the TR—without bound thyroid hormone—interacts with its own DNA response element, the TR acts as a repressor. In addition, the TR receptor isoform TR α can dimerize with one of the retinoic acid receptor isoforms (RXR β) to interfere with binding of ER to its response element. This competition may be one of the mechanisms by which retinoids inhibit estrogen-induced alterations in gene expression and growth in mammary tissue. Finally, nuclear receptors can also inhibit gene transcription by interacting with corepressors, such as N-CoR, Sin3A, and Sin3B. These corepressors can recruit HDACs that enhance nucleosome assembly, which results in transcriptional repression.

Box 4-2

Role of a Chimeric Transcription Factor in Acute Promyelocytic Leukemia

Correct regulation of gene expression involves both transcription factors and the DNA regulatory elements to which they bind. Abnormalities of either can and do result in abnormal regulation of gene expression, which is often manifested as disease. An example of a transcription factor abnormality is acute promyelocytic leukemia (APL), a hematological malignant state in which cells of the granulocyte lineage (promyelocytes) fail to differentiate. Normally, retinoic acid (RA) binds to **retinoic acid receptor- α (RAR α)**, a member of the steroid and thyroid hormone receptor superfamily. RAR α forms heterodimers with retinoid X receptor (RXR) and binds to retinoic acid response elements (RAREs) that are present in genes involved in cell differentiation. In the absence of RA, RAR α /RXR heterodimers bind to RAREs and recruit the corepressor N-CoR, which in turn recruits HDACs that inhibit gene transcription. Binding of RA to RAR α leads to dissociation of N-CoR, which permits binding of the coactivator CBP (see [p. 89](#)) and activation of RAR α -responsive genes that promote cell differentiation. Ninety percent of patients with APL have a translocation affecting chromosomes 15 and 17, t(15;17), that produces a chimeric transcription factor containing the DNA- and hormone-binding domains of RAR α , fused to the promyelocytic leukemia protein (PML). The PML/RAR α chimeric protein also binds to RA

and forms heterodimers with RXR but has an abnormally high affinity for N-CoR. At physiological levels of RA, N-CoR remains bound to PML/RAR α , blocking promyelocytic differentiation. However, high concentrations of RA induce dissociation of N-CoR and permit differentiation. This mechanism explains why high concentrations of exogenous RA can be used to induce clinical remissions in patients with APL.

Physiological stimuli can modulate transcription factors, which can coordinate complex cellular responses

In response to physiological stimuli, some transcription factors regulate the expression of several genes (see [Table 4-3](#)). As an example, we discuss how oxygen concentration ($[O_2]$) controls gene expression.

When chronically exposed to low $[O_2]$ (hypoxia), many cells undergo dramatic changes in gene expression. For example, cells switch from oxidative metabolism to glycolysis, which requires the induction of genes encoding glycolytic enzymes. Many tissues activate the gene encoding the vascular endothelial growth factor (VEGF), which stimulates angiogenesis (see [p. 481](#)) and improves the blood supply to chronically hypoxic tissues. The kidney activates the gene encoding erythropoietin (see [pp. 431–433](#)), a hormone that stimulates red cell production in the bone marrow. These changes in gene expression promote survival of the cell or organism in a hypoxic environment. A key mediator in the response to hypoxia is a transcription factor called **hypoxia-inducible factor 1 α (HIF-1 α)**.

HIF-1 α ([Fig. 4-16A](#)) belongs to the bHLH family of transcription factors (see [p. 83](#)). In addition, it contains a PAS domain [EN4-7](#) that mediates dimerization. HIF-1 α binds to DNA as a heterodimer with HIF-1 β . **HIF-1 β** is expressed at constant levels in cells, but the abundance of HIF-1 α changes markedly in response to changes in $[O_2]$. At a normal $[O_2]$ (normoxia), HIF-1 α levels are low. Under hypoxic conditions, the abundance of HIF-1 α increases. HIF-1 α together with HIF-1 β binds to an enhancer, called a **hypoxia response element**, that is present in many genes activated during hypoxia, including genes encoding glycolytic enzymes, VEGF, and erythropoietin.

A HYDROXYLATION

B NORMOXIA

C HYPOXIA

FIGURE 4-16 Regulation of HIF-1 α by oxygen. **A**, In the presence of oxygen, HIF-1 α is hydroxylated on proline and asparagine by hydroxylases. **B**, Hydroxylation of HIF-1 α promotes its degradation and inhibits its interaction with coactivators. **C**, In hypoxic conditions, dehydroxylation of HIF-1 α promotes its stabilization and transcriptional activity.

The cell regulates the abundance of HIF-1 α by hydroxylation—a post-translational modification—at

specific proline and asparagine residues. Oxygen activates the prolyl and asparaginyl hydroxylases (see [Fig. 4-16A](#)). Proline hydroxylation stimulates the interaction of HIF-1 α with VHL, a protein that targets HIF-1 α for proteasomal degradation (see [Fig. 4-16B](#)). Asparagine hydroxylation inhibits the interaction of HIF-1 α with the transcriptional coactivator CBP. Because both of these hydroxylations reduce transcriptional activity, normoxic conditions lower the expression of HIF-1 α target genes.

In contrast, under hypoxic conditions, the hydroxylases are inactive, and HIF-1 α is not hydroxylated on proline and asparagine residues. HIF-1 α accumulates in the nucleus and interacts with CBP, which activates the transcription of downstream target genes, including VEGF and erythropoietin (see [Fig. 4-16C](#)). The net result is a system in which the expression of multiple hypoxia-inducible genes is coordinately and tightly regulated through post-translational modification of a common transcriptional activator.

Epigenetic Regulation of Gene Expression

Although genetic information can flow from parent to child, or from parental cells to progeny cells, via the sequence of nucleotides in DNA, it can also flow via mechanisms that are independent of DNA sequence and yet stably inherited. This form of inheritance is referred to as **epigenetic** regulation of gene expression. We have already introduced one form of epigenetic gene regulation, which is the separation of chromatin into transcriptionally active euchromatin and transcriptionally inactive heterochromatin (see [p. 76](#)). Although shifting between euchromatin and heterochromatin does not change the DNA sequence, the progeny cells maintain this distinction. Thus, the formation of heterochromatin and euchromatin is an example of epigenetic gene regulation.

Epigenetic regulation can result in long-term gene silencing

Epigenetic regulation can have a long-term influence on gene expression. The following are three examples of long-term regulation of gene expression:

1. **X-inactivation.** Females carry two X chromosomes (see [p. 1074](#)), whereas males carry only one copy. To express X-linked genes at the same levels as males, females during development permanently inactivate one of the X chromosomes by globally converting one X chromosome from euchromatin to heterochromatin.
2. **Imprinting.** Cells contain two copies of every autosomal gene, one inherited from each parent, and usually express each copy identically. In a few cases, however, genes are differentially expressed, depending on whether they are inherited from the mother or the father. This phenomenon is called **genomic imprinting**.  **N4-13** For example, the insulin-like growth factor 2 gene (*IGF2*; see [pp. 996–997](#)) is *maternally* imprinted—only the copy inherited from the *father* is expressed; the maternal copy is silenced (i.e., not expressed).

N4-13

Genomic Imprinting

Contributed by Emile Boulpaep, Walter Boron, Sam Mesiano

Genomic imprinting is the process by which certain genes—about 1% of the genome—are silenced; particular genes are silenced only in female gametes, and others, only in male gametes. Thus, these genes are expressed in a manner specific to the parent of origin.

Note that a female diploid oogonium has some paternal genes imprinted or silenced (i.e., only the maternal gene is active) and some maternal genes silenced (i.e., only the paternal gene is active). When the 2N genome splits into two 1N genomes, it is important that all genes in the oocyte have the *female* pattern of imprinting, which occurs during oocyte maturation.

Failure of proper genomic imprinting causes aberrant gene expression and is associated with several human diseases, including Beckwith-Wiedemann, Prader-Willi, and Angelman syndromes. For example, the *IGF2* gene is normally *maternally* imprinted (i.e., silenced). In **Beckwith-Wiedemann syndrome**, the maternal *IGF2* gene becomes reactivated (by removal of methyl tags) during oocyte formation in the

mother or early embryonic development. The result is that the offspring has two (rather than one) active copies of *IGF2* and thus excess IGF-2 protein. The most obvious sign is macrosomia (large body size) in the newborn.

Wikipedia. s.v. *Genomic imprinting*. http://en.wikipedia.org/wiki/Genomic_imprinting [Accessed March 20, 2015].

3. Tissue-specific gene silencing. Many tissue-specific genes are globally inactivated during embryonic development, later to be reactivated only in particular tissues. For example, globin genes are silenced except in erythroid cells. The silencing of genes in nonexpressing tissues is associated with chromatin modifications that are similar to those found in heterochromatin.

X-inactivation, imprinting, and tissue-specific silencing require long-term inactivation of gene expression and the maintenance of this inactivation during DNA replication and cell division. For example, the inactivated X chromosome remains inactivated in the two progeny cells after mitosis. Similarly, genes silenced by imprinting or by tissue-specific silencing remain inactive in progeny cells.

Alterations in chromatin structure may mediate epigenetic regulation, stimulating or inhibiting gene transcription

DNA in the nucleus is organized into a higher-order structure called chromatin, which consists of DNA and associated histones (see p. 75–76). The building block of chromatin, the nucleosome, is composed of DNA wrapped twice around core histones to form a solenoid-like structure (see Fig. 4-3). Nucleosomes present a physical barrier to gene transcription by blocking access of transcription factors to their binding sites in DNA and by interfering with elongation of nascent RNA transcripts. In general, a high density of tightly packed nucleosomes, or a nucleosome positioned at the transcription start site, is associated with gene inactivation. Conversely, repositioning or removal of nucleosomes, creating a nucleosome-free region at the promoter, can lead to gene activation. ATP-dependent chromatin-remodeling enzymes—belonging to the SWI/SNF, ISWI, IO80, and CHD families—can alter the density and location of nucleosomes. Because chromatin remodeling does not change the underlying DNA sequence, it represents a form of epigenetic gene regulation.

Covalent modifications of histones or DNA can also produce alterations in chromatin structure that mediate epigenetic gene regulation. These chemical modifications are sometimes referred to as **epigenetic marks**. We have already introduced one type of epigenetic mark, histone acetylation (see p. 84). The N termini of core histone proteins contain many lysine residues that impart a highly positive charge. These positively charged domains can bind tightly to the negatively charged DNA via electrostatic interactions (Fig. 4-17). Tight binding between DNA and histones is associated with gene inactivity. However, if the ϵ -amino groups of lysine side chains are chemically modified by **acetylation**, the positive charge is neutralized and the interaction with DNA is relaxed, which facilitates the binding of transcription factors and the basal transcriptional machinery. We have already seen that many transcriptional coactivators have intrinsic histone acetylase activity, whereas transcriptional corepressors may function as histone deacetylases (see pp. 85–86). In general, euchromatin is characterized by high

levels of histone acetylation, whereas heterochromatin is characterized by low levels of acetylation.

FIGURE 4-17 Effect of histone acetylation on the interaction between histone proteins and DNA. When the histone octamer is deacetylated (*top*), positively charged lysine groups on the histone strongly attract a strand of DNA. When the histone octamer becomes acetylated (*bottom*), the acetyl groups neutralize the positive charge on the histone and allow the DNA strand to loosen.

Histone methylation may stimulate or inhibit gene expression

In addition to acetylation, histones are subject to other post-translational modifications that influence epigenetic gene regulation. Especially important is **methylation**, in which a methyltransferase covalently attaches methyl groups to arginine residues and, most significantly, to specific lysine residues in the core histones. Histone methylation is associated with gene activation or repression, depending on the specific amino-acid residue that is modified. Methylation of histone H3 at Lys-4, Lys-36, and Lys-79 on histone H3 correlates with transcriptionally *active* chromatin. Demethylation of these H3 residues—but methylation of Lys-9 and Lys-27 on histone H3—correlates with transcriptionally *inactive* chromatin (i.e.,

repression). This pattern of differential methylation in transcriptionally active and inactive chromatin is referred to as a **histone code**, inasmuch as it can be inherited just as the genetic code in DNA.

Methylation of histones affects gene expression by recruiting proteins that alter chromatin structure. For example, trimethylation of Lys-4 on histone H3, which is often found at active gene promoters, is specifically recognized by a subunit of the nucleosome-remodeling factor (NURF) chromatin-remodeling complex. Recruitment of the NURF complex results in the displacement of nucleosomes in the region and promotes gene transcription. Conversely, trimethylation of histone H3 at Lys-9 (H3-K9) is found in heterochromatin and is also characteristic of gene silencing by X-inactivation, imprinting, and tissue-specific silencing. Trimethylated H3-K9 recruits **heterochromatin protein 1 (HP1)**, which then self-dimerizes to produce higher-order structures ([Fig. 4-18A](#)). In addition, HP1 recruits HDAC (see [pp. 85–86](#)), which promotes nucleosome assembly. Together, these modifications produce a closed chromatin conformation. Cells maintain this H3-K9 methylation during division, possibly by using the HP1. After it binds to methylated histones, HP1 recruits a **histone methyltransferase (HMT)** that methylates other K9 residues on other H3 histones (see [Fig. 4-18B](#)); this provides a mechanism for propagation of histone methylation. During DNA replication, the HMT recruited to a silenced gene on a parental strand of chromatin adds methyl groups to histones on the daughter strands, which maintains gene silencing in the progeny.

A DIMERIZATION OF HP1

B RECRUITMENT OF HMT BY METHYLATED HISTONE

C RECRUITMENT OF HMT BY METHYLATED DNA

FIGURE 4-18 Gene silencing by chromatin modification. **A**, HP1 binds to methylated Lys-9 in histone H3. Because the HP1 self-dimerizes, the result is chromatin condensation. **B**, HP1 recruits an HMT that promotes further lysine methylation; this leads to recruitment of additional HP1, propagating histone methylation. **C**, MBD1 binds to methylated cytosine groups in DNA and can also recruit HMT.

DNA methylation is associated with gene inactivation

Methylation of cytosine residues at its 5 position is the only well-documented postsynthetic modification of DNA in higher eukaryotes. Approximately 5% of cytosine residues are 5-methylcytosines in mammalian DNA. Methylation usually occurs on a cytosine residue that is immediately upstream from a guanosine (i.e., a CpG dinucleotide on one DNA strand).

Several lines of evidence implicate DNA methylation in the control of gene expression.

1. Although CpG dinucleotides are relatively underrepresented in mammalian genomes, they are frequently clustered near the 5' ends of genes, forming so-called **CpG islands**. Moreover, methylation of cytosines in these locations is associated with inhibition of gene expression. For example, the inactivated X chromosome in females contains heavily methylated genes.
2. Methylation/demethylation may explain tissue-specific and stage-dependent gene expression. For example, globin genes are methylated in nonexpressing tissues but hypomethylated in erythroid cells. During fetal development, fetal globin genes are demethylated and then become methylated in the adult.
3. Foreign genes that are introduced into cells are transcriptionally inactive if they are methylated but active if demethylated at the 5' end.
4. Chemical demethylating agents, such as 5-azacytidine, can activate previously inactive genes.

How does DNA methylation cause gene inactivation? One simple mechanism is that methylation inhibits the binding of an essential transcriptional activator. For example, methylation of CpG dinucleotides within the GFAP (glial fibrillary acidic protein) promoter prevents STAT3 binding. A more common mechanism is that methylation produces binding sites for proteins that promote gene inactivation. Cells contain a protein called MeCP2 that binds specifically to methylated CpG dinucleotides as well as to the HDAC (see [pp. 85–86](#)). Thus, DNA methylation may silence genes by promoting histone deacetylation. In addition, methylated DNA binds to **methyl-CpG-binding protein 1 (MBD1)**, a protein that complexes with HMT (see [Fig. 4-18C](#)). These last two interactions provide mechanisms coupling DNA methylation to histone modifications that promote heterochromatin formation and gene silencing.

The cell maintains patterns of DNA methylation during division. To illustrate, imagine that the DNA at a particular locus is initially methylated on both strands. After replication, the two double strands of daughter DNA are each methylated on only one of the two strands. This hemimethylated DNA recruits proteins that in turn recruit **DNA methyltransferase 1 (DNMT1)** to copy the methylation pattern onto the newly synthesized DNA strand. This mechanism ensures that epigenetic marks in a parent cell are maintained in the progeny cells.

Post-Translational Regulation of Gene Expression

Although initiation of transcription (see [Fig. 4-4](#), step 2) is the most frequently regulated step in gene expression, for certain genes subsequent steps are more important for determining the overall level of expression. These processes are generally classified as **post-transcriptional regulation**. The mechanisms for regulating these steps are less well understood than are those for regulating transcription initiation, but some information comes from the study of model genes. Post-transcriptional processes that we review here are pre-mRNA splicing (step 5) and transcript degradation (step 8).

Alternative splicing generates diversity from single genes

Eukaryotic genes contain introns (see [p. 74](#)) that must be removed from the primary transcript to create mature mRNA; this process is called **pre-mRNA splicing**. Splicing involves the joining of two sites on the RNA transcript, the 5' **splice-donor site** and the 3' **splice-acceptor site**, and removal of the intervening intron. The first step involves cleavage of the pre-mRNA at the 5' splice-donor site. Second, joining of the 5' end of the intron to an adenosine residue located within the intron forms a “lariat” structure. Third, ligation of the 5' and 3' splice sites releases the lariat intron. The splicing reaction occurs in the nucleus, mediated by ribonucleoprotein particles (snRNPs) that are composed of proteins and small nuclear RNA (snRNA). Together, the assembly of pre-mRNA and snRNPs forms a large complex called the **spliceosome**.  **N4-14**

N4-14

Mechanism of Pre-mRNA Splicing

Contributed by Peter Igarashi

The location of the 5' and 3' splice sites is based, at least in part, on the sequences at the ends of the introns. The 5' splice-donor site has the consensus sequence 5'-(C/A)AG ↓GU(G/A)AGU-3'; the vertical arrow represents the boundary between the exon and the intron. The 3' splice-acceptor site has the consensus sequence 5'-Y_nNCAG ↓G-3'; Y_n represents a polypyrimidine tract (i.e., a long sequence of only C and U), and N represents any nucleotide. An intronic site located >17 nucleotides upstream from the 3' acceptor site (5'-YNCUGAC-3'), called the branch point, is also present and contains the adenosine (*red background* in eFig 4-7) that contributes to formation of the lariat structure.

FIGURE 4-7 Mechanism of pre-mRNA splicing. This example illustrates how a 5' splice-donor site at one end of exon 1 can link to the 3' splice-acceptor site at the end of exon 2 and thereby splice out the intervening intron. The process can be divided into three steps: (1) cleavage of the pre-mRNA at the 5'

splice-donor site; (2) joining of the 5' end of the intron to an adenosine residue that is located within the intron, forming a lariat structure; and (3) ligation of the 5' and 3' splice sites and release of the lariat intron.

Many genes undergo **alternative splicing**, which refers to differential splicing of the same primary transcript to produce mature transcripts that contain different combinations of exons. If the coding region is affected, the resulting splicing variants will encode proteins with distinct primary structures that may have different physiological functions. Thus, alternative splicing is a mechanism for increasing the diversity of proteins that a single gene can produce. [Figure 4-19](#) summarizes seven patterns of alternative splicing.

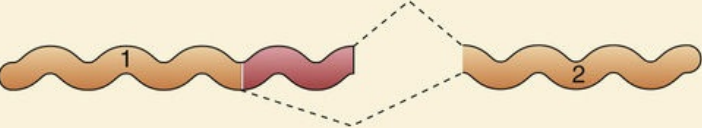

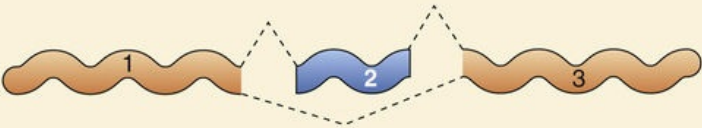

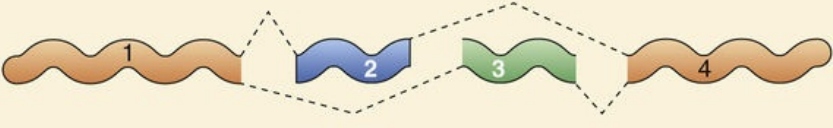

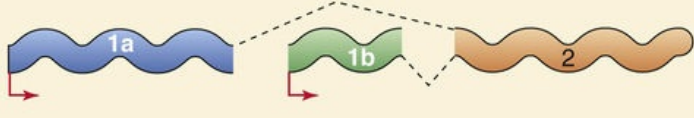

TYPES OF ALTERNATIVE SPLICING	mRNA	EXAMPLES
A Retained intron		γ -Fibrinogen
B Alternative 3' splice sites		Fibronectin
C Alternative 5' splice sites		HMG-CoA reductase
D Cassette exons		α -Tropomyosin Troponin
E Mutually exclusive exons		Na/K/Cl cotransporter (NKCC) α -Tropomyosin
F Alternative 5' ends		Na/HCO ₃ cotransporter (NBCe1) Myosin light chain α -Amylase
G Alternative 3' ends		α -Tropomyosin Calcitonin/CGRP

FIGURE 4-19 Types of alternative splicing. In F, the two red arrows represent alternative transcription initiation sites. Poly-A, polyadenylic acid.

Retained Intron

In some cases, the cell may choose whether to splice out a segment of RNA. For example, the γ A isoform

of rat γ -fibrinogen lacks the seventh intron, whereas the γ B isoform retains the intron, which encodes a unique C terminus of 12 amino acids (see [Fig. 4-19A](#)).

Alternative 3' Splice Sites

In this case, the length of an intron is variable because the *downstream* boundary of the intron can be at either of two or more different 3' splice-acceptor sites (see [Fig. 4-19B](#)). For example, in rat fibronectin, a single donor site may be spliced to any of three acceptor sites. The presence or absence of the amino acids encoded by the sequence between the different splice-acceptor sites results in fibronectin isoforms with different cell adhesion properties.

Alternative 5' Splice Sites

Here also, the length of the intron is variable. However, in this case, it is the *upstream* boundary of the intron that can be at either of two or more different 5' splice-donor sites (see [Fig. 4-19C](#)). For example, cells can generate mRNA encoding 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase (see [p. 968](#)) with different 5' UTRs by splicing from multiple donor sites for the first intron to a single acceptor site.

Cassette Exons

In some cases, the cell may choose either to splice in an exon or group of exons (**cassette exons**) or not to splice them in (see [Fig. 4-19D](#)). An example is the α -tropomyosin gene, which contains 12 exons. All α -tropomyosin transcripts contain the invariant exons 1, 4 to 6, 8, and 9. All muscle-like cells splice in exon 7, but hepatoma (i.e., liver tumor) cells do not splice in exon 7; they directly link exon 6 to exon 8.

Mutually Exclusive Exons

In yet other cases, the cell may splice in **mutually exclusive exons** (see [Fig. 4-19E](#)). One of the Na/K/Cl cotransporter genes (*NKCC2*) is an example. Isoforms containing distinct 96-bp exons are differentially expressed in the kidney cortex and medulla. Because the encoded amino-acid sequence is predicted to reside in the membrane, the isoforms may have different kinetic properties. The α -tropomyosin gene again is another example. Smooth-muscle cells splice in exon 2 but not exon 3. Striated-muscle cells and myoblasts splice in exon 3 but not exon 2. Fibroblasts and hepatoma cells do not splice in either of these two exons.

Alternative 5' Ends

Cells may select among different alternative promoters, creating alternative 5' ends, and then splice the selected end to a downstream portion of the pre-mRNA (see [Fig. 4-19F](#)). For example, the *SLC4A4* gene that encodes the electrogenic Na/HCO₃ cotransporter 1 (see [p. 122](#)) has 26 exons. The transcript that encodes the NBCe1-A variant expressed heavily in the renal proximal tubule (see [p. 829](#)) initiates from a promoter located upstream from exon 4 and then continues with exons 5 through 26. The transcript that encodes the NBCe1-B variant expressed heavily in pancreatic ducts (see [pp. 885–886](#)) initiates from a promoter located upstream from exon 1 and then continues with exons 2 through 26. This use of alternative promoters permits differential regulation of gene expression in kidney versus pancreas. The genes encoding myosin light chain (see [p. 233–234](#)) and α -amylase (see [p. 916](#)) are additional examples.

Myosin Light Chain Alternative Splicing

Contributed by Peter Igarashi

In the case of the myosin light chain (MLC) gene (see pp. 233–234), which consists of nine exons, one transcript is initiated from a promoter that is located upstream from exon 1, skips exons 2 and 3, and includes exons 4 to 9. The other transcript is initiated instead at a promoter located in the first *intron* and consists of exons 2, 3, and 5 to 9. Because the coding region is affected, the two transcripts encode proteins that differ at their N-terminal ends. These splice variants are found in different cells or different developmental stages.

Alternative 3' Ends

Finally, cells may differentially splice the transcript near the 3' end of the gene (see Fig. 4-19G) and thereby alter the site of cleavage and polyadenylation. Such splicing may also affect the coding region. Again, α -tropomyosin is an example. Striated-muscle cells splice in exon 11, which contains one alternative 3' UTR. Smooth-muscle cells splice in exon 12 instead of exon 11. Another example is the calcitonin gene, which encodes both the hormone calcitonin (see pp. 1067–1068) and calcitonin gene-related peptide- α (CGRP α). Thyroid C cells produce one splice variant that includes exons 1 to 4 and encodes calcitonin. Sensory neurons, on the other hand, produce another splice variant that excludes exon 4 but includes exons 5 and 6. It encodes a different protein, CGRP α .

These examples illustrate that some splicing variants are expressed only in certain cell types and not in others. Clearly, control of alternative splicing must involve steps other than initiation of transcription because many splice variants have identical 5' ends. In some genes, the control elements that are required for alternative splicing have been identified, largely on the basis of deletion mutations that result in aberrant splicing. These control elements can reside in either introns or exons and are located within or near the splice sites. The proteins that interact with such elements remain largely unknown, although some RNA-binding proteins that may be involved in regulation of splicing have been identified.

Regulatory elements in the 3' untranslated region control mRNA stability

Degradation of mRNA is mediated by enzymes called **ribonucleases**. These enzymes include 3'-5' exonucleases, which digest RNA from the 3' end; 5'-3' exonucleases, which digest from the 5' end; and endonucleases, which digest at internal sites. The stability of mRNA in cytoplasm varies widely for different transcripts. Transcripts that encode cytokines and immediate-early genes are frequently short-lived, with half-lives measured in minutes. Other transcripts are much more stable, with half-lives that exceed 24 hours. Moreover, cells can modulate the stability of individual transcripts and thus use this mechanism to affect the overall level of expression of the gene. 🟡N4-16

Degradation of mRNA by Ribonucleases

Contributed by Peter Igarashi

A structural feature of typical mRNA that contributes to its stability in cytoplasm is the 5' methyl cap, in which the presence of the 5'-5' phosphodiester bond makes it resistant to digestion by 5'-3' exonucleases. Similarly, the poly(A) tail at the 3' end of the transcript often protects messages from degradation. Deadenylation (i.e., removal of the tail) is often a prerequisite for mRNA degradation. Accordingly, transcripts with long poly(A) tails may be more stable in cytoplasm than are transcripts with short poly(A) tails.

Regulatory elements that stabilize mRNA, as well as elements that accelerate its degradation, are frequently located in the 3' UTR of the transcripts. A well-characterized example of a gene that is primarily regulated by transcript stability is the **transferrin receptor** (Fig. 4-20). The transferrin receptor is required for uptake of iron into most of the cells of the body (see p. 42). During states of iron deprivation, transferrin receptor mRNA levels increase, whereas transcript levels decrease when iron is plentiful. Regulation of expression of the gene encoding the transferrin receptor is primarily post-transcriptional: changes in the half-life (i.e., stability) of the message lead to alterations in the level of the mRNA.

FIGURE 4-20 The role of iron in regulating the stability of the mRNA for the transferrin receptor. The mRNA that encodes the transferrin receptor has a series of IREs in its 3' untranslated region.

Regulation of transferrin receptor mRNA stability depends on elements that are located in the 3' UTR called **iron response elements (IREs)**. An IRE is a stem-loop structure that is created by intramolecular formation of hydrogen bonds. The human transferrin receptor transcript contains five IREs in the 3' UTR. The IRE binds a cellular protein called IRE-binding protein (IRE-BP), which stabilizes transferrin receptor mRNA in the cytoplasm. When IRE-BP dissociates, the transcript is rapidly degraded. IRE-BP can also bind to iron, and the presence of iron decreases its affinity for the IRE. During states of iron deficiency, less iron binds to IRE-BP, and thus more IRE-BP binds to the IRE on the mRNA. The increased stability of the transcript allows the cell to produce more transferrin receptors. Conversely, when iron is plentiful and binds to IRE-BP, IRE-BP dissociates from the IRE, and the transferrin receptor transcript is rapidly degraded. This design prevents cellular iron overload.

MicroRNAs regulate mRNA abundance and translation

A major form of post-transcriptional gene regulation occurs via small RNA molecules called **microRNAs (miRNAs)**, which mediate a type of post-transcriptional gene regulation. miRNAs are typically ~22 nucleotides in length, too short to encode proteins. Instead, miRNAs play regulatory functions in many physiological and pathophysiological processes. They bind to specific mRNA targets and regulate mRNA abundance and translation. Because this regulation occurs after the transcription of mRNA, it is *post-transcriptional* in nature.

Figure 4-21 shows the biogenesis and function of miRNAs. Transcription of genomic DNA initially gives rise to a longer primary miRNA (pri-miRNA) transcript, which the endonuclease **Drosha** then cleaves to produce a precursor miRNA (pre-miRNA), typically 50 to 70 nucleotides in length. The pre-miRNA forms a hairpin structure because of intramolecular base pairing. The pre-miRNA, complexed with exportin-5 and Ran-GTP, then exits the nucleus via nuclear pores. In the cytoplasm, a second endonuclease called **Dicer** cleaves the pre-miRNA to produce the mature, single-stranded miRNA.

FIGURE 4-21 miRNA biogenesis and function. ORF, open reading frame.

In the cytoplasm, the newly synthesized miRNA associates with a protein complex called the **RNA-induced silencing complex (RISC)**. Once complexed with RISC, the miRNA binds via base pairing to an mRNA target. Usually, miRNAs bind to sites located in the 3' UTR of mRNA, although occasionally it binds to sites in the 5' UTR (see **Fig. 4-2**). Recall that the 5' and 3' UTRs flank the coding region of the

mRNA. Binding of the miRNA and the associated RISC complex results in degradation of the mRNA target or inhibits translation of the mRNA. In some cases, the targeted mRNA may be sequestered in subcellular organelles, called **processing bodies (P bodies)**, where it is no longer available for translation. Regardless of the exact mechanism, the net result is that the expression of the protein encoded by the mRNA is inhibited.  **N4-17**

N4-17

Small Interfering RNA

Contributed by Peter Igarashi

Small interfering RNAs (siRNA) may modulate gene expression both at the post-transcriptional level and at the level of chromatin structure. These siRNAs are short (~22 bp), double-stranded RNA molecules, one strand of which is complementary in sequence to a target mRNA. The process in which siRNAs silence the expression of specific genes is called **RNA interference (RNAi)**.

Recall that RNA is usually single stranded. However, certain non-protein-coding sequences in the genome may yield RNA transcripts that contain inverted repeats, which allows double-stranded hairpins to form via intramolecular hydrogen bonds (eFig. 4-8). Cleavage of the hairpin structure by an endonuclease called Dicer produces the mature siRNA.

Mature siRNA can assemble into a ribonucleoprotein complex called **RISC**, which specifically cleaves a target mRNA that is complementary in sequence to one of the strands of the siRNA (see eFig. 4-8). In addition, the binding of an siRNA to a complementary mRNA can inhibit translation of the mRNA into protein (see eFig. 4-8). Finally, siRNAs can assemble into another ribonucleoprotein complex called **RNA-induced transcriptional silencing (RITS)** complex, which promotes DNA and histone methylation and thus the formation of heterochromatin (see eFig. 4-8).

Hundreds of genes that are potentially regulated by RNAi have been identified, and it is likely that this number will continue to grow. Because the expression of siRNAs is often tissue specific and developmentally regulated, RNAi may be an important mechanism for silencing gene expression during cell differentiation.

FIGURE 4-8 Regulation of gene expression by RNA interference. The siRNA is produced from hairpin RNA by Dicer. 1, Assembly of siRNA in the RISC results in cleavage of the target mRNA. 2, The siRNA can also inhibit mRNA translation. 3, Assembly of siRNA in the RITS complex promotes DNA methylation and gene silencing.

The inhibition of gene expression by miRNAs represents a form of **RNA interference**. RNA interference refers to a process, found in most animal and plant species, in which short RNA molecules silence the expression of specific genes. Andrew Fire and Craig Mello—who shared the 2006 Nobel Prize in Physiology or Medicine **N4-18**—discovered RNA interference in 1998 in the roundworm *Caenorhabditis elegans*.

N4-18

Andrew Fire and Craig Mello

Since the discovery of the first mammalian miRNA in 2000, hundreds of miRNAs have been identified in humans and other species. The sequences of miRNAs are often evolutionarily conserved, consistent with their important functions. The binding of a particular miRNA to its mRNA targets is primarily dependent on a short seven-nucleotide sequence, the **seed sequence**, at the 5' end of the miRNA. Different miRNAs contain different seed sequences and thereby recognize and inhibit distinct mRNA targets.

Because the seed sequence is relatively short, an individual miRNA can bind many, perhaps hundreds, of different mRNA targets. miRNAs are thought to fine-tune gene expression, and the magnitude of their effects on individual mRNAs is relatively modest, typically less than 2-fold. However, the cumulative effect produced by targeting multiple mRNA targets in the same pathway may produce physiologically significant effects. miRNAs regulate hundreds of genes and, according to some estimates, may regulate more than one third of human genes.

miRNAs play important roles in embryonic development, stem-cell differentiation, cell proliferation, and cell death. Other physiological processes under the control of miRNAs include insulin secretion, the stress response, renin secretion, and lipid metabolism. By fine-tuning mRNA abundance and translation, miRNAs work in concert with gene transcription to maintain the levels of proteins in cells within an optimal range. Dysregulation of miRNAs commonly plays a role in pathological conditions such as cancer, viral infection, diabetes, and Alzheimer disease

Box 4-3

Roles of miRNAs in Cardiac Stress Responses

Elevated blood pressure imposes stress on the heart that, if sustained, results in pathological remodeling, leading to cardiac hypertrophy, fibrosis, heart failure, and increased arrhythmias. miRNAs play an important role in the cardiac response to stress, in which cardiac myocytes switch their expression of myosin heavy chains from the normally dominant adult α MHC to β MHC, which is normally weakly expressed (see Table 9-1). Embedded in one of the introns of the α MHC gene is the miRNA called miR-208. Therefore, expression of α MHC results in coexpression of miR-208, which targets a transcriptional corepressor called **thyroid hormone receptor–associated protein 1 (THRAP1)**. Normally, THRAP1 interacts with the thyroid hormone receptor (see pp. 1010–1011) to inhibit transcription of the *MYH7* gene, which encodes β MHC. Thus, by reducing THRAP1 expression, miR-208 disinhibits β MHC transcription. Indeed, miR-208 is necessary for expression of the β MHC and cardiac remodeling. Mice lacking miR-208 cannot upregulate β MHC and are protected from pathological remodeling in response to cardiac stress.

Pathological cardiac remodeling also results in increased cardiac fibrosis. The miRNA miR-29 inhibits the expression of collagen and other components of the extracellular matrix. Cardiac stress inhibits miR-29 expression, which results in increased production of extracellular matrix and fibrosis.

Glossary

AP-1 Activator protein 1, a heterodimer of, for example, c-Fos and c-Jun, that is a transcription factor (see [Table 4-1](#)).

AR Androgen receptor.

ATF-2 Activating transcription factor 2, a transcription factor (see [Table 4-1](#)).

bHLH Basic helix-loop-helix family of transcription factors.

Brg1 Brahma-related gene 1, central motor component of SWI/SNF.

bZIP Basic zipper family of transcription factors.

CAR Constitutive androstane receptor.

CARM1 Coactivator and methyltransferase that methylates histones.

cAMP Cyclic adenosine monophosphate.

CBP CREB-binding protein, 245 kDa, a coactivator.

C/EBP β CCAAT/enhancer-binding protein- β , a transcription factor (see [Table 4-1](#)).

c-Fos Transcription factor.

c-Jun Transcription factor.

c-Myc Transcription factor (see [Table 4-1](#)).

CRE cAMP response element, a DNA sequence.

CREB CRE-binding protein, 43 kDa.

CTCF CCCTC-binding factor, a protein that binds insulator elements.

CTD C-terminal domain of the largest subunit of Pol II.

DNA Deoxyribonucleic acid.

E box Sequence of six nucleotides (CANNTG, where N is any nucleotide) recognized by transcription factors MyoD and myogenin.

EGF Epidermal growth factor.

Egr-1 Transcription factor (activator) that binds through zinc fingers to the same DNA site as WT-1

(repressor).

EKLF Erythroid Kruppel-like factor (a transcription factor).

Elk-1 Transcription factor.

ER Estrogen receptor.

FGF Fibroblast growth factor.

FXR Bile acid receptor.

GAL4 Yeast transcription factor that activates certain genes when yeast grows in galactose-containing media.

GAS Interferon- γ activation site.

GATA-1 Transcription factor.

GFAP Glial fibrillary acidic protein.

GR Glucocorticoid receptor.

GRE Glucocorticoid response element.

HAT Histone acetyltransferase.

HDAC Histone deacetylase.

HIF-1 α , HIF-1 β Hypoxia-inducible factors.

HMT Histone methyltransferase.

HNF-1, HNF-3, HNF-4 Transcription factors.

HP1 Heterochromatin protein 1.

hsp90 90-kDa heat shock protein, a molecular chaperone.

HTH Helix-turn-helix family of transcription factors.

IFN- α , IFN- β , IFN- γ Interferons α , β , and γ .

I κ B Inhibitor of κ B.

IGF-1, IGF-2 Insulin-related growth factors 1 and 2.

Inr “Initiator,” a promoter sequence in both TATA-containing and TATA-less genes.

IRE Iron response element.

ISRE Interferon-stimulated response element.

JAK1, JAK2 Janus kinases 1 and 2, protein tyrosine kinases.

LCR Locus control region, a site distant from the structural genes.

MAPK or MAP kinase Mitogen-activated protein kinase; also known as ERK-1, ERK-2 for extracellular signal–regulated kinase.

MBD1 Methyl-CpG–binding protein 1.

MeCP2 Binds to methylated CpG dinucleotides on DNA.

miRNA microRNA.

mRNA Messenger RNA.

MR Mineralocorticoid receptor.

MyoD bHLH-type transcription factor.

N-CoR Corepressor of transcription; also known as SMRT.

NF-1 Nuclear factor 1, a transcription factor (see [Table 4-1](#)).

NF-E2 Nuclear factor E2, a heterodimeric protein complex composed of p45 and small Maf family proteins considered crucial for the proper differentiation of erythrocytes and megakaryocytes in vivo.

NF-κB Nuclear factor κB, a transcription factor and protein complex responsible for regulating the immune response to infection.

NF-Y Nuclear factor Y, a ubiquitous multisubunit CCAAT-binding protein composed of three subunits: NF-YA, NF-YB, and NF-YC.

NGF Nerve growth factor.

NRE Negative regulatory element.

Oct-1 Ubiquitous DNA-binding protein that recognizes a DNA sequence called the octamer motif (see [Table 4-1](#)).

P box Sequence of six amino acids at the C terminus of a zinc finger.

p62TCF Ternary complex factor, a transcription factor.

PDGF Platelet-derived growth factor.

PEPCK Phosphoenolpyruvate carboxykinase, the enzyme that catalyzes the rate-limiting step in gluconeogenesis.

Pit-1 HTH-type pituitary-specific transcription factor.

PML promyelocytic leukemia protein.

Pol II RNA polymerase II, the polymerase that transcribes DNA to mRNA.

PPAR Peroxisome proliferator–activated (i.e., lipid) receptor.

PR Progesterone receptor.

Pre-mRNA Precursor mRNA, primary transcript of DNA, unprocessed.

P-TEFb Positive transcription elongation factor b, a kinase that phosphorylates the CTD of Pol II.

RAR Retinoic acid receptor, which binds all-*trans* retinoic acid.

RARE Retinoic acid response element.

Ras Low-molecular-weight GTP-binding protein.

RIP Regulated intramembraneous proteolysis.

RISC RNA-induced silencing complex.

RITS RNA-induced transcriptional silencing.

RNA Ribonucleic acid.

RNAi RNA interference.

RNAPII Alternative designation for RNA polymerase II (Pol II).

rRNA ribosomal RNA.

RTK Receptor tyrosine kinase.

RXR Retinoid X receptor, which, unlike RAR, binds 9-*cis*-retinoic acid.

Sin3A, Sin3B Corepressors.

siRNA Small interfering RNA.

snRNA Small nuclear RNA.

snRNP Complex of proteins and snRNA.

Sp1 Stimulating protein 1, a transcription factor.

SRC Steroid receptor coactivator.

SREBP Sterol regulatory element-binding protein.

SRF Serum response factor, a transcription factor.

STAT Signal transducer and activator of transcription.

SUMO Small ubiquitin-like modifier.

SWI/SNF Multiprotein complexes initially identified in yeast as “switching mating type/sucrose nonfermenting.”

SXR Steroid and xenobiotic receptor.

TAF TBP-associated factor.

TATA box Common gene promoter sequence.

TBP TATA-binding protein.

TFIIA Transcription factor IIA.

TFIIB Transcription factor IIB.

TFIID Transcription factor IID.

TFIIE Transcription factor IIE.

TFIIF Transcription factor IIF.

TFIIH Transcription factor IIH.

THRAP1 Thyroid hormone receptor-associated protein 1.

TR Thyroid hormone receptor.

TRAP220 Component of Mediator.

tRNA Transfer RNA.

Tyk2 Protein tyrosine kinase related to JAK.

UTR Untranslated region of mRNA.

VDR Vitamin D receptor.

VEGF Vascular endothelial growth factor.

VHL Protein that targets HIF-1 α for proteasomal degradation.

VP16 Viral protein from herpes simplex virus, a transcription factor.

WT-1 Wilms tumor protein, a transcriptional repressor that binds through zinc fingers to the same DNA site as Egr-1 (activator).

CHAPTER 5

Transport of Solutes and Water

Peter S. Aronson, Walter F. Boron, Emile L. Boulpaep

The cells of the human body live in a carefully regulated fluid environment. The fluid inside the cells, the **intracellular fluid (ICF)**, occupies what is called the intracellular compartment, and the fluid outside the cells, the **extracellular fluid (ECF)**, occupies the extracellular compartment. The barriers that separate these two compartments are the **cell membranes**. For life to be sustained, the body must rigorously maintain the volume and composition of the intracellular and extracellular compartments. To a large extent, such regulation is the result of transport across the cell membrane. In this chapter, we discuss how cell membranes regulate the distribution of ions and water in the intracellular and extracellular compartments.

The Intracellular and Extracellular Fluids

Total-body water is the sum of the ICF and ECF volumes

Total-body water (TBW)  **N5-1** is ~60% of total-body weight in a young adult human male, ~50% of total-body weight in a young adult human female ([Table 5-1](#)), and 65% to 75% of total-body weight in an infant. TBW accounts for a lower percentage of weight in females because they typically have a higher ratio of adipose tissue to muscle, and fat cells have a lower water content than does muscle. Even if gender and age are taken into consideration, the fraction of total-body weight contributed by water is not constant for all individuals under all conditions. For example, variability in the amount of adipose tissue can influence the fraction. Because water represents such a large fraction of body weight, acute changes in TBW can be detected simply by monitoring body weight.

TABLE 5-1
Approximate Water Distribution in Adult Humans*

	MEN	TYPICAL VOLUME (L)	WOMEN	TYPICAL VOLUME (L)
Total-body water (TBW)	60% of BW	42	50% of BW	35
Intracellular fluid (ICF)	60% of TBW	25	60% of TBW	21
Extracellular fluid (ECF)	40% of TBW	17	40% of TBW	14
Interstitial fluid	75% of ECF	13	75% of ECF	10
Plasma (PV)	20% of ECF	3	20% of ECF	3
Transcellular fluid	5% of ECF	1	5% of ECF	1
Blood (BV)	PV/(1 – Hct)	6	PV/(1 – Hct)	5

*All of the above values are approximate and for illustration only. The volumes are rounded to the nearest liter, assuming a BW of 70 kg for both sexes, an Hct for men of 45%, and an Hct for women of 40%.
BW, body weight; Hct, hematocrit.

N5-1

Determination of the Volume of Body Fluid Compartments

Contributed by Peter Aronson, Emile Boulpaep, Walter Boron

The **TBW** can be determined by the use of a volume-of-distribution technique. The first step is to infuse intravenously a known quantity of a tracer for water (deuterium oxide [²HOH] or tritiated water [³HOH]) that will distribute everywhere there is water. Because water readily permeates most cell membranes, a tracer for water distributes into both the extracellular and ICF.

For example, suppose a 70-kg male is injected with 10⁸ counts per minute (cpm) of ³HOH contained in a small volume of physiological saline. After an equilibration period of 2 hours, a sample of the blood plasma is drawn and the ³HOH concentration in the plasma is found to be 2.5 × 10³ cpm/mL plasma. Measurement also reveals that 5 × 10⁵ cpm of ³HOH has been lost in urine, as well as from the skin and lungs. From this information, we can calculate the volume of distribution of the tracer, which is the same as the TBW:

$$\begin{aligned}
 \text{TBW} &= \text{Volume of distribution} \\
 &= \frac{(\text{Quantity infused}) - (\text{Quantity excreted})}{(\text{Concentration in the plasma})} \\
 &= \frac{(10^8 \text{ cpm}) - (5 \times 10^5 \text{ cpm})}{(2.5 \times 10^3 \text{ cpm/mL})} = 39.8 \text{ L} \\
 &\quad \textbf{(NE 5-1)}
 \end{aligned}$$

In this male, the TBW of 39.8 L is 57% of the 70-kg body weight.

How can we determine how this water is distributed among the various fluid compartments? In particular, we need to know the fraction of the TBW that is intracellular and the fraction that is extracellular. In practice, the **ICF volume** is calculated as the difference between TBW and **ECF volume**. The ECF volume is determined by using a marker that distributes uniformly throughout the compartments accessible to water but that does not enter the cells. Unfortunately, different markers thought to distribute within the ECF yield different values. For example, large polysaccharides (e.g., inulin) or polyalcohols (e.g., mannitol) that cannot cross cell membranes do not penetrate fully into dense connective tissue and bone. On the other hand, ions that are largely extracellular (e.g., Na^+ , Cl^-) are able to enter cells to some extent. Using the above techniques, the best estimate is that the total ECF represents between 20% and 25% of body weight (~40% of TBW). This leaves about 35% to 40% of the body weight (~60% of TBW) as intracellular water or ICF volume.

The **plasma volume** can be determined by measuring the volume of distribution of labeled albumin. Because albumin escapes only very slowly from the vascular compartment, measuring the final concentration of labeled albumin in the plasma and then using the above equation to compute the volume of distribution of the albumin label will yield the plasma volume.

The anatomy of the body fluid compartments is illustrated in [Figure 5-1](#). The prototypical 70-kg male has ~42 L of TBW (60% of 70 kg). Of these 42 L, ~60% (25 L) is intracellular and ~40% (17 L) is extracellular. ECF is composed of blood plasma, interstitial fluid, and transcellular fluid.

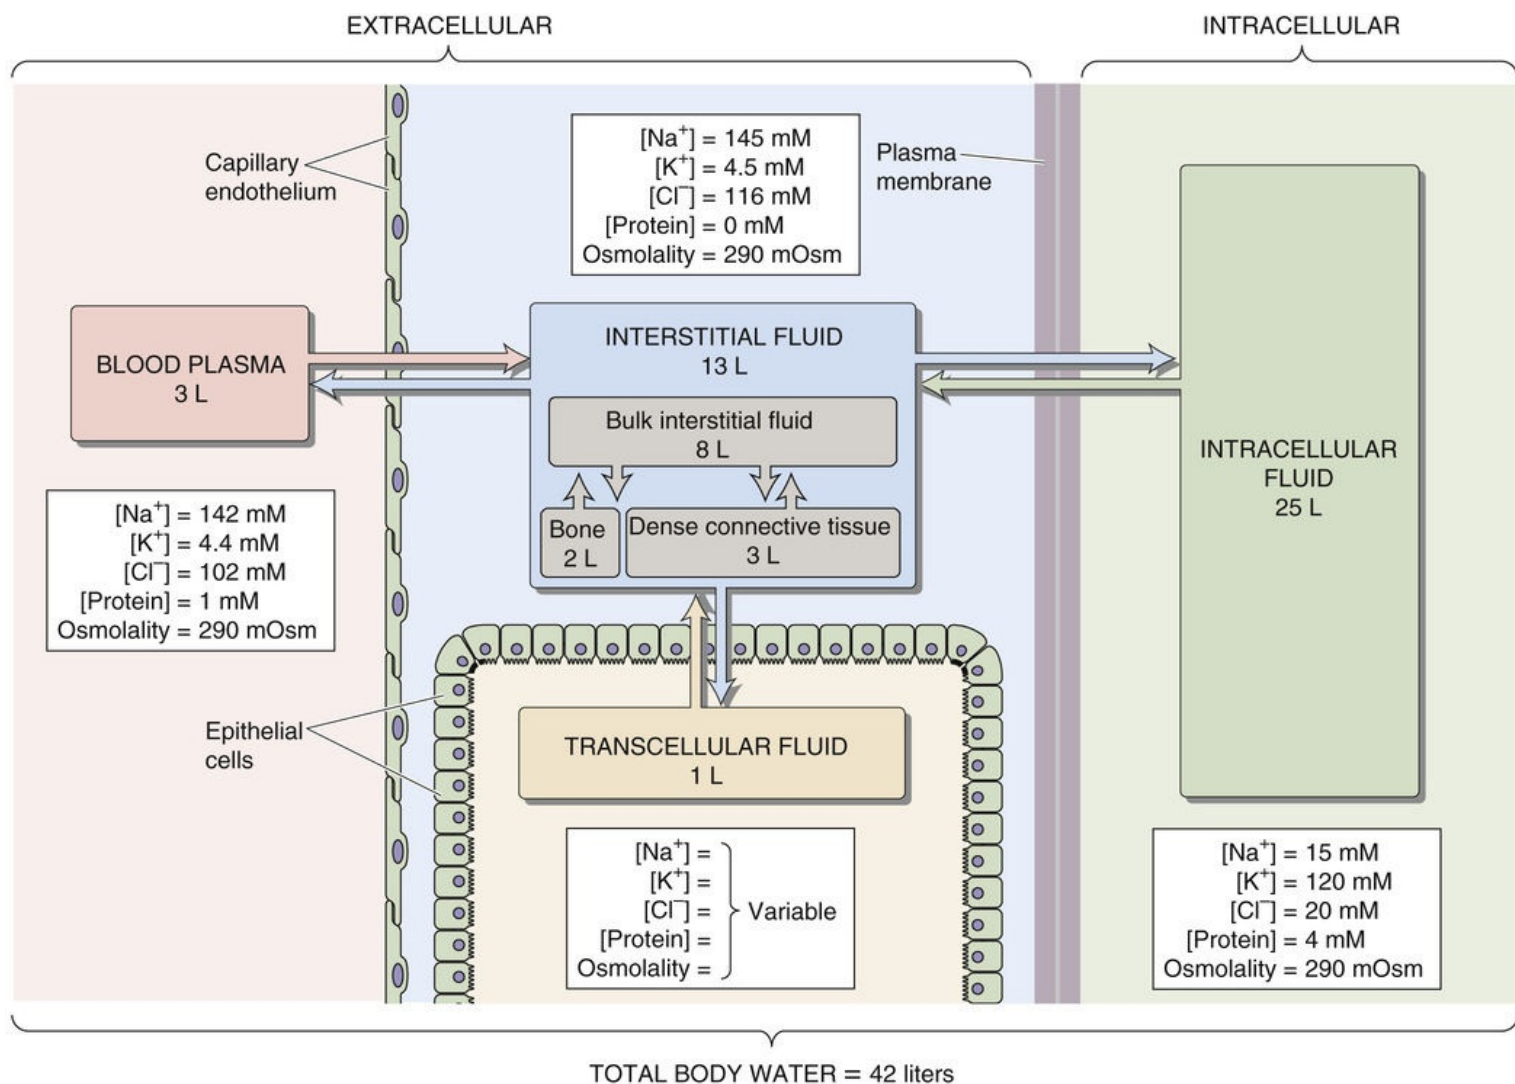

FIGURE 5-1 Fluid compartments of a prototypical adult human male weighing 70 kg. TBW is divided into four major compartments: ICF (green), interstitial fluid (blue), blood plasma (red), and transcellular water such as synovial fluid (tan). Color codes for each of these compartments are maintained throughout this book.

Plasma Volume

Of the ~17 L of ECF, only ~20% (~3 L) is contained within the cardiac chambers and blood vessels, that is, within the intravascular compartment. The *total* volume of this intravascular compartment is the **blood volume**, ~6 L. The extracellular 3 L of the blood volume is the plasma volume. The balance, ~3 L, consists of the cellular elements of blood: erythrocytes, leukocytes, and platelets. The fraction of blood volume that is occupied by these cells is called the **hematocrit**. The hematocrit is determined by centrifuging blood that is treated with an anticoagulant and measuring the fraction of the total volume that is occupied by the packed cells.

Interstitial Fluid

About 75% (~13 L) of the ECF is outside the intravascular compartment, where it bathes the nonblood cells of the body. Within this interstitial fluid are two smaller compartments that communicate only slowly with the bulk of the interstitial fluid: dense connective tissue, such as cartilage and tendons, and bone matrix.

The barriers that separate the intravascular and interstitial compartments are the walls of **capillaries**. Water and solutes can move between the interstitium and blood plasma by crossing capillary walls and

between the interstitium and cytoplasm by crossing cell membranes.

Transcellular Fluid

Finally, ~5% (~1 L) of ECF is trapped within spaces that are completely surrounded by epithelial cells. This transcellular fluid includes the synovial fluid within joints and the cerebrospinal fluid surrounding the brain and spinal cord. Transcellular fluid does *not* include fluids that are, strictly speaking, outside the body, such as the contents of the gastrointestinal tract or urinary bladder.

ICF is rich in K⁺, whereas ECF is rich in Na⁺ and Cl⁻

Not only do the various body fluid compartments have very different volumes, they also have radically different compositions, as summarized in [Figure 5-1](#). [Table 5-2](#) is a more comprehensive listing of these values. ICF is high in K⁺ and low in Na⁺ and Cl⁻; ECF (interstitial and plasma) are high in Na⁺ and Cl⁻ and low in K⁺. The cell maintains a relatively high K⁺ concentration ([K⁺]_i) and low Na⁺ concentration ([Na⁺]_i), not by making its membrane totally impermeable to these ions but by using the Na-K pump to extrude Na⁺ actively from the cell and to transport K⁺ actively into the cell.

TABLE 5-2
Approximate Solute Composition of Key Fluid Compartments

SOLUTE	PLASMA	PROTEIN-FREE PLASMA	INTERSTITIUM	CELL
Na ⁺ (mM)	142	153	145	15
K ⁺ (mM)	4.4	4.7	4.5	120
Ca ²⁺ (mM)	1.2 (ionized) 2.4 (total)*	1.3 (ionized)	1.2 (ionized)	0.0001 (ionized)
Mg ²⁺ (mM)	0.6 (ionized) 0.9 (total)*	0.6 (ionized)	0.55 (ionized)	1 (ionized) 18 (total)
Cl ⁻ (mM)	102	110	116	20
HCO ₃ ⁻ (mM)	22 [†]	24	25	16
H ₂ PO ₄ ⁻ and HPO ₄ ²⁻ (mM)	0.7 (ionized) 1.4 (total) [‡]	0.75 (ionized)	0.8 (ionized)	0.7 (free)
Proteins	7 g/dL 1 mmole/L 14 meq/L	—	1 g/dL	30 g/dL
Glucose (mM)	5.5	5.9	5.9	Very low
pH	7.4	7.4	7.4	~7.2
Osmolality (milliosmoles/kg H ₂ O)	291	290	290	290

*Total includes amounts ionized, complexed to small solutes, and protein bound.

[†]Arterial value. The value in mixed-venous blood would be ~24 mM.

[‡]As discussed on [pages 1054–1056](#), levels of total plasma inorganic phosphate are not tightly regulated and vary between 0.8 and 1.5 mM.

Transcellular fluids differ greatly in composition, both from each other and from plasma, because they are secreted by different epithelia. The two major constituents of ECF, the plasma and the interstitial fluid, have similar composition as far as small solutes are concerned. For most cells, it is the composition of the interstitial fluid enveloping the cells that is the relevant parameter. The major difference between plasma and interstitial fluid is the absence of plasma proteins from the interstitium. These plasma proteins, which cannot equilibrate across the walls of most capillaries, are responsible for the usually slight difference in small-solute concentrations between plasma and interstitial fluid. Plasma proteins affect solute distribution because of the volume they occupy and the electrical charge they carry.

Volume Occupied by Plasma Proteins

The proteins and, to a much lesser extent, the lipids in plasma ordinarily occupy ~7% of the total plasma volume. Clinical laboratories report the plasma composition of ions (e.g., Na^+ , K^+) in units of milliequivalents (meq) per liter of plasma solution. However, for cells bathed by interstitial fluid, a more meaningful unit would be **milliequivalents per liter of protein-free plasma solution** because it is only the protein-free portion of plasma—and not the proteins dissolved in this water—that can equilibrate across the capillary wall. For example, we can obtain $[\text{Na}^+]$ in protein-free plasma (which clinicians call plasma water) by dividing the laboratory value for plasma $[\text{Na}^+]$ by the plasma water content (usually 93%):

$$\begin{aligned} [\text{Na}^+]_{\text{plasma water}} &= \frac{142 \text{ meq/L plasma}}{0.93} \\ &= 153 \text{ meq/L plasma water} \end{aligned} \quad (5-1)$$

Similarly, for Cl^- ,

$$\begin{aligned} [\text{Cl}^-]_{\text{plasma water}} &= \frac{102 \text{ meq/L plasma}}{0.93} \\ &= 110 \text{ meq/L plasma water} \end{aligned} \quad (5-2)$$

[Table 5-2](#) lists solute concentrations in terms of both liters of *plasma* and liters of *plasma water*. If the plasma water fraction is <93% because of hyperproteinemia (high levels of protein in blood) or hyperlipemia (high levels of lipid in blood), the values that the clinical laboratory reports for electrolytes may appear abnormal even though the physiologically important concentration (solute concentration per liter of plasma water) is normal. For example, if a patient's plasma proteins and lipids occupy 20% of plasma volume and consequently plasma water is only 80% of plasma, a correction factor of 0.80 (rather than 0.93) should be used in [Equation 5-1](#). If the clinical laboratory were to report a very low plasma $[\text{Na}^+]$ of 122 meq/L plasma, the patient's $[\text{Na}^+]$ relevant to interstitial fluid would be $122/0.80 = 153$ meq/L plasma water, which is quite normal.

Effect of Protein Charge

For noncharged solutes such as glucose, the correction for protein and lipid volume is the only correction needed to predict interstitial concentrations from plasma concentrations. Because plasma proteins carry a net negative charge and because the capillary wall confines them to the plasma, they tend to retain cations in plasma. Thus, the **cation** concentration of the protein-free solution of the interstitium is lower by ~5%. Conversely, because these negatively charged plasma proteins repel anions, the **anion** concentration of the protein-free solution of the interstitium is higher by ~5%. We consider the basis for these 5% corrections in the discussion of the Gibbs-Donnan equilibrium (see [pp. 128–129](#)).

Thus, for a monovalent cation such as Na^+ , the interstitial concentration is 95% of the $[\text{Na}^+]$ of the protein-free plasma water, the value from [Equation 5-1](#):

$$\begin{aligned}
 [\text{Na}^+]_{\text{interstitium}} &= 153 \text{ meq/L plasma water} \times 0.95 \\
 &= 145 \text{ meq/L interstitial fluid}
 \end{aligned}
 \tag{5-3}$$

For a monovalent anion such as Cl^- , the interstitial concentration is 105% of the $[\text{Cl}^-]$ of the protein-free water of plasma, a value already obtained in [Equation 5-2](#):

$$\begin{aligned}
 [\text{Cl}^-]_{\text{interstitium}} &= 110 \text{ meq/L plasma water} \times 1.05 \\
 &= 116 \text{ meq/L interstitial fluid}
 \end{aligned}
 \tag{5-4}$$

Thus, for cations (e.g., Na^+), the two corrections (0.95/0.93) nearly cancel each other. On the other hand, for anions (e.g., Cl^-), the two corrections (1.05/0.93) are cumulative and yield a total correction of ~13%.

All body fluids have approximately the same osmolality, and each fluid has equal numbers of positive and negative charges

Osmolality

Despite the differences in solute composition among the intracellular, interstitial, and plasma compartments, they all have approximately the same osmolality. Osmolality describes the total concentration of all particles that are free in a solution.  **N5-2** Thus, glucose contributes one particle, whereas fully dissociated NaCl contributes two. Particles bound to macromolecules do not contribute at all to osmolality. In all body fluid compartments, humans have an osmolality—expressed as the number of osmotically active particles per kilogram of water—of ~290 milliosmoles/kg H_2O (290 mOsm).

N5-2

Osmolality versus Osmolarity

Contributed by Peter Aronson, Emile Boulpaep, Walter Boron

Osmolality is a measure of the number of osmotically active particles per kilogram of H_2O . The number of particles is expressed in units of moles. Thus, 1 osmole is 1 mole of osmotically active particles. Note that we express osmolality in terms of the mass of solvent (H_2O), not the mass of the entire solution (i.e., solutes and solvent). Unfortunately, it is rather impractical to measure the mass of H_2O in a solution (e.g., you could weigh the material before and after evaporating all the H_2O). For that reason, chemists have introduced **osmolarity**, the number of osmotically active particles per liter of total solution. It is easy to determine this volume. For very dilute solutions, the osmolality and osmolarity are quantitatively almost identical. Even for interstitial fluid, osmolality and osmolarity differ by <1%. Thus, for all practical purposes, one could use these terms interchangeably. On the other hand, the osmometers used to determine the number of osmoles in body fluids are usually calibrated with standards that are labeled in terms of osmoles per kilogram of H_2O (i.e., osmolality). Therefore, in this text, we express the osmotic

activity of solutions in terms of osmolality.

Blood plasma presents a special problem. Plasma proteins occupy ~7% of the total volume of plasma, but cannot cross the capillary wall. The solution that equilibrates across the capillary wall is the protein-free part of the blood plasma, which clinicians refer to as “plasma H₂O.” Therefore, the osmolality of the interstitial fluid will be the same as the osmolality of the protein-free portion of blood plasma. This value is ~290 milliosmoles/kg or 290 mOsm. The osmolality of the total volume of the blood plasma (i.e., the protein-free portion plus the proteins) is only 291 mOsm. The extra 1 mOsm is the osmotic pressure of the plasma proteins. This extra 1 mOsm has a special name: colloid osmotic pressure or oncotic pressure (p. 128). The reason that the plasma proteins contribute so little is that—although they have a large mass—they have a high molecular weight and thus represent very few particles.

Plasma proteins contribute ~14 meq/L (see [Table 5-2](#)). However, because these proteins usually have many negative charges per molecule, not many particles (~1 mM) are necessary to account for these milliequivalents. Moreover, even though the protein concentration—measured in terms of grams per liter—may be high, the high molecular weight of the average protein means that the protein concentration—measured in terms of moles per liter—is very low. Thus, proteins actually contribute only slightly to the total number of osmotically active particles (~1 mOsm).

Summing the *total* concentrations of all the solutes in the cells and interstitial fluid (including metabolites not listed in [Table 5-2](#)), we would see that the *total* solute concentration of the intracellular compartment is higher than that of the interstitium. Because the flow of water across cell membranes is governed by differences in osmolality across the membrane, and because the net flow is normally zero, intracellular and extracellular osmolality must be the same. How, then, do we make sense of this discrepancy? For some ions, a considerable fraction of their total intracellular store is bound to cellular proteins or complexed to other small solutes. In addition, some of the proteins are themselves attached to other materials that are out of solution. In computing osmolality, we count each particle once, whether it is a free ion, a complex of two ions, or several ions bound to a protein. For example, most of the intracellular Mg²⁺ and phosphate and virtually all the Ca²⁺ are either complexed or bound. Some of the electrolytes in blood plasma are also bound to plasma proteins; however, the bound fraction is generally much lower than the fraction in the cytosol.

Electroneutrality

All solutions must respect the principle of bulk electroneutrality: the number of positive charges in the overall solution must be the same as the number of negative charges. If we add up the major cations and anions in the cytosol (see [Table 5-2](#)), we see that the sum of [Na⁺]_i and [K⁺]_i greatly exceeds the sum of [Cl⁻]_i and [HCO₃⁻]_i. The excess positive charge reflected by this difference is balanced by the negative charge on intracellular macromolecules (e.g., proteins) as well as smaller anions such as organic phosphates.

There is a similar difference between major cations and anions in blood plasma, where it is often referred to as the **anion gap**. The clinical definition of anion gap is

$$\text{Anion gap}_{\text{plasma}} = [\text{Na}^+]_{\text{plasma}} - ([\text{Cl}^-]_{\text{plasma}} + [\text{HCO}_3^-]_{\text{plasma}})$$

(5-5)

Note that plasma $[\text{K}^+]$ is ignored. The anion gap, usually 9 to 14 meq/L, is the difference between ignored anions and ignored cations. Among the ignored anions are anionic proteins as well as small anionic metabolites. Levels of anionic metabolites, such as acetoacetate and β -hydroxybutyrate, can become extremely high, for example, in type 1 diabetic patients with very low levels of insulin (see [Box 51-5](#)). Thus, the anion gap increases under these conditions.

The differences in ionic composition between the ICF and ECF compartments are extremely important for normal functioning of the body. For example, because the K^+ gradient across cell membranes is a major determinant of electrical excitability, clinical disorders of extracellular $[\text{K}^+]$ can cause life-threatening disturbances in the heart rhythm. Disorders of extracellular $[\text{Na}^+]$ cause abnormal extracellular osmolality, with water being shifted into or out of brain cells; if uncorrected, such disorders lead to seizures, coma, or death.

These examples of clinical disorders emphasize the absolute necessity of understanding the processes that control the volume and composition of the body fluid compartments. These processes are the ones that move water and solutes between the compartments and between the body and the outside world.

Solute Transport Across Cell Membranes

In passive, noncoupled transport across a permeable membrane, a solute moves down its electrochemical gradient

We are all familiar with the way that water can flow from one side of a dike to another, provided the water levels on the two sides of the dike are different and the water has an open pathway (a breach in the dike) to move from one side to the other. In much the same way, a substance can passively move across a membrane that separates two compartments when there is both a favorable driving force and an open pathway through which the driving force can exert its effect.

When a pathway exists for transfer of a substance across a membrane, the membrane is said to be **permeable** to that substance. The **driving force** that determines the passive transport of solutes across a membrane is the **electrochemical gradient** or electrochemical potential energy difference acting on the solute between the two compartments. This **electrochemical potential energy difference** includes a contribution from the concentration gradient of the solute—the chemical potential energy difference—and, for charged solutes (e.g., Na^+ , Cl^-), a contribution from any difference in voltage that exists between the two compartments—the electrical potential energy difference.

This concept of how force and pathway determine passive movement of solutes is most easily illustrated by the example of passive, noncoupled transport. **Noncoupled transport** of a substance X means that movement of X across the membrane is not directly coupled to the movement of any other solute or to any chemical reaction (e.g., the hydrolysis of ATP). What, then, are the driving forces for the net movement of X? Clearly, if the concentration of X is higher in the outside compartment ($[\text{X}]_o$) than in the inside compartment ($[\text{X}]_i$), and assuming no voltage difference, the concentration gradient will act as the driving force to bring about the net movement of X across the membrane from outside to inside (Fig. 5-2). If [X] is the same on both sides but there is a voltage difference across the membrane—that is, the electrical potential energy on the outside (ψ_o) is not the same as on the inside (ψ_i)—this voltage difference will also drive the net movement of X, provided X is charged. The concentration gradient for X and the voltage difference across the membrane are the two determinants of the electrochemical potential energy difference for X between the two compartments. Because the movement of X by such a noncoupled mechanism is not directly coupled to the movement of other solutes or to any chemical reactions, the electrochemical gradient for X is the only driving force that contributes to the transport of X. Thus, the transport of X by a noncoupled, passive mechanism must always proceed “downhill,” in the direction down the electrochemical potential energy difference for X.

FIGURE 5-2 Uncoupled transport of a solute across a cell membrane. The net passive movement of a solute (X) depends on both the difference in concentration between the inside of the cell ($[X]_i$) and the outside of the cell ($[X]_o$) and the difference in voltage between the inside of the cell (ψ_i) and the outside of the cell (ψ_o).

Regardless of *how* X moves passively through the membrane—whether X moves through lipid or through a membrane protein—the direction of the overall driving force acting on X determines the direction of net transport. In the example in Figure 5-2, the overall driving force favors net transport from outside to inside (influx). However, X may still move from inside to outside (efflux). Movement of X across the membrane in one direction or the other is known as **unidirectional flux**. The algebraic sum of the two unidirectional fluxes is the **net flux**, or the net transport rate. Net transport occurs only when the unidirectional fluxes are unequal. In Figure 5-2, the overall driving force makes unidirectional influx greater than unidirectional efflux, which results in net influx.

When no net driving force is acting on X, we say that X is at **equilibrium** across the membrane and there is no net transport of X across the membrane. However, even when X is in equilibrium, there may be and usually are equal and opposite movements of X across the membrane. Net transport takes place only when the net driving force acting on X is displaced from the equilibrium point, and transport proceeds in the direction that would bring X back to equilibrium.

Equilibrium is actually a special case of a **steady state**. In a steady state, by definition, the conditions related to X do not change with time. Thus, a transport system is in a steady state when both the driving forces acting on it and the rate of transport are constant with time. Equilibrium is the particular steady state in which there is no net driving force and thus no net transport.

How can a steady state persist when X is not in equilibrium? Returning to the dike analogy, the downhill flow of water can be constant only if some device, such as a pump, keeps the water levels constant on both sides of the dike. A cell can maintain a nonequilibrium steady state for X only when some device, such as a mechanism for actively transporting X, can compensate for the passive movement of X and prevent the intracellular and extracellular concentrations of X from changing with time. This combination of a pump and a leak maintains both the concentrations of X and the passive flux of X.

At equilibrium, the chemical and electrical potential energy differences across the membrane are equal but opposite

As noted in the preceding section, the driving force for the passive, uncoupled transport of a solute is the electrochemical potential energy difference for that solute across the membrane that separates the inside (i) from the outside (o). We define the electrochemical potential energy difference as follows: **N5-3**

$$\underbrace{\Delta \tilde{\mu}_X}_{\text{Electrochemical potential energy difference}} = \underbrace{RT \ln \frac{[X]_i}{[X]_o}}_{\text{Chemical potential energy difference}} + \underbrace{z_X F(\psi_i - \psi_o)}_{\text{Electrical potential energy difference}}$$

(5-6)

N5-3

Electrochemical Potential Energy Difference for an Ion Across a Cell Membrane

Contributed by Peter Aronson, Emile Boulpaep, Walter Boron

The *chemical* potential energy, or partial molar Gibbs free energy, μ_X , of an uncharged solute X is

$$\mu_X = RT \ln [X]$$

(NE 5-2)

where $[X]$ is the concentration (more precisely, the chemical activity) of the solute, R is the gas constant ($R = 8.314 \text{ joules}/[\text{K} \cdot \text{mole}]$), and T is the temperature in kelvins ($K = 273.16 + ^\circ\text{C}$). Thus, μ_X has the units of energy per mole of X (joule/mole). Note that “potential” in the often-used term *chemical potential* is shorthand for “chemical potential energy.” In the case of a cell, we must consider the chemical potential energy both on the inside ($\mu_{X,i}$) and on the outside ($\mu_{X,o}$):

$$\begin{aligned}\mu_{X,i} &= RT \ln [X]_i \\ \mu_{X,o} &= RT \ln [X]_o\end{aligned}$$

(NE 5-3)

Thus, if $\mu_{X,o} > \mu_{X,i}$ (i.e., if $[X]_o > [X]_i$), then X will spontaneously move from the outside to the inside. On the other hand, if $\mu_{X,o} < \mu_{X,i}$, then X will spontaneously move from the inside to the outside.

We can define the chemical potential energy difference ($\Delta\mu_X$) as

$$\begin{aligned}\Delta\mu_X &= \mu_{X,i} - \mu_{X,o} \\ &= RT \ln [X]_i - RT \ln [X]_o \\ &= RT \ln \frac{[X]_i}{[X]_o}\end{aligned}$$

(NE 5-4)

If solute X is charged, we must also consider the difference in partial molar free energy ($\Delta\mu_{X,\text{elec}}$) due to the voltage difference across the cell membrane. If the voltage inside the cell is ψ_i and the voltage outside the cell is ψ_o , then this voltage difference is $(\psi_i - \psi_o)$, which is also known as the membrane

voltage (V_m). This electrical portion of the partial molar free energy change is the electrical work (joules/mole) needed to move the charge, which is on X, across the membrane and into the cell. According to the laws of physics, the electrical work per mole is the product of the voltage difference and the amount of charge/mole moved. Thus, we must multiply the voltage difference (joules/coulomb) by the Faraday constant, F (coulombs/mole), and the valence of the ion X, z_X (unitary charges/ion):

$$\Delta\mu_{X,\text{Elec}} = z_X F (\psi_i - \psi_o)$$

(NE 5-5)

The total free energy change ($\Delta\tilde{\mu}_X$) required to move X into the cell is simply the sum of the chemical and electrical terms:

$$\begin{aligned}\Delta\tilde{\mu}_X &= \Delta\mu_X + \Delta\mu_{X,\text{Elec}} \\ &= RT \ln \frac{[X]_i}{[X]_o} + z_X F (\psi_i - \psi_o)\end{aligned}$$

(NE 5-6)

Equation NE 5-6 is the same as Equation 5-6 on page 106 in the main text.

where z_X is the valence of X, T is absolute temperature, R is the gas constant, and F is the Faraday constant. The first term on the right-hand side of Equation 5-6, the difference in chemical potential energy, describes the energy change (joules per mole) as X moves across the membrane if we disregard the charge—if any—on X. The second term, the difference in electrical potential energy, describes the energy change as a mole of charged particles (each with a valence of z_X) moves across the membrane. The difference ($\psi_i - \psi_o$) is the **voltage difference across the membrane (V_m)**, also known as the **membrane potential**.

By definition, X is at equilibrium when the electrochemical potential energy difference for X across the membrane is zero:

$$\Delta\tilde{\mu}_X = 0$$

(5-7)

Thus, $\Delta\tilde{\mu}_X$ is the *net driving force* (units: joules/mole). When $\Delta\tilde{\mu}_X$ is *not* zero, X is *not* in equilibrium and will obviously tend either to enter the cell or to leave the cell, provided a pathway exists for X to cross the membrane.

It is worthwhile to consider two special cases of the equilibrium state (see Equation 5-7). First, when either the chemical or the electrical term in Equation 5-6 is zero, the other must also be zero. For example, when X is uncharged ($z_X = 0$), as in the case of glucose, equilibrium can occur only when [X] is equal on the two sides of the membrane. Alternatively, when X is charged, as in the case of Na^+ , but the voltage difference (i.e., V_m) is zero, equilibrium likewise can occur only when [X] is equal on the two

sides of the membrane. Second, when neither the chemical nor the electrical term in Equation 5-6 is zero, equilibrium can occur only when the two terms are equal but of opposite sign. Thus, if we set $\Delta\tilde{\mu}_X$ in Equation 5-6 to zero, as necessary for a state of equilibrium,

$$\begin{aligned}
 0 &= RT \ln \frac{[X]_i}{[X]_o} + z_X F V_m \\
 -\frac{RT}{z_X F} \ln \frac{[X]_i}{[X]_o} &= V_m \\
 V_m = E_X &= -\frac{RT}{z_X F} \ln \frac{[X]_i}{[X]_o}
 \end{aligned}
 \tag{5-8}$$

This relationship is the **Nernst equation**, which describes the conditions when an ion is in equilibrium across a membrane. Given values for $[X]_i$ and $[X]_o$, X can be in equilibrium only when the voltage difference across the membrane equals the **equilibrium potential (E_X)**, also known as the Nernst potential. Stated somewhat differently, E_X is the value that the membrane voltage *would have to have* for X to be in equilibrium.  **N5-4** If we express the logarithm to the base 10, then for the special case in which the temperature is 29.5°C,

$$V_m = E_X = -\frac{(60\text{mV})}{z_X} \log_{10} \frac{[X]_i}{[X]_o}
 \tag{5-9}$$

N5-4

Difference Between V_m and E_X

Contributed by Emile Boulpaep, Walter Boron

Equation 5-6 on page 106 in the text (shown here as Equation NE 5-7) states that—for ion X—the electrochemical potential energy difference across the cell membrane is

$$\underbrace{\Delta\tilde{\mu}_X}_{\text{Electrochemical potential energy difference}} = \underbrace{RT \ln \frac{[X]_i}{[X]_o}}_{\text{Chemical potential energy difference}} + \underbrace{z_X F (\psi_i - \psi_o)}_{\text{Electrical potential energy difference}}
 \tag{NE 5-7}$$

Here, each of the three major terms enclosed by horizontal braces has the dimension of **energy** per mole (e.g., joules/mole or kcal/mole). If we divide Equation NE 5-7 through by $z_X F$ we obtain:

$$\underbrace{\frac{\Delta \tilde{\mu}_X}{z_X F}}_{\text{Electrochemical potential difference}} = \underbrace{\frac{RT}{z_X F} \ln \frac{[X]_i}{[X]_o}}_{-E_X} + \underbrace{(\psi_i - \psi_o)}_{V_m}$$

(NE 5-8)

Each of the three major terms in Equation NE 5-8 now has the dimension of **voltage**. In other words, in dividing an energy term (*units*: joules/mole) by $z_X F$ (*units*: coulombs/mole), we are left with joules/coulomb, which is the definition of a volt. The first term on the right side of Equation NE 5-7 is nothing more than the negative of the Nernst potential that we introduced in Equation 5-8. The second term on the right side of Equation NE 5-8 is, of course, membrane potential. When $V_m = E_X$, the ion is in equilibrium. Otherwise, the difference ($V_m - E_X$) is the net electrochemical driving force—expressed in units of volts—that acts on ion X as the ion crosses the membrane. On page 151 of the text, we use this force to derive an expression in Equation 6-15 for the electrical current carried by ion X as the ion crosses the membrane:

$$I_X = G_X(V_m - E_X)$$

(NE 5-9)

Equation NE 5-9 is written in such a way that an inward current (i.e., the movement of a positively charged species into the cell or of a negatively charged species out of the cell) is negative.

Equation NE 5-9 allows us to predict the direction that ion X will passively move (if indeed it can move at all) across the membrane. Of course, if $V_m = E_X$, there will be no net movement of the ion at all. If V_m is more negative than E_X , then the membrane voltage is too negative for X to be in equilibrium. As a result, if X is positive, the cation will tend to passively enter the cell. For example, Na^+ generally tends to enter cells passively because V_m (e.g., -80 mV) is generally more negative than E_{Na} (e.g., $+67$ mV in Fig. 6-10). If X is negative, the anion will tend to passively exit the cell. For example, Cl^- generally tends to exit cells passively because, in most cells, V_m (-60 mV) is generally more negative than E_{Cl} (e.g., -47 mV).

The opposite is true, of course, if V_m is more positive than E_X .

At normal body temperature (37°C), the coefficient is ~ 61.5 mV instead of 60 mV. At 20°C , it is ~ 58.1 mV. **N5-5**

N5-5

60 mV per 10-fold Concentration Change

Contributed by Emile Boulpaep, Walter Boron

We start with Equation 5-8 (shown here as Equation NE 5-10):

$$V_m = E_x = -\frac{RT}{z_x F} \ln \frac{[X]_i}{[X]_o}$$

(NE 5-10)

R is 8.314 joules/(K · mole), F is 96,484 coulombs/mole, and T is the temperature in kelvins (K = 273.16 + °C). In order to convert the natural logarithm to the logarithm in base 10, we must multiply the “ln” term by $\ln(10)$, which is ~2.303. For the term $2.303 RT/F$ to be exactly 60 mV, the temperature must be 29.5°C (302.66 K):

$$\begin{aligned} V_m &= -\frac{1}{z_x} \times \frac{8.314 \text{ joule}}{\text{K} \cdot \text{mole}} \times 302.66 \text{ K} \\ &\quad \times \frac{\text{mole}}{96,484 \text{ coulomb}} \times 2.303 \times \log_{10} \frac{[X]_i}{[X]_o} \\ V_m &= -\frac{1}{z_x} \times \frac{0.060 \text{ joule}}{\text{coulomb}} \times \log_{10} \frac{[X]_i}{[X]_o} \\ V_m &= -\frac{1}{z_x} \times 0.060 \text{ volt} \times \log_{10} \frac{[X]_i}{[X]_o} \\ V_m = E_x &= -\frac{(60 \text{ mV})}{z_x} \times \log_{10} \frac{[X]_i}{[X]_o} \end{aligned}$$

(NE 5-11)

Indeed, this is Equation 5-9.

To illustrate the use of Equation 5-9 we compute E_x for a monovalent cation, such as K^+ . If $[K^+]_i$ is 100 mM and $[K^+]_o$ is 10 mM, a 10-fold concentration gradient, then

$$E_K = -\frac{(60 \text{ mV})}{1} \log_{10} \frac{100}{10} = -60 \text{ mV}$$

(5-10)

Thus, a 10-fold gradient of a monovalent ion such as K^+ is equivalent, as a driving force, to a voltage difference of 60 mV. For a divalent ion such as Ca^{2+} , a 10-fold concentration gradient can be balanced as a driving force by a voltage difference of 60 mV/2, or only 30 mV.

$(V_m - E_x)$ is the net electrochemical driving force acting on an ion

When dealing with an ion (X), it is more convenient to think about the net driving force in voltage (*units*: millivolts) rather than electrochemical potential energy difference (*units*: joules per mole). If we divide all terms in Equation 5-6 by the product of valence and the Faraday constant ($z_x F$), we obtain

$$\underbrace{\frac{\Delta\tilde{\mu}_X}{z_X F}}_{\text{Net driving force}} = \underbrace{\frac{RT}{z_X F} \ln \frac{[X]_i}{[X]_o}}_{-E_X} + \underbrace{(\psi_i - \psi_o)}_{V_m}$$

(5-11)

Because the energy terms previously expressed as *joules* per mole were divided by *coulombs* per mole (i.e., $z_X F$)—all three energy terms enclosed in braces are now in units of joules per coulomb or *volts*. The term on the left is the net electrochemical driving force acting on ion X. The first term on the right, as defined in Equation 5-8, is the negative of the Nernst equilibrium potential ($-E_X$). The second term on the right is the membrane voltage (V_m). Thus, a convenient equation expressing the net driving force is

$$\text{Net driving force in volts} = (V_m - E_X)$$

(5-12)

In Table 5-3, we use this equation—along with the values in Table 5-2 for extracellular (i.e., interstitial) and intracellular concentrations and a typical V_m of -60 mV—to compute the net driving force of Na^+ , K^+ , Ca^{2+} , Cl^- , HCO_3^- , and H^+ . When the net driving force is negative, cations will enter the cell and anions will exit. Stated differently, when V_m is more negative than E_X (i.e., the cell is *too negative* for X to be in equilibrium), a cation will tend to enter the cell and an anion will tend to exit.

In simple diffusion, the flux of an uncharged substance through membrane lipid is directly proportional to its concentration difference

The difference in electrochemical potential energy of a solute X across the membrane is a useful parameter because it allows us to predict whether X is in equilibrium across the cell membrane (i.e., Is $\Delta\tilde{\mu}_X = 0$?) or, if not, whether X would tend to passively move into the cell or out of the cell. As long as the movement of X is not coupled to the movement of another substance or to some biochemical reaction, the only factor that determines the direction of net transport is the driving force $\Delta\tilde{\mu}_X = 0$. The ability to

predict the movement of X is independent of any detailed knowledge of the actual transport pathway mediating its passive transport. In other words, we can understand the overall *energetics* of X transport without knowing anything about the transport mechanism itself, other than knowing that it is passive.

So far, we have discussed only the *direction* of net transport, not the *rate*. How will the rate of X transport vary if we vary the driving force $\Delta\tilde{u}_x$? Unlike determining the direction, determining the rate—that is, the **kinetics**—of transport requires knowing the peculiarities of the actual mechanism that mediates passive X transport.

Most transport systems are so complicated that a straightforward relationship between transport rate and $\Delta\tilde{u}_x$ may not exist. Here we examine the simplest case, which is **simple diffusion**. How fast does an uncharged, hydrophobic solute move through a lipid bilayer? Gases (e.g., CO₂), a few endogenous compounds (e.g., steroid hormones), and many drugs (e.g., anesthetics) are both uncharged and hydrophobic. Imagine that such a solute is present on both sides of the membrane but at a higher concentration on the outside (see Fig. 5-2). Because X has no electrical charge and because $[X]_o$ is greater than $[X]_i$, the net movement of X will be *into* the cell. How *fast* X moves is described by its **flux** (J_x); namely, the number of moles of X crossing a unit area of membrane (typically 1 cm²) per unit time (typically 1 second). Thus, J_x has the units of moles/(square centimeter · second). The better that X can dissolve in the membrane lipid (i.e., the higher the lipid-water **partition coefficient** of X), the more easily X will be able to traverse the membrane-lipid barrier. The flux of X will also be greater if X moves more readily once it is in the membrane (i.e., a higher **diffusion coefficient**) and if the distance that it must traverse is short (i.e., a smaller **membrane thickness**). We can combine these three factors into a single parameter called the **permeability coefficient of X** (P_x).  **N5-6** Finally, the flux of X will be greater as the difference in [X] between the two sides of the membrane increases (a large **gradient**).

N5-6

Definition of the Permeability Coefficient

Contributed by Emile Boulpaep, Walter Boron

The permeability coefficient (P) is

$$P = \frac{D \times \beta}{a}$$

(NE 5-12)

D is the diffusion coefficient (in cm²/s), β is the partition coefficient (concentration in the lipid divided by the concentration in the bulk aqueous phase; a dimensionless number), and a is the thickness of the membrane (in cm). Thus, the units of the permeability coefficient are cm/s.

$$P = \frac{D \times \beta}{a} = \frac{(\text{cm}^2/\text{s}) \times 1}{\text{cm}} = \frac{\text{cm}}{\text{s}}$$

(NE 5-13)

These concepts governing the simple diffusion of an electrically neutral substance were quantified by Adolf Fick in the 1800s and applied by others to the special case of a cell membrane. They are embodied in the following equation, which is a simplified version of **Fick's law**:

$$J_X = P_X ([X]_o - [X]_i) \tag{5-13}$$

As already illustrated in [Figure 5-2](#), we can separate the *net* flux of X into a *unidirectional influx* ($J_X^{o \rightarrow i}$) and a *unidirectional efflux* ($J_X^{i \rightarrow o}$). The net flux of X into the cell is simply the difference between the unidirectional fluxes:

$$\begin{array}{l} \text{Unidirectional influx: } J_X^{o \rightarrow i} = P_X [X]_o \\ \text{Unidirectional efflux: } J_X^{i \rightarrow o} = P_X [X]_i \\ \hline \text{Net flux: } J_X = P_X ([X]_o - [X]_i) \end{array} \tag{5-14}$$

Thus, unidirectional influx is proportional to the outside concentration, unidirectional efflux is proportional to the inside concentration, and net flux is proportional to the concentration *difference* (not the *ratio* $[X]_o/[X]_i$, but the *difference* $[X]_o - [X]_i$). In all cases, the proportionality constant is P_X .

A description of the *kinetic* behavior of a transport system (see [Equation 5-14](#))—that is, how fast things move—cannot violate the laws of *energetics*, or thermodynamics (see [Equation 5-6](#))—that is, the direction in which things move to restore equilibrium. For example, the laws of thermodynamics (see [Equation 5-6](#)) predict that when the concentration gradient for a neutral substance is zero (i.e., when $[X]_o/[X]_i = 1$), the system is in equilibrium and therefore the net flux must be zero. The law of simple diffusion (see [Equation 5-14](#)), which is a kinetic description, also predicts that when the concentration gradient for a neutral substance is zero (i.e., $[X]_o - [X]_i = 0$), the flux is zero.

Some substances cross the membrane passively through intrinsic membrane proteins that can form pores, channels, or carriers

Because most ions and hydrophilic solutes of biological interest partition poorly into the lipid bilayer, simple passive diffusion of these solutes through the lipid portion of the membrane is negligible. Noncoupled transport across the plasma membrane generally requires specialized pathways that allow particular substances to cross the lipid bilayer. In all known cases, such pathways are formed from **integral membrane proteins**. Three types of protein pathways through the membrane are recognized:

1. The membrane protein forms a **pore** that is always open ([Fig 5-3A](#)). Physiological examples are the porins in the outer membranes of mitochondria, cytotoxic pore-forming proteins such as the perforin released by lymphocytes, and perhaps the aquaporin water channels. A physical equivalent is a straight, open tube. If you look through this tube, you always see light coming through from the opposite side.

A PORE (NONGATED CHANNEL)**B CHANNEL (GATED PORE)****C CARRIER**

FIGURE 5-3 Three types of passive, noncoupled transport of a solute (X) through integral membrane proteins.

2. The membrane protein forms a **channel** that is alternately open and closed because it is equipped with a movable barrier or gate (see Fig. 5-3B). Physiological examples include virtually all ion channels, such as the ones that allow Na^+ , Cl^- , K^+ , and Ca^{2+} to cross the membrane. The process of opening and closing of the barrier is referred to as **gating**. Thus, a channel is a gated pore, and a pore is a nongated channel. A physical equivalent is a tube with a shutter near one end. As you look through this tube, you see the light flickering as the shutter opens and closes.

3. The membrane protein forms a **carrier** surrounding a conduit that never offers a continuous transmembrane path because it is equipped with at least two gates that are never open at the same time

(see [Fig. 5-3C](#)). Between the two gates is a compartment that can contain one or more binding sites for the solute. If the two gates are both closed, one (or more) of the transiting particles is trapped, or **occluded**, in that compartment. Physiological examples include carriers that move single solutes through the membrane by a process known as facilitated diffusion, which is discussed in the next section. A physical equivalent is a tube with shutters at both ends. As you look through this tube, you never see any light passing through because both shutters are never open simultaneously.

Water-filled pores can allow molecules, some as large as 45 kDa, to cross membranes passively

Some membrane proteins form **pores** that provide an aqueous transmembrane conduit that is always open (see [Fig. 5-3A](#)). Among the large-size pores are the **porins** ([Fig. 5-4](#)) found in the outer membranes of gram-negative bacteria and mitochondria. Mitochondrial porin allows solutes as large as 5 kDa to diffuse passively from the cytosol into the mitochondria's intermembrane space.

FIGURE 5-4 Structure of the PhoE porin of *Escherichia coli*. **A**, Top view of a porin trimer that shows the backbones of the polypeptide chains. Each of the three identical monomers, which are shown in different colors, contains 330 amino acids. The center of each monomer is a pore. **B**, Side view of a porin trimer. The extracellular surface is shown at the top. Each monomer consists of a β barrel with 16 antiparallel β sheets (i.e., adjacent polypeptide strands are oriented in opposite directions) surrounding a large cavity that at its narrowest point has an oval cross section (minimum and maximum internal diameters, 0.7×1.1 nm). The images are based on high-resolution electron microscopy at a resolution of 3.5 \AA (0.35 nm). (From Jap BK, Walian PJ: Structure and functional mechanisms of porins. *Physiol Rev* 76:1073–1088, 1996.)

One mechanism by which cytotoxic T lymphocytes kill their target cells is the release of monomers of a pore-forming protein known as **perforin**. Perforin monomers polymerize within the target cell membrane and assemble like staves of a barrel to form large, doughnut-like channels with an internal diameter of 16 nm. The passive flow of ions, water, and other small molecules through these pores kills the target cell. A similar pore plays a crucial role in the defense against bacterial infections. The binding of antibodies to an invading bacterium (“classic” pathway), or simply the presence of native polysaccharides on bacteria (“alternative” pathway), triggers a cascade of reactions known as the **complement cascade**. This cascade culminates in the formation of a doughnut-like structure with an internal diameter of 10 nm. This pore is made up of monomers of C9, the final component of the complement cascade.

The **nuclear pore complex (NPC)**, which regulates traffic into and out of the nucleus (see [p. 21](#)), is remarkably large. The NPC is made up of at least 30 different proteins and has a molecular mass of 10^8 Da and an outer diameter of ~100 nm. It can transport huge molecules (approaching 10^6 Da) in a complicated process that involves ATP hydrolysis. In addition to this active component of transport, the NPC also has a passive component. Contained within the massive NPC is a simple aqueous pore with an internal diameter of ~9 nm that allows molecules <45 kDa to move between the cytoplasm and nucleus but almost completely restricts the movement of globular proteins that are larger than ~60 kDa.

The plasma membranes of many types of cells have proteins that form channels just large enough to allow water molecules to pass through. The first water channel to be studied was **aquaporin 1 (AQP1)**, a 28-kDa protein. AQP1 belongs to a larger family of **aquaporins (AQPs)** that has representatives in organisms as diverse as bacteria, plants, and animals. In mammals, the various AQPs have different tissue distributions, different mechanisms of regulation, and varying abilities to transport small neutral molecules other than water. In the lipid bilayer, AQP1 ([Fig. 5-5](#)) exists as tetramers. Each monomer consists of six membrane-spanning helices as well as two shorter helices that dip into the plane of the membrane. These structures form a permeation pathway for the single-file diffusion of water. For his discovery of the aquaporins, Peter Agre shared the 2003 Nobel Prize in Chemistry. [N5-7](#)

FIGURE 5-5 Structure of the human AQP1 water channel. **A**, Top view of an AQP tetramer, showing transmembrane helices H1–H6 and shorter helices HE and HB. Each of the four identical monomers is made up of 269 amino acids and has a pore at its center. **B**, Side view of AQP. The extracellular surface is shown at the top. The images are based on high-resolution electron microscopy at a resolution of 3.8 Å (0.38 nm). Gated channels, which alternately open and close, allow ions to cross the membrane passively

Gated **ion channels**, like the AQPs just discussed, consist of one or more polypeptide subunits with α -helical membrane-spanning segments. These channels have several functional components (see Fig. 5-

3B). The first is a **gate** that determines whether the channel is open or closed, with each state reflecting a different conformation of the membrane protein. Second, the channel generally has one or more **sensors** that can respond to one of several different types of signals: (1) changes in membrane voltage, (2) second-messenger systems that act at the cytoplasmic face of the membrane protein, or (3) ligands, such as neurohumoral agonists, that bind to the extracellular face of the membrane protein. These signals regulate transitions between the open and closed states. A third functional component is a **selectivity filter**, which determines the *classes* of ions (e.g., anions or cations) or the *particular* ions (e.g., Na^+ , K^+ , Ca^{2+}) that have access to the channel pore. The fourth component is the actual **open channel pore** (see Fig. 5-3B). Each time that a channel assumes the open conformation, it provides a continuous pathway between the two sides of the membrane so that ions can flow through it passively by diffusion until the channel closes again. During each channel opening, many ions flow through the channel pore, usually a sufficient number to be detected as a small current by sensitive patch-clamp techniques (see p. 154).

Na⁺ Channels

Because the **electrochemical driving force for Na⁺** ($V_m - E_{\text{Na}}$) is always strongly *negative* (see Table 5-3), a large, inwardly directed net driving force or gradient favors the passive movement of Na^+ into virtually every cell of the body. Therefore, an open Na^+ channel will act as a conduit for the passive entry of Na^+ . One physiological use for channel-mediated Na^+ entry is the transmission of information. Thus, voltage-gated Na^+ channels are responsible for generating the action potential (e.g., “nerve impulse”) in many excitable cells. Another physiological use of Na^+ channels can be found in epithelial cells such as those in certain segments of the renal tubule and intestine. In this case, the ENaC Na^+ channels are largely restricted to the apical surface of the cell, where they allow Na^+ to enter the epithelial cell from the renal tubule lumen or intestinal lumen. This passive influx is a key step in the movement of Na^+ across the entire epithelium, from lumen to blood.

K⁺ Channels

The **electrochemical driving force for K⁺** ($V_m - E_K$) is usually fairly close to zero or somewhat *positive* (see Table 5-3), so K^+ is either at equilibrium or tends to move *out* of the cell. In virtually all cells, K^+ channels play a major role in generating a resting membrane voltage that is inside negative. Other kinds of K^+ channels play a key role in excitable cells, where these channels help terminate action potentials.

Ca²⁺ Channels

The **electrochemical driving force for Ca²⁺** ($V_m - E_{\text{Ca}}$) is always strongly *negative* (see Table 5-3), so Ca^{2+} tends to move *into* the cell. When Ca^{2+} channels are open, Ca^{2+} rapidly enters the cell down a steep electrochemical gradient. This inward movement of Ca^{2+} plays a vital role in transmembrane signaling for both excitable and nonexcitable cells as well as in generating action potentials in some excitable cells.

Proton Channels

The plasma membranes of many cell types contain Hv1 H^+ channels. Under normal conditions, the **electrochemical driving force for H⁺** generally tends to move H^+ *into* cells if Hv1 channels are open (see Table 5-3). However, Hv1 channels tend to be *closed* under normal conditions and activate only when the membrane depolarizes or the cytoplasm acidifies—that is, when the driving force favors the *outward* movement of H^+ . Hv1 channels may therefore help mediate H^+ extrusion from the cell during

states of strong membrane depolarization (e.g., during an action potential) or severe intracellular acidification.

Anion Channels

Most cells contain one or more types of anion-selective channels through which the passive, noncoupled transport of Cl^- —and, to a lesser extent, HCO_3^- —can take place. The **electrochemical driving force for Cl^-** ($V_m - E_{\text{Cl}}$) in most cells is modestly *negative* (see Table 5-3), so Cl^- tends to move *out of* these cells. In certain epithelial cells with Cl^- channels on their basolateral membranes, the passive movement of Cl^- through these channels plays a role in the transepithelial movement of Cl^- from lumen to blood.

Some carriers facilitate the passive diffusion of small solutes such as glucose

Carrier-mediated transport systems transfer a broad range of ions and organic solutes across the plasma membrane. Each carrier protein has a specific affinity for binding one or a small number of solutes and transporting them across the bilayer. The simplest passive carrier-mediated transporter is one that mediates *facilitated diffusion*. Below, we will introduce *cotransporters* (which carry two or more solutes in the same direction) and *exchangers* (which move them in opposite directions).

All carriers that do not either hydrolyze ATP or couple to an electron transport chain are members of the **solute carrier (SLC) superfamily**,  **N5-8** which is organized according to the homology of the deduced amino-acid sequences (Table 5-4). Each of the 52 SLC families contains up to 53 genes that encode proteins that share a relatively high amino-acid sequence identity (20% to 25%). Moreover, each gene may encode multiple variants (see Fig 4-19). Members of an SLC family may differ in molecular mechanism (i.e., facilitated diffusion, cotransport, exchange), kinetic properties (e.g., solute specificity and affinity), regulation (e.g., phosphorylation), sites of membrane targeting (e.g., plasma membrane versus intracellular organelles), tissues in which they are expressed (e.g., kidney versus brain), or developmental stage at which they are expressed.

TABLE 5-4
The SLC Superfamily of Solute Carriers 

FAMILY	DESCRIPTION	EXAMPLES
SLC1 (7)*	Glutamate transporters	EAAT 1, 2, 3, 4, 5 ASCT1, 2
SLC2 (14)	Facilitated transport of hexoses	GLUT1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 14; HMIT
SLC3 (2)	Heavy subunits of heterodimeric amino-acid transporters (with SLC7)	rBAT system 4F2hc system
SLC4 (10)	HCO_3^- exchangers and cotransporters	AE1, 2, 3 (Cl-HCO ₃ exchangers) NBCe1, 2 (electrogenic Na/HCO ₃ cotransporters) NBCn1, 2 (electroneutral Na/HCO ₃ cotransporters) NDCBE (Na ⁺ -driven Cl-HCO ₃ exchanger)
SLC5 (12)	Na/glucose cotransporters	SGLT 1, 2, 3, 4, 5 (glucose); NIS (iodide); SMIT 1, 2 (myoinositol) SMCT 1, 2 (monocarboxylates) SMVT (biotin) CHT (choline)
SLC6 (21)	Na ⁺ - and Cl ⁻ -coupled cotransport of “neurotransmitters”	B ⁰ AT 1 (Na ⁺ -coupled amino acid) GAT 1, 2, 3; GBT 1 (Na ⁺ - and Cl ⁻ -coupled GABA) ATB ⁰⁺ (Na ⁺ - and Cl ⁻ -coupled amino acids) NET (norepinephrine transporters) SERT (serotonin) DAT (dopamine)
SLC7 (14)	Transporter subunits of heterodimeric amino-acid transporters (with SLC3)	LAT 1, 2; y ⁺ LAT 1, 2

		CAT1, 2, 3, 4
SLC8 (3)	Na-Ca exchangers	NCX1, 2, 3
SLC9 (13)	Na-H exchangers	NHE1, 2, 3, 4, 5, 6, 7, 8, 9 NHA1, 2 Sperm-NHE
SLC10 (7)	Na/bile-salt cotransporters	ASBT
SLC11 (2)	H ⁺ -driven metal-ion cotransporters	DMT1 NRAMP1
SLC12 (9)	Cation-coupled Cl ⁻ cotransporters	NKCC1, 2 (Na/K/Cl cotransporter) NCC (Na/Cl cotransporter) KCC1, 2, 3, 4 (K/Cl cotransporter)
SLC13 (5)	Na ⁺ -coupled sulfate and carboxylate cotransporters	NaDC1, 3 (mono-, di-, and tricarboxylates) NaSI, 2 (sulfate)
SLC14 (2)	Facilitated transport of urea	UT-A1, 2, 3, 4, 5, 6; UT-B1, 2
SLC15 (4)	H ⁺ -driven oligopeptide cotransporters	PepT1, 2 PhT1, 2
SLC16 (14)	Monocarboxylate transporters	MCT1, 2, 3, 4 (H ⁺ -coupled monocarboxylate cotransporter) MCT8, 10 (facilitated diffusion of aromatic amino acids)
SLC17 (9)	Type I Na/phosphate cotransporters and vesicular Glu transporters	NaPi-I NPT1, 3, 4 VNUT VGLUT1, 2, 3
SLC18 (4)	Vesicular monoamine transporters	VMAT1, 2 (H ⁺ -amine exchanger) VACHT (H ⁺ -acetylcholine exchanger)
SLC19 (3)	Folate/thiamine transporters	RFC ThTr1, 2
SLC20 (2)	Type III Na/phosphate cotransporters	PiT-1, 2
SLC21 (11) or SLCO	Organic anion and cation transporters	OATP1, 2, 3, 4, 5, 6 (bile salts, thyroid hormones, prostaglandins)
SLC22 (23)	Organic cation, anion, zwitterion transporters	OCT1, 2, 3 (facilitated diffusion of organic <i>cations</i>) OCTN1 (organic <i>cation</i> -H exchanger) OCTN2 (Na/organic <i>cation</i> cotransporter) OAT1, 2, 3, 4, 5, 7, 10 (exchange or facilitated diffusion of organic <i>anions</i>) URAT1 (urate exchanger)
SLC23 (4)	Na/ascorbic acid transporters	SVCT1, 2, 3, 4
SLC24 (5)	Na ⁺ /(Ca ²⁺ -K ⁺) exchanger	NCKX1, 2, 3, 4, 5
SLC25 (53)	Mitochondrial carriers	ANC1, 2, 3, 4 (ANT1, 2, 3, 4)
SLC26 (11)	Multifunctional anion exchangers	DRA (Cl-HCO ₃ exchanger) Pendrin (exchanges HCO_3^- , Cl ⁻ or I ⁻) Prestin (exchanges Cl ⁻ , formate, oxalate; a motor in cochlear hair cells) CFEX (exchanges Cl ⁻ , HCO_3^- , oxalate, formate)
SLC27 (6)	Fatty-acid transporters	FATP1, 2, 3, 4, 5, 6
SLC28 (3)	Na/nucleoside transporters	CNT1, 2, 3
SLC29 (4)	Facilitative nucleoside transporters	ENT1, 2, 3, 4
SLC30 (10)	Zinc efflux transporter	ZnT1, 2, 3, 4, 5, 6, 7, 8, 9, 10
SLC31 (2)	Copper importer	CTR1, 2
SLC32 (1)	Vesicular inhibitory amino-acid transporter	VIAAT (exchange of H ⁺ for GABA or glycine)
SLC33 (1)	Acetyl-coenzyme A transporter	ACATN1
SLC34 (3)	Type II Na/phosphate cotransporters	NaPi-IIa, b, c
SLC35 (30)	Nucleoside-sugar transporter	HFRC CST UGT PAPST1, 2
SLC36 (4)	H ⁺ -coupled amino-acid cotransporters	PAT1, 2, 3, 4
SLC37 (4)	Sugar-phosphate/phosphate exchanger	SPX1, 2, 3, 4
SLC38 (11)	Na ⁺ -driven neutral amino acids (system A and N)	SNAT1, 2, 4 (system A, cotransports amino acids with Na ⁺) SNAT3, 5 (system N, cotransports amino acids with Na ⁺ in exchange for H ⁺)
SLC39 (14)	Metal-ion transporters	ZIP1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14 (uptake of Zn ²⁺)
SLC40 (1)	Basolateral Fe ²⁺ transporter	Ferroportin (FPN1)
SLC41 (3)	MgtE-like magnesium transporter	MgtE
SLC42 (3)	$\text{NH}_3/\text{NH}_4^+$, CO ₂ channels	RhAG, RhBG, RhCG
SLC43 (3)	Na ⁺ -independent, system L-like amino-acid transporter	LAT3, 4 EEG1
SLC44 (5)	Choline-like transporter	CTL1, 2, 3, 4, 5
SLC45 (4)	Putative sugar transporter	Past-A MATP Prostein
SLC46 (3)	Folate transporter	PCFT TSCOT
SLC47 (2)	Multidrug and toxin extrusion transporter	MATE1, 2
SLC48 (1)	Heme transporter	HRG-1 (heme responsive gene 1)
SLC49 (4)	FLVCR-related transporter	FLVCR1, 2 MFSD7 DIRC2
SLC50 (1)	Sugar efflux transporter	SWEET1
SLC51 (2)	Steroid-derived molecule transporters	OST α , OST β
SLC52 (3)	Riboflavin transporter	RFVT1, 2, 3

*In parentheses is the number of human genes in the family. Members of individual families generally are named SLCxAy (e.g., SLC4A4), where x is a number identifying the family and y is a number identifying the gene within that family.

GABA, gamma-aminobutyric acid.

N5-8

The SLC Superfamily of Solute Carriers

Contributed by Emile Boulpaep, Walter Boron

The SLC superfamily was the subject of a series of reviews—one per family member—in 2013. The reference below is the introduction to the series.

Reference

Hediger MA, Clémentçon B, Burrier RE, Bruford EA. The ABCs of membrane transporters in health and disease (SLC series): Introduction. *Mol Aspects Med.* 2013;34:95–107.

Carrier-mediated transport systems behave according to a general kinetic scheme for facilitated diffusion that is outlined in [Figure 5-3C](#). This model illustrates how, in a cycle of six steps, a carrier can passively move a solute X into the cell.

This mechanism can mediate only the downhill, or passive, transport of X. Therefore, it mediates a type of diffusion, called **facilitated diffusion**. When [X] is equal on the two sides of the membrane, no *net* transport will take place, although equal and opposite *unidirectional* fluxes of X may still occur.

In a cell membrane, a fixed number of carriers is available to transport X. Furthermore, each carrier has a limited speed with which it can cycle through the steps illustrated in [Figure 5-3C](#). Thus, if the extracellular X concentration is gradually increased, for example, the influx of X will eventually reach a maximal value once all the carriers have become loaded with X. This situation is very different from the one that exists with simple diffusion—that is, the movement of a solute through the lipid phase of the membrane. Influx by simple diffusion increases linearly with increases in [X]_o, with no maximal rate of transport. As an example, if X is initially absent on *both* sides of the membrane and we gradually increase [X] on *one* side, the net flux of X (*J_X*) is described by a straight line that passes through the origin ([Fig. 5-6A](#)). However, with carrier-mediated transport, *J_X* reaches a maximum (*J_{max}*) when [X] is high enough to occupy all the carriers in the membrane (see [Fig. 5-6B](#)). Thus, the relationship describing carrier-mediated transport follows the same Michaelis-Menten kinetics as do enzymes:

$$V = \frac{[S] V_{\max}}{K_m + [S]}$$

(5-15)

This equation describes how the velocity of an enzymatic reaction (*V*) depends on the substrate concentration ([S]), the Michaelis constant (*K_m*), and the maximal velocity (*V_{max}*). The comparable equation for carrier-mediated transport is identical, except that fluxes replace reaction velocities:

$$J_X = \frac{[X] J_{\max}}{K_m + [X]} \quad (5-16)$$

Thus, K_m is the solute concentration at which J_X is half of the maximal flux (J_{\max}). The lower the K_m , the higher the apparent **affinity** of the transporter for the solute.

FIGURE 5-6 Dependence of transport rates on solute concentration. **A**, The net flux of the solute X through the cell membrane is J_X . **B**, The maximal flux of X (J_{\max}) occurs when the carriers are saturated.

The flux is half of its maximal value ($\frac{1}{2} J_{\max}$) when the concentration of X is equal to the K_m .

Historically, the name *carrier* suggested that carrier-mediated transport occurs as the solute binds to a miniature ferryboat that shuttles back and forth across the membrane. Small polypeptides that act as shuttling carriers exist in nature, as exemplified by the antibiotic valinomycin. Such “ion carriers,” or **ionophores**, bind to an ion on one side of the membrane, diffuse across the lipid phase of the membrane, and release the ion on the opposite side of the membrane. Valinomycin is a K^+ ionophore that certain bacteria produce to achieve a selective advantage over their neighbors. However, none of the known carrier-mediated transport pathways in animal cell membranes are ferries.

Examples of membrane proteins that mediate facilitated diffusion are the **GLUT glucose transporters** (Fig. 5-7), members of the SLC2 family (see Table 5-4). The GLUTs have 12 membrane-spanning segments as well as multiple hydrophilic polypeptide loops facing either the ECF or the ICF. They could not possibly act as a ferryboat shuttling back and forth across the membrane. Instead, some of the membrane-spanning segments of carrier-mediated transport proteins most likely form a permeation pathway through the lipid bilayer, as illustrated by the amphipathic membrane-spanning segments 7, 8, and 11 in Figure 5-7. These membrane-spanning segments, as well as other portions of the protein, probably also act as the gates and solute-binding sites that allow transport to proceed in the manner outlined in Figure 5-3C.

FIGURE 5-7 Structure of the GLUT family of glucose transporters. The 12 membrane-spanning segments are connected to each other by intracellular and extracellular loops.

The SLC2 family includes 14 transporters (GLUTs). Whereas GLUT1 is constitutively expressed on the cell surface, GLUT4 in the basal state is predominantly present in the membranes of intracellular vesicles, which represent a storage pool for the transporters. Because a solute such as glucose permeates the lipid bilayer so poorly, its uptake by the cell depends strictly on the activity of a carrier-mediated transport system for glucose. Insulin increases the rate of carrier-mediated glucose transport into certain cells by recruiting the GLUT4 isoform to the plasma membrane from the storage pool (see [p. 1047](#)).

Two other examples of transporters that mediate facilitated diffusion are the **urea transporter (UT)** family, which are members of the SLC14 family (see [Table 5-4](#)), and the **organic cation transporter (OCT)** family, which are members of the SLC22 family. Because OCT moves an electrical charge (i.e., carries current), it is said to be **electrogenic**.

The physical structures of pores, channels, and carriers are quite similar

Pores, ion channels, and carriers all have multiple transmembrane segments surrounding a solute permeation pathway. Moreover, some channels also contain binding sites within their permeation pathways, so transport is saturable with respect to ion concentration. However, pores, channels, and carriers are fundamentally distinct kinetically ([Table 5-5](#)). *Pores*, such as the porins, are thought to be continuously open and allow vast numbers of particles to cross the membrane. No evidence suggests that pores have conformational states. *Channels* undergo conformational transitions between closed and open states. When they are open, they are open to both intracellular and extracellular solutions simultaneously. Thus, while the channel is open, it allows multiple ions, perhaps millions, to cross the membrane per open event. Because the length of time that a particular channel remains open varies from one open event to the next, the number of ions flowing through that channel per open event is not fixed. *Carriers* have a

permeation pathway that is virtually never open simultaneously to both intracellular and extracellular solutions. Whereas the fundamental event for a channel is opening, the fundamental event for a carrier is a complete cycle of conformational changes. Because the binding sites in a carrier are limited, each cycle of a carrier can transport only one or a *small, fixed* number of solute particles. Thus, the number of particles per second that can move across the membrane is generally several orders of magnitude lower for a single carrier than for a single channel.

TABLE 5-5
Comparison of Properties of Pores, Channels, and Carriers

	PORES	CHANNELS	CARRIERS
Example	Water channel (AQP1)	Shaker K ⁺ channel	Glucose transporter (GLUT1)
Conduit through membrane	Always open	Intermittently open	Never open
Unitary event	None (continuously open)	Opening	Cycle of conformational changes
Particles translocated per “event”	—	6 × 10 ⁴ *	1–5
Particles translocated per second	Up to 2 × 10 ⁹	10 ⁶ –10 ⁸ when open	200–50,000

*Assuming a 100-pS (pico Siemens) channel, a driving force of 100 mV, and an opening time of 1 ms.

We have seen how carriers can mediate facilitated diffusion of glucose, which is a passive or downhill process. However, carriers can also mediate **coupled** modes of transport. The remainder of this section is devoted to these carriers, which act as pumps, cotransporters, and exchangers.

The Na-K pump, the most important primary active transporter in animal cells, uses the energy of ATP to extrude Na⁺ and take up K⁺

Active transport is a process that can transfer a solute uphill across a membrane—that is, against its electrochemical potential energy difference. In **primary active transport**, the driving force needed to cause net transfer of a solute against its electrochemical gradient comes from the favorable energy change that is associated with an exergonic chemical reaction, such as ATP hydrolysis. In **secondary active transport**, the driving force is provided by coupling the *uphill* movement of that solute to the *downhill* movement of one or more other solutes for which a favorable electrochemical potential energy difference exists. A physical example is to use a motor-driven winch to lift a large weight into the air (primary active transport) and then to transfer this large weight to a seesaw, on the other end of which is a lighter child. The potential energy stored in the elevated weight will then lift the child (secondary active transport). For transporters, it is commonly the favorable inwardly directed Na⁺ electrochemical gradient, which itself is set up by a *primary* active transporter, that drives the *secondary* active transport of another solute. In this and the next section, we discuss primary active transporters, which are also referred to as **pumps**. The pumps discussed here are all energized by ATP hydrolysis and hence are **ATPases**.

As a prototypic example of a primary active transporter, consider the nearly ubiquitous **Na-K pump** (or **Na,K-ATPase, NKA**). This substance was the first enzyme recognized to be an ion pump, a discovery for which Jens Skou shared the 1997 Nobel Prize in Chemistry.  **N5-9** The Na-K pump is located in the plasma membrane and has both α and β subunits (**Fig. 5-8A**). The α subunit, which has 10 transmembrane segments, is the catalytic subunit that mediates active transport. The β subunit, which has one transmembrane segment, is essential for proper assembly and membrane targeting of the Na-K pump. Four α isoforms and two β isoforms have been described. These isoforms have different tissue and developmental patterns of expression as well as different kinetic properties.

A Na-K PUMP

B ENZYMIC CYCLE OF THE Na-K PUMP

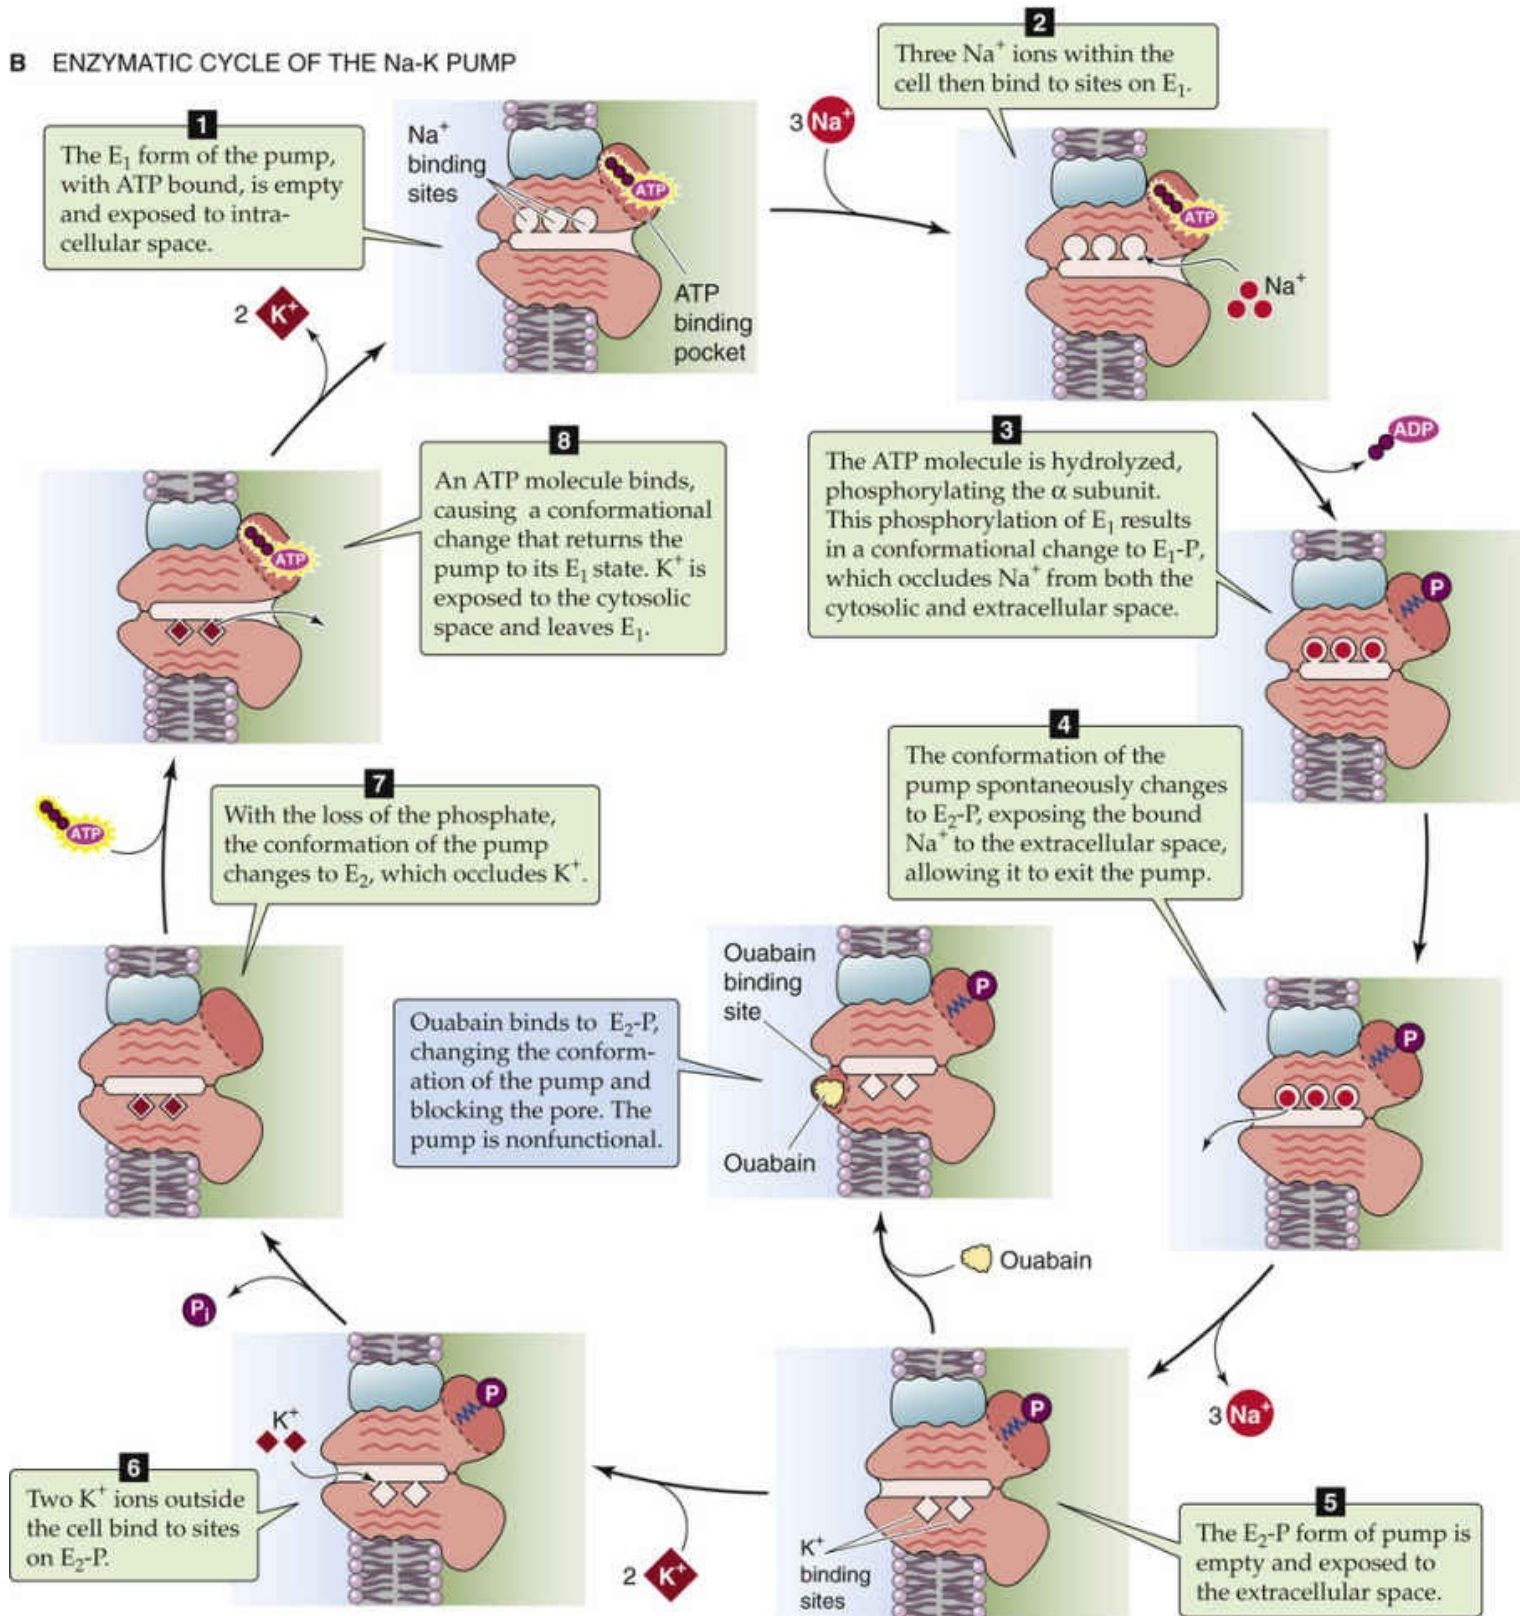

FIGURE 5-8 Model of the sodium pump. **A**, Schematic representation of the α and β subunits of the pump. **B**, The protein cycles through at least eight identifiable stages as it moves 3 Na^+ ions out of the cell and 2 K^+ ions into the cell. P_i , phosphate.

N5-9

Jens Skou

For more information about Jens Skou and the work that led to his Nobel Prize, visit <http://www.nobel.se/chemistry/laureates/1997/index.html> (accessed October 2014).

With each forward cycle, the pump couples the extrusion of three Na^+ ions and the uptake of two K^+ ions to the intracellular hydrolysis of one ATP molecule. By themselves, the transport steps of the Na-K pump are energetically uphill; that is, if the pump were not an ATPase, the transporter would run in reverse, with Na^+ leaking into the cell and K^+ leaking out. Indeed, under extreme experimental conditions, the Na-K pump can be reversed and forced to synthesize ATP! However, under physiological conditions, hydrolysis of one ATP molecule releases so much free energy—relative to the aggregate free energy needed to fuel the uphill movement of three Na^+ and two K^+ ions—that the pump is poised far from its equilibrium and brings about the net active exchange of Na^+ for K^+ in the desired directions.

Although animal cells may have other pumps in their plasma membranes, the Na-K pump is the only primary active transport process for Na^+ . The Na-K pump is also the most important primary active transport mechanism for K^+ . In cells throughout the body, the Na-K pump is responsible for maintaining a low $[\text{Na}^+]_i$ and a high $[\text{K}^+]_i$ relative to ECF. In most epithelial cells, the Na-K pump is restricted to the basolateral side of the cell.

The Na-K pump exists in two major conformational states: E_1 , in which the binding sites for the ions face the inside of the cell; and E_2 , in which the binding sites face the outside. The Na-K pump is a member of a large superfamily of pumps known as **E_1 - E_2 ATPases** or **P-type ATPases**. It is the ordered cycling between these two states that underlies the action of the pump. [Figure 5-8B](#) is a simplified model showing the eight stages of this catalytic cycle of the α subunit:

Stage 1: ATP-bound $\text{E}_1 \cdot \text{ATP}$ state. The cycle starts with the ATP-bound E_1 conformation, just after the pump has released its bound K^+ to the ICF. The Na^+ -binding sites face the ICF and have high affinities for Na^+ .

Stage 2: Na^+ -bound $\text{E}_1 \cdot \text{ATP} \cdot 3\text{Na}^+$ state. Three intracellular Na^+ ions bind.

Stage 3: Occluded $\text{E}_1\text{-P} \cdot (3\text{Na}^+)$ state. The ATP previously bound to the pump phosphorylates the pump at an aspartate residue. Simultaneously, ADP leaves. This phosphorylation triggers a minor conformational change in which the E_1 form of the pump now occludes the three bound Na^+ ions within the permeation pathway. In this state, the Na^+ -binding sites are inaccessible to both the ICF and ECF.

Stage 4: Deoccluded $\text{E}_2\text{-P} \cdot 3\text{Na}^+$ state. A major conformational change shifts the pump from the E_1 to the E_2 conformation and has two effects. First, the pump becomes deoccluded, so that the Na^+ -binding sites now communicate with the *extracellular* solution. Second, the Na^+ affinities of these binding sites

decrease.

Stage 5: Empty E_2 -P state. The three bound Na^+ ions dissociate into the external solution, and the protein undergoes a minor conformational change to the empty E_2 -P form, which has high affinity for binding of extracellular K^+ . However, the pore still communicates with the extracellular solution.

Stage 6: K^+ -bound E_2 -P \cdot 2K^+ state. Two K^+ ions bind to the pump.

Stage 7: Occluded $E_2 \cdot (2\text{K}^+)$ state. Hydrolysis of the acylphosphate bond, which links the phosphate group to the aspartate residue, releases the inorganic phosphate into the intracellular solution and causes a minor conformational change. In this $E_2 \cdot (2\text{K}^+)$ state, the pump occludes the two bound K^+ ions within the permeation pathway so that the K^+ -binding sites are inaccessible to both the ECF and ICF.

Stage 8: Deoccluded $E_1 \cdot \text{ATP} \cdot 2\text{K}^+$ state. Binding of intracellular ATP causes a major conformational change that shifts the pump from the E_2 back to the E_1 state. This conformational change has two effects. First, the pump becomes deoccluded, so that the K^+ -binding sites now communicate with the *intracellular* solution. Second, the K^+ affinities of these binding sites decrease.

Stage 1: ATP-bound $E_1 \cdot \text{ATP}$ state. Dissociation of the two bound K^+ ions into the intracellular solution returns the pump to its original $E_1 \cdot \text{ATP}$ state, ready to begin another cycle.

Because each cycle of hydrolysis of one ATP molecule is coupled to the extrusion of three Na^+ ions from the cell and the uptake of two K^+ ions, the *stoichiometry* of the pump is three Na^+ to two K^+ , and each cycle of the pump is associated with the net extrusion of one positive charge from the cell. Thus, the Na-K pump is *electrogenic*.

Just as glucose flux through the GLUT1 transporter is a saturable function of [glucose], the rate of active transport by the Na-K pump is a saturable function of $[\text{Na}^+]_i$ and $[\text{K}^+]_o$. The reason is that the number of pumps is finite and each must bind three Na^+ ions and two K^+ ions. The transport rate is also a saturable function of $[\text{ATP}]_i$ and therefore depends on the metabolic state of the cell. In cells with high Na-K pump rates, such as renal proximal tubules, a third or more of cellular energy metabolism is devoted to supplying ATP to the Na-K pump.

A hallmark of the Na-K pump is that it is blocked by a class of compounds known as **cardiac glycosides**, examples of which are ouabain and digoxin; digoxin is widely used for a variety of cardiac conditions. These compounds have a high affinity for the extracellular side of the E_2 -P state of the pump, which also has a high affinity for extracellular K^+ . Thus, the binding of extracellular K^+ competitively antagonizes the binding of cardiac glycosides. An important clinical correlate is that hypokalemia (a low $[\text{K}^+]$ in blood plasma) potentiates digitalis toxicity in patients.

Besides the Na-K pump, other P-type ATPases include the H-K and Ca pumps

The family of P-type ATPases—all of which share significant sequence similarity with the α subunit of the Na-K pump—includes several subfamilies.

H-K Pump

Other than the Na-K pump, relatively few primary active transporters are located on the plasma membranes of animal cells. In the parietal cells of the gastric gland, an H-K pump (HKA) extrudes H^+ across the apical membrane into the gland lumen. Similar pumps are present in the kidney and intestines. The H-K pump mediates the active extrusion of H^+ and the uptake of K^+ , all fueled by ATP hydrolysis, probably in the ratio of two H^+ ions, two K^+ ions, and one ATP molecule. Like the Na-K pump, the H-K pump is composed of α and β subunits, each with multiple isoforms. The α subunit of the H-K pump also undergoes phosphorylation through E_1 and E_2 intermediates during its catalytic cycle (see [Fig. 5-8B](#)) and, like the α subunit of the Na-K pump, is a member of the P2C subfamily of P-type ATPases. The Na-K and H-K pumps are the only two P-type ATPases with known β subunits, all of which share significant sequence similarity.

Ca Pumps

Most, if not all, cells have a primary active transporter at the plasma membrane that extrudes Ca^{2+} from the cell. These pumps are abbreviated (for plasma-membrane Ca-ATPase), and at least four PMCA isoforms appear in the P2B subfamily of P-type ATPases. These pumps exchange one H^+ for one Ca^{2+} for each molecule of ATP that is hydrolyzed.

Ca pumps (or Ca-ATPases) also exist on the membrane surrounding such intracellular organelles as the sarcoplasmic reticulum (SR) in muscle cells and the endoplasmic reticulum (ER) in other cells, where they play a role in the active sequestration of Ca^{2+} into intracellular stores. The **SERCAs** (for sarcoplasmic and endoplasmic reticulum calcium ATPases) appear to transport two H^+ and two Ca^{2+} ions for each molecule of ATP hydrolyzed.  [N5-10](#) The three known SERCAs, which are in the P2A subfamily of P-type ATPases, are expressed in different muscle types (see [Table 9-1](#)).

N5-10

Crystal Structure of SERCA1

Contributed by Emile Boulpaep, Walter Boron

SERCA is a P-type ATPase, as is the Na-K pump. In 2000, Toyoshima and colleagues determined the x-ray crystal structure of SERCA with two Ca^{2+} ions bound. This was the first crystal structure identified for any P-type pump or ATPase. In 2002, Toyoshima and Nomurai determined the x-ray crystal structure again, but with no Ca^{2+} bound. In their 2004 paper, Toyoshima and Mizutani crystallized the protein with a bound nonhydrolyzable ATP analog AMP-PNP (adenylyl-imidodiphosphate) and one Mg^{2+} (under physiological conditions, ATP—the energy source—binds as a complex with Mg^{2+}), as well as two Ca^{2+} ions (the transported species) occluded within a channel in the protein.

ATP Synthase

A Pump in Reverse

Contributed by Emile Boulpaep, Walter Boron

The apparent paradox of how the same “pump” protein can act both as an ATPase and an ATP synthase can be resolved if we recognize that the pump can either hydrolyze ATP and use the energy to pump H^+ out of the mitochondrion or—in the physiological direction—use the energy of the inwardly directed H^+ gradient to synthesize ATP.

The F_0F_1 ATPase of mitochondria ([Fig. 5-9A](#)) looks a little like a lollipop held in your hand. The hand-like F_0 portion is embedded in the membrane and serves as the pathway for H^+ transport. The F_0 portion has at least three different subunits (a, b, and c), for an overall stoichiometry of $\text{ab}_2\text{c}_{10-12}$. The lollipop-like F_1 portion is outside the plane of the membrane and points into the mitochondrial matrix. The “stick” consists of a γ subunit, with an attached ϵ subunit. The “candy” portion of F_1 , which has the ATPase activity, consists of three alternating pairs of α and β subunits as well as an attached δ subunit. Thus, the overall stoichiometry of F_1 is $\alpha_3\beta_3\gamma\delta\epsilon$. The entire F_0F_1 complex has a molecular mass of ~ 500 kDa.

A ATPase

B MODEL OF THE CHEMIOSMOTIC HYPOTHESIS

FIGURE 5-9 The F_0F_1 ATPase and its role as the ATP synthase in the mitochondrial synthesis of ATP.

A, A cartoon of the F_0F_1 ATPase. The pump has two functional units, F_0 (which historically stood for oligomycin-sensitive factor) and F_1 (which historically stood for factor 1). F_0 is the transmembrane portion that contains the ion channel through which the H^+ passes. The F_1 is the ATPase. In one complete cycle, the downhill movement of H^+ ions causes the c subunits of F_0 and the axle formed by the subunits of F_1 to rotate 360 degrees in three 120-degree steps, which causes the α and β subunits to sequentially synthesize and release 3 ATP molecules, for a synthase stoichiometry of $\sim 3 H^+$ per ATP. However, the mitochondrion uses ~ 1 additional H^+ to import inorganic phosphate (P_i) and to exchange cytosolic ADP for mitochondrial ATP. Thus, a total of $\sim 4 H^+$ would be needed per ATP. **B**, Complexes I, III, and IV of the respiratory chain use the energy of NADH to pump H^+ out of the mitochondrial matrix; the consensus is 10 H^+ ions per NADH molecule. The resulting H^+ gradient causes the mitochondrial F_0F_1 ATPase to run as an ATP synthase. Thus, the mitochondrion synthesizes $(10 H^+/NADH) \times (1 ATP/4 H^+) = 2.5 ATP/NADH$. Similarly, the consensus is that complexes III and IV use the energy of 1 $FADH_2$ molecule to pump 6 H^+

ions out of the mitochondrial matrix (not shown). Thus, the mitochondrion synthesizes $(6 \text{ H}^+/\text{FADH}_2) \times (1 \text{ ATP}/4 \text{ H}^+) = 1.5 \text{ ATP}/\text{FADH}_2$.

A fascinating property of the F_0F_1 ATPase is that parts of it rotate. We can think of the hand, stick, and candy portions of the F_0F_1 ATPase as having three distinct functions. (1) The hand (the c proteins of F_0) acts as a turbine that rotates in the plane of the membrane, driven by the H^+ ions that flow through the turbine—down the H^+ electrochemical gradient—into the mitochondrion. (2) The stick is an axle (γ and ϵ subunits of F_1) that rotates with the turbine. (3) The candy (the α and β subunits of F_1) is a stationary chemical factory—energized by the rotating axle—that synthesizes one ATP molecule for each 120-degree turn of the turbine/axle complex. In addition, the a and b subunits of F_0 , and possibly the δ subunit of F_1 , form a stator that holds the candy in place while the turbine/axle complex turns. Paul Boyer and John Walker shared part of the 1997 Nobel Prize in Chemistry for elucidating this “rotary catalysis” mechanism.  **N5-12**

Under physiological conditions, the mitochondrial F_0F_1 ATPase runs as an ATP synthase (i.e., “backward” for an H^+ pump)—the final step in oxidative phosphorylation—because of a large, inwardly directed H^+ gradient across the inner mitochondrial membrane (see [Fig. 5-9B](#)). The citric acid cycle captures energy as electrons and transfers these electrons to reduced nicotinamide adenine dinucleotide (NADH)  **N5-13** and reduced flavin adenine dinucleotide (FADH_2). NADH and FADH_2 transfer their high-energy electrons to the **electron transport chain**, which consists of four major complexes on the inner membrane of the mitochondrion (see [Fig. 5-9B](#)). As this “respiratory chain” transfers the electrons from one electron carrier to another, the electrons gradually lose energy until they finally combine with 2 H^+ and $\frac{1}{2} \text{ O}_2$ to form H_2O . Along the way, three of the four major complexes of the respiratory chain (I, III, IV) pump H^+ across the inner membrane into the intermembrane space (i.e., the space between the inner and outer mitochondrial membranes). These “pumps” are *not* ATPases. The net result is that electron transport has established a large out-to-in H^+ gradient across the mitochondrial inner membrane.

N5-13

NADH/NAD⁺ versus NADPH/NADP⁺

Contributed by Alisha Bouzaher

NADH and NAD^+ are, respectively, the reduced and oxidized forms of nicotinamide adenine dinucleotide (NAD) and their close analogs are NADPH and NADP^+ , the reduced and oxidized forms of nicotinamide adenine dinucleotide phosphate (NADP). The coenzymes NADH and NADPH each consist of two nucleotides joined at their phosphate groups by a phosphoanhydride bond. NADPH is structurally distinguishable from NADH by the additional phosphate group residing on the ribose ring of the

nucleotide, which allows enzymes to preferentially interact with either molecule.

Total concentrations of NAD^+/NADH (10^{-5}M) are higher in the cell by approximately 10-fold compared to $\text{NADP}^+/\text{NADPH}$ (10^{-6}M). Ratios of the oxidized and reduced forms of these coenzymes offer perspective into the metabolic activity of the cell. The high NAD^+/NADH ratio favors the transfer of a hydride from a substrate to NAD^+ to form NADH , the reduced form of the molecule and oxidizing agent. Therefore, NAD^+ is highly prevalent within catabolic reaction pathways where reducing equivalents (carbohydrate, fats, and proteins) transfer protons and electrons to NAD^+ . NADH acts as an energy carrier, transferring electrons from one reaction to another. Conversely, the $\text{NADP}^+/\text{NADPH}$ ratio is low, favoring the transfer of a hydride to a substrate oxidizing NADPH to NADP^+ . Thus, NADPH is utilized as a reducing agent within anabolic reactions, particularly the biosynthesis of fatty acids.

The F_0F_1 ATPase—which is complex V in the respiratory chain—can now use this large electrochemical potential energy difference for H^+ . The H^+ ions then flow backward (i.e., down their electrochemical gradient) into the mitochondrion through the F_0F_1 ATPase, which generates ATP in the matrix space of the mitochondrion from ADP and inorganic phosphate. The entire process by which electron transport generates an H^+ gradient and the F_0F_1 ATPase harnesses this H^+ gradient to synthesize ATP is known as the chemiosmotic hypothesis. Peter Mitchell, who proposed this hypothesis in 1961, received the Nobel Prize in Chemistry for his work in 1978. 🏆 [N5-14](#)

N5-14

Peter Mitchell

For more information about Peter Mitchell and the work that led to his Nobel Prize, visit http://nobelprize.org/nobel_prizes/chemistry/laureates/1978/index.html (accessed October 2014).

The precise stoichiometry is unknown but may be one ATP molecule synthesized for every three H^+ ions flowing downhill into the mitochondrion (one H^+ for each pair of $\alpha\beta$ subunits of F_1). 🏆 [N5-15](#) If the H^+ gradient across the mitochondrial inner membrane reverses, the F_0F_1 ATPase will actually function as an ATPase and use the energy of ATP hydrolysis to pump H^+ out of the mitochondrion. Similar F_0F_1 ATPases are also present in bacteria and chloroplasts.

N5-15

ATP Molecules Synthesized per NADH

Contributed by Emile Boulpaep, Walter Boron

Glycolysis and the citric acid cycle generate the reducing equivalents NADH and FADH_2 , and then the inner membrane of the mitochondria converts the energy of these reducing equivalents to ATP in two steps. First, the electron transport chain uses the energy from NADH and FADH_2 to pump H^+ from the mitochondrial matrix into the intermembrane space between the mitochondrial inner and outer membranes, converting O_2 to H_2O in the final step. Second, the ATP synthase uses the energy stored in the H^+ gradient to generate ATP from ADP plus inorganic phosphate.

Generation of the H^+ Gradient

For each NADH consumed in the inner matrix of the mitochondrion, it appears that complex I and complex III of the electron transport chain (see Fig. 5-9) each pump 4 H^+ from the matrix, across the inner membrane, and into the intermembrane space, and complex IV pumps out an additional 2 H^+ . Thus, for each NADH, the consensus is that the mitochondrion pumps 10 H^+ . The FADH_2 from succinate feeds into the electron transport chain at complex II (which is actually succinate dehydrogenase), bypassing complex I. Thus, for each FADH_2 , the consensus is that the mitochondrion pumps 6 H^+ .

Generation of ATP

Regardless of whether the reducing equivalents come from NADH or FADH_2 , the result of their being processed by the electron transport chain is a steep electrochemical H^+ gradient across the inner membrane. The F_0F_1 ATPase, also located in the inner membrane, uses the energy in this inwardly directed H^+ gradient to synthesize ATP from ADP and inorganic phosphate. In other words, the F_0F_1 ATPase usually functions as an **ATP synthase**. As outlined in the text on page 118 and in Figure 5-9, the ATP synthase consists of (1) a group of 10 to 12 c subunits that forms an H^+ channel, which rotates like a turbine in the plane of the membrane as protons pass through the channel; (2) a shaft (consisting of the γ and ϵ subunits), which rotates with the turbine and extends into the mitochondrial matrix; the shaft also projects deeply into (3) a stationary globular structure that consists of three pairs of $\alpha\beta$ subunits. In addition, one a subunit, two b subunits, and a δ subunit hold the complex together.

At any one time, the β subunit of one $\alpha\beta$ pair is empty (β -empty), the β subunit of another binds $\text{ADP} + \text{P}_i$ (β -ADP), and the β subunit of the third binds ATP (β -ATP). (Note: P_i is inorganic phosphate.) It is believed that each time *three* H^+ pass through the ATP synthase, the turbine (10 to 12 c subunits) and the shaft (γ and ϵ subunits) rotate together by 120 degrees. This rotation brings the tip of the γ subunit into contact with a new pair of $\alpha\beta$ subunits in the stationary F_1 portion of the ATP synthase, causing this β subunit to shift from the β -ATP to the β -empty conformation—and release a just-synthesized ATP. Simultaneously, the previously empty β subunit shifts from the β -empty to the β -ADP conformation (ready to create a new ATP), and the β subunit that previously was binding $\text{ADP} + \text{P}_i$ creates a new ATP by shifting to the β -ATP conformation. Thus, each time a trio of protons passes through the ATP synthase into the mitochondrial inner matrix, the shaft rotates by 120 degrees and completes the synthesis of one ATP molecule. A complete 360-degree rotation of the shaft (which would require nine protons) would generate three new ATP molecules, with each $\alpha\beta$ pair passing through each of the three possible conformations. It is important to note that the above H^+/ATP stoichiometry is inferred from the structure of the ATP synthase (*three* pairs of $\alpha\beta$ subunits) as well as a wealth of biochemical experiments.

Ancillary Transport Processes

Even though the ATP synthase per se appears to have a stoichiometry of one ATP for every three protons, we have not addressed the overall process of ATP synthesis. As we shall see, the mitochondrion must

accomplish two additional tasks in order to complete the process.

First, the mitochondrion must transport one P_i into its inner matrix for each ATP to be synthesized. This uptake of P_i appears to be accomplished by an $H^+/H_2PO_4^-$ cotransporter. In other words, the mitochondrion must take up one H^+ (previously pumped out by the electron transport chain) to energize the uptake of each P_i .

Second, the mitochondrion must import one ADP^{3-} molecule for each ATP to be synthesized. In addition, the mitochondrion must export the newly synthesized ATP^{4-} molecule. Both jobs are accomplished by the same ADP-ATP exchanger, which is energized in part by the electrical gradient ($\Delta\psi$) that the electron transport chain generates along with the chemical H^+ gradient as it pumps H^+ out across the mitochondrial inner membrane.

Thus, the consensus is that the mitochondrion needs to import four H^+ to synthesize one ATP molecule:

1. Three H^+ to energize a 120-degree turn of the ATP synthase and thus convert one $ADP + one P_i$ to one ATP.
2. One H^+ to take up the P_i .

Overall ATP/NADH Stoichiometry

In summary, it appears that, for each NADH processed, the electron transport chain extrudes 10 protons. Furthermore, it appears that the ATP synthase and ancillary transporters can generate one ATP molecule from the inward movement of four protons. Thus, the overall ATP/NADH stoichiometry would be 2.5 ATP molecules for each NADH molecule. Because the processing of $FADH_2$ results in the extrusion of only six protons, the overall ATP/ $FADH_2$ stoichiometry would be 1.5 ATP molecules for each $FADH_2$ molecule. Keep in mind that these figures—which we use in examples throughout the text after the first three printings of the text—are the best current estimates; more about this below.

NADH Shuttle Mechanisms

An additional consideration is the access of NADH to complex I in the respiratory chain. In animal cells, the NADH must approach complex I from the matrix side of the mitochondrial inner membrane. This is not a problem for NADH generated *inside* the mitochondrial matrix by pyruvate dehydrogenase or the citric acid cycle (see Fig. 58-11). However, NADH generated by glycolysis (see Fig. 58-6A) cannot directly cross the mitochondrial inner membrane. As a result, animal cells use two complicated shuttle mechanisms to move the NADH reducing equivalents *indirectly* across the mitochondrial inner membrane.

Cells throughout most of the body—but not skeletal muscle or brain—use **the malate-aspartate shuttle** to bring NADH equivalents across the mitochondrial inner membrane into the mitochondrial matrix. The process, which is described in comprehensive biochemistry texts, involves six steps: (1) Malate dehydrogenase uses NADH and H^+ to convert **oxaloacetate** to **malate** in the intermembrane space, regenerating NAD^+ in the process. (2) The malate- α -ketoglutarate exchanger in the mitochondrial inner membrane imports the malate into the matrix. (3) Malate dehydrogenase in the mitochondrial matrix uses NAD^+ to convert the newly imported malate back to oxaloacetate, regenerating $NADH^+$ and H^+ in the process. (4) Aspartate aminotransferase in the matrix converts the oxaloacetate and a glutamate to α -ketoglutarate and aspartate. (5) The aforementioned malate- α -ketoglutarate exchanger recycles the α -ketoglutarate back to the intermembrane space, and the glutamate-aspartate exchanger does the same for

aspartate. (6) In the intermembrane space, aspartate aminotransferase converts the newly exited aspartate and α -ketoglutarate to glutamate and oxaloacetate, completing the cycle.

The net effect is to shuttle NADH *indirectly* into the matrix, where it can approach complex I. Using NADH shuttled in this way, the electron transport chain can pump 10 protons from the matrix into the intermembrane space, a number that can produce 2.5 ATP molecules.

Skeletal muscle and brain use a very different two-step method to process the NADH that is produced by glycolysis, the **glycerol-3-phosphate shuttle**: (1) The cytosolic enzyme glycerol-3-phosphate dehydrogenase uses NADH and H^+ to convert dihydroxyacetone phosphate to glycerol-3-phosphate, regenerating NAD^+ in the process. (2) The enzyme glycerol-3-phosphate dehydrogenase on the outer surface of the mitochondrial inner membrane converts glycerol-3-phosphate dehydrogenase in the intermembrane space to dihydroxyacetone phosphate, thereby regenerating the latter and releasing it into the intermembrane space. In the process, the dehydrogenase converts FAD to $FADH_2$. Because this $FADH_2$ enters the electron transport chain at complex III, it can fuel the extrusion of only six protons across the mitochondrial inner membrane. Thus, using reducing equivalents shuttled this way, the electron transport chain has an ATP/NADH stoichiometry of only 1.5 ATP molecules per NADH molecule.

Note that after the third printing of the book, we have used the values of 2.5 *or* 1.5 ATP per NADH to indicate that the energy yield depends on the shuttle system. In the brain, of course, we can simply refer to the value of 1.5 (see Fig. 11-10).

Our Confidence in the Cited Figures for the ATP/NADH Stoichiometry

Although the figures of 2.5 or 1.5 ATP molecules per NADH are the consensus, they should not be considered absolute at this time. Although investigators have invested considerable effort in attempting to determine the stoichiometry experimentally, the task is a daunting one for several reasons. First, some of the protons extruded by the electron transport chain can leak back into the mitochondrial matrix by pathways *other than* the ATP synthase. In fact, brown fat cells make use of this bypass to generate heat (see Fig. 57-6). Second, the proton traffic is computed from measured pH changes and values of buffering power that are sometimes difficult to know with certainty. Third, the precise stoichiometry of the $H^+/H_2PO_4^-$ cotransporter depends on the precise pH values on either side of the mitochondrial inner membrane because the reaction $H_2PO_4^- \rightleftharpoons H^+ + HPO_4^{2-}$ has a pK of ~ 6.8 . Fourth, the intricacies of the ATP synthase have yet to be fully worked out (i.e., the stoichiometry may not always be precisely one ATP synthesized for every three protons entering through the ATP synthase per se).

V-type H Pump

The membranes surrounding such intracellular organelles as lysosomes, endosomes, secretory vesicles, storage vesicles, and the Golgi apparatus contain a so-called vacuolar-type (or V-type) H-ATPase that pumps H^+ from the cytoplasm to the interior of the organelles. The low pH generated inside these organelles is important for sorting proteins, dissociating ligands from receptors, optimizing the activity of acid hydrolases, and accumulating neurotransmitters in vesicles. The apical membranes of certain renal tubule cells as well as the plasma membranes of certain other cells also have V-type H pumps that extrude H^+ from the cell. These V-type H pumps, unlike the gastric H-K pump, are independent of K^+ . Instead, the V-type H pump is similar to the hand-held lollipop-like structure of the F-type ATPase, with which it shares a significant—although low—level of amino-acid homology. For example, the hand of the V-type pump has only six subunits, but each is twice as large as a c subunit in the F-type ATPase.

ATP-binding cassette transporters can act as pumps, channels, or regulators

The so-called ABC proteins all have a motif in their amino-acid sequence that is an ATP-binding cassette (ABC). In humans, this family includes at least 49 members in seven subfamilies named ABCA through ABCG (Table 5-6). Some are pumps that presumably hydrolyze ATP to provide energy for solute transport. Some may hydrolyze ATP, but they do not couple the liberated energy to perform active transport. In other cases, ATP regulates ABC proteins that function as ion channels or regulators of ion channels or transporters.

TABLE 5-6
ABC Transporters

SUBFAMILY*	ALTERNATE SUBFAMILY NAME	EXAMPLES
ABCA (12)	ABC1	ABCA1 (cholesterol transporter)
ABCB (11)	MDR†	ABCB1 (MDR1 or P-glycoprotein 1) ABCB4 (MDR2/3) ABCB11 (bile salt export pump, BSEP)
ABCC (13)	MRP/CFTR	ABCC1 (multidrug resistance–associated protein 1, MRP1) ABCC2 (MRP2) ABCC4 (MRP4) ABCC7 (CFTR) ABCC8 (sulfonylurea receptor, SUR1) ABCC9 (SUR2)
ABCD (4)	ALD	ABCD1 (ALD; mediates uptake of fatty acids by peroxisomes)
ABCE (1)	OABP	ABCE1 (RNASEL1; blocks ribonuclease L)
ABCF (3)	GCN20	ABCF1 (lacks transmembrane domains)
ABCG (5)	White	ABCG2 (breast cancer resistance protein, BCRP; transports sulfated steroids, uric acid, xenobiotics) ABCG5/ABCG8 (heterodimer of “half” ABCs that transport cholesterol)

*In parentheses is the number of human genes in the family.
†The nomenclature of the MDRs is especially confusing because different and conflicting numbering systems have been used for different species; we use the human numbering system.

ABCA Subfamily

ABC1 (ABCA1) is an important transporter for mediating the efflux of phospholipids and cholesterol from macrophages and certain other cells.

MDR Subfamily

The **multidrug-resistance transporters (MDRs)** are ATPases and primary active transporters. The MDR proteins are tandem repeats of two structures, each of which has six membrane-spanning segments and a **nucleotide-binding domain (NBD)** that binds ATP. MDR1, also called P-glycoprotein, extrudes cationic metabolites and drugs across the cell membrane. The substrates of MDR1 appear to have little in common structurally, except that they are hydrophobic. A wide variety of cells express MDRs, including those of the liver, kidney, and gastrointestinal tract. MDR1 plays an important and clinically antagonistic role in cancer patients in that it pumps a wide range of anticancer drugs out of cancer cells, thereby rendering cells resistant to these drugs.

MRP/CFTR Subfamily

Another member of the ABC superfamily that is of physiological interest is the **cystic fibrosis transmembrane conductance regulator (CFTR)**, which is mutated in the hereditary disease cystic

fibrosis ([Box 43-1](#)). CFTR is a 170-kDa glycoprotein that is present at the apical membrane of many epithelial cells. CFTR functions as a low-conductance Cl^- channel as well as a regulator of other ion channels.

Like MDR1, CFTR has two membrane-spanning domains (MSD1 and MSD2), each composed of six membrane-spanning segments ([Fig. 5-10](#)). Also like MDR1, CFTR has two NBDs (NBD1 and NBD2). Unlike MDR1, however, a large cytoplasmic regulatory (R) domain separates the two halves of CFTR. The regulatory domain contains multiple potential protein kinase A and protein kinase C phosphorylation sites. Phosphorylation of these sites, under the influence of neurohumoral agents that control fluid and electrolyte secretion, promotes activation of CFTR. The binding of ATP to the NBDs also controls channel opening and closing. Thus, ATP regulates the CFTR Cl^- channel by two types of mechanisms: protein phosphorylation and interaction with the NBDs. [N5-16](#)

FIGURE 5-10 Cystic fibrosis transmembrane conductance regulator (CFTR). The CFTR Cl^- channel has two membrane-spanning domains (MSD1 and MSD2). A large cytoplasmic regulatory (R) domain separates the two halves of the molecule, each of which has an ATP-binding domain (NBD1 and NBD2). The most common mutation in cystic fibrosis is the deletion of the phenylalanine at position 508 (ΔF508) in the NBD1 domain. (Model modified from Riordan JR, Rommens JM, Kerem B, et al: Identification of the cystic fibrosis gene: Cloning and complementary DNA. *Science* 245:1066–1073, 1989.)

N5-16

Regulation of the CFTR Channel by ATP

Contributed by Emile Boulpaep, Walter Boron

CFTR is phosphorylated by protein kinase A (PKA) at several sites within its R domain (eFig. 5-1).

Modest phosphorylation causes a conformational change in the R domain that makes NBD1 accessible to ATP. Additional phosphorylation also makes NBD2 accessible to ATP. When ATP binds to NBD1 and is subsequently hydrolyzed, the channel opens, but it then rapidly closes once the ADP and phosphate dissociate (“flickery opening”). However, if a second ATP binds to NBD2, the channel is stabilized in its open state (“long opening”). ATP hydrolysis at NBD2 terminates the long opening and is thus necessary for CFTR to return to its closed state. Dephosphorylation of the R domain by protein phosphatases returns CFTR to its resting state. The control of CFTR by ATP hydrolysis is reminiscent of the control of G-protein activity by GTP hydrolysis (see p. 53).

The R domain of CFTR can also be phosphorylated by PKC. PKC enhances the stimulatory effect of PKA on CFTR Cl^- transport, but alone it appears to have little direct effect on CFTR function.

FIGURE 5-1 A widely accepted model of how ATP regulates CFTR both by phosphorylation and ATP hydrolysis. The channel is closed in the three channel states in the top row (nothing bound to the NBDs). The channel is in a “flickery” open state as it makes the transition from the top row to the middle row (NBD1 occupied). Finally, the channel is in a stable or “long” open state in the third row (NBD1 and NBD2 occupied). P_i, inorganic phosphate. (Data from Gadsby DC, Dousmanis AG, Nairn AC: ATP hydrolysis cycles the gating of CFTR Cl⁻ channels. *Acta Physiol Scand Suppl* 643:247–256, 1998.)

Cotransporters, one class of secondary active transporters, are generally driven by the energy of the inwardly directed Na⁺ gradient

Like pumps or primary active transporters, secondary active transporters can move a solute uphill (against its electrochemical gradient). However, unlike the pumps, which fuel the process by hydrolyzing ATP, the secondary active transporters fuel it by coupling the uphill movement of one or more solutes to the downhill movement of other solutes. The two major classes of secondary active transporters are cotransporters (or symporters) and exchangers (or antiporters). Cotransporters are intrinsic membrane proteins that move the “driving” solute (the one whose gradient provides the energy) and the “driven” solutes (which move uphill) in the *same* direction.

Na/Glucose Cotransporter

The **Na/glucose cotransporter (SGLT)** is located at the apical membrane of the cells that line the proximal tubule and small intestine ([Fig. 5-11A](#)). The SGLTs, which belong to the SLC5 family (see [Table 5-4](#)), consist of a single subunit with 14 membrane-spanning segments. SGLT2 moves one Na^+ ion with each glucose molecule (i.e., 1 : 1 stoichiometry of Na^+ to glucose), whereas the SGLT1 isoform moves two Na^+ ions with each glucose molecule. Drugs that inhibit SGLT2 are useful in treating type 2 diabetes in adults because these agents reduce glucose reabsorption in the kidney, thereby lowering plasma [glucose].  [N5-17](#)

Clinical Use of SGLT2 Inhibitors

Contributed by Emile Boulpaep

SGLT2 inhibitors are novel “glucuretics” that have been approved for the treatment of type 2 diabetes. The low-affinity, high-capacity cotransporter SGLT2 reabsorbs the bulk of the filtered glucose in the S1/S2 segments of the proximal convoluted tubule, whereas the low-affinity, high-capacity cotransporter SGLT1 in the S3 segment reabsorbs the remainder. Thus, specific SGLT2 inhibition causes the bulk of filtered glucose to be excreted in the urine, whereas about 10% of filtered glucose is still reabsorbed by SGLT1, so that $[\text{glucose}]_{\text{plasma}}$ is prevented from falling below normal. However, in clinical practice, SGLT2 inhibitors inhibit only 30% to 50% of renal glucose reabsorption.

Phlorizin, the 2'-glucoside of phloretin, is a natural compound in the bark of fruit trees and a competitive inhibitor of both SGLT1 and SGLT2. Before the discovery of insulin, phlorizin was used in the treatment of diabetes, although the compound is poorly absorbed by the gastrointestinal tract and not stable. The U.S. Food and Drug Administration approved two specific SGLT2 inhibitors for oral use in the treatment of type 2 diabetes in adults: canagliflozin and dapagliflozin (Farxiga®). Urinary tract infections and genital fungal infections are common adverse effects of this treatment due to chronically high glucose concentration in the urine.

Reference

Abdul-Ghani MA, DeFronzo RA. Lowering plasma glucose concentration by inhibiting renal sodium-glucose co-transport. *J Intern Med.* 2014;276(4):352–363.

For an Na/glucose cotransporter with 1 : 1 stoichiometry, the overall driving force is the sum of the electrochemical potential energy difference for Na^+ and the chemical potential energy difference for glucose. Thus, the highly favorable, inwardly directed Na^+ electrochemical gradient can drive the uphill accumulation of glucose from the lumen of the kidney tubule or gut into the cell. Figure 5-12 shows how the Na^+ gradient drives glucose accumulation into membrane vesicles derived from the brush border of renal proximal tubules. Equilibrium is achieved when the electrochemical potential energy difference for Na^+ in one direction is balanced by the chemical potential energy difference for glucose in the opposite direction:

$$\Delta\tilde{\mu}_{\text{Na}} = -\Delta\mu_{\text{glucose}} \quad (5-17)$$

After the investigator disrupts tubule cells, the membranes spontaneously form small vesicles. Subsequent purification steps yield "brush-border membrane vesicles."

FIGURE 5-12 Na⁺-driven glucose uptake into brush-border membrane vesicles. N5-22

Using Membrane Vesicles to Study Glucose Transport

Contributed by Gerhard Giebisch, Erich Windhager, Emile Boulpaep, Walter Boron

We describe the membrane-vesicle technique in [N33-5](#). Figure 5-12 illustrates the use of this technique to explore how the Na^+ gradient affects glucose uptake. The vesicles are made from brush-border membrane vesicles (i.e., made from the apical membrane of the proximal tubule). In the absence of Na^+ in the experimental medium, glucose enters renal brush-border membrane vesicles slowly until reaching an equilibrium value (green curve in the central graph of Fig. 5-12). At this point, internal and external glucose concentrations are identical. The slow increase in intravesicular [glucose] occurs by diffusion in the absence of Na^+ . In contrast, adding Na^+ to the external medium establishes a steep inwardly directed Na gradient, which dramatically accelerates glucose uptake (red curve in the central graph of Fig. 5-12). The result is a transient “overshoot” during which glucose accumulates above the equilibrium level. Thus, in the presence of Na^+ , the vesicle clearly transports glucose uphill. Similar gradients of other cations, such as K^+ , have no effect on glucose movement beyond that expected from diffusion alone.

A negative cell voltage can also drive Na /glucose cotransport, even when there is no Na^+ gradient. In experiments in which the internal and external Na^+ concentrations are the same, making the inside of the vesicles electrically negative accelerates glucose uptake (not shown in Fig. 5-12).

In vesicle experiments performed on vesicles made from the basolateral membrane, the overshoot in intravesicular [glucose] does not occur, even in the presence of an inward Na^+ gradient. Thus, the Na /glucose cotransporter is restricted to the apical membrane.

We can express $\Delta\tilde{\mu}_{\text{Na}}$ in terms of the Na^+ concentrations and membrane voltage and can express $\Delta\mu_{\text{glucose}}$ in terms of the glucose concentrations. [N5-18](#) If we substitute these expressions into [Equation 5-17](#), we derive the following relationship for the maximal glucose concentration gradient that can be generated by a given electrochemical potential energy difference for Na^+ :

$$\frac{[\text{Glucose}]_i}{[\text{Glucose}]_o} = \frac{[\text{Na}^+]_o}{[\text{Na}^+]_i} \times 10^{-V_m/(60\text{mV})}$$

(5-18)

N5-18

Maximal Glucose Gradient Achievable by SGLT1 and SGLT2

Contributed by Emile Boulpaep, Walter Boron

SGLT2

As noted on page 121 (see Equation 5-17; shown here as Equation NE 5-14), SGLT2—the Na /glucose cotransporter with a 1 : 1 stoichiometry of Na^+ to glucose—is in equilibrium when

$$\Delta \tilde{\mu}_{\text{Na}} = -\Delta \mu_{\text{Glucose}}$$

(NE 5-14)

$\Delta \tilde{\mu}_{\text{Na}}$ is the electrochemical energy difference across the cell membrane for Na^+ , and $\Delta \mu_{\text{glucose}}$ is the chemical energy difference for glucose (because glucose has no charge, the electrical energy difference for glucose across the membrane is zero). Starting from the definition of electrochemical energy difference in Equation 5-6, we can express $\Delta \tilde{\mu}_{\text{Na}}$ in terms of the Na^+ concentrations and membrane potential:

$$\Delta \tilde{\mu}_{\text{Na}} = RT \ln \left(\frac{[\text{Na}^+]_i}{[\text{Na}^+]_o} \right) + zFV_m$$

(NE 5-15)

Similarly, we can express $\Delta \mu_{\text{glucose}}$ in terms of the glucose concentrations:

$$\Delta \mu_{\text{glucose}} = RT \ln \left(\frac{[\text{Glucose}]_i}{[\text{Glucose}]_o} \right)$$

(NE 5-16)

If we substitute these last two expressions into Equation NE 5-14, we obtain the following equation, which describes the relationships between the Na^+ and glucose concentrations when SGLT2 is in equilibrium:

$$\frac{[\text{Glucose}]_i}{[\text{Glucose}]_o} = \frac{[\text{Na}^+]_o}{[\text{Na}^+]_i} \times 10^{(V_m - \psi_o)/60 \text{ mV}}$$

(NE 5-17)

SGLT1

As noted in the text in Equation 5-19 (shown here as Equation NE 5-18), SGLT1—the Na/glucose cotransporter with a 2 : 1 stoichiometry of Na^+ to glucose—is in equilibrium when

$$2\Delta \tilde{\mu}_{\text{Na}} = -\Delta \mu_{\text{glucose}}$$

(NE 5-18)

If we substitute Equations NE 5-15 and NE 5-16 into Equation NE 5-18, we obtain the following equation, which describes the relationships between the Na^+ and glucose concentrations when SGLT1 is in equilibrium:

$$\frac{[\text{Glucose}]_i}{[\text{Glucose}]_o} = \left(\frac{[\text{Na}^+]_o}{[\text{Na}^+]_i} \right)^2 \times 10^{-2V_m/(60 \text{ mV})}$$

(NE 5-19)

We can use Equation NE 5-17 (for SGLT2) and Equation 5-6 (for SGLT1) to compute the maximum achievable glucose gradients. Simply insert the values for $[\text{Na}^+]_i$, $[\text{Na}^+]_o$, and V_m as discussed on page 121.

In an epithelial cell that has a 10-fold Na^+ concentration gradient and a 60-mV inside-negative voltage across the apical membrane, the Na^+ electrochemical gradient can generate a 10×10^1 , or 100-fold, glucose concentration gradient across the plasma membrane. In other words, the 10 : 1 Na^+ concentration gradient buys a 10-fold glucose gradient, and the V_m of -60 mV buys another 10-fold. However, the leakage of glucose out of the cell by other pathways at the basolateral membrane prevents the Na/glucose cotransporter from coming to equilibrium.

An Na/glucose cotransporter with 2 : 1 stoichiometry is capable of generating an even larger concentration gradient for glucose across the plasma membrane. Such a cotransporter would be in equilibrium when

$$2\Delta\tilde{\mu}_{\text{Na}} = -\Delta\mu_{\text{glucose}}$$

(5-19)

The maximal glucose gradient is

$$\frac{[\text{Glucose}]_i}{[\text{Glucose}]_o} = \left(\frac{[\text{Na}^+]_o}{[\text{Na}^+]_i} \right)^2 \times 10^{-2V_m/(60 \text{ mV})}$$

(5-20)

In the same epithelial cell with a 10-fold Na^+ concentration gradient and a V_m of -60 mV , the Na^+ electrochemical gradient can generate a glucose concentration gradient of $10^2 \times 10^2$, or 10,000-fold! In other words, the 10 : 1 Na^+ concentration gradient—when squared for two Na^+ ions—buys a 100-fold glucose gradient, and the -60 mV membrane voltage—when multiplied by two for the effective charge on two Na^+ ions—buys another 100-fold.

Because the cotransporter protein has specific sites for binding Na^+ and glucose and because the number of transporters is fixed, the rate of transport by SGLT is a saturable function of the glucose and Na^+ concentrations.

Na⁺-Driven Cotransporters for Organic Solutes

Functionally similar, but structurally distinct from one another, are a variety of Na^+ cotransporters in the proximal tubule and small intestine. **Na⁺-driven amino-acid transporters** (see Fig. 5-11B) belong to both the SLC6 and SLC38 families (see Table 5-4). SLC13 includes **Na⁺-coupled cotransporters for monocarboxylates, dicarboxylates, and tricarboxylates**; SLC5 includes Na⁺-coupled cotransporters for

monocarboxylates.

Na/HCO₃ Cotransporters

The **Na/HCO₃ cotransporters (NBCs)** belong to the SLC4 family, **N5-19** and are a key group of acid-base transporters. In the basolateral membranes of certain epithelial cells, the **electrogenic NBCs** (NBCe1/e2, *e* for *electrogenic*) appear to operate with an $\text{Na}^+:\text{HCO}_3^-$ stoichiometry of 1 : 3 (see Fig. 5-11D) and—for typical ion and voltage gradients—mediate electrogenic HCO_3^- efflux. Here, these NBCs mediate HCO_3^- absorption into the blood. In most other cells, these same two transporters operate with a stoichiometry of 1 : 2—probably because of the absence of a key protein partner—and mediate the electrogenic HCO_3^- influx (see Fig. 5-11E). Finally, the electroneutral NBCs (NBCn1/n2, *n* for *electroneutral*) operate with an $\text{Na}^+:\text{HCO}_3^-$ stoichiometry of 1 : 1 (see Fig. 5-11F) and also mediate HCO_3^- influx. In these last two cases, the Na^+ electrochemical gradient drives the uphill accumulation of HCO_3^- , which is important for epithelial HCO_3^- secretion and for the regulation of intracellular pH (pH_i) to relatively alkaline values.

N5-19

HCO₃⁻ Transporters in the SLC4 Family

Contributed by Emile Boulpaep, Walter Boron

So far, investigators have identified ten human genes in the SLC4 family of solute carriers. These genes include three that encode Cl-HCO₃ exchangers (the so-called anion exchangers, or AE1, AE2, and AE3), and five that encode Na⁺-coupled HCO₃⁻ transporters. In addition, one gene encodes an Na/borate cotransporter, and another gene encodes a protein—termed AE4—of controversial function. For a discussion of these subjects, consult the review by Romero and colleagues.

The five Na⁺-coupled HCO₃⁻ transporters include the two electrogenic Na/HCO₃ cotransporters (NBCe1 and NBCe2), two electroneutral Na/HCO₃ cotransporters (NBCn1 and NBCn2), and a single Na⁺-driven Cl-HCO₃ exchanger (NDCBE).

NBCe1 and NBCe2 appear to be able to transport Na⁺ and HCO₃⁻ in an $\text{Na}^+:\text{HCO}_3^-$ stoichiometry of either 1 : 3 (as in the renal proximal tubule; see Fig. 39-4A) or 1 : 2 (as in most other cells, including the pancreatic duct; Fig. 43-6). Preliminary evidence from the laboratory of Boron suggests that NBCe1 and NBCe2—at least when operating with a stoichiometry of 1 : 2—in fact transport CO₃²⁻ rather than HCO₃⁻. Of course, CO₃²⁻ arises from HCO₃⁻ in the reaction $\text{HCO}_3^- \rightleftharpoons \text{CO}_3^{2-} + \text{H}^+$, which has a pK of ~10.3.

NDCBE appears to move 1 Na⁺ and 2 HCO₃⁻ ions into the cell in exchange for 1 Cl⁻ (which moves out of the cell). Extensive kinetic data are consistent with the hypothesis that the NDCBE from the squid axon in fact transports either Na⁺ plus CO₃²⁻ (in exchange for Cl⁻) or perhaps the NaCO₃⁻ ion pair (in exchange for Cl⁻). The NaCO₃⁻ forms rapidly, and reversibly, from Na⁺ and CO₃²⁻: $\text{Na}^+ + \text{CO}_3^{2-} \rightleftharpoons \text{NaCO}_3^-$.

Work on NBCn2 (Parker et al, 2008) is consistent with the hypothesis that this electroneutral Na/HCO₃ cotransporter—which appears to transport 1 Na⁺ and 1 HCO₃⁻ into the cell—may in fact mediate the uptake of 1 Na⁺ and 1 CO₃²⁻ in exchange for 1 intracellular HCO₃⁻. The net effect of exchanging 1

extracellular CO_3^{2-} for 1 intracellular HCO_3^- would be the uptake of 1 HCO_3^- . In fact, it is intriguing to speculate that all members of the SLC4 family are in fact exchangers, and that the proteins that appear to mediate cotransport in fact mediate an exchange that “nets out” as apparent cotransport.

In addition to the SLC4 family, several members of the SLC26 family can also carry HCO_3^- , although these SLC26 proteins tend to be less selective in the anions that they transport. For a review of this gene family, consult Alper and Sharma.

Na^+ -Driven Cotransporters for Other Inorganic Anions

Important examples of other Na^+ -driven cotransporters include the Na/I cotransporter (SLC5A5), the sulfate cotransporter (SLC13 family; see Table 5-4), and the **inorganic phosphate cotransporter (NaPi)**; see Fig. 5-11C)—which are members of the SLC17, SLC20, and SLC34 families.

Na/K/Cl Cotransporter

The three types of cation-coupled Cl^- cotransporters all belong to the SLC12 family. The first is the **Na/K/Cl cotransporter (NKCC)**, which harnesses the energy of the inwardly directed Na^+ electrochemical gradient to drive the accumulation of Cl^- and K^+ (see Fig. 5-11G). One variant of this cotransporter, NKCC1 (SLC12A2), is present in a wide variety of nonepithelial cells (see p. 131), as well as in the *basolateral* membranes of some epithelial cells. Another variant of this cotransporter,

NKCC2 (SLC12A1), is present on the *apical* membrane of cells lining the thick ascending limb of the loop of Henle in the kidney (see [p. 757](#)). A characteristic of the NKCCs is that they are inhibited by furosemide and bumetanide, which are called loop diuretics because they increase urine flow by inhibiting transport at the loop of Henle. Because of its sensitivity to bumetanide, NKCC is sometimes called the bumetanide-sensitive cotransporter (BSC).

Na/Cl Cotransporter

The second type of cation-coupled Cl^- cotransporter is found in the apical membrane of the early distal tubule of the kidney (see [p. 758](#)). This K^+ -independent **Na/Cl cotransporter** (NCC or SLC12A3) is blocked by thiazide diuretics rather than by loop diuretics (see [Fig. 5-11H](#)). For this reason, NCC has also been called the thiazide-sensitive cotransporter (TSC).

K/Cl Cotransporter

The third type of cation-coupled Cl^- cotransporter is the Na^+ -independent **K/Cl cotransporter (KCC) family** (KCC1 to KCC4 or SLC12A4 to SLC12A7). Because the Na-K pump causes K^+ to accumulate inside the cell, the K^+ electrochemical gradient is outwardly directed across the plasma membrane (see [Fig. 5-11I](#)). In addition, pathways such as the Na/K/Cl cotransporter and the Cl^- - HCO_3^- anion exchanger (see below) bring Cl^- into the cell, so that in most cells the Cl^- electrochemical gradient is also outwardly directed. Thus, the net driving force acting on the KCC favors the exit of K^+ and Cl^- from the cell (see [pp. 131–132](#)).

H^+ -Driven Cotransporters

Although the majority of known cotransporters in animal cells are driven by the inward movement of Na^+ , some are instead driven by the downhill, inward movement of H^+ . The **H/oligopeptide cotransporter PepT1** and related proteins are members of the SLC15 family. PepT1 is electrogenic and responsible for the uptake of small peptides (see [Fig. 5-11J](#)) from the lumen into the cells of the renal proximal tubule (see [pp. 777–778](#)) and small intestine (see [p. 923](#)). The **H^+ -driven amino-acid cotransporters** (e.g., **PAT1**) are members of the SLC36 family. The **monocarboxylate cotransporters**, such as **MCT1**, are members of the SLC16 family. They mediate the electroneutral, H^+ -coupled flux of lactate, pyruvate, or other monocarboxylates across the cell membranes of most tissues in the body (see [Fig. 5-11K](#)). In the case of lactate, MCT1 can operate in either the net inward or net outward direction, depending on the lactate and H^+ gradients across the cell membrane. MCT1 probably moves lactate out of cells that produce lactate by glycolysis but into cells that consume lactate. The **divalent metal-ion cotransporter (DMT1)**, a member of the SLC11 family, couples the influx of H^+ to the influx of ferrous iron (Fe^{2+}) as well as to the influx of a variety of other divalent metals, some of which (Cd^{2+} , Pb^{2+}) are toxic to cells (see [Fig. 5-11L](#)). DMT1 is expressed at high levels in the kidney and proximal portions of the small intestine.

Exchangers, another class of secondary active transporters, exchange ions for one another

The other major class of secondary active transporters is the exchangers, or antiporters. Exchangers are intrinsic membrane proteins that move one or more “driving” solutes in one direction and one or more “driven” solutes in the *opposite* direction. In general, these transporters exchange cations for cations or

anions for anions.

Na-Ca Exchanger

The nearly ubiquitous **Na-Ca exchangers (NCXs)** belong to the SLC8 family (see [Table 5-4](#)). They most likely mediate the exchange of three Na^+ ions per Ca^{2+} ion ([Fig. 5-13A](#)). NCX is electrogenic and moves net positive charge in the same direction as Na^+ . Under most circumstances, the inwardly directed Na^+ electrochemical gradient across the plasma membrane drives the uphill extrusion of Ca^{2+} from the cell. Thus, in concert with the plasma-membrane Ca pump, this transport system helps maintain the steep, inwardly directed electrochemical potential energy difference for Ca^{2+} that is normally present across the plasma membrane of all cells.

FIGURE 5-13 Representative exchangers.

NCX uses the inwardly directed Na^+ electrochemical gradient to drive the secondary active efflux of Ca^{2+} . With a presumed stoichiometry of three Na^+ per Ca^{2+} , the effectiveness of the Na^+ electrochemical gradient as a driving force is magnified; thus, NCX is at equilibrium when the Ca^{2+} electrochemical

gradient is balanced by three times the Na⁺ electrochemical gradient:

$$\Delta\tilde{\mu}_{Ca} = 3\Delta\tilde{\mu}_{Na}$$

(5-21)

Alternatively,

$$\frac{[Ca^{2+}]_o}{[Ca^{2+}]_i} = \left(\frac{[Na^+]_o}{[Na^+]_i} \right)^3 \cdot 10^{-V_m/60\text{mV}}$$

(5-22)

In a cell with a 10-fold Na⁺ concentration gradient and a V_m of −60 mV, the electrochemical potential energy difference for Na⁺ can buy a Ca²⁺ concentration gradient of 10³ × 10¹, or 10,000-fold, which is the Ca²⁺ gradient across most cell membranes. Thus, the effect of the 10-fold inward Na⁺ concentration gradient is cubed and can account for a 10³-fold Ca²⁺ concentration gradient across the plasma membrane. In addition, the stoichiometry of three Na⁺ per Ca²⁺ produces a net inflow of one positive charge per transport cycle. Thus, the 60-mV inside-negative V_m acts as the equivalent driving force to another 10-fold concentration gradient.

Na-H Exchanger

The **Na-H exchangers (NHEs)**, which belong to the SLC9 family (see [Table 5-4](#)), mediate the 1 : 1 exchange of extracellular Na⁺ for intracellular H⁺ across the plasma membrane (see [Fig. 5-13B](#)). One or more of the nine [N5-20](#) known NHEs are present on the plasma membrane of almost every cell in the body. Through operation of NHEs, the inwardly directed Na⁺ electrochemical gradient drives the uphill extrusion of H⁺ from the cell and raises pH_i. The ubiquitous NHE1, which is present in nonepithelial cells as well as on the basolateral membranes of epithelia, plays a major role in pH_i regulation (see [p. 127](#)) and cell volume (see [p. 131](#)). NHE3 is present at the apical membranes of several epithelia, where it plays a major role in acid secretion (see [p. 827](#)) and Na⁺ absorption.

N5-20

The NHEs

Contributed by Emile Boulpaep, Walter Boron

Consult the review by Donowitz et al for an overview of the NHE family of Na-H exchangers (also known as the SLC9 family of “solute-linked carriers”).

Reference

Donowitz M, Ming Tse C, Fuster D. SLC9/NHE gene family, a plasma membrane and organellar family of Na⁺/H⁺ exchangers. *Mol Aspects Med.* 2013;34:236–251.

Another cation exchanger—the **multidrug and toxin extrusion transporter (MATE; SLC47 family)**—mediates the uptake of H^+ across the apical membrane of renal proximal tubule cells and hepatocytes in exchange for organic cations, which MATE secretes into the lumen.

Na⁺-Driven Cl-HCO₃ Exchanger

A second Na⁺-coupled exchanger that is important for pH_i regulation is the **Na⁺-driven Cl-HCO₃ exchanger (NDCBE)**, a member of the SLC4 family (see [Table 5-4](#)). This electroneutral transporter couples the movement of one Na⁺ ion and the equivalent of two HCO_3^- ions [N5-19](#) in one direction to the movement of one Cl⁻ ion in the opposite direction (see [Fig. 5-13C](#)). NDCBE uses the inwardly directed Na⁺ electrochemical gradient to drive the uphill entry of HCO_3^- into the cell. Thus, like the Na-H exchangers, NDCBE helps keep pH_i relatively alkaline. NDCBE may also participate in Na⁺ reabsorption (i.e., movement from lumen to blood) across certain tubule cells in the kidney.

Cl-HCO₃ Exchanger

A third group of exchangers that are involved in acid-base transport are the Cl-HCO₃ exchangers (see [Fig. 5-13D](#)) that function independently of Na⁺. These may be members of either the SLC4 or the SLC26 families. Virtually all cells in the body express one of the three electroneutral SLC4 or Cl-HCO₃ exchangers, also known as **anion exchangers (AE1 to AE3)**. AE1 is important for transporting HCO_3^- into the red blood cell in the lung and out of the red blood cell in peripheral tissues (see [p. 656](#)). In other cells, where the inwardly directed Cl⁻ gradient almost always drives HCO_3^- out of the cell, AE2 and AE3 play important roles in pH_i regulation (see [p. 127](#)) by tending to acidify the cell. Moreover, the uptake of Cl⁻ often plays a role in the regulation of cell volume (see [p. 130](#)).

Several members of the **SLC26 family** can function as Cl-HCO₃ exchangers and thereby play important roles in epithelial Cl⁻ and HCO_3^- transport. Because the stoichiometry need not be 1 : 1, SLC26 transport can be electrogenic. As described next, even SLC26 proteins that exchange Cl⁻ for HCO_3^- also transport a wide variety of *other* anions.

Other Anion Exchangers

A characteristic of the SLC26 family is their multifunctionality. For example, SLC26A6—present in the apical membranes of renal proximal tubule cells—can mediate **Cl-formate exchange** and **Cl-oxalate exchange** (see [Fig. 5-13E](#)). These activities appear to be important for the secondary active uptake of Cl⁻ and for secretion of oxalate. **Pendrin** not only mediates Cl-HCO₃ exchange but may also transport I⁻, which may be important in the thyroid gland (see [p. 1006](#)).

Anion exchangers other than those in the SLC4 and SLC26 families also play important roles. The **organic anion-transporting polypeptides (OATPs)** are members of the SLC21 family. In the liver, OATPs mediate the uptake of bile acids, bilirubin, and the test substrate bromsulphthalein. Another member of the SLC21 family is the **prostaglandin transporter (PGT)**, which mediates the uptake of prostanoids (e.g., prostaglandins E₂ and F_{2α} and thromboxane B₂).

The **organic anion transporters (OATs)** are members of the diverse SLC22 family. The OATs—by exchange or facilitated diffusion—mediate the uptake of endogenous organic anions (see [Fig. 5-13F](#)), as well as drugs, including penicillin and the test substrate *p*-aminohippurate. **URAT1**, another SLC22

member, is an exchanger that mediates urate transport in the renal proximal tubule. Surprisingly, the OCT transporters that mediate the facilitated diffusion of organic *cations* (see [p. 115](#)) are also members of SLC22.

Regulation of Intracellular Ion Concentrations

Figure 5-14 illustrates the tools at the disposal of a prototypic cell for managing its intracellular composition. Cells in different tissues—and even different cell types within the same tissue—have different complements of channels and transporters. Epithelial cells and neurons may segregate specific channels and transporters to different parts of the cell (e.g., apical versus basolateral membrane or axon versus soma/dendrite). Thus, different cells may have somewhat different intracellular ionic compositions.

FIGURE 5-14 Ion gradients, channels, and transporters in a typical cell.

The Na-K pump keeps [Na⁺] inside the cell low and [K⁺] high

The most striking and important gradients across the cell membrane are those for Na⁺ and K⁺. **Sodium** is the predominant cation in ECF, where it is present at a concentration of ~145 mM (see Fig. 5-14). Na⁺ is relatively excluded from the intracellular space, where it is present at only a fraction of the extracellular concentration. This Na⁺ gradient is maintained primarily by active extrusion of Na⁺ from the cell by the Na-K pump (see Fig. 5-14, No. 1). In contrast, **potassium** is present at a concentration of only ~4.5 mM in ECF, but it is the predominant cation in the intracellular space, where it is accumulated ~25- to 30-fold above the outside concentration. Again, this gradient is the direct result of primary active uptake of K⁺

into the cell by the Na-K pump. When the Na-K pump is inhibited with ouabain, $[\text{Na}^+]_i$ rises and $[\text{K}^+]_i$ falls.

In addition to generating concentration gradients for Na^+ and K^+ , the Na-K pump plays an important role in generating the inside-negative membrane voltage, which is ~ 60 mV in a typical cell. The Na-K pump accomplishes this task in two ways. First, because the Na-K pump transports three Na^+ ions out of the cell for every two K^+ ions, the pump itself is **electrogenic**. This electrogenicity causes a net outward current of positive charge across the plasma membrane and tends to generate an inside-negative V_m . However, the pump current itself usually makes only a small contribution to the negative V_m . Second, and quantitatively much more important, the active K^+ accumulation by the Na-K pump creates a concentration gradient that favors the exit of K^+ from the cell through K^+ channels (see Fig. 5-14, No. 2). The tendency of K^+ to *exit* through these channels, with unmatched negative charges left behind, is the main cause of the inside-negative membrane voltage. When K^+ channels are blocked with an inhibitor such as Ba^{2+} , V_m becomes considerably less negative (i.e., the cell depolarizes). In most cells, the principal pathway for current flow across the plasma membrane (i.e., the principal ionic conductance) is through K^+ channels. We discuss the generation of membrane voltage in Chapter 6.

The inside-negative V_m , together with the large concentration gradient for Na^+ , summates to create a large, inwardly directed Na^+ electrochemical gradient that strongly favors passive Na^+ entry. Given the large amount of energy that is devoted to generation of this favorable driving force for Na^+ entry, one might expect that the cell would permit Na^+ to move into the cell only through pathways serving important physiological purposes. The simple passive entry of Na^+ through channels—without harnessing of this Na^+ entry for some physiological purpose—would complete a futile cycle that culminates in active Na^+ extrusion. It would make little teleological sense for the cell to use up considerable energy stores to extrude Na^+ only to let it passively diffuse back in with no effect. Rather, cells harness the energy of Na^+ entry for three major purposes:

1. In certain **epithelial cells**, amiloride-sensitive Na^+ channels (ENaCs) are largely restricted to the *apical* or luminal surface of the cell (see Fig. 5-14, No. 3), and the Na-K pumps are restricted to the *basolateral* surface of the cell. In this way, *transepithelial* Na^+ transport takes place rather than a futile cycling of Na^+ back and forth across a single plasma membrane.
2. In **excitable cells**, passive Na^+ entry occurs through voltage-dependent Na^+ channels (see Fig. 5-14, No. 4) and plays a critical role in generation of the action potential. In such cells, Na^+ is cycled at high energy cost across the plasma membrane for the important physiological purpose of information transfer.
3. Virtually **every cell** in the body uses the electrochemical Na^+ gradient across the plasma membrane to drive the secondary active transport of nutrients and ions (see Fig. 5-14, No. 5).

The Ca pump and the Na-Ca exchanger keep intracellular $[\text{Ca}^{2+}]$ four orders of magnitude lower than extracellular $[\text{Ca}^{2+}]$

Whereas the concentration of Ca^{2+} in the extracellular space is ~ 1 mM (10^{-3} M), that in the ICF is only ~ 100 nM (10^{-7} M), a concentration gradient of 10^4 -fold. Because of the inside-negative membrane voltage of a typical cell and the large chemical gradient for Ca^{2+} , the inwardly directed electrochemical gradient for Ca^{2+} across the plasma membrane is enormous, far larger than that for any other ion. Many cells have a

variety of Ca^{2+} channels through which Ca^{2+} can enter the cell (see Fig. 5-14, No. 6). In general, Ca^{2+} channels are gated by voltage (see pp. 189–190) or by humoral agents (see pp. 323–324) so that rapid Ca^{2+} entry into the cell occurs only in short bursts. However, given the existence of pathways for passive Ca^{2+} transport *into* cells, we may ask what transport mechanisms keep $[\text{Ca}^{2+}]_i$ low and thus maintain the enormous Ca^{2+} electrochemical gradient across the plasma membrane.

Ca Pump (SERCA) in Organelle Membranes

Ca pumps (ATPases) are present on the membranes that surround various intracellular organelles, such as the sarcoplasmic and endoplasmic reticulum (see Fig. 5-14, No. 7). These pumps actively sequester cytosolic Ca^{2+} in intracellular stores. These stores of Ca^{2+} can later be released into the cytoplasm in bursts as part of a signal-transduction process in response to membrane depolarization or humoral agents. Even though Ca^{2+} sequestration in intracellular stores is an important mechanism for regulating $[\text{Ca}^{2+}]_i$ in the short term, there is a limit to how much Ca^{2+} a cell can store. Therefore, in the steady state, Ca^{2+} extrusion across the cell membrane must balance the passive influx of Ca^{2+} .

Ca Pump (PMCA) on the Plasma Membrane

The plasma membranes of most cells contain a Ca pump that plays a major role in extruding Ca^{2+} from the cell (see Fig. 5-14, No. 8). It would seem that rising levels of intracellular Ca^{2+} would stimulate the Ca pump to extrude Ca^{2+} and thereby return $[\text{Ca}^{2+}]_i$ toward normal. Actually, the pump *itself* is incapable of this type of feedback control; because it has such a high K_m for $[\text{Ca}^{2+}]_i$, the pump is virtually inactive at physiological $[\text{Ca}^{2+}]_i$. However, as $[\text{Ca}^{2+}]_i$ rises, the Ca^{2+} binds to a protein known as **calmodulin** (CaM; see p. 60), which has a high affinity for Ca^{2+} . The newly formed Ca^{2+} -CaM binds to the Ca pump, lowers the pump's K_m for $[\text{Ca}^{2+}]_i$ into the physiological range, and thus stimulates Ca^{2+} extrusion. As $[\text{Ca}^{2+}]_i$ falls, Ca^{2+} -CaM levels inside the cell also fall, so that Ca^{2+} -CaM dissociates from the Ca pump and the pump is thereby returned to its inactive state. At resting $[\text{Ca}^{2+}]_i$ levels of ~ 100 nM, the Ca pump is the major route of Ca^{2+} extrusion.

Na-Ca Exchanger (NCX) on the Plasma Membrane

The Na-Ca exchanger (see Fig. 5-14, No. 9) plays a key role in extruding Ca^{2+} only when $[\text{Ca}^{2+}]_i$ rises substantially above normal levels. Thus, NCX is especially important in restoring low $[\text{Ca}^{2+}]_i$ when large influxes of Ca^{2+} occur. This property is most notable in excitable cells such as neurons and cardiac muscle, which may be challenged with vast Ca^{2+} influxes through voltage-gated Ca^{2+} channels during action potentials.

In most cells, $[\text{Cl}^-]$ is modestly above equilibrium because Cl^- uptake by the $\text{Cl}^-/\text{HCO}_3^-$ exchanger and Na/K/Cl cotransporter balances passive Cl^- efflux through channels

The $[\text{Cl}^-]$ in all cells is below the $[\text{Cl}^-]$ in the extracellular space. Virtually all cells have **anion-selective channels** (see Fig. 5-14, No. 10) through which Cl^- can permeate passively. In a typical cell with a 60-mV inside-negative membrane voltage, $[\text{Cl}^-]_i$ would be a tenth that of $[\text{Cl}^-]_o$ if Cl^- were passively distributed across the plasma membrane. Such is the case for skeletal muscle. However, for most cell

types, $[\text{Cl}^-]_i$ is approximately twice as high as that predicted for passive distribution alone, which indicates the presence of transport pathways that mediate the active uptake of Cl^- into the cell. Probably the most common pathway for Cl^- uptake is the **Cl-HCO_3 exchanger** (see Fig. 5-14, No. 11). Because $[\text{HCO}_3^-]_i$ is several-fold higher than if it were passively distributed across the cell membrane, the outwardly directed electrochemical potential energy difference for HCO_3^- can act as a driving force for the uphill entry of Cl^- through Cl-HCO_3 exchange. Another pathway that can mediate uphill Cl^- transport into the cell is the **Na/K/Cl cotransporter** (see Fig. 5-14, No. 12), which is stimulated by low $[\text{Cl}^-]_i$.

Given the presence of these transport pathways mediating Cl^- uptake, why is $[\text{Cl}^-]_i$ only ~2-fold above that predicted for passive distribution? The answer is that the passive Cl^- efflux through anion-selective channels in the plasma membrane opposes Cl^- uptake mechanisms. Another factor that tends to keep Cl^- low in some cells is the **K/Cl cotransporter**. This KCC (see Fig. 5-14, No. 13), driven by the outward K^+ gradient, tends to move K^+ and Cl^- out of cells. Thus, the K^+ gradient promotes Cl^- efflux both by generating the inside-negative V_m that drives Cl^- out of the cell through channels and by driving K/Cl cotransport.

The Na-H exchanger and Na^+ -driven HCO_3^- transporters keep the intracellular pH and $[\text{HCO}_3^-]$ above their equilibrium values

H^+ , HCO_3^- , and CO_2 within a particular compartment are generally in equilibrium with one another. Extracellular pH is normally ~7.4, $[\text{HCO}_3^-]_o$ is 24 mM, and P_{CO_2} is ~40 mm Hg. In a typical cell, intracellular pH is ~7.2. Because $[\text{CO}_2]$ is usually the same on both sides of the cell membrane, $[\text{HCO}_3^-]_i$ can be calculated to be ~15 mM. Even though the ICF is slightly more acidic than the ECF, pH_i is actually much more alkaline than it would be if H^+ and HCO_3^- were passively distributed across the cell membrane. H^+ can enter the cell passively and HCO_3^- can exit the cell passively, although both processes occur at a rather low rate. H^+ can permeate certain **cation channels** and perhaps H^+ -selective channels (see Fig. 5-14, No. 14), and HCO_3^- moves fairly easily through most **Cl^- channels** (see Fig. 5-14, No. 15). Because a membrane voltage of -60 mV is equivalent as a driving force to a 10-fold concentration gradient of a monovalent ion, one would expect $[\text{H}^+]$ to be 10-fold higher within the cell than in the ECF, which corresponds to a pH_i that is 1 pH unit more acidic than pH_o . Similarly, one would expect $[\text{HCO}_3^-]_i$ to be only one tenth of $[\text{HCO}_3^-]_o$. The observation that pH_i and $[\text{HCO}_3^-]_i$ are maintained higher than predicted for passive distribution across the plasma membrane indicates that cells must actively extrude H^+ or take up HCO_3^- .

The transport of acid out of the cell or base into the cell is collectively termed acid extrusion. In most cells, the **acid extruders** are secondary active transporters that are energized by the electrochemical Na^+ gradient across the cell membrane. The most important acid extruders are the **Na-H** (see Fig. 5-14, No. 16) and the **Na^+ -driven Cl-HCO_3 exchangers** (see Fig. 5-14, No. 17), as well as the **Na/HCO_3 cotransporters** with $\text{Na}^+:\text{HCO}_3^-$ stoichiometries of 1 : 2 and 1 : 1 (see Fig. 5-11E, F). These transport systems are generally sensitive to changes in pH_i ; they are stimulated when the cell is acidified and inhibited when the cell is alkalinized. Thus, these transporters maintain pH_i in a range that is optimal for cell functioning. Less commonly, certain epithelial cells that are specialized for acid secretion use **V-type**

H pumps (see [Fig. 5-14](#), No. 18) or **H-K pumps** on their apical membranes to extrude acid. These epithelia include the renal collecting duct and the stomach. As noted above, virtually all cells have V-type H pumps on the membranes surrounding such intracellular organelles as lysosomes, endosomes, and Golgi.

Because most cells have powerful acid-extrusion systems, one might ask why the pH_i is not far more alkaline than ~ 7.2 . Part of the answer is that transport processes that act as **acid loaders** balance acid extrusion. Passive leakage of H^+ and HCO_3^- through *channels*, as noted above, tends to acidify the cell. Cells also have *transporters* that generally move HCO_3^- out of cells. The most common is the Cl-HCO_3 exchanger (see [Fig. 5-14](#), No. 11). Another is the electrogenic Na/HCO_3 cotransporter with an $\text{Na}^+ : \text{HCO}_3^-$ stoichiometry of 1 : 3 (see [Fig. 5-14](#), No. 19), which moves HCO_3^- out of the cell across the basolateral membrane of renal proximal tubules.

Water Transport and the Regulation of Cell Volume

Water transport is driven by osmotic and hydrostatic pressure differences across membranes

Transport of water across biological membranes is always passive. No H₂O pumps have ever been described. **N5-21** To a certain extent, single H₂O molecules can dissolve in lipid bilayers and thus move across cell membranes at a low but finite rate by simple diffusion. The ease with which H₂O diffuses through the lipid bilayer depends on the lipid composition of the bilayer. Membranes with low fluidity (see p. 10)—that is, those whose phospholipids have long saturated fatty-acid chains with few double bonds (i.e., few kinks)—exhibit lower H₂O permeability. The addition of other lipids that decrease fluidity (e.g., cholesterol) may further reduce H₂O permeability. Therefore, it is not surprising that the plasma membranes of many types of cells have specialized H₂O channels—the AQPs—that serve as passive conduits for H₂O transport. The presence of AQPs greatly increases membrane H₂O permeability. In some cells, such as erythrocytes or the renal proximal tubule, AQP1 is always present in the membrane. The collecting-duct cells of the kidney regulate the H₂O permeability of their apical membranes by inserting AQP2 H₂O channels into their apical membranes under the control of arginine vasopressin.

N5-21

The Water-Pump Controversy

Contributed by Emile Boulpaep, Walter Boron

Loo and colleagues have proposed that the Na/glucose cotransporter SGLT1 in the human small intestine cotransports not only Na⁺ and glucose, but water as well. In other words, with each cycle, SGLT1 would move 2 Na⁺ ions, 1 glucose molecule, and >200 water molecules. The authors envisage that the Na⁺ ions and glucose molecule—along with the water molecules—would diffuse from the extracellular fluid into a pore within the cotransporter protein. The cotransporter would then undergo a conformational change that would close an outer gate and thereby occlude these ions and molecules from the extracellular fluid. By opening an inner gate, the cotransporter would deocclude these particles and allow the 2 Na⁺ ions, the glucose molecule, and the 200+ water molecules to enter the cytoplasm of the intestinal cell (i.e., enterocyte). There is no controversy that this general model—minus the water—explains how SGLT1 works. The question is whether each cycle of the cotransporter *also* moves a fixed number of water molecules through the membrane protein along with the Na⁺ and glucose. Loo and colleagues suggest that the water pumped by SGLT1 would account for about half of the water taken up by the small intestine.

On the other hand, Lapointe and colleagues have challenged the conclusion of Loo and colleagues, suggesting that the data of Loo and colleagues can more easily be explained by the classical model. That is, as SGLT1 cotransport Na⁺ and glucose from the extracellular to the intracellular fluid, water would follow osmotically.

Water transport across a membrane is always a linear, nonsaturable function of its net driving force. The direction of net passive transport of an uncharged solute is always down its chemical potential energy difference. For H₂O, we must consider two passive driving forces. The first is the familiar chemical potential energy difference ($\Delta\mu_{\text{H}_2\text{O}}$), which depends on the difference in **water concentration** on the two sides of the membrane. The second is the energy difference, per mole of H₂O, that results from the difference in **hydrostatic pressure** ($\Delta\mu_{\text{H}_2\text{O},\text{pressure}}$) across the membrane. Thus, the relevant energy difference across the membrane is the sum of the chemical and pressure potential energy differences:

$$\begin{aligned}\Delta\mu_{\text{H}_2\text{O},\text{total}} &= \Delta\mu_{\text{H}_2\text{O}} + \Delta\mu_{\text{H}_2\text{O},\text{pressure}} \\ \underbrace{\Delta\mu_{\text{H}_2\text{O},\text{total}}}_{\text{Total energy difference}} &= \underbrace{RT \ln \frac{[\text{H}_2\text{O}]_i}{[\text{H}_2\text{O}]_o}}_{\text{Chemical part}} + \underbrace{\bar{V}_W (P_i - P_o)}_{\text{Pressure part}}\end{aligned}\tag{5-23}$$

P is the hydrostatic pressure and \bar{V}_W is the partial molar volume of H₂O (i.e., volume occupied by 1 mole of H₂O). Because the product of pressure and volume is work, the second term in Equation 5-23 is work per mole. Dealing with H₂O concentrations is cumbersome and imprecise because [H₂O] is very high (i.e., ~56 M) and does not change substantially in the dilute solutions that physiologists are interested in. Therefore, it is more practical to work with the inverse of [H₂O], namely, the concentration of osmotically active solutes, or **osmolality**.  **N5-21** The units of osmolality are osmoles per kilogram of H₂O, or Osm. In dilute solutions, the H₂O gradient across the cell membrane is roughly proportional to the difference in osmolalities across the membrane:

$$\ln \frac{[\text{H}_2\text{O}]_i}{[\text{H}_2\text{O}]_o} \cong \bar{V}_W (Osm_o - Osm_i)\tag{5-24}$$

where Osm is the total concentration of all osmotically active solutes in the indicated compartment (e.g., Na⁺ + Cl[−] + K⁺ + ...). Substituting Equation 5-24 into Equation 5-23 yields a more useful expression for the total energy difference across the membrane:

$$\underbrace{\Delta\mu_{\text{H}_2\text{O},\text{total}}}_{\substack{\text{Energy} \\ \text{mole}}} \cong \underbrace{\bar{V}_{\text{W}}}_{\substack{\text{Volume} \\ \text{mole}}} \underbrace{[RT(\text{Osm}_o - \text{Osm}_i) + (P_i - P_o)]}_{\text{Pressure}}$$

(5-25)

In this equation, the terms inside the brackets have the units of pressure (force per area) and thus describe the *driving force* for H₂O movement from the inside to the outside of the cell. This driving force determines the flux of H₂O across the membrane:

$$J_V = L_p [RT(\text{Osm}_o - \text{Osm}_i) + (P_i - P_o)]$$

(5-26)

J_V is positive when H₂O flows out of the cell and has the units of L/(cm² · s). The proportionality constant L_p is the **hydraulic conductivity**.

Water is in equilibrium across the membrane when the net driving force for H₂O transport is nil. If we set $\Delta\mu_{\text{H}_2\text{O},\text{total}}$ to zero in [Equation 5-25](#):

$$\underbrace{RT(\text{Osm}_i - \text{Osm}_o)}_{\substack{\text{Osmotic} \\ \text{pressure difference} \\ \Delta\pi}} = \underbrace{(P_i - P_o)}_{\substack{\text{Hydrostatic pressure} \\ \text{difference} \\ \Delta P}}$$

(5-27)

The term on the left is referred to as the **osmotic pressure difference ($\Delta\pi$)**. Thus, at equilibrium the osmotic pressure difference is equal to the **hydrostatic pressure difference (ΔP)**. An osmotic pressure difference of 1 milliosmole/kg H₂O (or 1 mOsm) is equivalent to a hydrostatic pressure difference of 19.3 mm Hg at normal body temperature.

The plasma membranes of animal cells are not rigid (unlike the walls of plant cells) and cannot tolerate any significant hydrostatic pressure difference without deforming. Therefore, the hydrostatic pressure difference *across a cell membrane* is virtually always near zero and is therefore not a significant driving force for H₂O transport.

Movement of H₂O in and out of cells is driven by osmotic gradients only, that is, by differences in osmolality across the membrane. For example, if the osmolality is greater outside the cell than inside, H₂O will flow out of the cell and the cell will shrink. Such a movement of H₂O driven by osmotic gradients is called **osmosis**. H₂O is at equilibrium across *cell membranes* only when the osmolality inside and outside the cell is the same.

Hydrostatic pressure differences are an important force for driving fluid out across the *walls of capillaries* (see [p. 468](#)). Small solutes permeate freely across most capillaries. Thus, any difference in *osmotic* pressure as a result of these small solutes does not exert a driving force for H₂O flow across that capillary. The situation is quite different for plasma proteins, which are too large to penetrate the capillary wall freely. As a result, the presence of a greater concentration of plasma proteins in the

intravascular compartment than in interstitial fluid sets up a difference in osmotic pressure that tends to pull fluid back into the capillary. This difference is called the **colloid osmotic pressure** or **oncotic pressure**. H_2O is at equilibrium across the wall of a *capillary* when the colloid osmotic and hydrostatic pressure differences are equal. When the hydrostatic pressure difference exceeds the colloid osmotic pressure difference, the result is movement of H_2O out of the capillary, called **ultrafiltration**.

Because of the presence of impermeant, negatively charged proteins within the cell, Donnan forces will lead to cell swelling

NaCl , the most abundant salt in ECF, is largely excluded from the intracellular compartment by the direct and indirect actions of the Na-K pump. This relative exclusion of NaCl from the intracellular space is vital for maintaining normal cell H_2O content (i.e., cell volume). In the absence of Na-K pumps, cells tend to swell even when both the intracellular and extracellular osmolalities are normal and identical. This statement may appear to contradict the principle that there can be no H_2O flux without a difference in osmolality across the cell membrane (see [Equation 5-26](#)). To understand this apparent paradox, consider a simplified model that illustrates the key role played by **negatively charged, impermeant macromolecules** (i.e., proteins) inside the cell ([Fig. 5-15](#)).

FIGURE 5-15 Gibbs-Donnan equilibrium. A semipermeable membrane separates two compartments that have rigid walls and equal volumes. The membrane is permeable to Na^+ , Cl^- , and water, but not to the macromolecule Y, which carries 150 negative charges. The calculations of ψ_i and P assume a temperature of 37°C .

Imagine that a semipermeable membrane separates a left compartment (analogous to the *extracellular* space) and a right compartment (analogous to the *intracellular* space). The two compartments are rigid and have equal volumes throughout the experiment. The right compartment is fitted with a pressure gauge. The membrane is nondeformable and permeable to Na^+ , Cl^- , and H_2O , but it is not permeable to a negatively charged macromolecule (Y). For the sake of simplicity, assume that each Y carries 150 negative charges and is restricted to the intracellular solution. [Figure 5-15A](#) illustrates the ionic conditions at the beginning of the experiment. At this initial condition, the system is far out of equilibrium; although $[\text{Na}^+]$ is the same on both sides of the membrane, $[\text{Cl}^-]$ and $[\text{Y}^{-150}]$ have opposing concentration gradients of 150 mM.

What will happen now? The system will tend toward equilibrium. Cl^- will move down its concentration gradient into the cell. This entry of negatively charged particles will generate an inside-negative membrane voltage, which in turn will attract Na^+ and cause Na^+ to move into the cell. In the final equilibrium condition, both Na^+ and Cl^- will be distributed so that the concentration of each is balanced against the same V_m , which is given by the Nernst equation ([Equation 5-8](#)):

$$V_m = -\frac{RT}{F} \ln \frac{[\text{Na}^+]_i}{[\text{Na}^+]_o}$$

(5-28)

$$V_m = -\frac{RT}{(-1)F} \ln \frac{[\text{Cl}^-]_i}{[\text{Cl}^-]_o}$$

(5-29)

Because V_m must be the same in the two cases, we combine the two equations, obtaining

$$\begin{aligned} -\ln \frac{[\text{Na}^+]_i}{[\text{Na}^+]_o} &= \ln \frac{[\text{Cl}^-]_i}{[\text{Cl}^-]_o} \\ \frac{[\text{Na}^+]_o}{[\text{Na}^+]_i} &= \frac{[\text{Cl}^-]_i}{[\text{Cl}^-]_o} = r \end{aligned}$$

(5-30)

where r is the Donnan ratio because this equilibrium state is a **Gibbs-Donnan equilibrium** (often shortened to Donnan equilibrium). All the values for ionic concentrations in [Equation 5-30](#) are *new* values. As Na^+ entered the cell, not only did $[\text{Na}^+]_i$ rise but $[\text{Na}^+]_o$ also fell, by identical amounts. The same is true for Cl^- . How much did the Na^+ and Cl^- concentrations have to change before the system achieved equilibrium? An important constraint on the system as it approaches equilibrium is that in each compartment, the total number of positive charges must balance the total number of negative charges (bulk electroneutrality) at all times. Imagine an *intermediate* state, between the initial condition and the final equilibrium state, in which 10 mM of Na^+ and 10 mM of Cl^- have moved into the cell (see [Fig. 5-15B](#)). This condition is still far from equilibrium because the Na^+ ratio in [Equation 5-30](#) is 0.875, whereas the Cl^- ratio is only 0.071; thus, these ratios are not equal. Therefore, Na^+ and Cl^- continue to move into the cell until the Na^+ ratio and the Cl^- ratio are both 0.5, the Donnan r ratio (see [Fig. 5-15C](#)). This *final* ratio corresponds to Nernst potentials of -18.4 mV for both Na^+ and Cl^- .

However, although the ions are in equilibrium, far more osmotically active particles are now on the inside than on the outside. Ignoring the osmotic effect of Y^{-150} , the sum of $[\text{Na}^+]$ and $[\text{Cl}^-]$ on the inside is 250 mM, whereas it is only 200 mM on the outside. Because of this 50-mOsm gradient (ΔOsm) across the membrane, H_2O cannot be at equilibrium and will therefore move into the cell. In our example, the right (inside) compartment is surrounded by a rigid wall so that only a minuscule amount of H_2O needs to enter the cell to generate a hydrostatic pressure of 967 mm Hg to oppose the additional net entry of H_2O . This equilibrium hydrostatic pressure difference (ΔP) opposes the osmotic pressure difference ($\Delta\pi$):

$$\begin{aligned}
\Delta P &= \Delta \pi \\
&= RT \Delta Osm \\
&= RT([Na^+]_i + [Cl^-]_i) - ([Na^+]_o + [Cl^-]_o) \\
&= RT(50mM) \\
&= 967 \text{ mm Hg} \\
&= 1.3 \text{ atm}
\end{aligned}$$

(5-31)

Thus, in the rigid “cell” of our example, achieving Gibbs-Donnan equilibrium would require developing within the model cell a hydrostatic pressure that is 1.3 atm greater than the pressure in the left compartment (outside).

The Na-K pump maintains cell volume by doing osmotic work that counteracts the passive Donnan forces

Unlike in the preceding example, the plasma membranes of animal cells are not rigid but deformable, so that transmembrane hydrostatic pressure gradients cannot exist. Thus, in animal cells, the distribution of ions toward the Donnan equilibrium condition would, it appears, inevitably lead to progressive water entry, cell swelling, and, ultimately, bursting. Although the Donnan equilibrium model is artificial (e.g., it ignores all ions other than Na^+ , Cl^- , and Y^{-150}), it nevertheless illustrates a point that is important for real cells: the negative charge on impermeant intracellular solutes (e.g., proteins and organic phosphates) will lead to bursting unless the cell does “osmotic work” to counteract the passive Donnan-like swelling. The net effect of this osmotic work is to largely exclude NaCl from the cell and thereby make the cell functionally impermeable to NaCl. In a sense, NaCl acts as a functionally impermeant solute in the extracellular space that offsets the osmotic effects of intracellular negative charges. This state of affairs is not an equilibrium but a *steady state* maintained by active transport.

As an illustration of the role of active transport, consider a somewhat more realistic model of a cell (Fig. 5-16). Under “normal” conditions, $[Na^+]_i$, $[K^+]_i$, and $[Cl^-]_i$ are constant because (1) the active extrusion of three Na^+ ions in exchange for two K^+ ions is balanced by the passive influx of three Na^+ ions and the passive efflux of two K^+ ions, and (2) the net flux of Cl^- is zero (i.e., we assume that Cl^- is in equilibrium). When the Na-K pump is inhibited, the passive entry of three Na^+ ions exceeds the net passive efflux of two K^+ ions and thereby results in a gain of one intracellular cation and an immediate small depolarization (i.e., the cell becomes less negative inside). In addition, as intracellular $[K^+]$ slowly declines after inhibition of the Na-K pump, the cell depolarizes even further because the outward K^+ gradient is the predominant determinant of the membrane voltage. The inside-negative V_m is the driving force that is largely responsible for excluding Cl^- from the cell, and depolarization of the cell causes Cl^- to enter through anion channels. Cl^- influx results in the gain of one intracellular anion. The net gain of one intracellular cation and one anion increases the number of osmotically active particles and in so doing creates the inward osmotic gradient that leads to cell swelling. Thus, in the normal environment in which cells are bathed, the action of the Na-K pump is required to prevent the cell swelling that would otherwise occur.

FIGURE 5-16 Role of the Na-K pump in maintaining cell volume.

A real cell, of course, is far more complex than the idealized cell in [Figure 5-16](#), having myriad interrelated channels and transporters (see [Fig. 5-14](#)). These other pathways, together with the Na-K pump, have the net effect of excluding NaCl and other solutes from the cell. Because the solute gradients that drive transport through these other pathways ultimately depend on the Na-K pump, inhibiting the Na-K pump will de-energize these other pathways and lead to cell swelling.

Cell volume changes trigger rapid changes in ion channels or transporters, returning volume toward normal

The joint efforts of the Na-K pump and other transport pathways are necessary for maintaining normal cell volume. What happens if cell volume is acutely challenged? A subset of “other pathways” respond to the cell volume change by transferring solutes across the membrane, thereby returning the volume toward normal.

Response to Cell Shrinkage

If we increase extracellular osmolality by adding an impermeant solute such as mannitol ([Fig. 5-17A](#)), the extracellular solution becomes **hyperosmolar** and exerts an osmotic force that draws H₂O out of the cell. The cell continues to shrink until the osmolality inside and out becomes the same. Many types of cells respond to this shrinkage by activating solute uptake processes to increase cell solute and H₂O content. This response is known as a **regulatory volume increase (RVI)**. Depending on the cell type, cell shrinkage activates different types of solute uptake mechanisms. In many types of cells, shrinkage

activates the ubiquitous NHE1 isoform of the *Na-H exchanger*. In addition to mediating increased uptake of Na^+ , extrusion of H^+ alkalinizes the cell and consequently activates *Cl-HCO_3 exchange*. The initial net effect is the entry of Na^+ and Cl^- . However, the Na-K pump then extrudes the Na^+ in exchange for K^+ , so that the final net effect is the gain of intracellular KCl. The resulting increase in intracellular osmoles then draws H_2O into the cell to restore cell volume toward normal. Alternatively, the RVI response may be mediated by activation of the NKCC1 isoform of the *Na/K/Cl cotransporter*.

FIGURE 5-17 Short-term regulation of cell volume.

Response to Cell Swelling

If extracellular osmolality is decreased by the addition of H_2O (see Fig. 5-17B), the extracellular solution becomes **hypo-osmolal** and exerts a lesser osmotic force so that H_2O moves into the cell. The cell

continues to swell until the osmolality inside and out becomes the same. Many cell types respond to this swelling by activating solute efflux pathways to decrease cell solute and H_2O content and thereby return cell volume toward normal. This response is known as a **regulatory volume decrease (RVD)**. Depending on the cell type, swelling activates different types of solute efflux mechanisms. In many types of cells, swelling activates Cl^- or K^+ channels (or both). Because the electrochemical gradients for these two ions are generally directed outward across the plasma membrane, activating these channels causes a net efflux of K^+ and Cl^- , which lowers the intracellular solute content and causes H_2O to flow out of the cell. The result is restoration of cell volume toward normal. Alternatively, the RVD response may be initiated by activating the *K/Cl cotransporter*.

In the normal steady state, the transport mechanisms that are responsible for RVI and RVD are usually not fully quiescent. Not only does cell shrinkage activate the transport pathways involved in RVI (i.e., solute loaders), it also appears to inhibit at least some of the transport pathways involved in RVD (i.e., solute extruders). The opposite is true of cell swelling. In all cases, the Na-K pump ultimately generates the ion gradients driving the movements of NaCl and KCl that regulate cell volume in response to changes in extracellular osmolality ([Box 5-1](#)).

Box 5-1

Disorders of Extracellular Osmolality

Regulatory adjustments in cell volume can be extremely important clinically. In major disorders of extracellular osmolality, the principal signs and symptoms arise from abnormal brain function, which can be fatal. For example, it is all too common for the elderly or infirm, unable to maintain proper fluid intake because of excessive heat or disability, to be brought to the emergency department in a state of severe dehydration. The hyperosmolality that results from dehydration can lead to brain shrinkage, which in extreme cases can cause intracerebral hemorrhage from tearing of blood vessels. If the brain cells compensate for this hyperosmolality by the long-term mechanisms discussed (e.g., manufacturing of idiogenic osmoles), cell shrinkage may be minimized. However, consider the consequence if an unsuspecting physician, unaware of the nuances of cell volume regulation, rapidly corrects the elevated extracellular hyperosmolality back down to normal. Rapid H_2O entry into the brain cells will cause cerebral edema (i.e., brain swelling) and may result in death from herniation of the brainstem through the tentorium. For this reason, severe disturbances in ECF osmolality must usually be corrected slowly.

Cells respond to long-term hyperosmolality by accumulating new intracellular organic solutes

Whereas the acute response (seconds to minutes) to hyperosmolality (i.e., RVI) involves the uptake of salts, long-term adaptation (hours to days) to hyperosmolality involves accumulation of organic solutes (*osmolytes*) within the cell. Examples of such intracellularly accumulated osmolytes include two relatively impermeant alcohol derivatives of common sugars (i.e., sorbitol and inositol) as well as two amines (betaine and taurine). Generation of organic solutes (*idiogenic osmoles*) within the cell plays a major role in raising intracellular osmolality and restoring cell volume during long-term adaptation to hyperosmolality—a response that is particularly true in brain cells. Sorbitol is produced from glucose by a reaction that is catalyzed by the enzyme **aldose reductase**. Cell shrinkage is a powerful stimulus for the synthesis of aldose reductase.

In addition to synthesizing organic solutes, cells can also transport them into the cytosol from the outside. For example, cells use distinct Na^+ -coupled cotransport systems to accumulate inositol, betaine, and taurine. In some types of cells, shrinkage induces greatly enhanced expression of these transporters, thereby leading to the accumulation of these intracellular solutes.

The gradient in tonicity—or effective osmolality—determines the osmotic flow of water across a cell membrane

Total-body water (TBW) is distributed among blood plasma and the interstitial, intracellular, and transcellular fluids. The mechanisms by which H_2O exchanges between interstitial fluid and ICF, and between interstitial fluid and plasma, rely on the principles that we have just discussed.

Water Exchange Across Cell Membranes

Because cell membranes are not rigid, hydrostatic pressure differences never arise between cell H_2O and interstitial fluid. Increasing the *hydrostatic* pressure in the interstitial space will cause the cell to compress so that the intracellular hydrostatic pressure increases to a similar extent. Thus, H_2O does not enter the cell under these conditions. However, increasing the interstitial *osmotic* pressure, and thus generating a $\Delta\pi$, is quite a different matter. If we suddenly increase ECF osmolality by adding an *impermeant* solute such as mannitol, the resulting osmotic gradient across the cell membrane causes H_2O to move out of the cell. If the cell does not have an RVI mechanism or if the RVI mechanism is blocked, cell volume will remain reduced indefinitely.

On the other hand, consider what would happen if we suddenly increase ECF osmolality by adding a *permeant* solute such as urea. Urea can rapidly penetrate cell membranes by facilitated diffusion through members of the UT family of transporters; however, cells have no mechanism for extruding urea. Because urea penetrates the membrane more slowly than H_2O does, the initial effect of applying urea is to shrink the cell (Fig. 5-18). However, as urea gradually equilibrates across the cell membrane and abolishes the initially imposed osmotic gradient, the cell reswells to its initial volume. Thus, sustained changes in cell volume do not occur with a change in the extracellular concentration of a permeant solute.

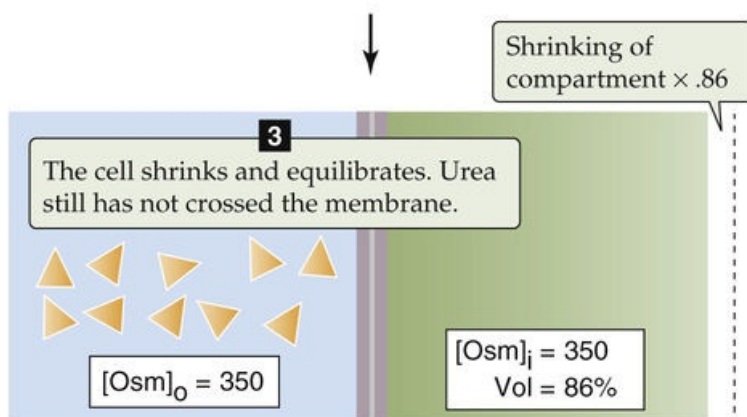

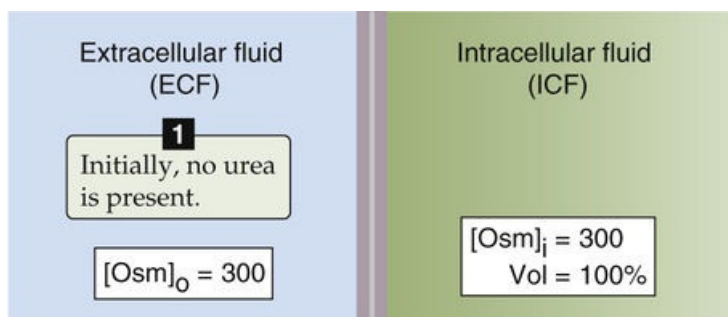

FIGURE 5-18 Effect of urea on the volume of a single cell bathed in an infinite volume of ECF. We assume that the cell membrane is permeable only to water during the initial moments in steps 2 and 3. Later, during steps 4 and 5, we assume that the membrane is permeable to both water and urea.

The difference between the effects of mannitol and urea on the final cell volume illustrates the need to distinguish between total osmolality and **effective osmolality** (also known as tonicity). In terms of clinically measured solutes, total and effective osmolality of the ECF can be approximated as

$$\begin{aligned} \text{Total osmolality (mOsm)} &\cong 2 \cdot [\text{Na}^+] + \frac{\text{Glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8} \\ \text{Tonicity or effective osmolality (mOsm)} &\cong 2 \cdot [\text{Na}^+] + \frac{\text{Glucose (mg/dL)}}{18} \end{aligned}$$

(5-32)

BUN stands for **blood urea nitrogen**, that is, the concentration of the nitrogen that is contained in the plasma as urea. The clinical laboratory reports the value of $[\text{Na}^+]$ in [Equation 5-32](#) in milliequivalents per liter. Because laboratories in the United States report the glucose and BUN concentrations in terms of milligrams per deciliter, we divide glucose by one tenth of the molecular weight of glucose and BUN by one tenth of the summed atomic weights of the two nitrogen atoms in urea. The computed tonicity does not include BUN because—as we saw above—urea easily equilibrates across most cell membranes. On the other hand, the computed tonicity includes both Na^+ and glucose. It includes Na^+ because Na^+ is *functionally* impermeant owing to its extrusion by the Na-K pump. Tonicity includes glucose because this solute does not appreciably accumulate in most cells as a result of metabolism. In some clinical situations, the infusion of impermeant solutes, such as radiographic contrast agents or mannitol, can also contribute to tonicity of the ECF.

Osmolality describes the number of osmotically active solutes in a single solution. If we regard a plasma osmolality of 290 mOsm as being normal, solutions having an osmolality of 290 mOsm are **isosmolal**, solutions with osmolalities >290 mOsm are hyperosmolal, and those with osmolalities <290 mOsm are hypo-osmolal. On the other hand, when we use the terms *isotonic*, *hypertonic*, and *hypotonic*, we are comparing one solution with another solution (e.g., ICF) across a well-defined membrane (e.g., a cell membrane). A solution is **isotonic** when its *effective* osmolality is the same as that of the reference solution, which for our purposes is the ICF. A **hypertonic** solution is one that has a higher effective osmolality than the reference solution, and a **hypotonic** solution has a lower effective osmolality.

Shifts of H_2O between the intracellular and interstitial compartments result from alterations in *effective* ECF osmolality, or *tonicity*. Clinically, such changes in tonicity are usually caused by decreases in $[\text{Na}^+]$ in the plasma and ECF (hyponatremia), increases in $[\text{Na}^+]$ (hypernatremia), or increases in glucose concentration (hyperglycemia). Changes in the concentration of a highly permeant solute such as urea, which accumulates in patients with kidney failure, have no effect on tonicity.

Water Exchange Across the Capillary Wall

The barrier separating the blood plasma and interstitial compartments—the capillary wall—is, to a first

approximation, freely permeable to solutes that are smaller than plasma proteins. Thus, the only *net* osmotic force that acts across the capillary wall is that caused by the asymmetric distribution of proteins in plasma versus interstitial fluid. Several terms may be used for the osmotic force that is generated by these impermeant plasma proteins, such as protein osmotic pressure, colloid osmotic pressure, and oncotic pressure. These terms are synonymous and can be represented by the symbol π_{oncotic} . The **oncotic pressure difference** ($\Delta\pi_{\text{oncotic}}$), which tends to pull H_2O from the interstitium to the plasma, is opposed by the hydrostatic pressure difference across the capillary wall (ΔP), which drives fluid from plasma into the interstitium. All net movements of H_2O across the capillary wall are accompanied by the small solutes dissolved in this H_2O , at their ECF concentrations; that is, the pathways taken by the H_2O across the capillary wall are so large that small solutes are not *sieved* out.

To summarize, fluid shifts between plasma and the interstitium respond only to changes in the balance between ΔP and $\Delta\pi_{\text{oncotic}}$. Small solutes such as Na^+ , which freely cross the capillary wall, do not contribute significantly to osmotic driving forces across this barrier and move along with the H_2O in which they are dissolved. We will return to this subject when we discuss capillary exchange of H_2O , beginning on [p. 467](#).

Adding isotonic saline, pure water, or pure NaCl to the ECF will increase ECF volume but will have divergent effects on ICF volume and ECF osmolality

Adding various combinations of NaCl and **solute-free water** to the ECF will alter the volume and composition of the body fluid compartments. Three examples illustrate the effects seen with intravenous therapy. In [Figure 5-19A](#), we start with a TBW of 42 L (60% of a 70-kg person), subdivided into an ICF volume of 25 L (60% of TBW) and an ECF volume of 17 L (40% of TBW). These numerical values are the same as those in [Figure 5-1](#) and [Table 5-1](#).

A INITIAL CONDITION

Extracellular fluid (ECF)	Intracellular fluid (ICF)
17 L × 290 mOsm ----- 4930 milliosmoles	25 L × 290 mOsm ----- 7250 milliosmoles

B AFTER ADDING 1.5 liters OF 145 mM NaCl IN H₂O TO ECF

ECF	ICF
18.5 L × 290 mOsm ----- 5365 milliosmoles	25 L × 290 mOsm ----- 7250 milliosmoles

Swelling of compartment by 1.5 L

C AFTER ADDING 1.5 liters OF PURE H₂O TO ECF

ECF	ICF	ECF	ICF
18.5 L × 266 mOsm ----- 4930 milliosmoles	25 L × 290 mOsm ----- 7250 milliosmoles	17.6 L × 280 mOsm ----- 4930 milliosmoles	25.9 L × 280 mOsm ----- 7250 milliosmoles
Early		Final	

Swelling of compartment by 1.5 L

0.9 L has left the compartment.

An extra 0.6 L remains in the compartment.

Swelling of compartment by 0.9 L

D AFTER ADDING 217.5 MILLIMOLES OF PURE NaCl TO ECF

ECF	ICF	ECF	ICF
17 L × 316 mOsm ----- 5365 milliosmoles	25 L × 290 mOsm ----- 7250 milliosmoles	17.9 L × 300 mOsm ----- 5365 milliosmoles	24.1 L × 300 mOsm ----- 7250 milliosmoles
Early		Final	

Swelling of compartment by 0.9 L

Shrinking of compartment by 0.9 L

Infusion of Isotonic Saline

Consider the case in which we infuse or ingest 1.5 L of isotonic saline, which is a 0.9% solution of NaCl in H₂O (see Fig. 5-19B). This solution has an effective osmolality of 290 mOsm in the ECF. This 1.5 L is initially distributed throughout the ECF and raises ECF volume by 1.5 L. Because the effective osmolality of the ECF is unaltered, no change occurs in the effective osmotic gradient across the cell membranes, and the added H₂O moves neither into nor out of the ICF. This outcome is, of course, in accord with the definition of an *isotonic* solution. Thus, we see that adding isotonic saline to the body is an efficient way to expand the ECF without affecting the ICF. Similarly, if it were possible to remove isotonic saline from the body, we would see that this measure would efficiently contract the ECF and again have no effect on the ICF.

Infusion of “Solute-Free” Water

Now consider a case in which we either ingest 1.5 L of pure H₂O or infuse 1.5 L of an isotonic (5%) glucose solution (see Fig. 5-19C). Infusing the glucose solution intravenously is equivalent, in the long run, to infusing pure H₂O because the glucose is metabolized to CO₂ and H₂O, with no solutes left behind in the ECF. Infusing pure H₂O would be unwise inasmuch as it would cause the cells near the point of infusion to burst.

How do the effects of adding 1.5 L of pure H₂O compare with those in the previous example? At first, the 1.5 L of pure H₂O will be rapidly distributed throughout the ECF and increase its volume from 17 to 18.5 L (see Fig. 5-19C, left side [Early]). This added H₂O will also dilute the pre-existing solutes in the ECF, thereby lowering ECF osmolality to $290 \text{ mOsm} \times 17/18.5 = 266 \text{ mOsm}$. Because intracellular osmolality remains at 290 mOsm at this imaginary, intermediate stage, a large osmotic gradient is created that favors the entry of H₂O from the ECF into the ICF. Water will move into the ICF and consequently lower the osmolality of the ICF and simultaneously raise the osmolality of the ECF until osmotic equilibrium is restored (see Fig. 5-19C, right side [Final]). Because the added H₂O is distributed between the ICF and ECF according to the initial ICF/ECF ratio of 60%/40%, the final ECF volume is 17.6 L (i.e., 17 L expanded by 40% of 1.5 L). Thus, infusion of solute-free H₂O is a relatively *ineffective* means of expanding the ECF. More of the added H₂O has ended up intracellularly (60% of 1.5 L = 0.9 L of expansion). The major effect of the H₂O has been to dilute the osmolality of body fluids. The initial total-body solute content was $290 \text{ mOsm} \times 42 \text{ L} = 12,180$ milliosmoles. This same solute has now been diluted in $42 + 1.5$ or 43.5 L, so the final osmolality is $12,180/43.5 = 280 \text{ mOsm}$.

Ingestion of Pure NaCl Salt

The preceding two “experiments” illustrate two extremely important principles that govern fluid and electrolyte homeostasis; namely, that adding or removing Na⁺ will mainly affect ECF volume (see Fig. 5-19B), whereas adding or removing solute-free H₂O will mainly affect the *osmolality* of body fluids (see Fig. 5-19C). The first point can be further appreciated by considering a third case, one in which we add the same amount of NaCl that is contained in 1.5 L of isotonic (i.e., 0.9%) saline: $1.5 \text{ L} \times 290 \text{ mOsm} = 435$ milliosmoles. However, we will not add any H₂O. At first, these 435 milliosmoles of NaCl will

rapidly distribute throughout the 17 L of ECF and increase the osmolality of the ECF (see [Fig. 5-19D](#), left side [Early]). The initial total osmolal content of the ECF was $290 \text{ mOsm} \times 17 \text{ L} = 4930$ milliosmoles. Because we added 435 milliosmoles, we now have 5365 milliosmoles in the ECF. Thus, the ECF osmolality is $5365/17 = 316 \text{ mOsm}$. The resulting hyperosmolality draws H_2O out of the ICF into the ECF until osmotic equilibrium is re-established. What is the final osmolality? The total number of milliosmoles dissolved in TBW is the original 12,180 milliosmoles plus the added 435 milliosmoles, for a total of 12,615 milliosmoles. Because these milliosmoles are dissolved in 42 L of TBW, the final osmolality of the ICF and ECF is $12,615/42 = 300 \text{ mOsm}$. In the new equilibrium state, the ECF volume has increased by 0.9 L even though no H_2O at all was added to the body. Because the added ECF volume has come from the ICF, the ICF shrinks by 0.9 L. This example further illustrates the principle that the total-body content of Na^+ is the major determinant of ECF volume.

Whole-body Na^+ content determines ECF volume, whereas whole-body water content determines osmolality

Changes in ECF volume are important because they are accompanied by proportional changes in the volume of blood plasma, which in turn affects the adequacy with which the circulatory system can perfuse vital organs with blood (see [pp. 554-555](#)). The blood volume that is necessary to achieve adequate perfusion of key organs is sometimes referred to as the **effective circulating volume**. Because the body generally stabilizes osmolality, an increase in extracellular Na^+ content will increase ECF volume:

$$\underbrace{\text{Extracellular } \text{Na}^+ \text{ content}}_{\text{millimoles}} = \underbrace{[\text{Na}^+]_o}_{\text{millimoles/liter}} \times \underbrace{\text{ECF volume}}_{\text{liters}}$$

$$\equiv \left(\frac{\text{Osmolality}}{2} \right) \times \underbrace{\text{ECF volume}}_{\text{liters}}$$

(5-33)

Because cells contain very little Na^+ , extracellular Na^+ content is nearly the same as **total-body Na^+ content**.

We will see in [Chapter 40](#) how the body regulates effective circulating volume. Increases in effective circulating volume, which reflect increases in ECF volume or total-body Na^+ content, stimulate the renal excretion of Na^+ . In contrast, the plasma Na^+ concentration does *not* regulate renal excretion of Na^+ . It makes sense that regulation of Na^+ excretion is not sensitive to the plasma Na^+ concentration because the concentration is not an indicator of ECF volume.

As discussed, when we hold osmolality constant, Na^+ content determines ECF volume. What would happen if we held constant the Na^+ content, which is a major part of **total-body osmoles**? An increase in TBW would decrease **osmolality**. [N5-2](#)

$$\underbrace{\text{Total body osmoles}}_{\text{milliosmoles}} = \underbrace{[\text{Osmolality}]}_{\text{milliosmoles/liter}} \times \underbrace{\text{Total body water}}_{\text{liters}}$$

(5-34)

Thus, a net gain or loss of solute-free H₂O has a major impact on the *osmolality* and [Na⁺] of the ECF. Moreover, because a large part (~60%) of the added solute-free water distributes into the ICF, a gain or loss of solute-free H₂O affects ICF more than ECF. We will see beginning on [p. 844](#) how the body regulates osmolality: a small decrease in osmolality triggers osmoreceptors to diminish thirst (which results in diminished intake of solute-free H₂O) and increase renal H₂O excretion. In emergency states of very low ECF and effective circulating volume, some crosstalk occurs between the control systems for volume and osmolality. As a result, the body not only will try to conserve Na⁺ but will also seek H₂O (by triggering thirst) and conserve H₂O (by concentrating the urine). Although water (in comparison to saline) is not a very good expander of plasma and ECF volume, it is better than nothing.

Transport of Solutes and Water Across Epithelia

Thus far we have examined how cells transport solutes and H_2O across their membranes and thereby control their intracellular composition. We now turn our attention to how the body controls the milieu intérieur, namely, the ECF that bathes the cells. Just as the cell membrane is the barrier between the ICF and ECF, epithelia are the barriers that separate the ECF from the outside world. In this subchapter, we examine the fundamental principles of how epithelial cells transport solutes and H_2O across epithelial barriers.

An epithelium is an uninterrupted sheet of cells that are joined together by junctional complexes (see p. 43). These junctions serve as a selectively permeable barrier between the solutions on either side of the epithelium and demarcate the boundary between the apical and basolateral regions of the cell membrane. The apical and basolateral membranes are remarkably different in their transport function. This polarization allows the epithelial cell to transport H_2O and selected solutes from one compartment to another. In other words, the epithelium is capable of vectorial transport. In many cases, transport of solutes across an epithelium is an active process.

Membranes may be called by different names in different epithelia. The **apical membrane** can be known as the brush border, the mucosal membrane, or the luminal membrane. The **basolateral membrane** is also known as the serosal or peritubular membrane.

The epithelial cell generally has different electrochemical gradients across its apical and basolateral membranes

Imagine an artificial situation in which an epithelium separates two identical solutions. Furthermore, imagine that there is no difference in voltage across the epithelium and no difference in hydrostatic pressure. Under these circumstances, the driving forces for the *passive movement* of solutes or H_2O across the epithelium would be nil. Because the apical and basolateral membranes of the cell share the same cytosol, the electrochemical gradients across the apical and basolateral membranes would be identical.

However, this example is virtually never realistic for two reasons. First, because the composition of the “outside world” is not the same as that of ECF, transepithelial concentration differences occur. Second, transepithelial voltage is usually not zero. Thus, the electrochemical gradients across the apical and basolateral membranes of an epithelial cell are generally very different.

Electrophysiological methods provide two major types of information about ion transport by epithelial cells. First, electrophysiological techniques can define the electrical driving forces that act on ions either across the entire epithelium or across the individual apical and basolateral cell membranes. Second, these electrical measurements can define the overall electrical resistance of the epithelium or the electrical resistance of the individual apical and basolateral cell membranes.

The voltage difference between the solutions on either side of the epithelium is the **transepithelial voltage (V_{te})**. We can measure V_{te} by placing one microelectrode in the lumen of the organ or duct of which the epithelium is the wall and a second reference electrode in the blood or interstitial space (Fig. 5-20A). If we instead insert the first microelectrode directly into an epithelial cell (see Fig. 5-20A), the voltage difference between this cell and the reference electrode in blood or the interstitial space measures

the **basolateral cell membrane voltage (V_{bl})**. Finally, if we compare the intracellular electrode with a reference electrode in the lumen (see [Fig. 5-20A](#)), the voltage difference is the **apical cell membrane voltage (V_a)**. Obviously, the sum of V_a and V_{bl} is equal to the transepithelial voltage (see [Fig. 5-20B](#)). It is also possible to insert ion-sensitive microelectrodes into the lumen or the epithelial cells and thereby determine the local activity of ions such as Na^+ , K^+ , H^+ , Ca^{2+} , and Cl^- .

A EPITHELIAL VOLTAGES

B ELECTRICAL PROFILE ACROSS AN EPITHELIAL CELL

FIGURE 5-20 Measurement of voltages in an epithelium. **A**, The transepithelial voltage difference between electrodes placed in the lumen and interstitial space (or blood) is V_{te} . The basolateral voltage difference between electrodes placed in the cell and interstitial space is V_{bl} . The apical voltage difference between electrodes placed in the lumen and cell is V_a . **B**, Relative to the reference voltage of zero in the interstitial space, the voltage inside the cell in this example is -70 mV, and the voltage in the lumen is -3 mV. These values are typical of a cell in the renal proximal tubule or a small intestine.

By using the same voltage electrodes that we introduced in the preceding paragraph, we can pass

electrical current across either the whole epithelium or the individual apical and basolateral membranes. From Ohm's law, it is thus possible to calculate the **electrical resistance** of the entire wall of the epithelium, or transepithelial resistance (R_{te}); that of the apical membrane, or apical resistance (R_a); or that of the basolateral membrane, or basolateral resistance (R_{bl}).

Tight and leaky epithelia differ in the permeabilities of their tight junctions

One measure of how tightly an epithelium separates one compartment from another is its resistance to the flow of electrical current. The range of transepithelial electrical resistance is quite large. For example, 1 cm² of a rat proximal tubule has a resistance of only 6 Ω , whereas 1 cm² of a rabbit urinary bladder has a resistance of 70,000 Ω . Why is the range of R_{te} values so great? The cells of these epithelia do not differ greatly in either their apical or basolateral membrane resistances. Instead, the epithelia with low electrical resistances have a low-resistance pathway located in their tight junctions. Epithelia are thus classified as either “tight” (high electrical resistance) or “leaky,” depending on the relative resistance of their tight junctions. In other words, the tight junctions of leaky epithelia are relatively more permeant to the diffusion of ions than the tight junctions of tight epithelia.

Now that we have introduced the concept that solutes and H₂O can move between epithelial cells through tight junctions, we can define two distinct pathways by which substances can cross epithelia. First, a substance can cross through the cell by sequentially passing across the apical and then the basolateral membranes, or vice versa. This route is called the **transcellular pathway**. Second, a substance can bypass the cell entirely and cross the epithelium through the tight junctions and lateral intercellular spaces. This route is called the **paracellular pathway**.

As might be expected, leaky epithelia are not so good at maintaining large transepithelial ion or osmotic gradients. In general, **leaky epithelia** perform bulk transepithelial transport of solutes and H₂O in a nearly isosmotic fashion (i.e., the transported fluid has nearly the same osmolality as the fluid from which it came). Examples include the small intestine and the proximal tubule of the kidney. As a general rule, **tight epithelia** generate or maintain large transepithelial ion concentration or osmotic gradients. Examples include the distal nephron of the kidney, the large intestine, and the tightest of all epithelia, the urinary bladder (whose function is to be an absolutely impermeable storage vessel).

In addition to tight junctions, epithelia share a number of basic properties. First, the Na-K pump is located exclusively on the basolateral membrane (Fig. 5-21). The only known exception is the choroid plexus, where the Na-K pump is located on the apical membrane.

A Na^+ ABSORPTION ("USSING MODEL")

B K^+ SECRETION

C GLUCOSE ABSORPTION

D Cl^- SECRETION

FIGURE 5-21 Models of epithelial solute transport.

Second, most of the K^+ that is taken up by the Na-K pump generally recycles back out across the basolateral membrane through K^+ channels (see Fig. 5-21). A consequence of the abundance of these K^+ channels is that the K^+ gradient predominantly determines V_{bi} , which is usually 50 to 60 mV, inside negative.

Third, as in other cells, $[\text{Na}^+]_i$, typically 10 to 30 mM, is much lower in an epithelial cell than in the ECF. This low $[\text{Na}^+]_i$ is a consequence of the active extrusion of Na^+ by the Na-K pump. The large, inwardly directed Na^+ electrochemical gradient serves as a driving force for Na^+ entry through apical Na^+ channels and for the secondary active transport of other solutes across the apical membrane (e.g., by Na/glucose cotransport, Na-H exchange, Na/K/Cl cotransport) or the basolateral membrane (e.g., by Na-Ca exchange).

Epithelial cells can absorb or secrete different solutes by inserting specific channels or transporters at either the apical

or basolateral membrane

By placing different transporters at the apical and basolateral membranes, epithelia can accomplish net transepithelial transport of different solutes in either the absorptive or secretory direction. For example, the renal proximal tubule moves glucose from the tubule lumen to the blood by using an Na/glucose cotransporter (SGLT) to move glucose into the cell across the apical membrane, but it uses facilitated diffusion of glucose (GLUT) to move glucose out of the cell across the basolateral membrane. Clearly, the proximal tubule cell could not use the same Na/glucose cotransporter at both the apical and basolateral membranes because the electrochemical Na^+ gradient is similar across both membranes.

We will now look at four examples to illustrate how epithelia can absorb or secrete various solutes by using the transporters discussed above in this chapter.

Na^+ Absorption

Consider the model in [Figure 5-21A](#), which is similar to that first proposed by Hans Ussing and coworkers to explain NaCl absorption across the frog skin. The basolateral Na-K pump pumps Na^+ out of the cell, thereby lowering $[\text{Na}^+]_i$ and generating an inward Na^+ electrochemical gradient across the apical membrane. This apical Na^+ gradient, in turn, provides the driving force for Na^+ to enter the cell passively across the apical membrane through ENaC Na^+ channels. The Na^+ that enters the cell in this way is pumped out across the basolateral membrane in exchange for K^+ , which recycles back out across the basolateral membrane. Note that the Na-K pump generates a current of positive charge across the cell from lumen to interstitium. This current, in turn, creates a lumen-negative transepithelial voltage that can then provide a driving force for passive Cl^- absorption across the tight junctions—through the so-called paracellular pathway. The net result is NaCl absorption. This process contributes to NaCl reabsorption in the collecting tubule of the kidney.

K^+ Secretion

With slight alterations, the same basic cell model can explain K^+ secretion as well as Na^+ absorption (see [Fig. 5-21B](#)). Adding K^+ channels to the apical membrane allows some of the K^+ that is taken up by the Na-K pump across the basolateral membrane to be secreted across the apical membrane. This mechanism is the basis of K^+ secretion in the collecting tubule of the kidney. Such a model accurately predicts that drugs such as amiloride, which blocks apical ENaC Na^+ channels in these cells, will inhibit K^+ secretion as well as Na^+ reabsorption.

Glucose Absorption

The small intestine and proximal tubule absorb nutrients that are present in the luminal compartment by secondary active cotransport of Na^+ with organic solutes. An example is Na^+ cotransport with glucose by SGLT (see [Fig. 5-21C](#)). The inwardly directed electrochemical Na^+ gradient across the apical membrane, generated by the Na-K pump, now drives the entry of both Na^+ and glucose. Glucose, which has accumulated in the cell against its concentration gradient, exits passively across the basolateral membrane by a carrier-mediated transporter (GLUT) that is not coupled to Na^+ . Again, the flow of positive current across the cell generates a lumen-negative transepithelial voltage that can drive passive Cl^- absorption across the tight junctions. The net effect is absorption of both NaCl and glucose.

Cl^- Secretion

If the Na^+ -coupled Cl^- entry mechanism is located on the basolateral membrane, the same basic cell model can account for NaCl *secretion* into the lumen (see [Fig. 5-21D](#)). The inwardly directed Na^+ electrochemical gradient now drives secondary active Cl^- uptake across the basolateral membrane by the $\text{Na}/\text{K}/\text{Cl}$ cotransporter NKCC1. Cl^- accumulated in the cell in this way can then exit across the apical membrane passively through Cl^- channels such as CFTR. Notice that negative charges now move across the cell from interstitium to lumen and generate a lumen-negative voltage that can drive passive Na^+ secretion across the tight junctions (paracellular pathway). The net process is NaCl secretion, even though the primary active transporter, the Na-K pump, is pumping Na^+ from the cell to the interstitium. Secretory cells in the intestine and pulmonary airway epithelium use this mechanism for secreting NaCl .

Water transport across epithelia passively follows solute transport

In general, H_2O moves passively across an epithelium in response to osmotic gradients. An epithelium that secretes salt will secrete fluid, and one that absorbs salt will absorb fluid. The finite permeability of the bare lipid bilayer to H_2O and the presence of AQPs in most cell membranes ensure that osmotic equilibration for most cells is rapid. In addition, particularly in leaky epithelia, tight junctions provide a pathway for H_2O movement between the epithelial cells. However, epithelial H_2O permeability (hydraulic conductivity) varies widely because of differences in membrane lipid composition and in abundance of AQPs. The presence of AQPs in the plasma membrane may be either constitutive or highly regulated.

Absorption of a Hyperosmotic Fluid

If the epithelium absorbs more salt than its isotonic equivalent volume of H_2O , the absorbate is hyperosmotic. An example is the thick ascending limb of the loop of Henle in the kidney, which reabsorbs a large amount of salt but relatively little H_2O . As a result, dilute fluid is left behind in the lumen, and the renal interstitium is rendered hyperosmotic.

Absorption of an Isosmotic Fluid

In certain epithelia, such as the renal proximal tubule and small intestine, net H_2O movement occurs with no detectable osmotic gradients across the epithelium ([Fig. 5-22](#)). Moreover, the reabsorbed fluid appears to be nearly isosmotic with respect to luminal fluid. Of course, fluid absorption could not really occur without the requisite solute driving force across the epithelium. Two explanations, which are not exclusive, have been offered.

FIGURE 5-22 Model of isotonic water transport in a leaky epithelium. Na-K pumps present on the lateral and basal membrane pump Na^+ into two restricted spaces: the lateral intercellular space and restricted spaces formed by infoldings of the basal membrane. The locally high osmolality in the lateral intercellular space pulls water from the lumen and the cell. Similarly, the locally high osmolality in the restricted basal spaces pulls water from the cell. The solution that emerges from these two restricted spaces—and enters the interstitial space—is only slightly hypertonic (virtually isotonic) compared with the luminal solution.

First, the H_2O permeability of epithelia performing isosmotic H_2O reabsorption might be extremely high because of the high constitutive expression of AQP in the apical and basolateral membranes. Thus, modest transepithelial osmotic gradients (perhaps only 1 to 2 mOsm), which are the product of solute absorption, are sufficient to drive H_2O transport at the rates observed. Measurements cannot distinguish such small osmotic gradients from no gradient at all.

Second, the lateral intercellular spaces between the epithelial cells (lateral interspaces; see Fig. 5-22, option 1) as well as the spaces between the infoldings of the basal membrane (basal labyrinth; see Fig. 5-22, option 2) might be modestly hyperosmotic as a consequence of the accumulation of absorbed solutes in a localized region. The resulting localized osmotic gradient would pull H_2O into the lateral interspaces from the cell (across the lateral portion of the basolateral membrane) or from the lumen (across the tight junction). Similarly, a localized osmotic gradient would pull H_2O into the basal labyrinth from the cell (across the basal portion of the basolateral membrane). By the time that the fluid emerges from these spaces and reaches the interstitium, it would have become nearly isosmotic.

Absorption of a Hypo-osmotic Fluid

If both sides of an epithelium are bathed by isosmotic solutions, it is not possible to concentrate the fluid in the lumen. You might imagine that the epithelium could accomplish the task by absorbing a hypo-osmotic fluid. However, this would require absorbing more H_2O than solute, which would require H_2O transport to “lead” rather than to follow solute transport. Indeed, active transport of H_2O does not occur,  **N5-21** and H_2O cannot move against an osmotic gradient. Hypo-osmotic fluid absorption does indeed occur in the body but requires that the osmolality of the basolateral compartment exceed that of the apical compartment. As discussed on [p. 816](#), the medullary collecting duct uses this approach to concentrate the urine. The collecting duct absorbs a hypo-osmotic fluid because (1) the interstitial fluid in the renal medulla is hyperosmotic and (2) the H_2O permeability of the renal collecting duct is high due to the insertion of AQP2—under hormonal control—into the apical membrane.

Epithelia can regulate transport by controlling transport proteins, tight junctions, and the supply of the transported substances

A large range of physiological stimuli regulate the rates at which specific epithelia transport specific solutes. Virtually all known intracellular signaling cascades (see [Chapter 3](#)) have been implicated in mediating these regulatory effects. Ultimately, these cascades must affect the rates at which specific solutes move through transporters or channels.

Increased Synthesis (or Degradation) of Transport Proteins

One approach for modifying transport activity is to change the number of transport molecules in the cell. For example, the hormone aldosterone directly or indirectly increases the transcription rate of genes that encode Na-K pump subunits, thereby increasing Na-K pump synthesis in the distal nephron of the kidney.

Recruitment of Transport Proteins to the Cell Membrane

Cells can also change the functional activity of transporters by storing some of them in an intracellular organelle “pool” and then inserting them into the cell membrane. For example, histamine causes cytoplasmic “tubulovesicles” containing H-K pumps (the pool) to fuse with the apical membrane of gastric parietal cells, which initiates gastric acid secretion.

Post-translational Modification of Pre-existing Transport Proteins

Another approach for modulating the transporter rate is to change the activity of pre-existing transport proteins. For example, increases in the level of intracellular cAMP enhance the phosphorylation of apical membrane Cl^- channels that are involved in NaCl secretion by intestinal and airway epithelia. The cystic fibrosis gene product (CFTR) is a Cl^- channel whose function is regulated by phosphorylation. A defect in the regulation of apical membrane Cl^- channels is the primary physiological abnormality in cystic fibrosis.

Changes in the Paracellular Pathway

The passive movement of solutes across the tight junction can contribute to either “forward”

transepithelial movement of the solute or backleak of the solute, depending on the solute gradients. Thus, the epithelium can modulate net transport by changing the permeability of the paracellular pathway. For example, the Na^+ permeability of the tight junctions of the proximal tubule increases when ECF volume increases. This increase in the permeability of the paracellular pathway may lower net Na^+ reabsorption because of increased backleak of absorbed Na^+ from the lateral interspace, across the tight junction, and into the lumen.

Luminal Supply of Transported Species and Flow Rate

Changes in the concentration of transported solutes can have profound effects on rates of net solute transport. As fluid moves along the renal proximal tubule, for example, the very process of glucose absorption depletes glucose from the lumen and thereby slows further glucose absorption. Increasing the rate at which fresh high-glucose fluid enters the proximal-tubule lumen raises the glucose concentration at the site of glucose uptake and thus increases the rate of glucose absorption. In addition, flow itself—most likely sensed by bending of the central cilium (see [p. 43](#)) present at the apical membrane of most types of epithelial cells—can trigger signaling cascades resulting in alteration of transporter and channel function.

CHAPTER 6

Electrophysiology of the Cell Membrane

Edward G. Moczydlowski

Physics is concerned with the fundamental nature of matter and energy, whereas the goal of medical physiology is to understand the workings of living tissue. Despite their different perspectives, physics and physiology share common historical roots in the early investigations of charge and electricity. In the late 1700s, Luigi Galvani, a professor of anatomy in Bologna, Italy, used the leg muscles of a dissected frog to assay the presence of electrical charge stored in various ingenious devices that were the predecessors of modern capacitors and batteries. He observed that frog legs vigorously contracted when electrical stimulation was applied either directly to the leg muscle or to the nerves leading to the muscle ([Fig. 6-1](#)). Such early physiological experiments contributed to the development of electromagnetic theory in physics and electrophysiological theory in biology.

Early Electrophysiological Experiments of Galvani

Contributed by Ed Moczydlowski

Figure 6-1 in the text illustrates a well-known series of experiments by Luigi Galvani. **A**, Electrical stimulation of a dissected frog with diverse sources of electricity. On the center of the table is a board with a dissected frog that has been prepared for an experiment (Fig. Ω). A hand with a charged metal rod (G) is about to touch the sacral nerves (D), contracting the limbs (C). A metal wire (F) penetrates the spinal cord; a second metal wire (K) grounds the first wire to the floor. On the left side of the table (Fig. 1) is a large “electrical machine” with a rotating disk (A), a conductor (C), and a hand holding a metal rod (B) that is about to be charged. On the extreme left of the room (Fig. 2), a dissected frog is suspended from an iron wire that penetrates the spinal cord (F); the wire is attached to the wall by a hook. A hand with a charged metal rod (G) is touching the wire, stimulating the sacral nerves (D) and causing the legs (C) to twitch. Outside the room on the extreme right side (Fig. 3) is a frog in a glass jar (A). Emerging from the glass jar is an iron wire (B) that is attached at one end to a hook on the frog and ends in a hook (C) in the air. A silk loop (D) near this hook connects to a long conductor (F) that runs near the ceiling to a hook in the wall at the extreme left of the main room. At the far right/front of the table in the main room (Fig. 4) is a dissected frog with one conductor connected to a nerve (C) and another connected to a muscle (D). Just behind this frog (Fig. 5) is a “Leiden jar” (A) containing small lead shot used by hunters. A hand with a charged metal rod (C) is about to touch a conductor (B) emerging from the jar. To the left of the Leiden jar (Fig. 6) is an inverted jar (A) with lead shot (C). This jar sits on top of a similar jar (B) containing a suspended, dissected frog and is connected by a conductor to the lead shot in the upper jar. The legs of the frog are grounded to lead shot near the bottom of the jar. **B**, Electrical stimulation of the leg muscles of a dissected frog by “natural electricity” (i.e., lightning). In one experiment (Fig. 7), an iron wire (A) runs from near the roof, through several insulating glass tubes (B), to a flask (C) that contains a freshly dissected frog. A second wire (D) grounds the frog's legs to the water in the well. In a second experiment (Fig. 8), a noninsulated wire extends from an iron hook fastened to the wall and to the spinal cord of a frog (E), which is on a table coated with oil.

The phenomenon of “animal electricity” is central to the understanding of physiological processes. Throughout this book, we describe many basic functions of tissues and organs in terms of electrical signals mediated by cell membranes. Whereas electrical currents in a metal wire are conducted by the flow of electrons, electrical currents across cell membranes are carried by the major inorganic ions of physiological fluids: Ca^{2+} , Na^{+} , K^{+} , Cl^{-} , and HCO_3^{-} . Many concepts and terms used in cellular

electrophysiology are the same as those used to describe electrical circuits. At the molecular level, electrical current across cell membranes flows via three unique classes of integral membrane proteins (see [pp. 17–18](#)): ion channels, electrogenic ion transporters, and electrogenic ion pumps. The flow of ions via specific types of channels is the basis of electrical signals that underlie neuronal activity and animal behavior. Opening and closing of such channels is the fundamental process behind electrical phenomena such as the nerve impulse, the heartbeat, and sensory perception. Channel proteins are also intimately involved in hormone secretion, ionic homeostasis, osmoregulation, and regulation of muscle contractility.

This chapter begins with a review of basic principles of electricity and introduces the essentials of electrophysiology. We also discuss the molecular biology of ion channels and provide an overview of channel structure and function.

Ionic Basis of Membrane Potentials

Principles of electrostatics explain why aqueous pores formed by channel proteins are needed for ion diffusion across cell membranes

The plasma membranes of most living cells are electrically polarized, as indicated by the presence of a transmembrane voltage—or a **membrane potential**—in the range of 0.1 V. In [Chapter 5](#), we discussed how the energy stored in this miniature battery can drive a variety of transmembrane transport processes. Electrically excitable cells such as brain neurons and heart myocytes also use this energy for signaling purposes. The brief electrical impulses produced by such cells are called **action potentials**. To explain these electrophysiological phenomena, we begin with a basic review of electrical energy.

Atoms consist of negatively (−) and positively (+) charged elementary particles, such as electrons (e^-) and protons (H^+), as well as electrically neutral particles (neutrons). Charges of the same sign repel each other, and those of opposite sign attract. Charge is measured in units of **coulombs (C)**. The **unitary charge** of one electron or proton is denoted by e_0 and is equal to 1.6022×10^{-19} C. Ions in solution have a charge valence (z) that is an integral number of elementary charges. For example, $z = +2$ for Ca^{2+} , $z = +1$ for K^+ , and $z = -1$ for Cl^- . The charge of a single ion (q_0), measured in coulombs, is the product of its valence and the elementary charge:

$$q_0 = ze_0$$

(6-1)

In an aqueous solution or a bulk volume of matter, the number of positive and negative charges is always equal. Charge is also conserved in any chemical reaction.

The attractive electrostatic force between two ions that have valences of z_1 and z_2 can be obtained from Coulomb's law.  **N6-1** This **force (\mathcal{F})** is proportional to the product of these valences and inversely proportional to the square of the distance (a) between the two. The force is also inversely proportional to a dimensionless term called the **dielectric constant (ϵ_r)**:

N6-1

Coulomb's Law

Contributed by Ed Moczydlowski

The attractive electrostatic force between two charged particles of opposite sign and the repulsive electrostatic force between two charged particles of the same sign are described by **Coulomb's law**. The coulombic force between two interacting particles with charges of q_1 and q_2 is

$$\mathcal{F} = \frac{q_1 q_2}{4\pi\epsilon_r \epsilon_0 a^2}$$

(NE 6-1)

The above equation shows that the electrostatic force is directly proportional to the product of the charges and is inversely proportional to the square of the distance, a , between them. ϵ_0 is a physical constant called the **permittivity** of free space (or the vacuum permittivity) and is equal to $8.854 \times 10^{-12} \text{ C}^2\text{N}^{-1}\text{m}^{-2}$, where C is coulomb, N is newton, and m is meter. The denominator of the equation also includes a dimensionless parameter called the **dielectric constant** (ϵ_r), also known as the *relative* permittivity. The dielectric constant of a vacuum is defined as 1.0. The dielectric constant is a property that depends on the polarizability of the medium surrounding the two charges. Polarizability refers to the ability of molecules of the medium to orient themselves around ions to reduce electrostatic interactions. Polar water molecules are able to solvate ions effectively by orienting themselves around ions in solutions and thereby reducing coulombic forces between neighboring ions. The dielectric constant of water is therefore relatively high and has a value of ~ 80 . For a nonpolar hydrocarbon, such as decane or the alkyl-chain interior of a phospholipid bilayer, ϵ is comparatively low and has a value of ~ 2 .

$$\mathcal{F} \propto \frac{z_1 \cdot z_2}{\epsilon_r a^2}$$

(6-2)

Because the dielectric constant of water is ~ 40 -fold greater than that of the hydrocarbon interior of the cell membrane, the electrostatic force between ions is reduced by a factor of ~ 40 in water compared with membrane lipid.

If we were to move an Na^+ ion from the extracellular to the intracellular fluid without the aid of any proteins, the Na^+ would have to cross the membrane by “dissolving” in the lipids of the bilayer. However, the energy required to transfer an Na^+ ion from water (high ϵ) to the interior of a phospholipid membrane (low ϵ) is $\sim 36 \text{ kcal/mole}$. This value is 60-fold higher than molecular thermal energy at room temperature. Thus, the probability that an ion would dissolve in the bilayer (i.e., partition from an aqueous solution into the lipid interior of a cell membrane) is essentially zero. This analysis explains why inorganic ions cannot readily cross a phospholipid membrane without the aid of other molecules such as specialized transporters or channel proteins, which provide a favorable polar environment for the ion as it moves across the membrane (Fig. 6-2).

FIGURE 6-2 Formation of an aqueous pore by an ion channel. The dielectric constant of water ($\epsilon = 80$) is ~40-fold higher than the dielectric constant of the lipid bilayer ($\epsilon = 2$).

Membrane potentials can be measured with microelectrodes as well as dyes or fluorescent proteins that are voltage sensitive

The voltage difference across the cell membrane, or the **membrane potential (V_m)**, is the difference between the electrical potential in the cytoplasm (ψ_i) and the electrical potential in the extracellular space (ψ_o). [Figure 6-3A](#) shows how to measure V_m with an intracellular electrode. The sharp tip of a microelectrode is gently inserted into the cell and measures the transmembrane potential with respect to the electrical potential of the extracellular solution, defined as ground (i.e., $\psi_o = 0$). If the cell membrane is not damaged by electrode impalement and the impaled membrane seals tightly around the glass, this technique provides an accurate measurement of V_m . Such a voltage measurement is called an **intracellular recording**.

A MICROELECTRODE METHOD**B FLUORESCENT DYE METHOD****C MICROELECTRODE VERSUS DYE****D CELL BODY VERSUS PROCESSES**

FIGURE 6-3 Recording of membrane potential. (C and D, Data modified from Grinvald A: Real-time optical mapping of neuronal activity: From single growth cones to the intact mammalian brain. *Annu Rev Neurosci* 8:263–305, 1985. © Annual Reviews www.annualreviews.org. **N6-1**

For an amphibian or mammalian skeletal muscle cell, resting V_m is typically about -90 mV, which means that the interior of the resting cell is ~ 90 mV more negative than the exterior. There is a simple relationship between the electrical potential difference across a membrane and another parameter, the electric field (E): **N6-2**

N6-2**Electric Fields and Potentials**

Contributed by Ed Moczydlowski

A useful way to represent the electrical force (\mathcal{F}) acting on a charged particle is by the concept of an electric field. The *electric field* (E) is defined as the *force* that a particle with positive charge q_0 would sense in the vicinity of a charge source. Forces are vector parameters that are described by a magnitude and a direction. The direction of an electrostatic force is defined by the direction in which a positive charge would move: namely, away from a positively charged source or toward a negatively charged source. Similarly, the direction of an electric field is the direction in which a positive test charge would move within the field. The definition of an **electric field** is

$$E = \frac{\mathcal{F}}{q_0}$$

(NE 6-2)

Although the net charge of any bulk system must be equal to zero, other forms of energy, such as chemical energy, can be used to separate positive and negative charges. The **electrical potential (ψ)** describes the potential energy that arises from such a separation of charge. The **electrical potential difference ($\Delta\psi$)** is a measure of the work (W_{12}) needed to move a test charge q_0 between two points (1 and 2) in an electric field:

$$\Delta\psi = \psi_2 - \psi_1 = V = \frac{W_{12}}{q_0} = \frac{\text{joules}}{\text{coulombs}} = \text{volts}$$

The electrical potential difference (V) is measured in volts (i.e., joules per coulomb). Because work is also equal to force times distance, the electrical potential difference may also be expressed in terms of the magnitude of the force required to move a test charge (q_0) over a distance (d , in centimeters), along the same direction as the force. With the help of the preceding two equations, we can therefore define the electrical potential difference in terms of the electric field (volts per centimeter):

$$V = \frac{W_{12}}{q_0} = \frac{\mathcal{F} d}{q_0} = E d$$

(NE 6-4)

Thus, the voltage difference between two points is the product of electric field and the distance between those points. Conversely, the electric field is the voltage difference divided by the distance:

$$E = \frac{V}{d}$$

(NE 6-5)

$$E = \frac{V_m \leftarrow}{a \leftarrow} \begin{array}{l} \text{Electrical potential difference} \\ \text{across the membrane} \\ \text{Distance across the membrane} \end{array}$$

(6-3)

Accordingly, for a V_m of -0.1 V and a membrane thickness of $a = 4$ nm (i.e., 40×10^{-8} cm), the magnitude of the electric field is $\sim 250,000$ V/cm. Thus, despite the small transmembrane *voltage*, cell membranes actually sustain a very large electric *field*. Below, we discuss how this electric field influences the activity of a particular class of membrane signaling proteins called voltage-gated ion channels (see [pp. 182–199](#)).

Skeletal muscle cells, cardiac cells, and neurons typically have resting membrane potentials of approximately -60 to -90 mV; smooth-muscle cells have membrane potentials in the range of -55 mV;

and the V_m of the human erythrocyte is only about -9 mV. However, certain bacteria and plant cells have transmembrane voltages as large as -200 mV. For very small cells such as erythrocytes, small intracellular organelles such as mitochondria, and fine processes such as the synaptic endings of neurons, V_m cannot be directly measured with a microelectrode. Instead, spectroscopic techniques allow the membrane potentials of such inaccessible membranes to be measured indirectly (see Fig. 6-3B). Such techniques involve labeling of the cell or membrane with an appropriate organic dye molecule and monitoring of the absorption or fluorescence of the dye. The optical signal of the dye molecule can be independently calibrated as a function of V_m .

Another approach for monitoring changes in V_m optically is to use cells that express genetically engineered voltage-sensing proteins that have been coupled to a modified version of the jellyfish green fluorescent protein (GFP).  **N6-3** For their work on GFP, Osamu Shimomura, Martin Chalfie, and Roger Tsien shared the 2008 Nobel Prize in Chemistry.  **N6-4** Whether V_m is measured directly by a microelectrode or indirectly by a spectroscopic technique, virtually all biological membranes are found to have a nonzero membrane potential. This transmembrane voltage is an important determinant of any physiological transport process that involves the movement of charge.

N6-3

Measuring Membrane Potential with Fluorescent Proteins

Contributed by Ed Moczydlowski

Figure 6-3 illustrates well-established methods for measuring the membrane potential of cells with a sharp intracellular microelectrode connected to a voltage amplifier or with the use of voltage-sensitive membrane dyes that can be calibrated to known values of V_m . In recent years it has become possible to express a genetically engineered fluorescent voltage-sensing protein in a cell of interest and record changes in V_m such as neuronal action potential signals by measuring the fluorescence signal. This method became feasible with the discovery of proteins that exhibit natural fluorescence in the visible spectral region of light. One such fluorescent protein is the green fluorescent protein (GFP) of the luminescent jellyfish *Aequorea victoria*. The discovery, determination of the mechanism of fluorescence, and wide application of GFP in biotechnology was recognized with the awarding of the 2008 Nobel Prize in Chemistry to Osamu Shimomura, Martin Chalfie, and Roger Tsien.  **N6-4**

So that GFP could be used to measure V_m , the GFP gene was inserted into a nonconducting mutant of the *Drosophila* K^+ channel, *Shaker*. Expression of the GFP-tagged Shaker results in observable green fluorescence in the membrane of a transfected cell, which changes fluorescence intensity in response to changes in V_m . More recently, a pair of GFP variants called CYP for cyan (blue) and YFP for yellow fluorescent protein were fused to the C terminus of a voltage-sensor domain of a voltage-sensing phosphatase enzyme (Ci-VSP) of *Ciona intestinalis*. The voltage-sensing domain of VSP is homologous to the S1 to S4 domains of voltage-gated channels. Expression of such fluorescent Ci-VSP in neurons allows V_m changes corresponding to a fast action potential to be recorded optically. The mechanism of V_m measurement by these engineered proteins involves voltage-dependent conformational changes of the protein that result in a spectroscopic change of the fluorescent protein tag. With improvement of these methods, it should be possible to optically record electrical signals from cells of appropriately engineered transgenic animals. This technique thus has the potential to greatly advance understanding of cellular electrophysiology.

Measurements of V_m have shown that many types of cells are electrically excitable. Examples of excitable cells are neurons, muscle fibers, heart cells, and secretory cells of the pancreas. In such cells, V_m exhibits characteristic time-dependent changes in response to electrical or chemical stimulation. When the cell body, or soma, of a neuron is electrically stimulated, electrical and optical methods for measuring V_m detect an almost identical response at the cell body (see Fig. 6-3C). The optical method provides the additional insight that V_m changes are similar but delayed in the more distant neuronal processes inaccessible to a microelectrode (see Fig. 6-3D). When the cell is not undergoing such active responses, V_m usually remains at a steady value that is called the **resting potential**. In the next section, we discuss the origin of the membrane potential and lay the groundwork for understanding its active responses.

Membrane potential is generated by ion gradients

Chapter 5 introduced the concept that some integral membrane proteins are electrogenic transporters in that they generate an electrical current that sets up an electrical potential across the membrane. One class of electrogenic transporters includes the ATP-dependent *ion pumps*. These proteins use the energy of ATP hydrolysis to produce and to maintain concentration gradients of ions across cell membranes. In animal cells, the Na-K pump and Ca pump are responsible for maintaining normal gradients of Na^+ , K^+ , and Ca^{2+} . The reactions catalyzed by these ion transport enzymes are electrogenic because they lead to separation of charge across the membrane. For example, enzymatic turnover of the Na-K pump (see pp. 115–117) results in the translocation of three Na^+ ions out of the cell and two K^+ ions into the cell, with a net movement of one positive charge out of the cell. In addition to electrogenic pumps, cells may express *secondary active transporters* that are electrogenic, such as the Na/glucose cotransporter (see pp. 121–122).

It may seem that the inside negative V_m originates from the continuous pumping of positive charges out of the cell by the electrogenic Na-K pump. The resting potential of large cells—whose surface-to-volume ratio is so large that ion gradients run down slowly—is maintained for a long time even when metabolic poisons block ATP-dependent energy metabolism. This finding implies that an ATP-dependent pump is not the immediate energy source underlying the membrane potential. Indeed, the squid giant axon normally has a resting potential of -60 mV. When the Na-K pump in the giant axon membrane is specifically inhibited with a cardiac glycoside (see p. 117), the immediate positive shift in V_m is only 1.4 mV. Thus, in

most cases, the direct contribution of the Na-K pump to the resting V_m is very small.

In contrast, many experiments have shown that cell membrane potentials depend on ionic **concentration gradients**. In a classic experiment, Paul Horowicz and Alan Hodgkin measured the V_m of a frog muscle fiber with an intracellular microelectrode. The muscle fiber was bathed in a modified physiological solution in which SO_4^{2-} replaced Cl^- , a manipulation that eliminates the contribution of anions to V_m . In the presence of normal extracellular concentrations of K^+ and Na^+ for amphibians ($[\text{K}^+]_o = 2.5 \text{ mM}$ and $[\text{Na}^+]_o = 120 \text{ mM}$), the frog muscle fiber has a resting V_m of approximately -94 mV . As $[\text{K}^+]_o$ is increased above 2.5 mM by substitution of K^+ for Na^+ , V_m shifts in the positive direction. As $[\text{K}^+]_o$ is decreased below 2.5 mM , V_m becomes more negative (Fig. 6-4). For $[\text{K}^+]_o$ values $>10 \text{ mM}$, the V_m measured in Figure 6-4 is approximately a linear function of the *logarithm* of $[\text{K}^+]_o$. Numerous experiments of this kind have demonstrated that the *immediate* energy source of the membrane potential is not the active pumping of ions but rather the potential energy stored in the ion concentration gradients themselves. Of course, it is the ion pumps—and the secondary active transporters that derive their energy from these pumps—that are responsible for generating and maintaining these ion gradients.

FIGURE 6-4 Dependence of resting potential on extracellular K^+ concentration in a frog muscle fiber. The slope of the linear part of the curve is 58 mV for a 10-fold increase in $[\text{K}^+]_o$. Note that the horizontal axis for $[\text{K}^+]_o$ is plotted using a logarithmic scale. (Data from Hodgkin AL, Horowicz P: The influence of potassium and chloride ions on the membrane potential of single muscle fibers. *J Physiol* 148:127–160, 1959.)

One way to investigate the role of ion gradients in determining V_m is to study this phenomenon in an in vitro (cell-free) system. Many investigators have used an artificial model of a cell membrane called a **planar lipid bilayer**. This system consists of a partition with a hole $\sim 200 \mu\text{m}$ in diameter that separates two chambers filled with aqueous solutions (Fig. 6-5). It is possible to paint a planar lipid bilayer having

a thickness of only ~4 nm across the hole, thereby sealing the partition. By incorporating membrane proteins and other molecules into planar bilayers, one can study the essential characteristics of their function in isolation from the complex metabolism of living cells. Transmembrane voltage can be measured across a planar bilayer with a voltmeter connected to a pair of Ag/AgCl electrodes that are in electrical contact with the solution on each side of the membrane via salt bridges. This experimental arrangement is much like an intracellular voltage recording, except that both sides of the membrane are completely accessible to manipulation.

FIGURE 6-5 Diffusion potential across a planar lipid bilayer containing a K^+ -selective channel. [N6-28](#)

N6-28

Planar Lipid Bilayers

Contributed by Ed Moczydlowski

Planar bilayers can be readily formed by spreading a solution of phospholipids across a small hole in a thin plastic partition that separates two chambers filled with aqueous solution. The lipid solution seals the hole and spontaneously thins to produce a stable phospholipid bilayer. This artificial membrane, by itself, is structurally much like a cell membrane, except that it is completely devoid of protein. In the example in Figure 6-5, purified K^+ channels have been incorporated into the membrane. Because of the large K^+ gradient across this K^+ -permeable membrane, a transmembrane voltage of 92.4 mV (right-side negative) develops spontaneously across the membrane.

The ionic composition of the two chambers on opposite sides of the bilayer can be adjusted to simulate cellular concentration gradients. Suppose that we put 4 mM KCl on the left side of the bilayer and 155 mM KCl on the right side to mimic, respectively, the external and internal concentrations of K^+ for a mammalian muscle cell. To eliminate the osmotic flow of water between the two compartments (see p. 128), we also add a sufficient amount of a nonelectrolyte (e.g., mannitol) to the side with 4 mM KCl. **N6-5** We can make the membrane selectively permeable to K^+ by introducing purified K^+ channels or K^+ ionophores into the membrane. **N6-6** Assuming that the K^+ channels are in an open state and are impermeable to Cl^- , the right (“internal”) compartment quickly becomes electrically negative with respect to the left (“external”) compartment because positive charge (i.e., K^+) diffuses from high to low concentration. However, as the negative voltage develops in the right compartment, the negativity opposes further K^+ efflux from the right compartment. Eventually, the voltage difference across the membrane becomes so negative that further net K^+ movement halts. At this point, the system is in **equilibrium**, and the transmembrane voltage reaches a value of 92.4 mV, right-side negative. In the process of generating the transmembrane voltage, a separation of charge has occurred in such a way that the excess *positive* charge on the left side (low $[K^+]$) balances the same excess *negative* charge on the right side (high $[K^+]$). Thus, the stable voltage difference (−92.4 mV) arises from the separation of K^+ ions from their counterions (in this case Cl^-) across the bilayer membrane.

N6-5

An Impermeant Bilayer

Contributed by Ed Moczydlowski

If a totally impermeant bilayer were *not* separating the two solutions, the unequal concentrations of KCl would lead to diffusion of the salt in the direction of high to low $[KCl]$. However, by sealing the hole in the partition with a pure lipid bilayer having no permeability to K^+ or Cl^- , we ensure that the system does not have any separation of charge, and therefore the measured transmembrane voltage is 0 mV.

N6-6

Ionophores

Contributed by Ed Moczydlowski

We can create a perfectly K^+ -selective membrane by adding certain organic molecules, known as K^+ **ionophores**, to a planar lipid bilayer. Examples are valinomycin and gramicidin. These molecules have the ability to partition into bilayers and catalyze the diffusion of K^+ across phospholipid membranes. Valinomycin and gramicidin act by different mechanisms, but both allow a current of K^+ ions to flow

across membranes. **Valinomycin**, which is isolated from *Streptomyces fulvissimus*, is an example of a carrier molecule that binds K^+ and literally ferries it across the lipid bilayer. On the other hand, **gramicidin** catalyzes K^+ movement by the same basic mechanism that has been established for ion channel proteins in cell membranes. Gramicidin, a small, unusual peptide produced by *Bacillus brevis*, forms a water-filled pore across the membrane with a very small diameter (0.4 nm). The pore is small enough to permit only water molecules or K^+ ions to move through in single file. Both gramicidin and valinomycin share another property of channel proteins, called ionic selectivity. These ionophores are strongly cation selective: they accept certain inorganic cations but not Cl^- or other anions.

For mammalian cells, Nernst potentials for ions typically range from -100 mV for K^+ to $+100\text{ mV}$ for Ca^{2+}

The model system of a planar bilayer (impermeable membrane), unequal salt solutions (ionic gradient), and an ion-selective channel (conductance pathway) contains the minimal components essential for generating a membrane potential. The hydrophobic membrane bilayer is a formidable barrier to inorganic ions and is also a poor conductor of electricity. Poor conductors are said to have a high **resistance** to electrical current—in this case, ionic current. On the other hand, ion channels act as molecular conductors of ions. They introduce a **conductance pathway** into the membrane and lower its resistance.

In the planar-bilayer experiment of [Figure 6-5](#), V_m originates from the diffusion of K^+ down its concentration gradient. Membrane potentials that arise by this mechanism are called **diffusion potentials**. At equilibrium, the diffusion potential of an ion is the same as the equilibrium potential (E_x) given by the **Nernst equation** previously introduced as [Equation 5-8](#).

$$E_x = -\frac{RT}{z_x F} \ln \frac{[X]_i}{[X]_o}$$

(6-4)

The Nernst equation predicts the equilibrium membrane potential for any concentration gradient of a particular ion across a membrane. E_x is often simply referred to as the **Nernst potential**. The Nernst potentials for K^+ , Na^+ , Ca^{2+} , and Cl^- are written as E_K , E_{Na} , E_{Ca} , and E_{Cl} , respectively.

The linear portion of the plot of V_m versus the logarithm of $[K^+]_o$ for a frog muscle cell (see [Fig. 6-4](#)) has a **slope** that is $\sim 58.1\text{ mV}$ for a 10-fold change in $[K^+]_o$, as predicted by the Nernst equation. Indeed, if we insert the appropriate values for R and F into [Equation 6-4](#), select a temperature of 20°C , and convert the logarithm base e (\ln) to the logarithm base 10 (\log_{10}), we obtain a coefficient of -58.1 mV , and the Nernst equation becomes

$$E_K = (-58.1\text{ mV}) \log_{10} \frac{[K^+]_i}{[K^+]_o}$$

(6-5)

For a negative ion such as Cl^- , where $z = -1$, the sign of the slope is positive:

$$E_{\text{Cl}} = (+58.1 \text{ mV}) \log_{10} \frac{[\text{Cl}^-]_{\text{i}}}{[\text{Cl}^-]_{\text{o}}} \quad (6-6)$$

For Ca^{2+} ($z = +2$), the slope is half of -58.1 mV , or approximately -30 mV . Note that a Nernst slope of 58.1 mV is the value for a univalent ion at 20°C . For mammalian cells at 37°C , this value is 61.5 mV .

At $[\text{K}^+]_{\text{o}}$ values above $\sim 10 \text{ mM}$, the magnitude of V_{m} and the slope of the plot in [Figure 6-4](#) are virtually the same as those predicted by the Nernst equation (see [Equation 6-5](#)), which suggests that the resting V_{m} of the muscle cell is almost equal to the K^+ diffusion potential. When V_{m} follows the Nernst equation for K^+ , the membrane is said to behave like a potassium electrode because ion-specific electrodes monitor ion concentrations according to the Nernst equation.

[Table 6-1](#) lists the expected Nernst potentials for K^+ , Na^+ , Ca^{2+} , Cl^- , and HCO_3^- as calculated from the known concentration gradients of these physiologically important inorganic ions for mammalian skeletal muscle and typical nonmuscle cells. For a mammalian muscle cell with a V_{m} of -80 mV , E_{K} is $\sim 15 \text{ mV}$ more negative than V_{m} , whereas E_{Na} and E_{Ca} are about $+67$ and $+123 \text{ mV}$, respectively, far more positive than V_{m} . E_{Cl} is $\sim 9 \text{ mV}$ more negative than V_{m} in muscle cells but slightly more positive than the typical V_{m} of -60 mV in most other cells.

TABLE 6-1
Ion Concentration Gradients in Mammalian Cells

ION	OUT (mM)	IN (mM)	OUT/IN	E_X^* (mV)
Skeletal Muscle				
K^+	4.5	155	0.026	-95
Na^+	145	12	12	+67
Ca^{2+}	1.0	10^{-4}	10,000	+123
Cl^-	116	4.2	28	-89
HCO_3^-	24	12	2	-19
Most Other Cells				
K^+	4.5	120	0.038	-88
Na^+	145.4	15	9.67	+61
Ca^{2+}	1.0	10^{-4}	10,000	+123
Cl^-	116	20	5.8	-47
HCO_3^-	24	15	1.6	-13

*Nernst equilibrium potential of X at 37°C .

What determines whether the cell membrane potential follows the Nernst equation for K^+ or Cl^- rather than that for Na^+ or Ca^{2+} ? As we shall see in the next two sections, V_{m} depends on the relative permeabilities of the cell membrane to the various ions and the concentrations of ions on both sides of the membrane. Thus, the stability of V_{m} depends on the constancy of plasma ion concentrations—an important aspect of the homeostasis of the *milieu intérieur* (see [pp. 3–4](#)). Changes in the ionic composition of blood plasma can therefore profoundly affect physiological function. For example, conditions of low or high plasma $[\text{K}^+]$ —termed hypokalemia and hyperkalemia (see [pp. 792–793](#)), respectively—result in neurological and cardiac impairment (see [Box 37-1](#)) due to changes in V_{m} of excitable cells.

Currents carried by ions across membranes depend on the concentration of ions on both sides of the membrane, the

membrane potential, and the permeability of the membrane to each ion

Years before ion channel proteins were discovered, physiologists devised a simple but powerful way to predict the membrane potential, even if several different kinds of permeable ions are present at the same time. The first step, which we discuss in this section, is to compute an ionic current, that is, the movement of a single ion species through the membrane. The second step, which we describe in the following section, is to obtain V_m by summing the currents carried by each species of ion present, assuming that each species moves independently of the others.

The process of ion permeation through the membrane is called **electrodiffusion** because both electrical and concentration gradients are responsible for the ionic current. To a first approximation, the permeation of ions through most channel proteins behaves as though the flow of these ions follows a model based on the Nernst-Planck electrodiffusion theory, which was first applied to the diffusion of ions in simple solutions. This theory leads to an important equation in medical physiology called the constant-field equation, which predicts how V_m will respond to changes in ion concentration gradients or membrane permeability. Before introducing this equation, we first consider some important underlying concepts and assumptions.

Without knowing the molecular basis for ion movement through the membrane, we can treat the membrane as a “black box” characterized by a few fundamental parameters (Fig. 6-6). We must assume that the rate of ion movement through the membrane depends on (1) the external and internal concentrations of the ion X ($[X]_o$ and $[X]_i$, respectively), (2) the transmembrane voltage (V_m), and (3) a permeability coefficient for the ion X (P_X). In addition, we make four major assumptions about how the ion X behaves in the membrane:

1. The membrane is a homogeneous medium with a thickness a .
2. The voltage difference varies linearly with distance across the membrane (see Fig. 6-6). This assumption is equivalent to stating that the *electric field*—that is, the change in voltage with distance—is constant  **N6-2** throughout the thickness of the membrane. This requirement is therefore called the **constant-field assumption**.
3. The movement of an ion through the membrane is independent of the movement of any other ions. This assumption is called the **independence principle**.
4. The permeability coefficient P_X is a constant (i.e., it does not vary with the chemical or electrical driving forces). P_X (units: centimeters per second) is defined as $P_X = D_X \beta / a$. D_X is the diffusion coefficient for the ion in the membrane, β is the membrane/water partition coefficient for the ion, and a is the thickness of the membrane. Thus, P_X describes the ability of an ion to dissolve in the membrane (as described by β) and diffuse from one side to the other (as described by D_X) over the distance a .

FIGURE 6-6 Electrodiffusion model of the cell membrane.

With these assumptions, we can calculate the current carried by a single ion X (I_X) through the membrane by using the basic physical laws that govern (1) the movement of molecules in solution (Fick's law of diffusion; see [Equation 5-13](#)), (2) the movement of charged particles in an **electric field** (electrophoresis), and (3) the direct proportionality of current to voltage (Ohm's law). The result is the **Goldman-Hodgkin-Katz (GHK) current equation**, named after the pioneering electrophysiologists who applied the constant-field assumption to Nernst-Planck electrodiffusion:

$$I_X = \frac{z^2 F^2 V_m P_X}{RT} \left(\frac{[X]_i - [X]_o e^{(-zFV_m/RT)}}{1 - e^{(-zFV_m/RT)}} \right) \quad (6-7)$$

I_X , or the rate of ions moving through the membrane, has the same units as electrical current: amperes (coulombs per second). **N6-7** Thus, the GHK current equation relates the current of ion X through the membrane to the internal and external concentrations of X, the transmembrane voltage, and the permeability of the membrane to X. The GHK equation thus allows us to predict how the current carried by X depends on V_m . This **current-voltage (I - V) relationship** is important for understanding how ionic currents flow into and out of cells.

Calculating an Ionic Current from an Ionic Flow

Contributed by Ed Moczydlowski

On page 147 of the text, we pointed out that the current carried by ion X through the membrane (I_x) has the units of amperes, which is the same as **coulombs per second** (the coulomb is the fundamental unit of charge). In order to compute how many **moles per second** of X are passing through the membrane, we need to convert from coulombs to moles. We can compute a macroscopic quantity of charge by using a conversion factor called the Faraday (F). The Faraday is the charge (in coulombs) of a mole of univalent ions. Put another way, F is the product of the elementary charge (e_0 ; see p. 141) and Avogadro's number:

The Faraday	=	Elementary charge	×	Avogadro's number
F	=	e_0	×	N_0
	=	$(1.6022 \times 10^{-19} \text{ coulombs/electron})$		
		$\times (6.022 \times 10^{23} \text{ electrons/mole})$		
	=	$96,484 \text{ coulombs/mole}$		

(NE 6-6)

Thus, given an ionic current, we can easily compute the flow of the ion:

$$I_x = F (\text{flow of ion X})$$

(NE 6-7)

Figure 6-7A shows how the K^+ current (I_K) depends on V_m , as predicted by Equation 6-7 for the normal internal (155-mM) and external (4.5-mM) concentrations of K^+ . By convention, a current of ions flowing into the cell (**inward current**) is defined in electrophysiology as a negative-going current, and a current flowing out of the cell (**outward current**) is defined as a positive current. (As in physics, the direction of current is always the direction of movement of positive charge. This convention means that an inward flow of Cl^- is an outward current.) For the case of 155 mM K^+ inside the cell and 4.5 mM K^+ outside the cell, an inward current is predicted at voltages that are more negative than -95 mV and an outward current is predicted at voltages that are more positive than -95 mV (see Fig. 6-7A). The value of -95 mV is called the **reversal potential (V_{rev})**, because it is precisely at this voltage that the direction of current reverses (i.e., the net current equals zero). If we set I_K equal to zero in Equation 6-7 and solve for V_{rev} , we find that the GHK current equation reduces to the Nernst equation for K^+ (see Equation 6-5). Thus, the GHK current equation for an ion X predicts a reversal potential (V_{rev}) equal to the Nernst potential (E_X) for that ion; that is, the current is zero when the ion is in electrochemical equilibrium. At V_m values more negative than V_{rev} , the net driving force on a cation is inward; at voltages that are more positive than V_{rev} , the net driving force is outward. 🟡N6-8

FIGURE 6-7 Current-voltage relationships predicted by the GHK current equation. **A**, The solid curve is the K^+ current predicted from the GHK equation (see Equation 6-7)—assuming that the membrane is perfectly selective for K^+ —for a $[K^+]_i$ of 155 mM and a $[K^+]_o$ of 4.5 mM. The dashed line represents the current that would be expected if both $[K^+]_i$ and $[K^+]_o$ were 155 mM (Ohm's law). **B**, The solid curve is the Na^+ current predicted from the GHK equation—assuming that the membrane is perfectly selective for Na^+ —for an $[Na^+]_i$ of 12 mM and an $[Na^+]_o$ of 145 mM. The dashed line represents the current that would be expected if both $[Na^+]_i$ and $[Na^+]_o$ were 145 mM.

N6-8

Shape of the I - V Relationship

Contributed by Ed Moczydlowski

In the text, we introduced the **GHK current equation** as Equation 6-7 (shown here as Equation NE 6-8):

$$I_X = \frac{z^2 F^2 V_m P_X}{RT} \left(\frac{[X]_i - [X]_o e^{(-zFV_m/RT)}}{1 - e^{(-zFV_m/RT)}} \right)$$

(NE 6-8)

In the nonphysiological case in which $[K^+]_i$ and $[K^+]_o$ are equal to $[K^+]$, the above equation reduces to

$$I_K = \frac{z^2 F^2 V_m P_X}{RT} [K^+]$$

(NE 6-9)

In this case, the relationship between the K^+ current (I_K) and V_m should be a straight line that passes through the origin, as shown by the dashed line in Figure 6-7A.

Similarly, in the nonphysiological case in which $[Na^+]_i$ and $[Na^+]_o$ are equal to $[Na^+]$, the GHK current equation reduces to

$$I_{Na} = \frac{z^2 F^2 V_m P_X [Na^+]}{RT}$$

(NE 6-10)

Again, the preceding equation predicts that the relationship between the Na^+ current (I_{Na}) and V_m also should be a straight line, as shown by the dashed line in Figure 6-7B in the text. These relationships are “**ohmic**” because they follow Ohm's law: $\Delta I = \Delta V/R$, **NE-31** where R in this equation represents **resistance**. Thus, the slope of the line is $1/R$ or the conductance:

$$\text{Current} = \text{Conductance} \times \text{Voltage}$$

(NE 6-11)

Comparing the above equation with the two that precede it, we see that—for the special case in which the ion concentrations ($[X]$) are identical on both sides of the membrane—the **conductance** is

$$\frac{z^2 F^2 P_X [X]}{RT}$$

(NE 6-12)

Thus, according to the GHK current equation, the membrane's conductance to an ion is proportional to the membrane's permeability and also depends on ion concentration.

What does the GHK current equation predict for more realistic examples in which $[K^+]_i$ greatly exceeds $[K^+]_o$, or $[Na^+]_i$ is much lower than $[Na^+]_o$? The solid curve in Figure 6-7A in the text is the prediction of the GHK current equation for the normal internal (155 mM) and external (4.5 mM) concentrations of K^+ . By convention, a current of ions flowing into the cell (**inward current**) is defined in electrophysiology as a negative-going current, and a current flowing out of the cell (**outward current**) is defined as a positive current. (As in physics, the direction of current is always the direction of movement of positive charge. This means that an inward flow of Cl^- is an outward current.) The nonlinear behavior of the I - V relationship in Figure 6-7A in the text is solely due to the asymmetric internal and external concentrations of K^+ . Because K^+ is more concentrated inside than outside, the *outward* K^+ currents will tend to be larger than the *inward* K^+ currents. That is, the K^+ current will tend to exhibit **outward rectification**, as shown by the solid I - V curve in Figure 6-7A. Such I - V rectification is known as **Goldman rectification**. It is due solely to asymmetric ion concentrations and does not reflect an asymmetric behavior of the channels through which the ion moves.

For the case of 155 mM K^+ inside the cell and 4.5 mM K^+ outside the cell, the GHK current equation predicts an inward current at voltages more negative than -95 mV and an outward current for voltages more positive than -95 mV. The value of -95 mV is called the **reversal potential** (V_{rev}) because it is precisely at this voltage that the direction of current reverses (i.e., the net current equals zero). If we set

I_K equal to zero in the GHK current equation and solve for V_{rev} , we find that this rather complicated equation reduces to the Nernst equation for K^+ (see Equation 6-5 in the text, shown here as Equation NE 6-13):

$$E_K = (-58.1 \text{ mV}) \log_{10} \frac{[K^+]_i}{[K^+]_o}$$

(NE 6-13)

Thus, the GHK current equation for an ion X predicts a reversal potential (V_{rev}) equal to the Nernst potential (E_X) for that ion; that is, the current is zero when the ion is in electrochemical equilibrium. At voltages more negative than V_{rev} , the net driving force on a cation is inward; at voltages more positive than V_{rev} , the net driving force is outward.

Figure 6-7B in the text shows a similar treatment for Na^+ . Again, the dashed line that passes through the origin refers to the artificial situation in which $[Na^+]_i$ and $[Na^+]_o$ are each equal to 145 mM. This line describes an ohmic relationship. The solid curve in Figure 6-7B shows the I - V relationship for a physiological set of Na^+ concentrations: $[Na^+]_o = 145 \text{ mM}$, $[Na^+]_i = 12 \text{ mM}$. The relationship is nonlinear solely because of the asymmetric internal and external concentrations of Na^+ . Because Na^+ is more concentrated outside than inside, the *inward* Na^+ currents will tend to be larger than the *outward* Na^+ currents. That is, the Na^+ current will tend to exhibit **inward rectification**. Again, such I - V rectification is known as Goldman rectification.

N6-31

Ohmic I - V Curve

Contributed by Ed Moczydlowski

According to Ohm's law ($I = V/R$), the I - V relationship is a straight line if $1/R$ (i.e., the conductance) is constant. The slope is positive. For a simple electrical circuit consisting of a resistor and a voltage source, the line passes through the origin (i.e., $I = 0$ when $V = 0$). However, if the Na^+ current (I_{Na}) were ohmic (i.e., we assume that the $[Na^+]$ is the same on both sides of the membrane), I_{Na} is zero when the driving force ($V_m - E_{Na}$) is zero (see Equation 7-2 on p. 180 of the text). Therefore, the I - V plot for an Na^+ current passes through the x-axis at the equilibrium potential for Na^+ (E_{Na}).

In real-life situations, the I - V curve for Na^+ currents is much more complicated, following the Goldman-Hodgkin-Katz current equation, as discussed in 🔥N6-8.

Figure 6-7B shows the analogous I - V relationship predicted by Equation 6-7 for physiological concentrations of Na^+ . In this case, the Na^+ current (I_{Na}) is inward at V_m values more negative than V_{rev} (+67 mV) and outward at voltages that are more positive than this reversal potential. Here again, V_{rev} is the same as the Nernst potential, in this case, E_{Na} .

Membrane potential depends on ionic concentration gradients

and permeabilities

In the preceding section, we discussed how to use the GHK current equation to predict the current carried by any *single* ion, such as K^+ or Na^+ . If the membrane is permeable to the monovalent ions K^+ , Na^+ , and Cl^- —and only to these ions—the **total ionic current** carried by these ions across the membrane is the sum of the individual ionic currents:

$$I_{\text{total}} = I_K + I_{Na} + I_{Cl} \quad (6-8)$$

The individual ionic currents given by Equation 6-7 can be substituted into the right-hand side of Equation 6-8. Note that for the sake of simplicity, we have not considered currents carried by electrogenic pumps or other ion transporters; we could have added extra “current” terms for such electrogenic transporters. At the resting membrane potential (i.e., V_m is equal to V_{rev}), the sum of all ion currents is zero (i.e., $I_{\text{total}} = 0$). When we set I_{total} to zero in the expanded Equation 6-8 and solve for V_{rev} , we get an expression known as the **GHK voltage equation** or the **constant-field equation**:

$$V_{\text{rev}} = \frac{RT}{F} \ln \left(\frac{P_K [K^+]_o + P_{Na} [Na^+]_o + P_{Cl} [Cl^-]_i}{P_K [K^+]_i + P_{Na} [Na^+]_i + P_{Cl} [Cl^-]_o} \right) \quad (6-9)$$

Because we derived Equation 6-9 for the case of $I_{\text{total}} = 0$, it is valid only when zero net current is flowing across the membrane. This zero net current flow is the steady-state condition that exists for the cellular *resting* potential, that is, when V_m equals V_{rev} . The logarithmic term of Equation 6-9 indicates that resting V_m depends on the concentration gradients and the permeabilities of the various ions. However, resting V_m depends primarily on the concentrations of the most permeant ion. **N6-9**

N6-9 Contribution of Ions to Membrane Potential

Contributed by Ed Moczydlowski

In the text, we introduced Equation 6-9 (shown here as Equation NE 6-14)

$$V_{\text{rev}} = \frac{RT}{F} \ln \left(\frac{P_K [K^+]_o + P_{Na} [Na^+]_o + P_{Cl} [Cl^-]_i}{P_K [K^+]_i + P_{Na} [Na^+]_i + P_{Cl} [Cl^-]_o} \right) \quad (\text{NE 6-14})$$

and pointed out that the resting V_m depends mostly on the concentrations of the most permeant ion. This last statement is only true on the condition that the most permeant ion is also present at a reasonable

concentration. It would be more precise to state that V_m depends on a series of *permeability-concentration products*. Thus, an ion contributes to V_m to the extent that its *permeability-concentration product* dominates the above equation. An interesting example is the H^+ ion, which we omit from Equation NE 6-14. Although its permeability P_H may be quite high in some cells, H^+ concentrations on both sides of the membrane are usually extremely low (at a pH of 7, $[H^+]$ is $10^{-7}M$). Thus, even though P_H may be large, the product $P_H \times [H^+]$ is usually negligibly small, so that H^+ usually does not contribute noticeably to V_m via a $P_H \times [H^+]$ term, which is why we omitted it from the above equation.

The principles underlying Equation 6-9 show why the plot of V_m versus $[K^+]_o$ in Figure 6-4—which summarizes data obtained from a frog muscle cell—bends away from the idealized Nernst slope at very low values of $[K^+]_o$. Imagine that we expose a mammalian muscle cell to a range of $[K^+]_o$ values, always substituting extracellular K^+ for Na^+ , or vice versa, so that the sum of $[K^+]_o$ and $[Na^+]_o$ is kept fixed at its physiological value of $4.5 + 145 = 149.5$ mM. To simplify matters, we assume that the membrane permeability to Cl^- is very small (i.e., $P_{Cl} \cong 0$). We can also rearrange Equation 6-9 by dividing the numerator and denominator by P_K and representing the ratio P_{Na}/P_K as α . At $37^\circ C$, this simplified equation becomes

$$V_{rev} = (61.5mV) \times \log_{10} \left(\frac{[K^+]_o + \alpha[Na^+]_o}{[K^+]_i + \alpha[Na^+]_i} \right) \quad (6-10)$$

Figure 6-8 shows that when α is zero—that is, when the membrane is impermeable to Na^+ —Equation 6-10 reduces to the Nernst equation for K^+ (see Equation 6-4), and the plot of V_m versus the logarithm of $[K^+]_o$ is linear. If we choose an α of 0.01, however, the plot bends away from the ideal at low $[K^+]_o$ values. This bend reflects the introduction of a slight permeability to Na^+ . As we increase this P_{Na} further by increasing α to 0.03 and 0.1, the curvature becomes even more pronounced. Thus, as predicted by Equation 6-10, increasing the permeability of Na^+ relative to K^+ tends to shift V_m in a positive direction, toward E_{Na} . In some skeletal muscle cells, an α of 0.01 best explains the experimental data.

FIGURE 6-8 Dependence of the resting membrane potential on $[K^+]_o$ and on the P_{Na}/P_K ratio, α . The blue line describes the instance in which there is no Na^+ permeability (i.e., $P_{Na}/P_K = 0$). The three orange curves describe the V_m predicted by Equation 6-10 for three values of α greater than zero and assumed values of $[Na^+]_o$, $[Na^+]_i$, and $[K^+]_i$ for skeletal muscles, as listed in Table 6-1. The deviation of these orange curves from linearity is greater at low values of $[K^+]_o$, where the $[Na^+]_o$ is relatively larger.

The constant-field equation (see Equation 6-9) and simplified relationships derived from it (e.g., Equation 6-10) show that steady-state V_m depends on the concentrations of all permeant ions, weighted according to their relative permeabilities. Another very useful application of the constant-field equation is determination of the ionic selectivity of channels. For example, when $[K^+]_o$ is in the normal range, a particular K^+ channel in human cardiac myocytes (i.e., the TWIK-1 K2P channel introduced below in Table 6-2 and Fig. 6-20F) has an extremely low α —as we could calculate from V_{rev} and the ion concentrations using Equation 6-10. However, under conditions of hypokalemia (plasma $[K^+] < 3.5$ mM), α becomes substantially larger, which causes a depolarization that can trigger cardiac arrhythmias that may lead to cardiac arrest and sudden death. **N6-10**

TABLE 6-2

Major Families of Human Ion-Channel Proteins

CHANNEL FAMILY	DESCRIPTION AND SUBFAMILIES	HUMAN GENE SYMBOLS (NUMBER OF GENES): PROTEIN NAMES	NOTED PHYSIOLOGICAL FUNCTIONS	KNOWN HUMAN GENETIC AND AUTOIMMUNE DISEASES	NOTES FOR TOPOLOGY FIGURE
1. Connexin channels	Hexameric gap junction channels	<i>GJA</i> (7)	Cell-cell communication, electrical coupling and cytoplasmic diffusion of molecules between interconnected cells; mediate Ca^{2+} waves of coupled cells	<i>GJA1</i> : oculodentodigital dysplasia <i>GJA3</i> , 8: congenital cataract <i>GJA5</i> : familial atrial standstill and fibrillation	Hexamer of 4-TM subunits (Fig. 6-20A)
		<i>GJB</i> (7)		<i>GJB1</i> : Charcot-Marie-Tooth disease <i>GJB2</i> , 3, 6: keratitis-ichthyosis-deafness syndrome <i>GJB3</i> , 4: erythrokeratoderma variabilis	
		<i>GJC</i> (3) <i>GJD</i> (3) <i>GJE</i> (1)		<i>GJC2</i> : spastic paraplegia, lymphedema	

2. Potassium channels (canonical members of VGL channel superfamily)	Homo- or heterotetrameric voltage-gated channels (Kv channels)	<i>KCNA</i> (8): Shaker-related or Kv1 <i>KCNB</i> (2): Shab-related or Kv2	Electrical signaling; repolarization of action potentials; frequency encoding of action potentials	<i>KCNA1</i> : episodic ataxia 1 and myokymia 1 <i>KCNA5</i> : atrial fibrillation 7	Tetramer of 6-TM subunits (Fig. 6-20B)
		<i>KCNC</i> (4): Shaw-related or Kv3		<i>KCNC3</i> : spinocerebellar ataxia 3	
		<i>KCND</i> (3): Shal-related or Kv4 <i>KCNF</i> (1): modulatory <i>KCNG</i> (4): modulatory			
		<i>KCNH</i> (8): eag-related	<i>KCNH2</i> (cardiac HERG): promiscuously drug-sensitive K ⁺ channel responsible for acquired long QT syndrome	<i>KCNH2</i> : long QT syndrome 2, short QT syndrome 1	
		<i>KCNQ</i> (5): KvLQT-related		<i>KCNQ1</i> (cardiac KvLQT1): long QT syndrome 1, Romano-Ward syndrome, Jervell and Lange-Nielsen syndrome 1 and congenital deafness, atrial fibrillation 3, short QT syndrome 2 <i>KCNQ2</i> , 3: benign familial neonatal seizures, early infantile epileptic encephalopathy 7 <i>KCNQ4</i> : deafness 2A	
		<i>KCNS</i> (3): modulatory			
		<i>KCNV</i> (2)		<i>KCNV2</i> : cone dystrophy with night blindness	
	Tetrameric small- and intermediate-conductance Ca ²⁺ -activated K ⁺ channels	<i>KCNN</i> (4) <i>KCNN1</i> , 2, 3: SK _{Ca} 1, 2, 3 = K _{Ca} 2.1, 2.2, 2.3 <i>KCNN4</i> : IK _{Ca} = SK _{Ca} 4 = K _{Ca} 3.1	Repolarization of APs; slow phase of AP afterhyperpolarization; regulation of AP interspike interval and firing frequency; activated by Ca ²⁺ -calmodulin; voltage-insensitive		Tetramer of 6-TM subunits (Fig. 6-20C)
	Tetrameric large-conductance Ca ²⁺ -, Na ⁺ -, or H ⁺ -activated K ⁺ channels	<i>KCNMA</i> (1): K _{Ca} 1.1 = Slo1 = BK _{Ca}	Slo1 (BK _{Ca}): voltage- and Ca ²⁺ -activated K ⁺ channel; mediation of fast component of AP afterhyperpolarization; feedback regulation of contractile tone of smooth muscle; feedback regulation release of neurotransmitters at nerve terminals and auditory hair cells	<i>KCNMA1</i> : generalized epilepsy and paroxysmal dyskinesia	Tetramer of 7-TM subunits (Fig. 6-20D)
		<i>KCNT1</i> (1): K _{Ca} 4.1 = Slo2.1 = Slick <i>KCNT2</i> (1): K _{Ca} 4.2 = Slo2.2 = Slack	Slo2.1 (Slick) and Slo2.2 (Slack): low intrinsic voltage dependence and synergistically activated by internal Na ⁺ and Cl ⁻		
		<i>KCNU</i> (1): KCa5.1 = Slo3	Slo3: activated by voltage and internal pH; involved in sperm capacitation and acrosome; exclusively expressed in spermatocytes and mature spermatozoa		
	Homo- or heterotetrameric inward-rectifier channels	<i>KCNJ</i> (16): Kir	Genesis and regulation of resting membrane potential, regulation of electrical excitability		Tetramer of 2-TM subunits (Fig. 6-20E)
		<i>KCNJ1</i> , 10, 13: Kir1.1 = ROMK1, Kir1.2, 1.4	Renal outer medullary K ⁺ channel	<i>KCNJ1</i> : Bartter syndrome 2 <i>KCNJ10</i> : SESAME complex disorder <i>KCNJ13</i> : snowflake vitreoretinal degeneration	
		<i>KCNJ2</i> , 12, 4, 14: Kir2.1, 2, 3, 4 = IRK1, 2, 3, 4	IRK: strong inward rectifiers; blocked by intracellular Mg ²⁺ and polyamines, activated by PIP ₂	<i>KCNJ2</i> : long QT syndrome 7 (Anderson syndrome), short QT syndrome 3, atrial fibrillation 9	
		<i>KCNJ3</i> , 6, 9, 5: Kir3.1, 2, 3, 4 = GIRK1, 2, 3, 4	GIRK: G protein-coupled K ⁺ channels	<i>KCNJ5</i> : long QT syndrome 13, familial hyperaldosteronism 3	
		<i>KCNJ8,11</i> : Kir6.1, 2 = K _{ATP}	K _{ATP} : coupling of metabolism to excitability, release of insulin in pancreas	<i>KCNJ11</i> : familial persistent hyperinsulinemic hypoglycemia 2, neonatal diabetes mellitus	
		<i>KCNJ18</i> : Kir2.6		<i>KCNJ18</i> : thyrotoxic hypokalemic periodic paralysis	
	Dimeric 2-TM tandem two-pore channels	<i>KCNK</i> (15): K2P <i>KCNK1</i> : TWIK-1	Genesis and regulation of resting membrane potential; regulation of AP firing frequency; sensory perception of touch, stretch, and temperature; involved in mechanism of general anesthesia; activated by chloroform, halothane, heat, internal pH, PIP ₂ , fatty acids, G proteins	<i>KCNK9</i> : Birk-Barel mental retardation syndrome <i>KCNK18</i> : Migraine with or without aura 13	Dimer of 4-TM subunits (Fig. 6-20F)
3. Hyperpolarization-activated cyclic	Tetrameric cation-selective HCN channels	<i>HCN</i> (4)	Na ⁺ /K ⁺ selective, cAMP- and cGMP-activated, I _f current in heart; hyperpolarization-activated I _h current in heart and neurons; generation of AP automaticity in heart and CNS neurons; mediate	<i>HCN4</i> : sick sinus syndrome 2, Brugada syndrome 8 (tachyarrhythmia)	Tetramer of 6-TM subunits (Fig. 6-20G)

nucleotide-gated cation channels (VGL superfamily member)			depolarizing current that triggers the next AP in rhythmically firing cells		
4. Cyclic nucleotide-gated cation channels (VGL superfamily member)	Tetrameric CNG channels	<i>CNGA</i> (4)	Cation nonselective channels permeable to Na ⁺ , K ⁺ , and Ca ²⁺ ; sensory transduction mechanism in vision, and olfaction, cGMP- and cAMP-gated cation-selective channels in rods, cones, and olfactory receptor neurons	<i>CNGA1</i> , <i>CNGB1</i> : retinitis pigmentosa <i>CNGA3</i> : achromatopsia 2 (total colorblindness)	Tetramer of 6-TM subunits (Fig. 6-20H)
		<i>CNGB</i> (2)		<i>CNGB3</i> : Stargardt disease 1 (macular degeneration), achromatopsia 3	
5. Transient receptor potential cation channels (VGL superfamily member)	Tetrameric TRP channels	<i>TRPA</i> (1)	Cation nonselective channels permeable to Na ⁺ , K ⁺ , and Ca ²⁺ ; involved in polymodal sensory transduction of pain, itch, thermosensation, various chemicals, osmotic and mechanical stress, taste (TRPM5); TRPV family is also called the vanilloid receptor family, which includes the capsaicin receptor (TRPV1); TRPM8 is the menthol receptor	<i>TRPA1</i> : familial episodic pain syndrome	Tetramer of 6-TM subunits (Fig. 6-20I)
		<i>TRPC</i> (6)		<i>TRPC6</i> : focal segmental glomerulosclerosis (proteinuric kidney disease)	
		<i>TRPV</i> (6)		<i>TRPV4</i> : hereditary motor and sensory neuropathy	
		<i>TRPM</i> (8)		<i>TRPM1</i> : congenital stationary night blindness <i>TRPM4</i> : progressive familial heart block <i>TRPM6</i> , 7: hypomagnesia with secondary hypocalcemia	
		<i>PKD</i> (3)		<i>PKD1</i> , 2, 3: polycystic kidney disease	
		<i>MCOLN</i> (3)		<i>MOCLN1</i> : mucopolipidosis IV	
6. NAADP receptor Ca ²⁺ -release channels (VGL superfamily member)	Dimeric 6-TM tandem two-pore Ca ²⁺ channels (related to TRP, CatSper, and Cav channels)	<i>TPCN</i> (2)	Ca ²⁺ -selective channels activated by NAADP that mediate release of Ca ²⁺ from acidic stores and lysosomes	<i>TPCN2</i> : Genetic differences are linked to variations in human skin, hair, and eye pigmentation	Dimer of 12-TM subunits (Fig. 6-20J)
7. Voltage-gated sodium channels (VGL superfamily member) (see Table 7-1)	Pseudo-tetrameric voltage-gated channels (Nav channels)	<i>SCN</i> (10): Nav	Na ⁺ selective, voltage-activated channels that mediate the depolarizing upstroke of propagating APs in neurons and muscle; blocked by local anesthetics <i>SCN7A</i> (Nax, Nav2.1) senses plasma [Na ⁺] in brain circumventricular organs	<i>SCN1A</i> : generalized epilepsy with febrile seizures <i>SCN2A</i> : infantile epileptic encephalopathy <i>SCN4A</i> : hyperkalemic periodic paralysis, paramyotonia congenita, potassium-aggravated myotonia <i>SCN5A</i> : cardiac long QT syndrome 3 <i>SCN9A</i> : primary erythralgia, paroxysmal extreme pain disorder, congenital indifference to pain	Monomer of 4 × 6 TMs (Fig. 6-20K)
8. Voltage-gated calcium channels (VGL superfamily member) (see Table 7-2)	Pseudo-tetrameric voltage-gated channels (Cav channels)	<i>CACNA</i> (10): Cav	<i>CACNA</i> genes encode Ca ²⁺ -selective, voltage-activated channels that mediate prolonged depolarizing phase of APs in muscle and neurons; entry of Ca ²⁺ via Cav triggers release of transmitter and hormone secretion; molecular target of Ca-blocker drugs	<i>CACNA1A</i> : episodic ataxia 2, familial hemiplegic migraine, spinocerebellar ataxia 6 <i>CACNA1A</i> , 1B: antibodies to channel proteins cause Lambert-Eaton syndrome <i>CACNA1C</i> : Timothy syndrome arrhythmia, Brugada syndrome 3 <i>CACNA1F</i> : congenital stationary night blindness, X-linked cone-rod dystrophy 3 <i>CACNA1H</i> : idiopathic generalized epilepsy 6 <i>CACNA1S</i> : hypokalemic periodic paralysis, malignant hyperthermia	Monomer of 4 × 6 TMs (Fig. 6-20L)
		<i>NALCN</i> (1): Na ⁺ leak	<i>NALCN</i> gene encodes a voltage-insensitive cation channel that mediates a resting Na ⁺ leak current in neurons		
9. CatSper cation channels of sperm (VGL superfamily member)	Heterotetrameric 6-TM voltage-gated Ca ²⁺ -selective channels of sperm	<i>CATSPER</i> (4)	Essential for hyperactivation of sperm cell motility; located in sperm tail membrane; activated by high pH; required for male fertility	<i>CATSPER1</i> : spermatogenic failure <i>CATSPER2</i> : deafness-infertility syndrome	Tetramer of 6-TM subunits (Fig. 6-20M)
10. Hv voltage-gated proton channels (VGL superfamily member)	Dimeric 4-TM H ⁺ channels	<i>HVCN1</i>	4-TM monomer is similar to S1–S4 region of voltage-gated channels; mediates H ⁺ efflux from sperm flagellum, innate immune function of neutrophils where H ⁺ efflux compensates outward charge movement of electrons via NADPH oxidase in phagocytes; inhibited by Zn ²⁺		Dimer of 4-TM subunits (Fig. 6-20N)
11. Ligand-gated ion channels (pentameric Cys-loop receptor superfamily)	Pentameric nicotinic, cholinergic ionotropic receptors	<i>CHRNA</i> (10): α subunits <i>CHRNB</i> (4): β subunits <i>CHRNA</i> (1): γ subunits <i>CHRNA</i> (1): δ	Na ⁺ , K ⁺ non-selective cation channels activated by binding of ACh; mediate depolarizing postsynaptic potentials, EPSPs; site of action of nicotine	<i>CHCRNA1</i> , B1, E, D: slow-channel syndromes, fast-channel syndromes <i>CHRNA2</i> , A4, B2: nocturnal frontal lobe epilepsy <i>CHRNA1</i> : antibodies to channel proteins cause	Pentamer of 4-TM subunits (Fig. 6-20O)

		subunits <i>CHRNE</i> (1): ϵ subunits		myasthenia gravis	
	Pentameric serotonin 5HT ₃ ionotropic receptors	<i>HTR3A</i> (1) <i>HTR3B</i> (1) <i>HTR3C</i> (1) <i>HTR3D</i> (1) <i>HTR3E</i> (1)	Na ⁺ , K ⁺ nonselective, cation channels activated by binding of serotonin; mediate depolarizing postsynaptic potentials, EPSPs		Same as above
	Pentameric GABA _A ionotropic receptors	<i>GABRA</i> (6) <i>GABRB</i> (3) <i>GABRD</i> (1) <i>GABRE</i> (1) <i>GABRG</i> (3) <i>GABRP</i> (1) <i>GABRQ</i> (1) <i>GABRR</i> (3)	Cl ⁻ -selective anion channels activated by binding of GABA; mediate hyperpolarizing postsynaptic potentials, IPSPs; site of action of benzodiazepines and barbiturates		Same as above
	Pentameric glycine ionotropic receptors	<i>GLRA</i> (4) <i>GLRB</i> (1)	Cl ⁻ -selective anion channels activated by binding of glycine; mediate IPSPs	<i>GLRA1</i> , <i>1B</i> : hyperekplexia or startle disease	Same as above
12. Glutamate-activated cation channels (see Fig. 13-15 and Table 13-2)	Tetrameric AMPA receptor cation-selective channels	<i>GRIA</i> (4) <i>GRIA1</i> , 2, 3, 4: GluR1, 2, 3, 4 = GluA1, 2, 3, 4	Na ⁺ , K ⁺ nonselective cation channels activated by binding of glutamate; mediate depolarizing postsynaptic potentials, EPSPs; involved in long-term potentiation of neuronal memory		Tetramer of 3-TM subunits (Fig. 6-20P)
	Tetrameric kainate receptor cation-selective channels	<i>GRIK</i> (5) <i>GRIK1</i> : GluR5 = GluK1 <i>GRIK2</i> : GluR6 = GluK2 <i>GRIK3</i> : GluR7 = GluK3 <i>GRIK4</i> : KA1 = GluK4 <i>GRIK5</i> : KA2 = GluK5	Same as above		
	Tetrameric NMDA receptor cation-selective channels	<i>GRIN</i> (7) <i>GRIN1</i> : NR1 = GluN1 <i>GRIN2A</i> : NR2A = GluN2A <i>GRIN2B</i> : NR2B = GluN2B <i>GRIN2C</i> : NR2C = GluN2C <i>GRIN2D</i> : NR2D = GluN2D <i>GRIN3A</i> : NR3A = GluN3A <i>GRIN3B</i> : NR3B = GluN3B	Same as above but also permeable to Ca ²⁺		Same as above
13. Purinergic ligand-gated cation channels	Trimeric P2X receptor cation channels	<i>P2RX</i> (7) <i>P2RX1</i> , 2, 3, 4, 5, 6, 7: P2X1, P2X2, P2X3, P2X4, P2X5, P2X6, P2X7	ATP-activated cation channels permeable to Na ⁺ , K ⁺ , Ca ²⁺ ; involved in excitatory synaptic transmission and nociception, regulation of blood clotting; channel activated by synaptic co-release of ATP in catecholamine-containing synaptic vesicles		Trimer of 2-TM subunits (Fig. 6-20Q)
14. Epithelial sodium channels/degenerins	Heterotrimeric ENaC epithelial amiloride-sensitive Na ⁺ channels and homotrimeric ASIC acid-sensing cation channels	<i>SCNN1A</i> (1): α subunit <i>SCNN1B</i> (1): β subunit <i>SCNN1D</i> (1): δ subunit <i>SCNN1G</i> (1): γ subunit <i>ACCN</i> (5)	SCNN1 genes encode amiloride-sensitive Na ⁺ -selective channels mediating Na ⁺ transport across tight epithelia; ACCN genes encode ASIC cation channels activated by external H ⁺ , which are involved in pain sensation in sensory neurons following acidosis	<i>SCNN1A</i> , <i>1B</i> : pseudohypoaldosteronism 1 <i>SCNN1A</i> , <i>1B</i> , <i>1G</i> : bronchiectasis with or without elevated sweat chloride <i>SCNN1B</i> , <i>1G</i> : Liddle syndrome (hypertension)	Trimer of 2-TM subunits (Fig. 6-20R)
15. Cystic fibrosis transmembrane regulator (see Table 5-6)	CFTR; channel protein contains two internally homologous domains	<i>ABCC7</i> : CFTR Part of the ABC family (49)	Cl ⁻ -selective channel coupled to cAMP regulation; Cl ⁻ transport pathway in secretory and absorptive epithelia; regulated by ATP binding and hydrolysis at two intracellular nucleotide-binding domains	<i>ABCC7</i> : cystic fibrosis	Monomer of 2 \times 6 TMs (Fig. 6-20S)
16. ClC chloride channels	Dimeric ClC Cl ⁻ channels	<i>CLCN</i> (9) <i>CLCN1</i> , 2, 3, 4, 5, 6, 7: CLC-1, 2, 3, 4, 5, 6, 7 <i>CLCNKA</i> : CLC-K1 <i>CLCNKB</i> : CLC-K2	Cl ⁻ -selective, voltage-sensitive anion channels in muscle, neurons, and many other tissues; many ClC channels also function as H ⁺ /Cl ⁻ exchange transporters in endosomes, synaptic vesicles, and lysosomes; involved in regulation of electrical excitability in skeletal muscle, mediation of Cl ⁻ transport in epithelia, regulatory volume decrease	<i>CLCN1</i> : Becker disease, Thomsen disease (congenital myotonia) <i>CLCN2</i> : idiopathic and juvenile epilepsy <i>CLCN5</i> : Dent disease complex, nephrolithiasis <i>CLCN7</i> : osteopetrosis <i>CLCNKA</i> , <i>CLCNKB</i> : Bartter syndromes	Monomer of 14 TMs (Fig. 6-20T)
17. CaCC Ca ²⁺ -activated chloride	Anoctamin family of Ca ²⁺ - and	<i>ANO</i> (10) <i>ANO1</i> , 2, 3, 4, 5,	Present in epithelia, smooth muscle, photoreceptors, olfactory sensory neurons; activated at more than ~1 μ M cytosolic Ca ²⁺ ;		Dimer of 8-TM subunits

channels	voltage-activated Cl ⁻ channels	6, 7, 8, 9, 10: TMEM16A, B, C, D, E, F, G, H, I, J	involved in Cl ⁻ secretion, smooth muscle contraction, amplification of olfactory stimulus		(Fig. 6-20U)
18. IP ₃ -activated Ca ²⁺ channels	Tetrameric IP ₃ receptor channels	<i>ITPR</i> (3) <i>ITPR1</i> , 2, 3: IP ₃ R1, 2, 3 = InsP3R-1, 2, 3	Intracellular cation channel permeable to Na ⁺ , K ⁺ , and Ca ²⁺ ; activated by binding of IP ₃ and Ca ²⁺ ; coupled to receptor activation of PLC and hydrolysis of PIP ₂ ; regulated by binding of ATP; mediates excitation-contraction coupling in smooth muscle and participates in intracellular Ca ²⁺ release and signaling in many cells	<i>ITPR1</i> : spinocerebellar ataxia	Tetramer of 6-TM subunits (Fig. 6-20V)
19. RYR Ca ²⁺ -release channels	Tetrameric ryanodine receptor Ca ²⁺ -release channels	<i>RYR</i> (3) <i>RYR1</i> , 2, 3: RYR1, 2, 3	Intracellular cation channel permeable to Ca ²⁺ ; intracellular Ca ²⁺ -release channel activated by mechanical coupling to Cav channel in skeletal muscle or by plasma membrane Ca ²⁺ entry in heart and smooth muscle	<i>RYR1</i> : malignant hyperthermia, central core disease, congenital myopathy <i>RYR2</i> : familial arrhythmogenic right ventricular dysplasia, catecholaminergic polymorphic ventricular tachycardia	Tetramer of 4-TM subunits (Fig. 6-20W)
20. Orai store-operated Ca ²⁺ channels	Multimeric Orai Ca ²⁺ -selective channels	<i>ORAI</i> (3) (also known as ICRAC for Ca ²⁺ -release activated Ca ²⁺ current or SOC channels for store-operated Ca ²⁺ entry)	Plasma membrane, low-conductance Ca ²⁺ channel predominantly found in nonexcitable cells such as epithelia and lymphocytes; activated via PLC-coupled pathways leading to IP ₃ -activated Ca ²⁺ release from ER; Ca ²⁺ depletion in ER activates an ER membrane protein (STIM) which activates Orai, resulting in entry of extracellular Ca ²⁺ ; functions in lymphocyte activation and epithelial secretion	<i>ORAI1</i> : severe combined immunodeficiency syndrome (SCID)	Tetramer of 4-TM subunits (Fig. 6-20X)

AP, action potential; CNS, central nervous system; ER, endoplasmic reticulum; EPSP, excitatory postsynaptic potential; IPSP, inhibitory postsynaptic potential; PIP₂, phosphatidylinositol 4,5-bisphosphate; PLC, phospholipase C; SESAME, seizures, sensorineural deafness, ataxia, mental retardation, and electrolyte imbalance; TM, transmembrane segment.

Role of TWIK-1 Channels in Cardiac Arrhythmias

Contributed by Ed Moczydlowski

As noted in the text, the resting V_m of many cells, particularly muscle cells and neurons, is dominated by high K⁺ permeability due to certain K⁺ channels that are spontaneously open at negative membrane potentials. Maintaining Na⁺ and Ca²⁺ channels in a predominantly closed state is an important aspect of cellular physiology since the transient opening of these channels allows their efficient function in membrane signaling processes dependent on intracellular Ca²⁺. Thus, in typical excitable cells we would expect K⁺ channels to maintain a negative V_m , close to E_K , except when Na⁺ and Ca²⁺ channels are stimulated to open and trigger activation of cellular processes such as muscle contraction or secretion.

The human genome includes 79 genes that encode K⁺ channels, comprising five major families of K⁺-selective–channel proteins (see Table 6-2):

- Voltage-gated (Kv)
- Small-conductance Ca²⁺ activated (SK and IK)
- Large-conductance Ca²⁺ activated (BK)
- Inward rectifier (Kir)
- Two-pore (K2P)

Of these K⁺ channels, only the Kir and K2P channels show gating behavior compatible with significant

open-state probability at negative V_m . Thus, these latter channels are expected to have the greatest role in determining the resting V_m .

Because the K^+ channels that have been studied most extensively appear to conduct very little inward Na^+ current under physiological conditions, it is not entirely clear why V_m deviates from strict Nernst behavior in experiments such as that for which results are shown in Figure 6-4, where the measured V_m is more positive than expected at low extracellular $[K^+]$. It has often been assumed that this deviation is simply due to a low but finite permeability of K^+ channels to Na^+ (e.g., $\alpha \cong 0.01$ in Equation 6-10) or an unspecified Na^+ leak. However, structural and biophysical studies of K^+ channel proteins **N7-13** indicate that K^+ binding to the ion-selectivity filter actually stabilizes the filter in a K^+ -selective conformation. When K^+ concentration is reduced to low-millimolar levels, the selectivity filter may deform and permit other ions such as Na^+ to permeate the channel. Thus, at low extracellular K^+ concentration it is possible that K^+ channels in cell membranes could become less selective for K^+ relative to Na^+ .

An example of this effect has been described in human cardiac myocytes, in which pathological conditions of blood hypokalemia (plasma $[K^+] < 3$ mM) may lead to paradoxical depolarization, cardiac arrhythmia, and sudden death. Evidence suggests that this phenomenon may be caused by a certain K^+ channel called TWIK-1 (human gene *KCNK1*) that exhibits increased permeability to Na^+ at low extracellular K^+ . Serum hypokalemia can be secondary to diuretic therapy, diarrhea (including laxative abuse) or vomiting, or starvation. Plasma K^+ concentration should be raised to normal levels of 3.5 to 4.8 mM to prevent dangerous cardiac arrhythmia in such instances.

In general, the resting potential of most vertebrate cells is dominated by high permeability to K^{+} , which accounts for the observation that the resting V_m is typically close to E_K . The resting permeability to Na^{+} and Ca^{2+} is normally very low. Skeletal muscle cells, cardiac cells, and neurons typically have resting membrane potentials ranging from -60 to -90 mV. As discussed in [Chapter 7](#), excitable cells generate action potentials by transiently increasing Na^{+} or Ca^{2+} permeability and thus driving V_m in a positive direction toward E_{Na} or E_{Ca} . A few cells, such as vertebrate skeletal muscle fibers, have high permeability to Cl^{-} , which therefore contributes to the resting V_m . This high permeability also explains why the Cl^{-} equilibrium potential in skeletal muscle is essentially equivalent to the resting potential (see [Table 6-1](#)).

Electrical Model of a Cell Membrane

The cell membrane model includes various ionic conductances and electromotive forces in parallel with a capacitor

The current carried by a particular ion varies with membrane voltage, as described by the I - V relationship for that ion (e.g., [Fig. 6-7](#)). This observation suggests that the contribution of each ion to the electrical properties of the cell membrane may be represented by elements of an electrical circuit. The various ionic gradients across the membrane provide a form of stored electrical energy, much like that of a battery. In physics, the voltage source of a battery is known as an **emf** (electromotive force). The equilibrium potential of a given ion can be considered an emf for that ion. Each of these batteries produces its own ionic **current** across the membrane, and the sum of these individual ionic currents is the total ionic current (see [Equation 6-8](#)). According to **Ohm's law**, the emf or voltage (V) and current (I) are related directly to each other by the **resistance** (R)—or inversely to the reciprocal of resistance, **conductance** (G):

$$\begin{aligned} V &= IR \quad \text{Ohm's law} \\ &= I/G \\ &\quad \textbf{(6-11)} \end{aligned}$$

Thus, the slopes of the theoretical curves in [Figure 6-7](#) represent conductances because $I = GV$. In a membrane, we can represent each ionic permeability pathway with an electrical conductance. Ions with high permeability or conductance move via a low-resistance pathway; ions with low permeability move via a high-resistance pathway. For cell membranes, V_m is measured in millivolts, membrane current (I_m) is given in amperes per square centimeter of membrane area, and membrane resistance (R_m) has the units of ohms \times square centimeter. Membrane conductance (G_m), the reciprocal of membrane resistance, is thus measured in units of ohms⁻¹ (or siemens) per square centimeter. 🏠N6-11

N6-11

Electrical Units

Contributed by Ed Moczydlowski

Unit of **resistance**: ohm. 1 ohm = 1 volt/ampere.

Unit of **conductance** (the reciprocal of resistance): siemens. 1 siemens = 1/ohm. In English, *siemens*—named after Ernst von Siemens—is used for both the singular and plural.

Unit of **charge**: coulomb. 1 coulomb = the electrical charge separated by the plates of a 1-farad capacitor charged to 1 volt.

Unit of **capacitance**: farad. 1 farad = 1 coulomb/volt. Thus, if we charge a 1-farad capacitor to 1 volt, the charge on each plate will be 1 coulomb.

Unit of **electrical work**: joule. 1 joule = 1 volt \times 1 coulomb.

Currents of Na^+ , K^+ , Ca^{2+} , and Cl^- generally flow across the cell membrane via distinct pathways. At the molecular level, these pathways correspond to specific types of ion channel proteins ([Fig. 6-9A](#)). It is helpful to model the electrical behavior of cell membranes by a circuit diagram (see [Fig. 6-9B](#)). The electrical current carried by each ion flows via a separate parallel branch of the circuit that is under the control of a **variable resistor** and an emf. For instance, the variable resistor for K^+ represents the conductance provided by K^+ channels in the membrane (G_{K}). The emf for K^+ corresponds to E_{K} . Similar parallel branches of the circuit in [Figure 6-9B](#) represent the other physiologically important ions. Each ion provides a component of the total conductance of the membrane, so $G_{\text{K}} + G_{\text{Na}} + G_{\text{Ca}} + G_{\text{Cl}}$ sum to G_{m} .

A MODEL OF A CELL MEMBRANE

B EQUIVALENT CIRCUIT MODEL

C PARALLEL-PLATE CAPACITOR

LIPID MEMBRANE

FIGURE 6-9 Electrical properties of model cell membranes. **A**, Four different ion channels are arranged in parallel in the cell membrane. **B**, The model represents each channel in **A** with a variable resistor. The model represents the Nernst potential for each ion as a battery in series with each variable resistor. The

four parallel current paths correspond to the four parallel channels in **A**. Also shown is the membrane capacitance, which is parallel with each of the channels. **C**, On the left is an idealized capacitor, which is formed by two parallel conductive plates, each with an area A and separated by a distance a . On the right is a capacitor that is formed by a piece of lipid membrane. The two *plates* are, in fact, the electrolyte solutions on either side of the membrane.

The GHK voltage equation (see [Equation 6-9](#)) predicts steady-state V_m , provided the underlying assumptions are valid. We can also predict steady-state V_m (i.e., when the net current across the membrane is zero) with another, more general equation that assumes channels behave like separate ohmic conductances:

$$V_m = \frac{G_K}{G_m} E_K + \frac{G_{Na}}{G_m} E_{Na} + \frac{G_{Ca}}{G_m} E_{Ca} + \frac{G_{Cl}}{G_m} E_{Cl} \dots$$

(6-12)

Thus, V_m is the sum of equilibrium potentials (E_x), each weighted by the ion's fractional conductance (e.g., G_x/G_m).

One more parallel element, a **capacitor**, is needed to complete our model of the cell membrane as an electrical circuit. A capacitor is a device that is capable of storing separated charge. Because the lipid bilayer can maintain a separation of charge (i.e., a voltage) across its ~4-nm width, it effectively functions as a capacitor. In physics, a capacitor that is formed by two parallel plates separated by a distance a can be represented by the diagram in [Figure 6-9C](#). When the capacitor is charged, one of the plates bears a charge of $+Q$ and the other plate has a charge of $-Q$. **N6-12** Such a capacitor maintains a potential difference (V) between the plates. **Capacitance (C)** is the magnitude of the charge stored per unit potential difference:

N6-12

Charge Carried by a Mole of Monovalent Ions

Contributed by Ed Moczydlowski

We can compute a macroscopic quantity of charge by using a conversion factor called the Faraday (F). The Faraday is the charge of a mole of univalent ions, or $e_0 \times$ Avogadro's number:

The Faraday	=	Elementary charge	×	Avogadro's number
F	=	e_0	×	N_0
	=	$(1.6022 \times 10^{-19} \text{ coulombs/electron})$		
		$\times (6.022 \times 10^{23} \text{ electrons/mole})$		
	=	96,484 coulombs/mole		

(NE 6-15)

$$C = \frac{Q}{V}$$

(6-13)

Capacitance is measured in units of farads (F);  **N6-11** 1 farad = 1 coulomb/volt. For the particular geometry of the parallel-plate capacitor in [Figure 6-9C](#), capacitance is directly proportional to the surface area (A) of one side of a plate, to the relative permittivity (dielectric constant) of the medium between the two plates (ϵ_r), and to the vacuum permittivity constant (ϵ_0), and it is inversely proportional to the distance (a) separating the plates.

$$C = \frac{A\epsilon_r\epsilon_0}{a}$$

(6-14)

Because of its similar geometry, the cell membrane has a capacitance that is analogous to that of the parallel-plate capacitor. The capacitance of 1 cm² of most cell membranes is ~1 μF; that is, most membranes have a specific capacitance of 1 μF/cm². We can use [Equation 6-14](#) to estimate the thickness of the membrane. If we assume that the average dielectric constant of a biological membrane is $\epsilon_r = 5$ (slightly greater than the value of 2 for pure hydrocarbon), [Equation 6-14](#) gives a value of 4.4 nm for a —that is, the thickness of the membrane. This value is quite close to estimates of membrane thickness that have been obtained by other physical techniques.

The separation of relatively few charges across the bilayer capacitance maintains the membrane potential

We can also use the capacitance of the cell membrane to estimate the amount of charge that the membrane actually separates in generating a typical membrane potential. For example, consider a spherical cell with a diameter of 10 μm and a $[K^+]_i$ of 100 mM. This cell needs to lose only 0.004% of its K^+ to charge the capacitance of the membrane to a voltage of −61.5 mV. [N6-13](#) This small loss of K^+ is clearly insignificant in comparison with a cell's total ionic composition and does not significantly perturb concentration gradients. In general, cell membrane potentials are sustained by a very small separation of charge.

N6-13

Charge Separation Required to Generate the Membrane Potential

Contributed by Ed Moczydlowski

To generate a membrane potential, there must be a tiny separation of charge across the membrane. How large is that charge? Imagine that we have a spherical cell with a diameter of 10 μm. If $[K^+]_i$ is 100 mM and $[K^+]_o$ is 10 mM, the V_m according to the Nernst equation would be −61.5 mV (or −0.0615 V) for a perfectly K^+ -selective membrane at 37°C. What is the charge (Q) on 1 cm² of the “plates” of the membrane capacitor? We assume that the specific capacitance is 1 μF/cm². From Equation 6-13 on page 150 in the text, we know that

$$Q = CV$$

(NE 6-16)

where Q is measured in coulombs (C), C is in farads (F), and V is in volts (V). Thus,

$$Q = (1 \times 10^{-6} \text{ F cm}^{-2}) \times (0.0615 \text{ V})$$

$$= 61.5 \times 10^{-9} \text{ C cm}^{-2}$$

(NE 6-17)

The Faraday is the charge of 1 mole of univalent ions—or 96,480 C. **N6-12** To determine how many moles of K^+ we need to separate in order to achieve an electrical charge of $61.5 \times 10^{-9} \text{ C cm}^{-2}$ (i.e., the Q in the previous equation), we merely divide Q by the Faraday. Because V_m is negative, the cell needs to lose K^+ :

$$\text{K}^+ \text{ deficit per cm}^2 \text{ of membrane} = \frac{\left(\frac{61.5 \times 10^{-9} \text{ C}}{\text{cm}^2} \right)}{\left(\frac{96,480 \text{ C}}{\text{mole}} \right)}$$

$$= 6.37 \times 10^{-13} \text{ moles cm}^{-2}$$

(NE 6-18)

The surface area for a spherical cell with a diameter of $10 \mu\text{m}$ is $3.14 \times 10^{-6} \text{ cm}^2$. Therefore,

$$\text{Total K}^+ \text{ deficit per cell} = \frac{6.37 \times 10^{-13} \text{ moles}}{\text{cm}^2} \times \frac{3.14 \times 10^{-6} \text{ cm}^2}{1}$$

$$= 2.0 \times 10^{-18} \text{ moles}$$

The volume of this cell is $0.52 \times 10^{-12} \text{ L}$. Given a $[\text{K}^+]_i$ of 100 mM,

$$\text{Total K}^+ \text{ content of cell} = (0.1 \text{ mole/L}) \times (0.52 \times 10^{-12} \text{ L})$$

$$= 0.52 \times 10^{-13} \text{ moles}$$

(NE 6-19)

What fraction of the cell's total K^+ content represents the charge separated by the membrane?

$$\begin{aligned}
 \text{Fraction of cell K}^+ &= \frac{\text{K}^+ \text{ deficit of cell}}{\text{Total K}^+ \text{ content of cell}} \\
 &= \frac{2.0 \times 10^{-18} \text{ moles}}{0.52 \times 10^{-13} \text{ moles}} \\
 &= 4 \times 10^{-5} \text{ or } 0.004\%
 \end{aligned}$$

(NE 6-20)

Thus, in the process of generating a V_m of -61.5 mV, our hypothetical cell needs to lose only 0.004% of its total K^+ content to charge the capacitance of the cell membrane.

Because of the existence of membrane capacitance, total membrane current has two components (see Fig. 6-9), one carried by ions through channels, and the other carried by ions as they charge the membrane capacitance.

Ionic current is directly proportional to the electrochemical driving force (Ohm's law)

Figure 6-10 compares the equilibrium potentials for Na^+ , K^+ , Ca^{2+} , and Cl^- with a resting V_m of -80 mV. In our discussion of Figure 6-7, we saw that I_K or I_{Na} becomes zero when V_m equals the reversal potential, which is the same as the E_x or emf for that ion. When V_m is more negative than E_x , the current is negative or inward, whereas when V_m is more positive than E_x , the current is positive or outward. Thus, the ionic current depends on the difference between the actual V_m and E_x . In fact, the ionic current through a given conductance pathway is proportional to the difference ($V_m - E_x$), and the proportionality constant is the ionic conductance (G_x):

$$I_X = G_X (V_m - E_X)$$

(6-15)

FIGURE 6-10 Electrochemical driving forces acting on various ions. For each ion, we represent the equilibrium potential (e.g., $E_{Na} = +67$ mV) as a horizontal bar and the net driving force for the ion (e.g., $V_m - E_{Na} = -147$ mV) as an arrow, assuming a resting potential (V_m) of -80 mV. The values for the equilibrium potentials are those for mammalian skeletal muscle given in [Table 6-1](#), as well as a typical value for E_{Cl} in a nonmuscle cell. **N6-29**

N6-29

Electrochemical Driving Forces and Predicted Direction of Net Fluxes

Contributed by Ed Moczydlowski

In Figure 6-10, for Na^+ and Ca^{2+} , the arrows—which indicate the driving force—point down, indicating that the driving force favors the passive *influx* of these ions. For K^+ , the arrow points up, indicating that the driving force favors the passive *efflux* of K^+ . For Cl^- in skeletal muscle cells, the arrow points up, indicating that the driving force favors a small passive *influx*. In other cells, the arrow for Cl^- points down, indicating that the driving force favors passive *efflux*.

This equation simply restates Ohm's law (see [Equation 6-11](#)). The term $(V_m - E_x)$ is often referred to as the **driving force** in electrophysiology. In our electrical model of the cell membrane (see [Fig. 6-9](#)), this driving force is represented by the difference between V_m and the emf of the battery. The larger the

driving force, the larger the observed current. Returning to the I - V relationship for K^+ in [Figure 6-7A](#), when V_m is more positive than E_K , the driving force is positive, producing an outward (i.e., positive) current. Conversely, at V_m values more negative than E_K , the negative driving force produces an inward current. [N6-14](#)

N6-14

Conductance Varies with Driving Force

Contributed by Ed Moczydlowski

In [N6-8](#), we pointed out that when $[K^+]_i = [K^+]_o$, the I - V relationship for K^+ currents is linear and passes through the origin (see dashed line in Fig 6-7A). In this special case, the K^+ conductance (G_K) is simply the slope of the line because, according to Ohm's law, $I_K = G_K \times V_m$. In other words, $G_K = \Delta I_K / \Delta V_m$.

In webnote Equation NE 6-8, we also pointed out that when $[K^+]_i$ *does not equal* $[K^+]_o$, the I - V relationship is curvilinear (see solid curve in Fig. 6-7A in the text) as described by the GHK current equation for K^+ :

$$I_K = \frac{z^2 F^2 V_m P_K}{RT} \left(\frac{[K^+]_i - [K^+]_o e^{(-zFV_m/RT)}}{1 - e^{(-zFV_m/RT)}} \right)$$

(NE 6-21)

The above equation is identical to Equation 6-7 in the text, but with K^+ replacing the generic ion X . Note that for K^+ , all of the z values are +1.

Because slope conductance for K^+ (G_K) is the change in K^+ current (I_K) divided by the change in membrane voltage (V_m), we could in principle derive an equation for G_K by taking the derivative of Equation NE 6-21 with respect to V_m (i.e., $G_K = dI_K/dV_m$). Because V_m appears three times in Equation NE 6-21 (and twice in an exponent), this derivative—that is, G_K —turns out to be extremely complicated (not shown). Nevertheless, it is possible to show that, in general, G_K increases with increasing values of V_m . For the special case in which $V_m = E_K$, the equation for G_K simplifies to

$$\left(\frac{dI_K}{dV_m} \right)_{V_m = E_K} = G_K = - \frac{z^3 F^3 P_K}{R^2 T^2} V_m \left(\frac{[K^+]_o \times [K^+]_i}{[K^+]_o - [K^+]_i} \right)$$

(NE 6-22)

It is clear from Equation NE 6-22 that G_K increases as V_m becomes more positive. However, this relationship is not linear because as V_m increases, E_K (the equilibrium potential for K^+) must also increase, and thus the $[K^+]_o$ or the $[K^+]_i$ terms in Equation NE 6-22 must also change.

Equation NE 6-22 describes G_K at exactly one point—when $V_m = E_K$ at -95 mV. At other values of V_m , the appropriate expression for G_K is far more complicated than Equation NE 6-22. Nevertheless, it is clear from the graph in Figure 6-7A that the slope of the I - V relationship (i.e., G_K) increases with V_m .

Thus, the slope of the curve in Figure 6-7A is relatively shallow (i.e., low G_K) for the inward currents at relatively negative V_m values (lower portion of the plot) and steeper (i.e., high G_K) for outward currents at more positive V_m values (upper portion of the plot).

In Figure 6-10, the arrows represent the magnitudes and directions of the driving forces for the various ions. For a typical value of the resting potential (-80 mV), the driving force on Ca^{2+} is the largest of the four ions, followed by the driving force on Na^+ . In both cases, V_m is more negative than the equilibrium potential and thus draws the positive ion *into* the cell. The driving force on K^+ is small. V_m is more positive than E_K and thus pushes K^+ out of the cell. In muscle, V_m is slightly more positive than E_{Cl} and thus draws the anion inward. In most other cells, however, V_m is more negative than E_{Cl} and pushes the Cl^- out.

Capacitance current is proportional to the rate of voltage change

The idea that ionic channels can be thought of as conductance elements (G_x) and that ionic current (I_x) is proportional to driving force ($V_m - E_x$) provides a framework for understanding the electrical behavior of cell membranes. Current carried by inorganic ions flows through open channels according to the principles of electrodiffusion and Ohm's law, as explained above. However, when V_m is changing—as it does during an action potential—another current due to the membrane capacitance also shapes the electrical responses of cells. This current, which flows only while V_m is changing, is called the capacitance current. How does a capacitor produce a current? When voltage across a capacitor changes, the capacitor either gains or loses charge. This movement of charge onto or off the capacitor is an electrical (i.e., the capacitance) current.

The simple membrane circuit of Figure 6-11A, which is composed of a capacitor (C_m) in parallel with a resistor (R_m) and a switch, can help illustrate how capacitance currents arise. Assume that the switch is open and that the capacitor is initially charged to a voltage of V_0 , which causes a separation of charge (Q) across the capacitor. According to the definition of capacitance (see Equation 6-13), the charge stored by the capacitor is a product of capacitance and voltage.

$$Q = C_m V_0$$

(6-16)

A EQUIVALENT CIRCUIT

B TIME COURSE OF VOLTAGE

C TIME COURSE OF CURRENT

FIGURE 6-11 Capacitive current through a resistance-capacitance (RC) circuit.

As long as the switch in the circuit remains open, the capacitor maintains this charge. However, when the switch is closed, the charge on the capacitor discharges through the resistor, and the voltage difference

between the circuit points labeled “In” and “Out” in [Figure 6-11A](#) decays from V_0 to a final value of zero (see [Fig. 6-11B](#)). This voltage decay follows an exponential time course. The time required for the voltage to fall to 37% of its initial value is a characteristic parameter called the **time constant (τ)**, which has units of time: **N6-15**

N6-15

Units of the “Time Constant”

Contributed by Emile Boulpaep, Walter Boron

As described in Equation 6-17 in the text (shown here as Equation NE 6-23), the time constant (τ) is

$$\tau = R \cdot C$$

(NE 6-23)

where R is resistance (in ohms) and C is capacitance (in farads). The units of τ are thus

$$\tau = R \cdot C = \text{ohm} \cdot \text{farad}$$

(NE 6-24)

Because an ohm is a volt per ampere, and a farad is a coulomb per volt,

$$\tau = \frac{\text{volt}}{\text{amp}} \cdot \frac{\text{coulomb}}{\text{volt}}$$

$$\tau = \frac{\text{coulomb}}{\text{amp}}$$

(NE 6-25)

Because electrical current (in amperes) is the number of charges (in coulombs) moving per unit time (in seconds), an ampere is a coulomb per second:

$$\tau = \frac{\text{coulomb}}{\text{coulomb/s}} = \text{s}$$

(NE 6-26)

Thus, the unit of the “time constant” is seconds.

$$\tau = R_m \cdot C_m$$

(6-17)

Thus, the time course of the decay in voltage is

$$V = V_0 e^{-t/RC}$$

(6-18)

Figure 6-11C shows that the **capacitive current** (I_C) is zero before the switch is closed, when the voltage is stable at V_0 . When we close the switch, charge begins to flow rapidly off the capacitor, and the magnitude of I_C is maximal. As the charge on the capacitor gradually falls, the rate at which charge flows off the capacitor gradually falls as well until I_C is zero at “infinite” time. Note, however, that V and I_C relax with the same time constant.  **N6-16**

N6-16

Time Constant of Capacitive Current

Contributed by Ed Moczydlowski

In Figure 6-11 in the text, we saw that closing a switch (panel **A**) causes the voltage to decline exponentially with a time constant τ (panel **B**), and it causes a current to flow maximally at time zero and then to decay with the same time constant as voltage. In other words, the capacitive current flows only while voltage is changing. Why? Current is charge flowing per unit time. Thus, we can obtain the **capacitive current** (I_C) by taking the derivative of charge (Q) in Equation 6-16 with respect to time:

$$I_C = \frac{dQ}{dt} = C \frac{dV}{dt}$$

(NE 6-27)

By definition, the derivative of charge with respect to time is current (i.e., $I_C = dQ/dt$). Thus, if voltage is constant (i.e., $dV/dt = 0$), no capacitive current can flow. In Figure 6-11C, I_C is zero before the switch is closed (i.e., before the downward deflection of I_C) and again is zero at “infinite” time, when the voltage is stable at 0. On the other hand, when the voltage is changing, the above equation indicates that I_C is nonzero and is directly proportional to C and to the rate at which the voltage is changing. Note, however, that V and I_C relax with the same time constant. To understand the exponential time course, note that Ohm's law can be used to express the current through the resistor in Figure 6-11A as V/R . If V/R is substituted for I_C in Equation NE 6-27, we have

$$I_C = \frac{V}{R} = C \frac{dV}{dt}$$

(NE 6-28)

We can rearrange the above differential equation to solve for V :

$$V = RC \frac{dV}{dt}$$

(NE 6-29)

We can now solve this differential equation to obtain the time course of the decay in voltage:

$$\frac{V}{V_0} = e^{-t/RC}$$

$$V = V_0 e^{-t/RC}$$

(NE 6-30)

Equation NE 6-30 is the same as Equation 6-18 in the text. Thus, the voltage falls exponentially with time. We now go back to the first equation and plug in our newly derived expression for V :

$$I_C = C \frac{dV}{dt} = C \frac{d}{dt} (V_0 e^{-t/RC}) = -\frac{V_0}{R} e^{-t/RC}$$

(NE 6-31)

Thus, the capacitive current decays with the same time constant as does voltage. At time zero, the current is $-V_0/R$, and at infinite time the current is zero.

In [Figure 6-11](#), current and voltage change freely. [Figure 6-12](#) shows two related examples in which either current or voltage is abruptly changed to a fixed value, held constant for a certain time, and returned to the original value. This pattern is called a square pulse. In [Figure 6-12A](#), we control, or “clamp,” the current and allow the voltage to follow. When we inject a square pulse of current across the membrane, the voltage changes to a new value with a rounded time course determined by the RC value of the membrane. In [Figure 6-12B](#), we clamp voltage and allow the current to follow. When we suddenly change voltage to a new value, a transient capacitive current flows as charge flows onto the capacitor. The capacitive current is maximal at the beginning of the square pulse, when charge flows most rapidly onto the capacitor, and then falls off exponentially with a time constant of RC . When we suddenly decrease the voltage to its original value, I_C flows in the direction opposite that observed at the beginning of the pulse. Thus, I_C appears as brief spikes at the beginning and end of the voltage pulse.

N6-30

Voltage and Current Transients due to Membrane Capacitance

Contributed by Ed Moczydlowski

In panel **A** of Figure 6-12 in the text (current clamp), we instruct the electronics to suddenly increase the current that we are injecting into the cell and to hold this new current at a constant value. The sudden increase in the current flowing through the membrane causes V_m to rise exponentially until we fully charge the membrane capacitance (C_m). Thus, V_m rises with a time constant 🔥N6-15 of $R_m \times C_m$ (R_m is membrane resistance). At infinite time, the charge on the capacitor is at its maximal value, and all the

current flowing through the membrane flows through R_m , the “ohmic” membrane resistance.

In panel **B** of Figure 6-12 in the text (voltage clamp), we instruct the electronics to inject enough current into the cell to suddenly increase in the membrane potential (V_m) of the cell. The current required to charge the membrane capacitance (C_m) is at first extremely large. However, as we charge the membrane capacitance, that current decays exponentially with a time constant **⦿N6-15** of $R_m \times C_m$. At infinite time, the membrane capacitance is fully charged, and no current is required to hold the command voltage. However, this current decays exponentially, with a time course also determined by the $R \times C$ of the membrane.

A voltage clamp measures currents across cell membranes

Electrophysiologists use a technique called **voltage clamping** to deduce the properties of ion channels. In this method, specialized electronics are used to inject current into the cell to set the membrane voltage to a value that is different from the resting potential. The device then measures the total current required to clamp V_m to this value. A typical method of voltage clamping involves impaling a cell with two sharp electrodes, one for monitoring V_m and one for injecting the current. [Figure 6-13A](#) illustrates how the technique can be used with a *Xenopus* (i.e., frog) oocyte. **⦿N6-17** When the voltage-sensing electrode detects a difference from the intended voltage, called the command voltage, a feedback amplifier rapidly injects opposing current to maintain a constant V_m . The magnitude of the injected current needed to keep V_m constant is equal, but opposite in sign, to the membrane current and is thus an accurate measurement of the **total membrane current** (I_m).

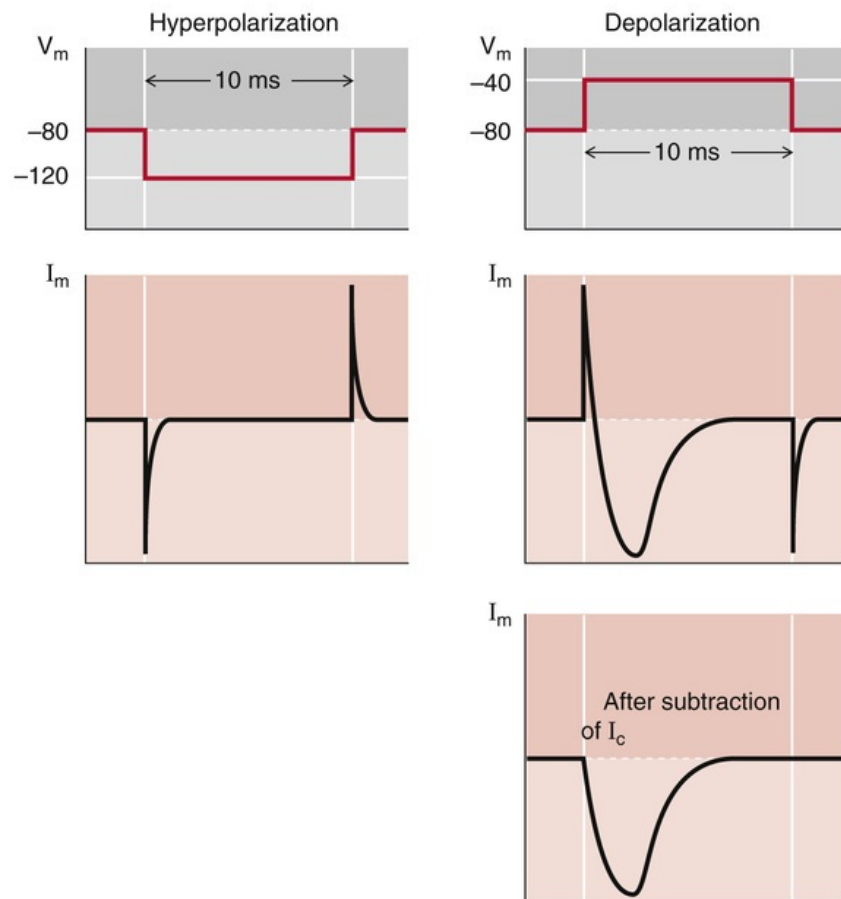

FIGURE 6-13 Two-electrode voltage clamp. **A**, Two microelectrodes impale a *Xenopus* oocyte. One electrode monitors membrane potential (V_m) and the other passes enough current (I_m) through the membrane to clamp V_m to a predetermined command voltage (V_{command}). **B**, In the left panel, the membrane is clamped for 10 ms to a hyperpolarized potential (40 mV more negative). Because a hyperpolarization does not activate channels, no ionic currents flow. Only transient capacitive currents flow after the beginning and end of the pulse. In the right panel, the membrane is clamped for 10 ms to a depolarized potential (40 mV more positive). Because the depolarization opens voltage-gated Na^+ channels, a large inward Na^+ current flows, in addition to the transient capacitive current. Adding the transient capacitive currents in the left panel to the total current in the right panel cancels the transient capacitive currents (I_c) and yields the pure Na^+ current shown at the bottom in the right panel.

N6-17

Two-Electrode Voltage Clamping

Contributed by Ed Moczydlowski

Historically, the technique of two-electrode voltage clamping was first used to analyze the ionic currents in a preparation known as the perfused squid giant axon. Certain nerve fibers of the squid are so large that their intracellular contents can be extruded and the hollow fiber can be perfused with physiological solutions of various ionic composition. Electrodes in the form of thin wires can be inserted into the axon to clamp the axon membrane potential along its length and measure the current. This technique was used by Alan L. Hodgkin and Andrew F. Huxley in 1952 to deduce the nature of ionic conductance changes that underlie the nerve action potential. For this work, Hodgkin and Huxley shared (with J.C. Eccles) the Nobel Prize in Physiology or Medicine in 1963. **N6-32** The Hodgkin-Huxley analysis is discussed further beginning on page 176.

Another, more recent, application of the two-electrode voltage-clamp technique is called **oocyte recording** (see Fig. 6-13A). A large oocyte from the African clawed frog, *Xenopus laevis*, is simultaneously impaled with two micropipette electrodes that serve to clamp the voltage and record current. Native *Xenopus* oocytes have only small endogenous currents, but they can be induced to express new currents by preinjecting the cell with messenger RNA (mRNA) transcribed from an isolated gene that codes for an ion channel protein. The oocyte system can therefore be used to characterize the conductance behavior of a relatively pure population of ion channels that are expressed in the plasma membrane after protein translation of the injected mRNA by the oocyte. This approach has proven to be an invaluable assay system for isolating complementary DNA molecules coding for many different types of channels and electrogenic transporters (see Chapter 5). This approach also has become a standard technique used to study the molecular physiology and pharmacology of ion channels.

I_m is the sum of the individual currents through each of the parallel branches of the circuit in [Figure 6-9B](#). For a simple case in which only one type of ionic current (I_X) flows through the membrane, I_m is simply the sum of the capacitative current and the ionic current:

$$\begin{aligned} I_m &= \underbrace{I_C}_{\text{Capacitative current}} + \underbrace{I_X}_{\text{Ionic current}} \\ &= I_C + G_X(V_m - E_X) \end{aligned} \quad \textbf{(6-19)}$$

[Equation 6-19](#) suggests a powerful way to analyze how ionic conductance (G_X) changes with time. For instance, if we abruptly change V_m to another value and then hold V_m constant (i.e., we *clamp* the voltage), the capacitative current flows for only a brief time at the voltage transition and disappears by the time that V_m reaches its new steady value (see [Fig. 6-12B](#)). Therefore, after I_C has decayed to zero, any additional changes in I_m must be due to changes in I_X . Because V_m is clamped and the ion concentrations do not change (i.e., E_X is constant), only one parameter on the right side of [Equation 6-19](#) is left free to vary, G_X . In other words, we can directly monitor changes in G_X because this conductance parameter is directly proportional to I_m when V_m is constant (i.e., clamped).

[Figure 6-13B](#) shows examples of records from a typical voltage-clamp experiment on an oocyte expressing voltage-gated Na^+ channels. In this experiment, a cell membrane is initially clamped at a resting potential of -80 mV. V_m is then stepped to -120 mV for 10 ms (a step of -40 mV) and finally returned to -80 mV. Such a negative-going V_m change is called a **hyperpolarization**. With this protocol, only brief spikes of current are observed at the beginning and end of the voltage step and are due to the charging of membrane capacitance. No current flows in between these two spikes.

What happens if we rapidly change V_m in the opposite direction by shifting the voltage from -80 to -40 mV (a step of $+40$ mV)? Such a positive-going change in V_m from a reference voltage is called a **depolarization**. In addition to the expected transient *capacitative* current, a large, inward, time-dependent current flows. This current is an *ionic* current and is due to the opening and closing kinetics of a particular class of channels called voltage-gated Na^+ channels, which open only when V_m is made sufficiently positive. We can remove the contribution of the capacitative current to the total current by subtracting the inverse of the rapid transient current recorded during the hyperpolarizing pulse of the same magnitude. The remaining slower current is inward (i.e., downward or negative going) and represents I_{Na} , which is directly proportional to G_{Na} (see [Equation 6-19](#)).

The ionic current in [Figure 6-13B](#) (lower right panel) is called a **macroscopic current** because it is due to the activity of a large population of channels sampled from a whole cell. Why did we observe Na^+ current only when we shifted V_m in a positive direction from the resting potential? As described below, such Na^+ channels are actually members of a large family of voltage-sensitive ion channels that are activated by *depolarization*. A current activated by depolarization is commonly observed when an electrically excitable cell, such as a neuron, is voltage clamped under conditions in which Na^+ is the sole extracellular cation.

A modern electrophysiological method called **whole-cell voltage clamping** involves the use of a single microelectrode both to monitor V_m and to pass current into the cell. In this method, one presses onto the cell surface a glass micropipette electrode with a smooth, fire-polished tip that is ~ 1 μm in diameter ([Fig. 6-14A](#)). Applying slight suction to the inside of the pipette causes a high-resistance seal to form between the circular rim of the pipette tip and the cell membrane. The piece of sealed membrane is called a **patch**, and the pipette is called a **patch pipette**. Subsequent application of stronger suction causes the patch to rupture, creating a continuous, low-resistance pathway between the inside of the cell and the pipette. In this configuration, **whole-cell currents** can be recorded (see [Fig. 6-14B](#)). Because single cells can be dissociated from many different tissues and studied in culture, this method has proved very powerful for analyzing the physiological roles of various types of ion channels and their regulation at the cellular level. The approach for recording whole-cell currents with a patch pipette was introduced by Erwin Neher and Bert Sakmann, who received the Nobel Prize in Physiology or Medicine in 1991. 🍷[N6-18](#)

N6-18

Erwin Neher and Bert Sakmann

For more information about Erwin Neher and Bert Sakmann and the work that led to their Nobel Prize, visit <http://www.nobel.se/medicine/laureates/1991/index.html> (accessed October 2014).

The patch-clamp technique resolves unitary currents through single channel molecules

Voltage-clamp studies of ionic currents at the whole-cell (i.e., macroscopic) level led to the question of how many channels are involved in the production of a macroscopic current. Electrophysiologists realized that if the area of a voltage-clamped membrane was reduced to a very small fraction of the cell surface area, it might be possible to observe the activity of a single channel.

This goal was realized when Neher and Sakmann developed the **patch-clamp technique**. Applying suction to a patch pipette creates a high-resistance seal between the glass and the cell membrane, as described in the preceding section for whole-cell voltage clamping. However, rather than rupturing the enclosed membrane patch as in the whole-cell approach, one keeps the tiny membrane area within the patch intact and records current from channels within the patch. A current recording made with the patch pipette attached to a cell is called a **cell-attached recording** (see Fig. 6-14A). After a cell-attached patch is established, it is also possible to withdraw the pipette from the cell membrane to produce an **inside-out patch configuration** by either of two methods (see Fig. 6-14E and Fig. 6-14F–H). In this configuration, the *intracellular* surface of the patch membrane faces the bath solution. One can also arrive at the opposite orientation of the patch of membrane by starting in the cell-attached configuration (see Fig. 6-14A), rupturing the cell-attached patch to produce a whole-cell configuration (see Fig. 6-14B), and then pulling the pipette away from the cell (see Fig. 6-14C). When the membranes reseal, the result is an **outside-out patch configuration** in which the *extracellular* patch surface faces the bath solution (see Fig. 6-14D).

The different patch configurations summarized in Figure 6-14 are useful for studying drug channel interactions, receptor-mediated processes, and biochemical regulatory mechanisms that take place at either the inner or external surface of cell membranes.

Single channel currents sum to produce macroscopic membrane currents

Figure 6-15 illustrates the results of a patch-clamp experiment that are analogous to the macroscopic experiment results on the right-hand side of Figure 6-13B. Under the diagram of the voltage step in Figure 6-15A are eight current records, each of which is the response to an identical step of depolarization lasting 45 ms. The smallest, nearly rectangular transitions of current correspond to the opening and closing of a single Na^+ channel. When two or three channels in the patch are open simultaneously, the measured current level is an integral multiple of the single channel or “unitary” transition.

A**B**

FIGURE 6-15 Outside-out patch recordings of Na^+ channels. **A**, Eight single-current responses—in the same patch on a myotube (a cultured skeletal muscle cell)—to a depolarizing step in voltage (cytosolic side of patch negative). **B**, Average current. The record in black shows the average of many single traces, such as those in **A**. The blue record shows the average current when tetrodotoxin blocks the Na^+ channels. (Data from Weiss RE, Horn R: Single-channel studies of TTX-sensitive and TTX-resistant sodium channels in developing rat muscle reveal different open channel properties. *Ann N Y Acad Sci* 479:152–161, 1986.)

The opening and closing process of ion channels is called **gating**. Patch-clamp experiments have demonstrated that macroscopic ionic currents represent the gating of single channels that have discrete unitary currents. Averaging consecutive microscopic Na^+ current records produces a time-dependent current (see [Fig. 6-15B](#)) that has the same shape as the macroscopic I_m shown in [Figure 6-13B](#). If one does the experiment in the same way but blocks Na^+ channels with tetrodotoxin, the averaged current is equivalent to the zero current level, which indicates that Na^+ channels are the only channels present within the membrane patch.

Measuring the current from a single channel in a patch at different clamp voltages reveals that the size of the discrete current steps depends on voltage ([Fig. 6-16A](#)). Plotting the **unitary current (*i*)** of single channels versus the voltage at which they were measured yields a single channel *I-V* relationship (see [Fig. 6-16B](#)) that is similar to the one we discussed above for macroscopic currents (see [Fig. 6-7](#)). This single channel *I-V* relationship reverses direction at a certain potential (V_{rev}), just like a macroscopic current does. If a channel is permeable to only one type of ion present in the solution, the V_{rev} equals the equilibrium potential for that ion (E_x). However, if the channel is permeable to more than one ion, the single channel reversal potential depends on the relative permeabilities of the various ions, as described by the GHK voltage equation (see [Equation 6-9](#)).

FIGURE 6-16 Voltage dependence of currents through single Cl^- channels in outside-out patches. **A**, The channel is a GABA_A receptor channel, which is a Cl^- channel activated by GABA. Identical solutions, containing 145 mM Cl^- , were present on both sides of the patch. **B**, The magnitudes of the single channel current transitions (y-axis) vary linearly with voltage (x-axis). (Data from Bormann J, Hamill OP, Sakmann B: Mechanism of anion permeation through channels gated by glycine and γ -aminobutyric acid in mouse cultured spinal neurones. *J Physiol* 385:243–286, 1987.)

The slope of a single channel I - V relationship is a measure of the conductance of a single channel, the **unitary conductance (g)**. Every type of ion channel has a characteristic value of g under a defined set of ionic conditions. The single channel conductance of most known channel proteins is in the range of 1 to 500 pS, where 1 pS is equal to $10^{-12} \Omega^{-1}$.

How do we know that the unitary current in fact corresponds to just a single channel? One good indication is that such conductance measurements are close to the theoretical value expected for ion diffusion through a cylindrical, water-filled pore that is long enough to span a phospholipid membrane and that has a diameter large enough to accept an ion. The unitary conductance of typical channels corresponds to rates of ion movement in the range of 10^6 to 10^8 ions per second per channel at 100 mV of driving force. These rates of ion transport through single channels are many orders of magnitude greater than typical rates of ion transport by ion pumps (~ 500 ions/s) or by the fastest ion cotransporters and exchangers ($\sim 50,000$ ions/s). The high ionic flux through channels places them in a unique class of transport proteins whose unitary activity can be resolved by patch-clamp current recordings.

Single channels can fluctuate between open and closed states

When a channel has opened from the **closed state** (zero current) to its full unitary conductance value, the channel is said to be in the **open state**. Channel gating thus represents the transition between closed and open states. A single channel record is actually a record of the conformational changes of a single protein molecule as monitored by the duration of opening and closing events.

Examination of the consecutive records of a patch recording, such as that in [Figure 6-15A](#), shows that

the gating of a single channel is a probabilistic process. On average, there is a certain probability that a channel will open at any given time, but such openings occur randomly. For example, the average record in [Figure 6-15B](#) indicates that the probability that the channels will open is highest ~4 ms after the start of the depolarization.

The process of channel gating can be represented by kinetic models that are similar to the following hypothetical two-state scheme.

This scheme indicates that a channel can reversibly change its conformation between closed (C) and open (O) states according to first-order reactions that are determined by an opening rate constant (k_o) and a closing rate constant (k_c). The **probability of channel opening (P_o)** is the fraction of total time that the channel is in the open state.

We already have seen in [Figure 6-15](#) that the *average* of many single channel records from a given patch produces a time course that is similar to a macroscopic current recorded from the same cell. The same is true for the *sum* of the individual single channel current records. This conclusion leads to an important relationship: macroscopic ionic current is equal to the product of the **number of channels (N)** within the membrane area, the unitary current of single channels, and the probability of channel opening:

$$I = NP_o i$$

(6-21)

Comparison of the magnitude of macroscopic currents recorded from large areas of voltage-clamped membrane with the magnitude of unitary current measured by patch techniques indicates that the surface density of ion channels typically falls into the range of 1 to 1000 channels per square micrometer of cell membrane, depending on the channel and cell type.

Molecular Physiology of Ion Channels

Classes of ion channels can be distinguished on the basis of electrophysiology, pharmacological and physiological ligands, intracellular messengers, and sequence homology

Mammalian cells express a remarkable array of ion channels. One way of making sense of this diversity is to classify channels according to their functional characteristics. Among these characteristics are electrophysiological behavior, inhibition or stimulation by various pharmacological agents, activation by extracellular agonists, and modulation by intracellular regulatory molecules. In addition, we can classify channels by structural characteristics, such as amino-acid sequence homology and the kinds of subunits of which they are composed.

Electrophysiology

The electrophysiological approach consists of analyzing ionic currents by voltage-clamp techniques and then characterizing channels on the basis of ionic selectivity, dependence of gating on membrane potential, and kinetics of opening and closing.

One of the most striking differences among channels is their **selectivity** for various ions. Indeed, channels are generally named according to which ion they are most permeable to—for example, Na^+ channels, Ca^{2+} channels, K^+ channels, and Cl^- channels.

Another major electrophysiological characteristic of channels is their **voltage dependence**. In electrically excitable cells (e.g., nerve, skeletal muscle, heart), a major class of channels becomes activated—and often inactivated—as a steep function of V_m . For example, the opening probability of the Na^+ channel in nerve and muscle cells increases steeply as V_m becomes more positive (see [Figs. 7-7B](#) and [7-8B](#)). Such voltage-gated channels are generally highly selective for Na^+ , Ca^{2+} , or K^+ .

Channels are also distinguished by the kinetics of **gating** behavior. For example, imagine two channels, each with an open probability (P_o) of 0.5. One channel might exhibit openings and closures with a duration of 10 ms each on average, whereas the other may have the same P_o with openings and closures of 1 ms each on average. Complex gating patterns of some channels are characterized by bursts of many brief openings, followed by longer silent periods.

Pharmacological Ligands

Currents that are virtually indistinguishable by electrophysiological criteria can sometimes be distinguished pharmacologically. For example, subtypes of voltage-gated Na^+ channels can be distinguished by their sensitivity to the peptide toxin μ -conotoxin, which is produced by *Conus geographus*, a member of a family of venomous marine mollusks called cone snails. This toxin strongly inhibits the Na^+ channels of adult rat skeletal muscle but has little effect on the Na^+ channels of neurons and cardiac myocytes. Another conotoxin (ω -conotoxin) from a different *Conus* species specifically inhibits voltage-gated Ca^{2+} channels in the spinal cord. A synthetic version of this conotoxin (ziconotide) is available for treatment of neuropathic pain in patients.

Physiological Ligands

Some channels are characterized by their unique ability to be activated by the binding of a particular molecule termed an **agonist**. For example, at the vertebrate neuromuscular junction, a channel called the nicotinic acetylcholine (ACh) receptor  **N6-19** opens in response to the binding of ACh released from a presynaptic nerve terminal. This ACh receptor is an example of the pentameric Cys-loop superfamily of **ligand-gated channels** or agonist-gated channels (see [p. 213](#)). Other agonist-gated channels are activated directly by neurotransmitters such as glutamate, serotonin (5-hydroxytryptamine [5-HT]), gamma-aminobutyric acid (GABA), and glycine.

N6-19

Structure of the Nicotinic Acetylcholine Receptor

Contributed by Ed Moczydlowski

The nicotinic acetylcholine receptors (AChRs), which are all ligand-gated ion channels, come in two major subtypes, N_1 and N_2 . The N_1 nicotinic AChRs are at the neuromuscular junction, whereas the N_2 AChRs are found in the autonomic nervous system (on the postsynaptic membrane of the postganglionic sympathetic and parasympathetic neurons) and in the central nervous system. Both N_1 and N_2 are ligand-gated ion channels activated by ACh or nicotine. However, whereas the N_1 receptors at the neuromuscular junction are stimulated by decamethonium and preferentially blocked by *d*-tubocurarine and α -bungarotoxin, the autonomic N_2 receptors are stimulated by tetramethylammonium, blocked by hexamethonium, but resistant to α -bungarotoxin. When activated, N_1 and N_2 receptors are both permeable to Na^+ and K^+ , with the entry of Na^+ dominating. Thus, the nicotinic stimulation leads to rapid depolarization.

The nicotinic AChRs in skeletal muscle and autonomic ganglia are heteropentamers. That is, five nonidentical protein subunits surround a central pore, in a rosette fashion.  **N6-20** Because the five subunits are not identical, the structure exhibits *pseudosymmetry*, rather than true symmetry. There are at least ten α subunits (α_1 to α_{10}) and four β subunits (β_1 to β_4). As we will see below, the basis for these differences is a difference in subunit composition.

The **N_1 receptors** have different subunit compositions depending upon location and developmental stage. The subunit composition of **$\alpha_2\beta\gamma\delta$** is found in fetal skeletal muscle, as well as the nonjunctional regions of denervated adult skeletal muscle. The electric organ of the electric eel (*Torpedo*), from which the channel was first purified, has the same subunit composition. The subunit composition of **$\alpha_2\beta\epsilon\delta$** is found at the neuromuscular junction of adult skeletal muscle. Here, the ϵ subunit replaces the γ subunit. In both the $\alpha_2\beta\gamma\delta$ and $\alpha_2\beta\epsilon\delta$ pentamers, the α subunits are of the α_1 subtype and the β subunits are of the β_1 subtype.

In the *Torpedo* N_1 AChRs, the α , β , γ , and δ subunits have polypeptide lengths of 437 to 501 amino acids. eFigure 6-1 shows side and top views of this AChR.

The **N_2 receptors** in the nervous system, like those in muscle, are heteromers, probably heteropentamers. N_2 receptors use α_2 to α_{10} and β_2 to β_4 .

Nicotinic Receptors		
Receptor Type	Agonists	Antagonists
N ₁ nicotinic ACh	ACh (nicotine decamethonium)	<i>d</i> -tubocurarine α -bungarotoxin
N ₂ nicotinic ACh	ACh (nicotine tetramethylammonium)	Hexamethonium

Intracellular Messengers

Channels can be categorized by their physiological regulation by intracellular messengers. For example, increases in $[Ca^{2+}]_i$ stimulate some ionic currents, in particular K^+ and Cl^- currents. Channels underlying such currents are known as Ca^{2+} -gated K^+ channels and Ca^{2+} -gated Cl^- channels, respectively. Another example is seen in the plasma membrane of light-sensitive rod cells of the retina, in which a particular type of channel is directly activated by intracellular cGMP.

The four functional criteria for characterizing channels—electrophysiology, pharmacology, extracellular agonists, and intracellular regulators—are not mutually exclusive. For example, one of the major types of Ca^{2+} -activated K^+ channels is also voltage gated.

Sequence Homology

The diversity of channels implied by functional criteria ultimately requires a molecular biological approach to channel classification. Such an approach began in the 1970s and 1980s with the biochemical purification of channel proteins. Membrane biochemists originally used rich natural sources of ion channels, such as the electric organs of the *Torpedo* ray and *Electrophorus* eel, to isolate channel proteins such as the nicotinic ACh receptor (see pp. 210–212) and the voltage-gated Na^+ channel, respectively. Partial amino-acid sequencing of purified channel proteins provided the information needed to prepare oligonucleotide probes for isolating the complete coding sequences of the channel. Genes encoding many different types of ion channel proteins were initially identified in this way. Sequences of ion channel genes—now available directly from the human genome—show that channels are far more diverse than first suggested by physiological studies.

On the basis of amino-acid sequences of mammalian channel proteins, we now can identify 20 distinct families of channel proteins, which are further subclassified into a larger number of gene subfamilies (Table 6-2). Substantial progress in revealing the three-dimensional structures of channels comes from two sources: x-ray crystallographic analysis of three-dimensional protein crystals and cryoelectron microscopy of membrane preparations containing densely packed, two-dimensional crystalline arrays of proteins. Molecular information gleaned from sequence and structural analyses of channel proteins has revealed a number of important themes that we discuss in the remainder of this subchapter.

Many channels are formed by a radially symmetric arrangement of subunits or domains around a central pore

The essential function of a channel is to facilitate the passive flow of ions across the hydrophobic membrane bilayer according to the electrochemical gradient. This task requires the channel protein to form an aqueous pore. The ionophore gramicidin is a small peptide that forms a unique helix dimer that spans the membrane; the hollow cylindrical region inside the helix is the channel pore. Another interesting type of channel structure is that of the **porin** channel proteins (see [p. 109](#)), which are present in the outer membranes of mitochondria and gram-negative bacteria. This protein forms a large pore through the center of a barrel-like structure; the 16 staves of the barrel are formed by 16 strands of the protein, each of which is in a β -sheet conformation. However, the structural motifs of a hole through a helix (gramicidin) or a hole through a 16-stranded β barrel (porin) appear to be exceptions rather than the rule.

For the majority of eukaryotic channels, the aqueous pores are located at the center of an oligomeric rosette-like arrangement of homologous subunits in the plane of the membrane ([Fig. 6-17](#)). Channels can have three, four, five, or six of these subunits, each of which is a polypeptide that weaves through the membrane several times. In some cases (e.g., voltage-gated Na^+ and Ca^{2+} channels), the channel is not a true homo-oligomer or hetero-oligomer but rather a pseudo-oligomer in which a single polypeptide contains repetitive, homologous domains. In these channels, the rosette-like arrangement of repetitive domains—rather than distinct subunits—surrounds a central pore. 🍌[N6-20](#)

FIGURE 6-17 Structure of ion channels. Most ion channels consist of three to six subunits that are arranged like a rosette in the plane of the membrane. The channel can be made up of (1) identical, distinct subunits (homo-oligomer); (2) distinct subunits that are homologous but not identical (hetero-oligomer); or (3) repetitive subunit-like domains within a single polypeptide (pseudo-oligomer). In any case, these subunits surround the central pore of the ion channel. Note that each subunit is itself made up of several transmembrane segments.

N6-20

Rosette Arrangement of Channel Subunits

Contributed by Ed Moczydlowski

The radial arrangement of subunits or domains around a central pore appears to be a common theme of channel structure. Figure 6-17 in the text illustrates that various membrane protein channels can be classified according to whether they are formed from three, four, five, or six separate subunits or from a number of subunit-like domains within a single polypeptide. An example of a channel composed of nonidentical subunits is the nicotinic ACh receptor channel. An example of a channel composed of identical subunits is the voltage-gated K⁺ channel. Thus, such K⁺ channels have a homotetrameric, symmetric subunit arrangement, whereas the gap junction has a homohexameric structure. Finally, the voltage-sensitive Na⁺ and Ca²⁺ channels are examples of channels formed by four internally homologous,

nonidentical subunit-like domains within a single large ~250-kDa polypeptide α subunit. These latter channels are formed by a pseudosymmetrical arrangement of four homologous domains, rather than distinct subunits. We discuss the voltage-sensitive cation channels in more detail beginning on page 182. Thus, the major families of channel proteins found in membranes have apparently solved the problem of how to get an ion across a membrane by forming a channel at the central interface of protein subunits or domains.

Gap junction channels are made up of two connexons, each of which has six identical subunits called connexins

Gap junctions are protein channels that connect two cells via a large, unselective pore—having a diameter of ~1.4 nm at the narrowest constriction—that allows solutes as large as 1 kDa (e.g., Ca^{2+} , glucose, cyclic nucleotides, inositol 1,4,5-trisphosphate [IP_3], ADP, ATP) to pass between cells ([Fig. 6-18A](#)). These channels have been found in virtually all mammalian cells with only a few exceptions, such as adult skeletal muscle and erythrocytes. For example, gap junctions interconnect hepatocytes of the liver, cardiac muscle fibers of the heart and smooth muscle of the gut, β cells of the pancreas, and epithelial cells in the cornea of the eye, to name just a few. Gap junctions provide pathways for chemical communication and electrical coupling between cells. The gap junction comprises two apposed hexameric structures called **connexons**, one contributed by each cell. Two connexons contact each other to form an end-to-end protein channel with a total length of 15.5 nm, bridging a gap of ~4 nm between the two cell membranes. Each connexon has six identical subunits—**connexins (Cx)**—that surround a central pore in so-called radial hexameric symmetry (see [Fig. 6-18B](#)). Each Cx is an integral membrane protein with four transmembrane helices (TM1 to TM4) and a molecular mass ranging from 26 to 62 kDa for different connexin subtypes.

A GAP-JUNCTION CHANNELS IN APPOSING MEMBRANES

C ELECTRICAL COUPLING OF TWO CELLS CONNECTED BY GAP JUNCTIONS

D OPEN AND CLOSED CONFIGURATIONS OF A CONNEXON

FIGURE 6-18 Gap junction channels. **A**, Connexins, connexons, and gap junction channels in apposing

membranes. **B**, Crystal structure of human Cx26, showing two connexons consisting of six connexins (shown in six colors), each made up of four transmembrane segments. The aqueous pore—lined primarily by the TM1 transmembrane helix—has an inner diameter ranging from 4.0 nm at the wide funnel-like cytoplasmic entrance to 1.4 nm near the middle of the membrane. **C**, The left panel shows the preparation of the two cells, each of which is voltage clamped by means of a patch pipette in the whole-cell configuration (see Fig. 6-14). Because cell 1 is clamped to -40 mV and cell 2 is clamped to -80 mV, current flows through the gap junctions from cell 1 to cell 2. The right panel shows that the current recorded by the electrode in cell 1 is the mirror image of the current recorded in cell 2. The fluctuating current transitions represent the openings and closings of individual gap junction channels. **D**, The short N-terminal helix (NTH, shown in red) of each of the six connexins forms a circular girdle that lines the funnel of the cytoplasmic opening of the channel. The NTH contains an aspartate residue (D) as well as a tryptophan residue (W) that interacts with a methionine (M) on a transmembrane segment. The left side of the panel shows an open configuration of the gap junction channel when the transjunctional potential (V_j) is zero, that is, when the upper and lower cells are at the same potential. When the upper cell is more positive than the lower ($V_j > 0$), the six NTHs in the upper connexon move inward and assemble into a plug that blocks the pore. When the lower cell is more positive than the upper ($V_j < 0$), the six NTHs in the lower connexon move inward and assemble into a plug. (**B** and **D** adapted with permission from Maeda S, Nakagawa S, Suga M, et al: Structure of the connexin 26 gap junction channel at 3.5 Å resolution. *Nature* 458:597–602, 2009. **C**, Data from Veenstra RD, DeHaan RL: Measurement of single channel currents from cardiac gap junctions. *Science* 233:972–974, 1986.)

A given connexon hexamer in a particular cell membrane may be formed from a single connexin (homomeric) or a mixture of different connexin proteins (heteromeric). The apposition of two identical connexon hexamers forms a **homotypic channel**; the apposition of dissimilar connexon hexamers forms a **heterotypic channel**. Such structural variation in the assembly of connexons provides for greater diversity of function and regulation.

The gating properties of gap junctions can be studied by measuring electrical currents through gap junctions using two patch electrodes simultaneously placed in a pair of coupled cells (see Fig. 6-18C). When the two cells are clamped at different values of V_m , so that current flows from one cell to the other via the gap junctions, the current measured in either cell fluctuates as a result of the opening and closing of individual gap junction channels. Because the amount of current that enters one cell is the same as the amount of current that leaves the other cell, the current fluctuations in the two cells are mirror images of one another. Studies of this type show that increases in $[Ca^{2+}]_i$ or decreases in intracellular pH generally favor the closing of gap junction channels. Phosphorylation can also regulate gap junction channels.

The gating of many gap junction channels responds to the difference in transjunctional voltage (V_j) of the two coupled cells, a process known as transjunctional voltage gating. Gap junction channels formed by Cx26 connexin close when the V_m on the cytoplasmic side is positive (see Fig. 6-18D).

Human Cx26 connexin is present in many organs such as the liver, brain, skin, and inner ear. Point mutations throughout the sequence of human Cx26 are the major cause of nonsyndromic sensorineural deafness, the genetic basis for more than half of all cases of congenital deafness (Box 6-1).

Box 6-1

Genetic Defects in Connexin Genes

Many human genetic diseases have been identified in which the primary defect has been mapped to mutations of ion channel proteins. For example, mutations in the 21 connexin genes in the human genome cause diverse hereditary diseases resulting in craniofacial and bone deformities (Cx43), deafness (Cx26, Cx30, Cx31), myelin-related disease (Cx32), skin disorders (Cx26, Cx30), and congenital cataracts (Cx46, Cx50). Charcot-Marie-Tooth disease is a rare form of hereditary neuropathy that involves the

progressive degeneration of peripheral nerves. Patients with this inherited disease have been found to have various mutations in the human gene *GJB1*, which encodes Cx32 **🔴N6-24** and is located on the X chromosome. Cx32 appears to be involved in forming gap junctions between the folds of Schwann cell membranes. These **Schwann cells** wrap around the axons of peripheral nerves and form a layer of insulating material called **myelin**, which is critical for the conduction of nerve impulses. Mutations in Cx32 appear to hinder diffusion across the concentric layers of myelin, which results in disruption of myelin and hence axonal degeneration. Mutations in Cx26, Cx30, Cx30.3, and Cx31 all cause sensorineural deafness, which may result from poor secretion of K^+ into the endolymph (see Fig. 15-21). Mutations in Cx46 and Cx56—expressed in lens cells of the eye—cause a variety of congenital cataract disorders. **🔴N6-25** Many other human diseases—call **channelopathies**—involve either a genetic defect of a particular channel protein or an autoimmune response directed against a channel protein (see Table 6-2).

Genetic and Autoimmune Ion Channel Defects

Contributed by Ed Moczydlowski

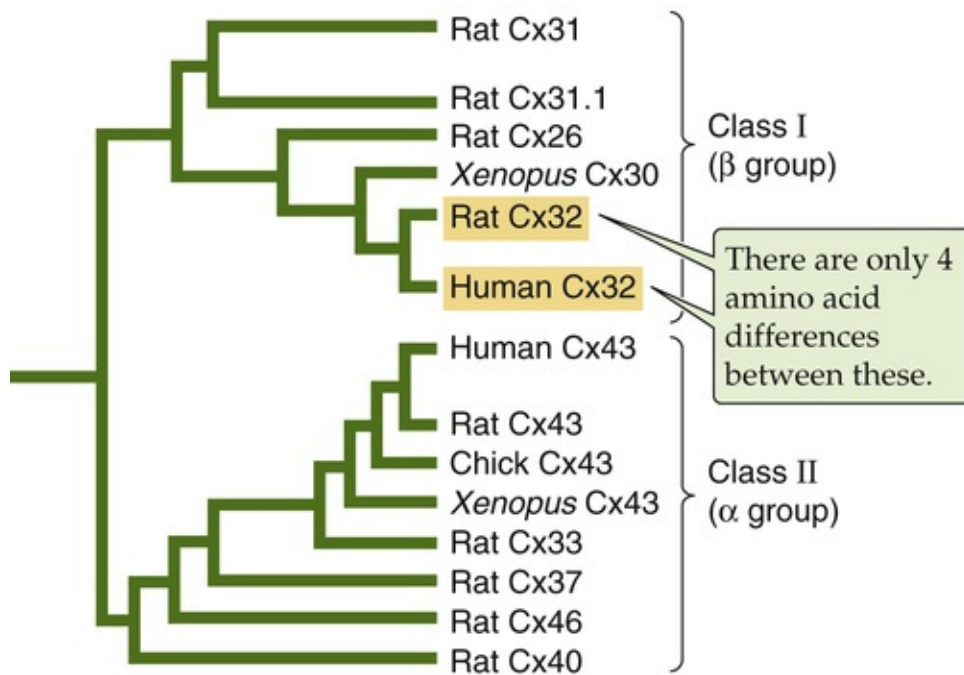

Channel	Disease	Etiology
Voltage-Gated K⁺ Channels		
KvLQT1 (old terminology) cardiac K ⁺ channel, also known as KCNQ1	A form of long QT syndrome	Mutation of KCNQ gene on chromosome 11. See Box 7-3.
Cardiac K ⁺ channel (HERG)	A form of long QT syndrome	Mutation. See Box 7-3.
Voltage-Gated Na⁺ Channels		
Skeletal muscle Na ⁺ channel (Nav1.4)	A form of hyperkalemic periodic paralysis (HYPP)	Mutation of SCN4A gene located on human chromosome 17. See Box 7-1.
Skeletal muscle Na ⁺ channel (Nav1.4)	Paramyotonia congenita (PC)	Mutation of SCN4A gene located on human chromosome 17. See Box 7-1.
Cardiac muscle Na ⁺ channel (Nav1.5)	A form of long QT syndrome	Mutation of SCN5A gene located on human chromosome 17. See Box 7-1.
Voltage-Gated Ca²⁺ Channels		
α _{1S} subunit (old terminology) of skeletal muscle L-type Ca ²⁺ channel, also known as Cav1.1	A form of muscular dysgenesis	Mutation of CACNA1S gene on chromosome 1.
Presynaptic (i.e., on motor neuron) Ca ²⁺ channels at neuromuscular junction	Lambert-Eaton syndrome	Autoimmune; most often seen in patients with certain types of cancer, such as small-cell lung carcinoma. See Box 8-1.
α _{1S} subunit (old terminology) of skeletal muscle L-type Ca ²⁺ channel, also known as Cav 1.1	A form of hypokalemic periodic paralysis	Mutation of CACNA1S gene on chromosome 1.
α _{1A} subunit (old terminology) of P/Q-type Ca ²⁺ channel, also known as Cav2.1	Familial hemiplegic migraine	Mutation of CACNA1A gene on chromosome 19. See Box 7-2.
α _{1A} subunit (old terminology) of P/Q-type Ca ²⁺ channel, also known as Cav2.1	Episodic ataxia type 2	Mutation of CACNA1A gene on chromosome 19; ataxia originating from the cerebellum. See Box 7-2.
Ligand-Gated Channels		
N ₁ nicotinic ACh receptor (AChR)	Myasthenia gravis	Autoimmune disease attacking the junctional nicotinic AChR (α ₂ βεδ pentamer). See Box 8-1.
Other Channels		
Cx32 (connexin making up gap junction)	Charcot-Marie-Tooth disease	Mutation.
CFTR	Cystic fibrosis	Mutation. See p. 120 of the text for a discussion of the channel, and Box 43-1 for a discussion of the disease.
β or γ subunit of ENaC epithelial Na ⁺ channel	Liddle syndrome	Gain-of-function mutation due to defective endocytosis of ENaC channels on the apical membrane. See pp. 758–759 of the text for a discussion of the channel. For a discussion of the syndrome, see  N23-14.

An evolutionary tree called a dendrogram illustrates the relatedness of ion channels

Comparisons of amino-acid sequences of channels and of the nucleotide sequences of genes that encode them provide insight into the molecular evolution of these proteins. The current human genome database contains at least 263 different genes encoding channel proteins. Like other proteins, specific isoforms of channels are differentially expressed in different parts of cells in various tissues and at certain stages of development. In particular, many different kinds of channels are expressed in the brain. In the central nervous system, the great diversity of ion channels provides a means of specifically and precisely regulating the complex electrical activity of 100 billion brain neurons that are connected in numerous functional pathways.

As an example of the diversity and species interrelatedness of a channel family, consider the connexins. [Figure 6-19A](#) compares 14 sequences of homologous proteins that are members of the connexin family. Like many other proteins, connexins are encoded by a family of related genes that evolved by gene duplication and divergence. In the connexin family, various subtypes are named according to their protein molecular masses. Thus, rat Cx32 refers to a rat connexin with a protein molecular mass of ~32 kDa. The various connexins differ primarily in the length of the intracellular C-terminal domain.

A VARIOUS SPECIES

B HUMAN

FIGURE 6-19 Family tree of hypothetical evolutionary relationships among connexin sequences of gap junction channels. **A**, Dendrogram based on amino-acid sequence differences among 14 connexins in various species. The summed length of the horizontal line segments connecting two connexins is a measure of the degree of difference between the two connexins. **B**, Dendrogram based strictly on human sequences. (**A**, Data from Dermietzel R, Spray DC: Gap junctions in the brain: Where, what type, how many and why? Trends Neurosci 16:186–192, 1993; **B**, data from White TW: Nonredundant gap junction functions. News Physiol Sci 18:95–99, 2003.)

By aligning connexin sequences according to identical amino acids and computing the relative similarity of each pair of connexin sequences, it is possible to reconstruct a hypothetical phylogenetic tree of evolutionary relationships. Such a tree is called a **dendrogram**. The one in Figure 6-19A includes nine rat, two human, one chicken, and two frog (*Xenopus*) connexins. The horizontal branch lengths of the tree

are approximately proportional to the sequence differences or evolutionary divergence between protein members of the family. Closely grouped clusters of sequences in the tree represent evolutionarily related groups of proteins. The connexin tree indicates that the Cx32 genes from rats and humans are very closely related, differing by only 4 amino acids of a total of 284 residues. Thus, these Cx32 proteins probably represent the same functional genes in these two species—**orthologous genes**. The closely related Cx43 genes from the rat and human are also likely to be orthologs.

A sequence analysis restricted to only *human* connexin genes reveals five families—*GJA* through *GJE*—that cluster in the dendrogram in [Figure 6-19B](#). Related channel proteins often exhibit different patterns of tissue expression. For example, Cx32 is expressed in the liver, Schwann cells, and oligodendrocytes, whereas Cx43 is expressed in heart and many other tissues.

The functional properties of channels are generally consistent with the classification of channel subtypes based on molecular evolution. For example, ion channels that are voltage gated (see [p. 189](#)) share sequence homology of their voltage-sensing domain.

Hydrophobic domains of channel proteins can predict how these proteins weave through the membrane

From sequence information and atomic-resolution structures of many ion channels, a number of common structural principles emerge. Like other integral membrane proteins (see [pp. 16–19](#)), channel proteins generally have several segments of hydrophobic amino acids, each long enough (~20 amino acids) to span the lipid bilayer as an α helix. If the channel has N membrane-spanning segments, it also has $N + 1$ hydrophilic domains of variable length that connect or terminate the membrane spans. Many putative transmembrane segments predicted by hydropathy analysis (see [Table 2-1](#)) have proven to be transmembrane segments in an α -helical conformation. The intervening hydrophilic segments that link the transmembrane regions together typically fold to form extracellular and intracellular protein domains that contact the aqueous solution.

The primary sequences of channel proteins are often schematically represented by hypothetical folding diagrams, such as those shown in [Figure 6-20](#). For example, connexin monomers have four identifiable hydrophobic transmembrane segments, known as M1, M2, M3, and M4 (see [Fig. 6-20A](#)). The crystal structure of Cx26 indicates that the N-terminal and C-terminal hydrophilic segments of connexin are located on the cytoplasmic side of the membrane. The N terminus is involved in voltage gating of the channel, and TM1 is the major pore-lining helix (see [Fig. 6-18B](#)). Mutations in Cx32 and many other connexin genes result in a wide variety of physiological abnormalities (see [Box 6-1](#)).

Protein superfamilies, subfamilies, and subtypes are the structural bases of channel diversity

Table 6-2 summarizes the basic functional and structural aspects of currently recognized families of the pore-forming subunits of human ion channel proteins. The table (1) groups these channels into structurally related protein families; (2) describes their properties; (3) lists the assigned human gene symbols, number of genes, and protein names; (4) summarizes noted physiological functions; (5) lists human diseases associated with the corresponding ion channels; and (6) provides a reference to [Figure 6-20](#) that indicates the hypothetical membrane topology. Because some of the membrane-topology diagrams in [Figure 6-20](#) are based primarily on hydropathy analysis, they should be considered “best-guess” representations unless the three-dimensional structure has been established by structural biology. Here, we briefly summarize major aspects of the molecular physiology of human ion channel families, in the order of their presentation in [Table 6-2](#).  **N6-22**

N6-22

Voltage-Gated Channels

Contributed by Ed Moczydlowski

Some families of channel proteins are so large and diverse that they are known as **superfamilies**. For example, the superfamily of **voltage-gated channels** consists of K⁺, Na⁺, and Ca²⁺ channels, respectively denoted Kv, Nav, and Cav. These channels have a common structural motif (see pp. 182–199). These channels play a primary role in electrical signaling in the nervous system, where they underlie the voltage-dependent depolarization (Nav, Cav) and hyperpolarization (Kv) of propagating action potentials (discussed in Chapter 7). The pore-forming complex of each of these channels consists of four subunits or domains, each of which contains six transmembrane segments denoted as S1 through S6. Voltage-gated **K⁺ channels** are believed to represent an evolutionary precursor to Nav and Cav channels because their pore-forming subunit contains only one S1 through S6 domain (see Fig. 6-20B). Voltage-gated K⁺ channels are homotetramers or heterotetramers of monomer subunits. The pore-forming subunits of **Na⁺ and Ca²⁺ channels** (see Fig. 6-20K, L) both comprise four domains (I, II, III, and IV), each of which contains the S1 through S6 structural motif that is homologous to the basic voltage-gated K⁺ channel subunit or monomer. Because domains I through IV of Nav and Cav channels are organized as four tandem repeats within the membrane, these domains are referred to as **pseudosubunits**. The molecular evolution of the four-repeat structure of Nav and Cav channels is believed to have occurred by a process involving consecutive gene duplication from a primordial gene containing S1 through S6. Members of the voltage-gated superfamily of channels are also recognized by a characteristic structure of the S4 transmembrane segment in which four to seven positively charged residues (lysine or arginine) are located at every third position. This unique S4 domain appears to function as the voltage-sensing element of voltage-gated ion channels (see p. 184).

Voltage-gated Ca²⁺ channels also illustrate another feature of some ion channels: they are multisubunit

complexes consisting of **accessory proteins** in addition to the channel-forming subunits. For example, Cav channels are composed of a large pseudotetrameric α_1 subunit with domains I through IV that form the pore, plus four additional structurally unrelated subunits known as α_2 , β , γ , and δ (see Fig. 6-20L). Like the homologous α subunit of Nav channels, the large α_1 subunit of Cav channels specifies most of the basic channel functions, including ionic selectivity, voltage sensitivity, and the binding sites of various drugs. It appears that the β , γ , and δ subunits are important for modulating the activity of Ca^{2+} channels, but their exact functional roles are largely unknown. In some cases, accessory subunits modulate the gating activity and pharmacology of channel complexes, whereas in other cases such accessory subunits of channels may help target newly synthesized channels to their proper cellular locations.

Connexins

We discussed these channels above in the section on gap junctions, in [Figures 6-18, 6-19, and 6-20A](#), as well as in [Box 6-1](#).

K⁺ Channels

The tetrameric K⁺ channels form the largest and most diverse family of ion channels. They are part of the voltage-gated-like (VGL) superfamily of channels, which includes all channels in [Figure 6-20B through M](#). The K⁺-selective pore of K⁺ channels is formed by a highly conserved domain containing two transmembrane segments linked by a pore loop labeled *P* in the figure. The family includes five distinct subfamilies, all of which we will discuss beginning on [p. 189](#): (1) **Kv** voltage-gated K⁺ channels (see [pp. 193–196](#)), (2) **SK_{Ca}** small- and **IK_{Ca}** intermediate-conductance Ca^{2+} -activated K⁺ channels (see [pp. 193–196](#)), (3) **BK_{Ca}** large-conductance Ca^{2+} - and voltage-activated K⁺ channels (see [p. 196](#)), (4) **Kir** inward-rectifier K⁺ channels (see [p. 196](#)), and (5) **K2P** dimeric tandem two-pore K⁺ channels (see [p. 199](#)). For the first two subfamilies, each of the four subunits contains six TMs denoted S1 to S6 (see [Fig. 6-20B, C](#)). BK_{Ca} channels are similar to Kv channels but have an additional S0 TM (see [Fig. 6-20D](#)). Kir channels are structurally the simplest members of the K⁺ channel family because each of the four subunits contains two TMs analogous to S5 and S6 in the Kv channels (see [Fig. 6-20E](#)). K2P channels are the equivalent of a tandem duplication of Kir channels so that two K2P subunits form a pseudotetrameric channel (see [Fig. 6-20F](#)).

HCN, CNG, and TRP Channels

HCN hyperpolarization-activated, cyclic nucleotide-gated cation channels (see [Fig. 6-20G](#)) play a critical role in electrical automaticity of the heart (see [p. 488](#)) and rhythmically firing neurons of the brain. **CNG** channels form a family of cation-selective channels that are directly activated by intracellular cGMP or cAMP. These channels play an important role in visual (see [p. 368](#)) and olfactory sensory transduction (see [p. 359](#)). The CNGs have the same basic S1 through S6 motif as K⁺ channels, but they contain a unique cyclic nucleotide-binding domain at the C terminus (see [Fig. 6-20H](#)). **TRP** transient receptor potential cation channels (see [Fig. 6-20I](#)) function in diverse sensory processes and include six subfamilies: TRPA (for ankyrin like), TRPC (for canonical), TRPM (for melastatin), MCOLN or TRPML (for mucolipin), PKD or TRPP (for polycystin 2), and TRPV (for vanilloid). TRPV1 is activated by capsaicin, the “hot” ingredient of chili peppers, whereas TRPM8 responds to menthol, the “cool”-tasting substance in eucalyptus leaves. The capsaicin receptor TRPV1 functions in pain and temperature sensation.

NAADP Receptor

NAADP (nicotinic acid adenine dinucleotide phosphate) is an intracellular signaling molecule. Two TPCN genes in the human genome encode a protein with two tandem repeats of an S1 to S6 motif (see [Fig. 6-20J](#)). These proteins function in NAADP-activated release of Ca^{2+} from the endoplasmic reticulum and acidic compartments.

Voltage-Gated Na^+ Channels

The 10 pore-forming subunits of **Nav** voltage-gated Na^+ channels comprise four domains (I, II, III, and IV), each of which contains the S1 to S6 structural motif (see [Fig. 6-20K](#)) that is homologous to Kv K^+ channel monomers. Because domains I to IV of Nav channels are organized as four tandem repeats within the membrane, these domains are referred to as **pseudosubunits**. The Nav channels are associated with a unique family of auxiliary β subunits that are known to modify the gating behavior and membrane localization of the channel-forming α subunit.

Voltage-Gated Ca^{2+} Channels

The pore-forming subunits of **Cav** voltage-gated Ca^{2+} channels (see [pp. 190–191](#)) are analogous to those for the Nav channels (see [Fig. 6-20L](#)). Like Nav channels, Cav channels are multisubunit complexes consisting of **accessory proteins** in addition to the channel-forming subunits.

CatSper Channels

The unique class of CatSper tetrameric channels—with an S1 to S6 motif (see [Fig. 6-20M](#))—is expressed in the sperm tail membrane. These channels mediate a voltage-dependent Ca^{2+} current that is essential for male fertility (see [Fig. 56-1](#)).

Hv Channels

The unusual Hv channel protein consists of an S1 to S4 voltage-sensing motif but lacks a conventional S5-P-S6 pore domain (see [Fig. 6-20N](#)). The Hv protein functions as an H^+ channel that opens only when the cell is sufficiently depolarized to mediate H^+ *efflux*. Hv, as a functional component of the NADPH (reduced nicotinamide adenine dinucleotide phosphate) oxidase complex, is important in the innate immune response of neutrophils; Hv is also involved in sperm activation.

Ligand-Gated Channels

The agonist-activated channels are also represented by three large and diverse gene families. The **pentameric Cys-loop receptor family** (see [Fig. 6-20O](#)) includes cation- or Cl^- -selective ion channels that are activated by binding of ACh (see [pp. 212–213](#)), serotonin, GABA, and glycine (see [pp. 326–327](#)). **Glutamate-activated cation channels** (see [Fig. 6-20P](#)) include two subfamilies of excitatory AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid)–kainate and NMDA (*N*-methyl-D-aspartate) receptors (see [pp. 323–324](#)). **Purinergic ligand-gated cation channels** (see [Fig. 6-20Q](#)) are activated by binding of extracellular ATP and other nucleotides (see [p. 327](#)).

Other Ion Channels

ENaC amiloride-sensitive Na^+ channels are prominent in Na^+ -transporting epithelia (see [Fig. 6-20R](#) and [pp. 758–759](#)). The **cystic fibrosis transmembrane conductance regulator (CFTR)** is a Cl^- channel (see

Fig. 6-20S and p. 120) that is a member of the ABC (ATP-binding cassette) protein family. The unrelated ClC family of Cl⁻ channels are dimeric (see Fig. 6-20T).  **N6-23** Two unique genes coding for the **anoctamin** family of Ca²⁺- and voltage-activated Cl⁻ channels have been added to the channel gene collection (see Fig. 6-20U). Table 6-2 includes two types of Ca²⁺ release channels. **ITPR** (see p. 60) is present in the endoplasmic reticulum membrane and is gated by the intracellular messenger IP₃ (see Fig. 6-20V). **RyR** (see p. 230) is located in the sarcoplasmic reticulum membrane of muscle and plays a critical role in the release of Ca²⁺ during muscle contraction (see Fig. 6-20W). A recently discovered family of Ca²⁺-selective-channel proteins known as **Orai store-operated Ca²⁺ channels** (see Fig. 6-20X) plays a role in entry of extracellular Ca²⁺ across the plasma membrane linked to IP₃ metabolism and depletion of intracellular Ca²⁺ from the endoplasmic reticulum of nonexcitable cells, such as lymphocytes (see p. 247).

CHAPTER 7

Electrical Excitability and Action Potentials

Edward G. Moczydlowski

Cellular communication in the nervous system is based on electrical and chemical signaling events that are mediated by ion channels. Certain types of cells, including neurons and myocytes, have a remarkable property called **electrical excitability**. In cells with this property, depolarization of the membrane above a certain **threshold** voltage triggers a spontaneous all-or-none response called an **action potential**. This action potential is a transient, regenerative electrical impulse in which the membrane potential (V_m) rapidly rises to a peak that is ~ 100 mV more positive than the normal, negative resting voltage (V_{rest}). Such signals, also called spikes, can propagate for long distances along nerve or muscle fibers. Conduction of action potentials allows information from sensory organs to be transmitted along afferent nerves leading to the brain. Conversely, the brain exerts voluntary and involuntary control over muscles and other effector organs by efferent nerves leading away from it.

In the first part of this chapter, we examine the biophysical and molecular basis of action potentials and the mechanisms that underlie their genesis and propagation. The second part deals with the structure and function of voltage-gated ion channel proteins. Finally, we examine the conduction properties of neurons—called cable properties—and how they determine the spread of action potentials along the axon.

Mechanisms of Nerve and Muscle Action Potentials

An action potential is a transient depolarization triggered by a depolarization beyond a threshold

The change in membrane potential that occurs during an action potential can be accurately measured by recording V_m with an intracellular microelectrode. [Figure 7-1A](#) is a diagram illustrating various features of a typical action potential recorded from a nerve or muscle cell stimulated with an electrode. Alternatively, for cells that are not easily accessible, such as brain neurons, one can induce expression of light-activated ion channels, such as channelrhodopsins from unicellular algae, and use light to change V_m experimentally. **N7-1** If the depolarizing stimulus causes V_m to become more positive than a threshold voltage, the depolarization triggers an action potential. The initial depolarizing (positive-going) phase of an action potential consists of a rapid and smooth increase in V_m from the negative resting potential to a maximum positive value that typically lies between +10 and +40 mV. This sharp rise in V_m to the peak voltage of the action potential is then followed by a slower repolarizing (negative-going) phase. The part of the action potential that lies above 0 mV is called the **overshoot**. As we will see, the time course and shape of the repolarization phase vary considerably among different excitable tissues and cells. The repolarization phase may lead directly back to V_{rest} , or it may undershoot and give rise to a voltage minimum that is more negative than V_{rest} before relaxing back to V_{rest} . Such an undershoot is an example of an **afterhyperpolarization**.

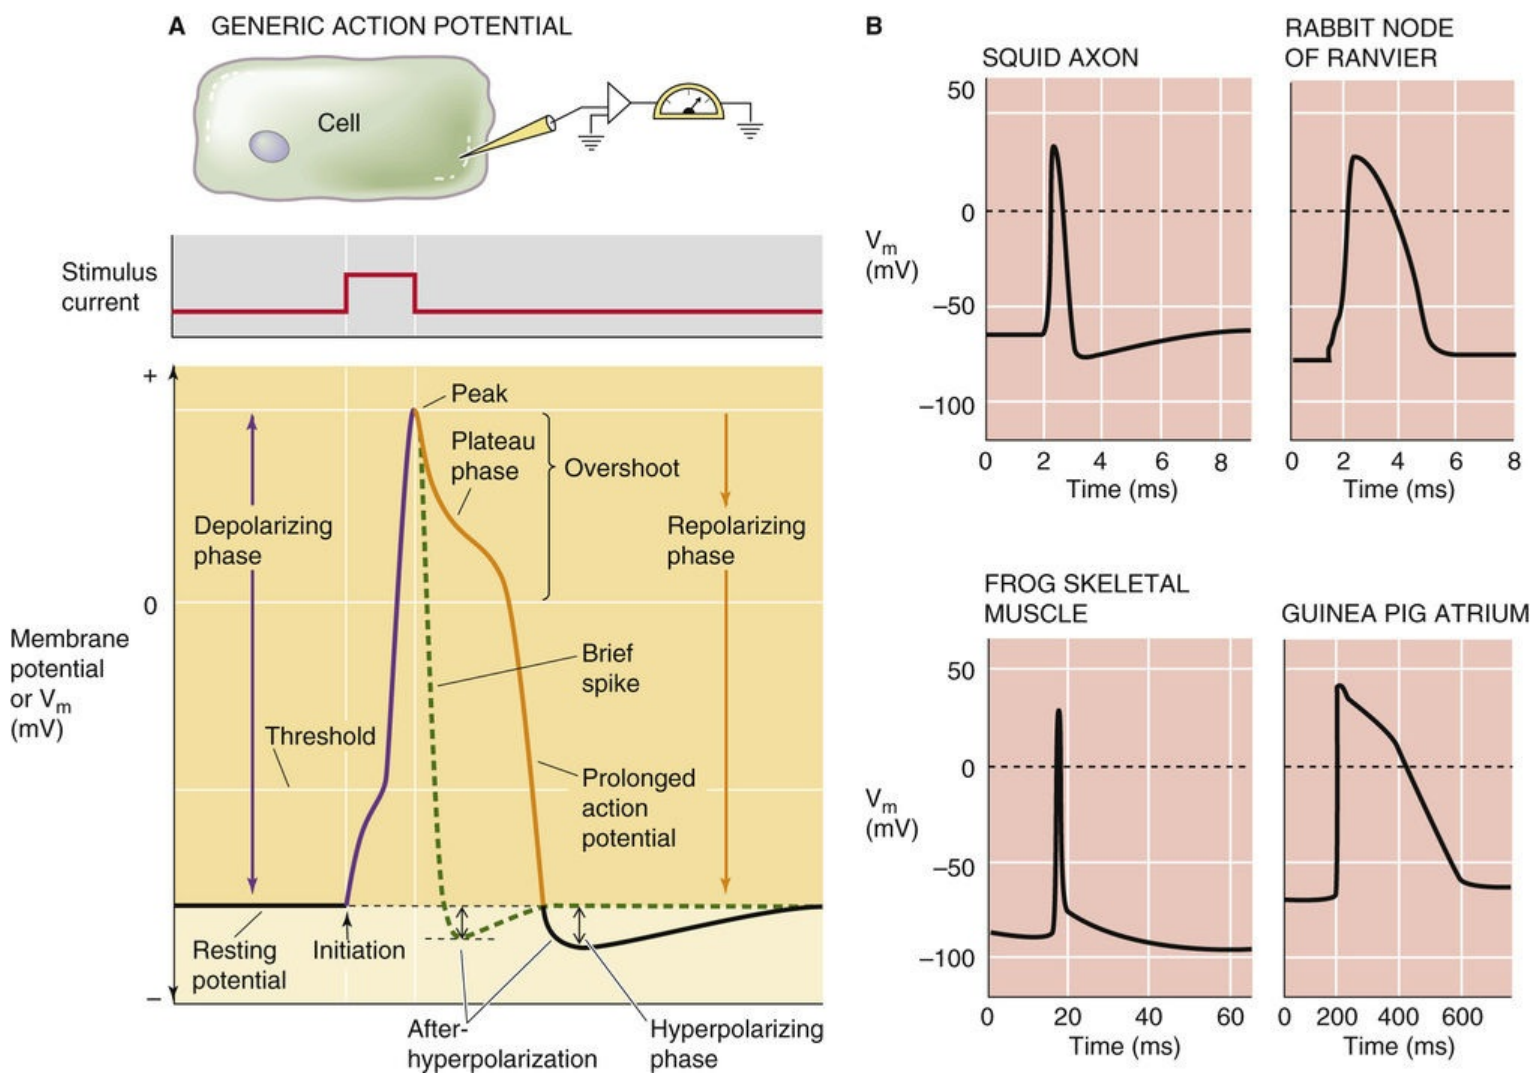

FIGURE 7-1 The action potential.

N7-1

Controlling Membrane Potential with Channelrhodopsins

Contributed by Ed Moczydlowski

An exciting new optical technique involves the use of membrane proteins called channelrhodopsins (ChRs) discovered in single-celled algae such as *Chlamydomonas reinhardtii*. ChR is homologous to the rhodopsin protein of mammalian photoreceptor cells except that it functions as a light-activated ion channel. Expression of engineered ChR in mammalian neurons allows the V_m of the transfected neurons to be changed by simple illumination with light of an appropriate wavelength absorbed by the ChR. Thus, ChR and related light-gated channels can be used as optical switches to turn on or off the electrical activity of specific cells in various tissues such as the brain. This method has initiated a new field called *optogenetics* which enables the function of individual cells in the nervous system to be studied by observing the physiological response to light activation in living transgenic animals. Someday it may be possible to control arrhythmia in a diseased heart with light or to restore visual perception to a defective retina with the use of such approaches.

The threshold, amplitude, time course, and duration of the action potential depend on the following factors:

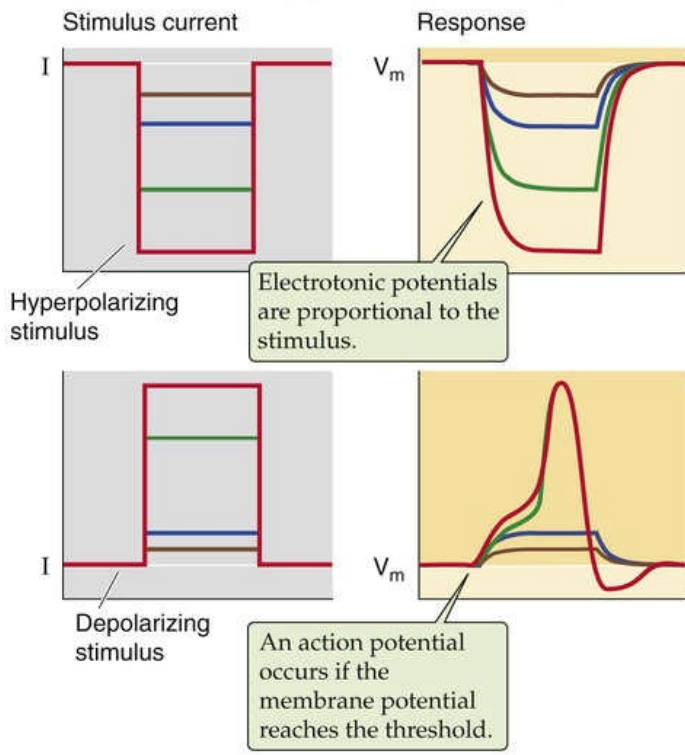

1. The gating (opening and closing) and permeability properties of specific types of ion channels—these properties depend on both V_m and time.
2. The intracellular and extracellular concentrations of the ions that pass through these channels, such as Na^+ , K^+ , Ca^{2+} , and Cl^- .
3. Membrane properties such as capacitance, resistance, and the geometry of the cell.

The shape of the action potential in a given cell reflects the specialized functions of that cell. For example, the brief action potentials of a nerve axon permit rapid signaling, whereas the prolonged, repetitive action potentials of cardiac and certain types of smooth-muscle cells mediate the slower, rhythmic contractions of these tissues. [Figure 7-1B](#) compares action potentials recorded from an invertebrate nerve fiber (unmyelinated squid axon), a vertebrate nerve fiber (myelinated rabbit axon), a skeletal muscle fiber, and a cardiac atrial myocyte. This comparison illustrates the diversity in the duration and shape of the repolarizing phase of action potentials. The shape of the action potential is subject to hormonal modulation in certain cell types. As one example, the peptide hormone endothelin, produced by vascular endothelial cells, shortens the duration of the action potential when it is applied to a guinea pig atrial myocyte. Modulation of the shape and frequency of action potentials occurs by various biochemical regulatory mechanisms that affect the function of ion channels.

In contrast to an action potential, a graded response is proportional to stimulus intensity and decays with distance along the axon

Not all electrical activity in nerve or muscle cells is characterized by an all-or-none response. When we apply a small square pulse of hyperpolarizing current to a cell membrane, V_m gradually becomes more negative and then stabilizes ([Fig. 7-2A](#)). In such an experiment, the observed change in V_m approximates an exponential time course, with a time constant (see [p. 151](#)) that is determined by the product of membrane resistance and capacitance ($\tau = RC$). [Figure 7-2A](#) also shows that progressively greater hyperpolarizing currents produce progressively larger V_m responses, but the time constant is always the same. The size of the **graded voltage change** (i.e., the steady-state ΔV_m) is proportional to the strength of the stimulus (i.e., the current), in accord with Ohm's law.

A RESPONSE TO GRADED CURRENT STIMULI

B RESPONSE TO STIMULI AS A FUNCTION OF DISTANCE

FIGURE 7-2 Basic properties of action potentials. **A**, The upper panels show four graded hyperpolarizing stimuli and the V_m responses. The lower panels show four graded depolarizing stimuli and the V_m responses. Note that the two largest stimuli evoke identical action potentials. **B**, A stimulating electrode injects current at the extreme left of the cell. Four recording electrodes monitor V_m at equidistant sites to the right. If the stimulus is hyperpolarizing, the graded V_m responses decay with distance from the stimulus site. If the stimulus is depolarizing and large enough to evoke an action potential, a full action potential appears at each of the recording sites. However, the action potential arrives at the more distant

If instead of imposing a hyperpolarizing stimulus we impose a small *depolarizing* stimulus, V_m changes to the same extent and with the same time course as we described for the hyperpolarizing stimulus, but in the opposite direction (see [Fig. 7-2A](#)). The size of ΔV_m is also proportional to the size of the depolarizing stimulus—up to a point. If the membrane is excitable, a square-wave depolarization above the threshold triggers an action potential, or voltage spike. Smaller or **subthreshold depolarizations** do not elicit an action potential. *Hyperpolarizations* are always ineffective. Thus, both hyperpolarizations and subthreshold depolarizations behave like graded voltage changes. That is, the magnitude of a cell's voltage change increases proportionally with the size of the stimulus. Such graded responses can be seen in the response of certain cells to synaptic transmitters, to sensory stimuli (e.g., light), or, in the laboratory, to the injection of current into cells through a microelectrode.

Why do excitable cells exhibit threshold behavior? As V_m becomes progressively more and more positive, the **gating** process (i.e., transitions from closed to open states) of certain types of voltage-gated ion channels becomes activated. When V_m passes the threshold, opening of these voltage-gated channels initiates the runaway depolarization that characterizes the rising phase of the action potential. Thus, the firing of an action potential is a binary, all-or-none event; that is, the spike has a constant, nongraded voltage peak that occurs only if the depolarizing stimulus exceeds the threshold.

Thus far we have seen that graded responses and action potentials differ markedly from one another if we examine the cell at one particular site. However, graded responses and action potentials also behave very differently in the way that they spread along the membrane from the site of origin. [Figure 7-2B](#) illustrates how a graded hyperpolarizing response spreads along the axon of a neuron or along a skeletal muscle fiber. As the graded response spreads, its magnitude decays exponentially with the distance from the site of stimulation because of passive loss of electrical current to the medium. This decay is called **electrotonic conduction**. We see the same kind of electrotonic spread for a subthreshold, depolarizing stimulus. The electrotonic spread of graded responses is governed by the same physical principles that determine the spread of electrical current in an electrical cable. We briefly discuss **cable theory** at the end of this chapter.

Active propagation of an action potential signal is very different from the passive spread of a graded signal. In a healthy axon or muscle fiber, action potentials propagate at a constant velocity (up to ~ 130 m/s), without change in amplitude or shape. The amplitude of a propagating action potential does not diminish with distance, as would a graded, subthreshold response, because excitation of voltage-gated channels in adjacent regions of the excitable membrane progressively regenerates the original response. Because the action potential in a given nerve fiber propagates at a constant velocity, the time delay between the stimulus and the peak of the action potential increases linearly with distance from the point of the stimulus.

Excitation of a nerve or muscle depends on the product (strength \times duration) of the stimulus and on the refractory period

In the preceding section, the importance of the *magnitude* (intensity) of the depolarizing stimulus emerged as a critical factor for firing of an action potential. However, the *duration* of the stimulus pulse is also important. A large stimulus is effective in triggering an action potential even at short duration, and a small

stimulus may be effective at long duration (Fig. 7-3A). This strength-duration relationship arises because the same minimum electrical charge necessary to excite an action potential can come from a current that is either brief but large or prolonged but small. It is the *product* of strength and duration that determines excitability, and thus these two parameters are inversely related in their effectiveness. However, regardless of the stimulus strength, successful stimulation requires a minimum duration (vertical asymptote in Fig. 7-3A). Conversely, regardless of the stimulus duration, successful stimulation requires a minimum strength (horizontal asymptote in Fig. 7-3A). **N7-2**

FIGURE 7-3 Determinants of nerve and muscle excitability. The curve in **A** represents the combination of the minimum stimulus intensity and duration that is required to reach threshold and to evoke an action potential. **B** shows a typical action potential with corresponding refractory periods.

N7-2

Rheobase and Chronaxie

Contributed by Emile Boulpaep, Walter Boron

Figure 7-3A in the text shows a strength-duration curve for nerve or muscle. As the duration of a stimulus increases, the minimum intensity of stimulation required to elicit an action potential decreases. The **rheobase** is the minimum intensity of stimulation required to generate an action potential when the stimulation is of infinite duration (i.e., the horizontal dashed line in Fig. 7-3A). Stimuli with an intensity greater than the rheobase require shorter times. When the stimulus intensity is twice the rheobase, the minimum duration required to achieve an action potential is the **chronaxie**.

An important feature of excitable cells is their ability to fire repetitive action potentials. Once a cell fires an action potential, how quickly can it fire a second? Suppose we inject a small step of current to produce a graded voltage response and then add a second current step while maintaining the first step. As long as V_m does not exceed the threshold, the resulting voltage response would be a simple algebraic and instantaneous summation of the two graded responses. The situation for action potentials is quite different. First, action potentials never summate. Second, after one action potential fires, a finite time must elapse

before it is possible to trigger a second. The interval after initiation of an action potential when it is impossible or more difficult to produce a second spike is the **refractory period** (see Fig. 7-3B). The refractory period consists of two distinct phases. The initial phase—the **absolute refractory period**—lasts from initiation of the spike to a time after the peak when repolarization is almost complete. Throughout this first phase, a second action potential cannot be elicited, regardless of the stimulus strength or duration. During the second phase—the **relative refractory period**—the minimal stimulus necessary for activation is stronger or longer than predicted by the strength-duration curve for the first action potential. The two phases of the refractory period arise from the gating properties of particular Na^+ and K^+ channels and the overlapping time course of their currents. The refractory periods determine the upper limit of firing frequency.

The action potential arises from changes in membrane conductance to Na^+ and K^+

Approximately 200 years after Luigi Galvani (1737–1798) discovered “animal electricity,” (see p. 141), the electrochemical basis of the nerve action potential was finally elucidated by the combined application of modern electrical recording techniques and the theory of electrodiffusion (see pp. 146–147). We now understand that the nerve action potential is a phenomenon involving voltage-dependent currents of Na^+ and K^+ that flow through distinct molecular pathways called Na^+ channels and K^+ channels. In 1963, Alan L. Hodgkin and Andrew F. Huxley shared the Nobel Prize in Physiology or Medicine  **N7-3** for their quantitative description of these ionic currents in the squid giant axon in studies involving two-electrode voltage-clamp recordings.  **N7-4** Invertebrate axons are unmyelinated, and axons in certain squid nerves have an unusually large diameter (500 to 1000 μm), which allows both external and internal ionic concentrations to be manipulated experimentally. The basic concepts underlying the Hodgkin-Huxley analysis have since been extended to a wide variety of voltage-dependent ionic currents.

N7-3

Alan L. Hodgkin and Andrew F. Huxley

N7-4

Two-Electrode Voltage Clamping

Contributed by Ed Moczydlowski

Historically, the technique of two-electrode voltage clamping was first used to analyze the ionic currents in a preparation known as the perfused squid giant axon. Certain nerve fibers of the squid are so large that their intracellular contents can be extruded and the hollow fiber can be perfused with physiological solutions of various ionic composition. Electrodes in the form of thin wires can be inserted into the axon to clamp the axon membrane potential along its length and measure the current. This technique was used by Alan L. Hodgkin and Andrew F. Huxley in 1952 to deduce the nature of ionic conductance changes that underlie the nerve action potential. For this work, Hodgkin and Huxley shared (with J.C. Eccles) the

Nobel Prize in Physiology or Medicine in 1963. **N7-3** The Hodgkin-Huxley analysis is discussed further beginning on pages 176–177.

Another, more recent, application of the two-electrode voltage-clamp technique is called **oocyte recording** (see Fig. 6-13A). A large oocyte from the African clawed frog, *Xenopus laevis*, is simultaneously impaled with two micropipette electrodes that serve to clamp the voltage and record current. Native *Xenopus* oocytes have only small endogenous currents, but they can be induced to express new currents by preinjecting the cell with messenger RNA (mRNA) transcribed from an isolated gene that codes for an ion channel protein. The oocyte system can therefore be used to characterize the conductance behavior of a relatively pure population of ion channels that are expressed in the plasma membrane after protein translation of the injected mRNA by the oocyte. This approach has proven to be an invaluable assay system for isolating complementary DNA molecules coding for many different types of channels and electrogenic transporters (see Chapter 5). This approach also has become a standard technique used to study the molecular physiology and pharmacology of ion channels.

The squid axon generates a very brief action potential signal without a significant plateau phase (Fig. 7-4). Ionic permeability changes underlying this impulse can be interpreted with a form of the constant-field equation (see Equation 6-9) that includes only Na^+ and K^+ :

$$V_{\text{rev}} = \frac{RT}{F} \ln \left(\frac{P_{\text{K}}[\text{K}^+]_{\text{o}} + P_{\text{Na}}[\text{Na}^+]_{\text{o}}}{P_{\text{K}}[\text{K}^+]_{\text{i}} + P_{\text{Na}}[\text{Na}^+]_{\text{i}}} \right) \quad (7-1)$$

According to Equation 7-1, V_{rev} would correspond to a resting V_{m} of -60 mV for a K^+/Na^+ permeability ratio ($P_{\text{K}}/P_{\text{Na}}$) of $\sim 14 : 1$. The change in V_{m} to a value near $+40$ mV at the peak of the action potential must involve a transient and selective increase in the permeability to either Na^+ or Ca^{2+} because the equilibrium potential of these cations lies in the positive voltage range (see Fig. 6-10). Experimentally, if $[\text{Na}^+]_{\text{o}}$ is reduced by replacing it with a nonelectrolyte such as sucrose, the nerve action potential decreases in amplitude. Complementary experiments measuring radioactive tracer fluxes of Na^+ and K^+ also demonstrate that action potentials are accompanied by a small influx of Na^+ and an efflux of K^+ . These and related findings showed that the waveform of the squid action potential is produced by separate permeability pathways for Na^+ and K^+ .

FIGURE 7-4 Changes in ionic conductance that underlie the action potential. (Data from Hodgkin AL, Huxley AF: A quantitative description of membrane current and its application to conduction and excitation in nerve. *J Physiol* 117:500–544, 1952.)

The time course of the action potential (see Fig. 7-4) can be dissected into an initial, transient increase in Na^+ conductance (and thus permeability), followed by a similar but delayed increase in K^+ conductance. As one predicts from Equation 6-12, a transient increase in Na^+ conductance shifts V_m toward the positive Na^+ equilibrium potential (E_{Na}). The subsequent increase in K^+ conductance shifts V_m back toward the K^+ equilibrium potential (E_{K}), thereby restoring the original negative resting potential. Thus, the depolarizing and repolarizing phases of the action potential reflect a transient reversal of the ratio of K^+/Na^+ conductances.

The Na^+ and K^+ currents that flow during the action potential are time and voltage dependent

The assumption of independent, distinct channels for Na^+ and K^+ has been verified by ion substitution and pharmacological experiments. Figure 7-5 illustrates the use of inhibitors to dissect Na^+ and K^+ currents (I_{Na} and I_{K}) from the total membrane current (I_m) in a typical excitable membrane preparation, such as a myelinated vertebrate nerve fiber bathed in a normal physiological solution. In a myelinated nerve, these currents flow through small segments of the bare axon that are *not* covered with myelin—nodes of Ranvier. The pharmacological dissection of Na^+ and K^+ currents allows us to determine how they depend on time and V_m .

A HYPERPOLARIZATION**B DEPOLARIZATION****C PHARMACOLOGICAL DISSECTION OF CURRENTS**

FIGURE 7-5 Dissection of Na^+ and K^+ currents by voltage-clamp analysis and pharmacological methods. **A**, In a typical voltage-clamp experiment, a sudden *hyperpolarization* from -80 to -140 mV results in a transient capacitive current but no ionic currents. **B**, In a voltage-clamp experiment, a sudden *depolarization* from -80 to -20 mV results in a transient capacitive current followed first by an inward ionic current and then by an outward ionic current. **C**, Blockade of the outward current by TEA leaves only the inward current, which is carried by Na^+ . Conversely, a blockade of the inward current by TTX or STX leaves only the outward current, which is carried by K^+ .

Time Dependence of Na^+ and K^+ Currents

Stepwise *hyperpolarization* of the nerve membrane (from a “holding potential” of -80 to -140 mV) by a voltage-clamp technique produces a transient capacitive current (see p. 151), but little or no ionic current (see Fig. 7-5A). However, a step *depolarization* of equivalent magnitude produces a capacitive transient current that is followed by a large, time-dependent ionic current (see Fig. 7-5B). This ionic current first flows inward, reaches a maximum in the inward direction, and then reverses to the outward direction. The initial inward current corresponds to a movement of cations into the axon. After the reversal of I_m , the outward current corresponds to an outward movement of cations. Ion substitution experiments—in which selected ions are removed from either the outside or the inside of the cell—have shown that the inward current corresponds to Na^+ current and the outward current corresponds to K^+ current. Applying a particular organic cation, tetraethylammonium (TEA), to an axon prevents the outward I_K and reveals the isolated inward I_{Na} (see Fig. 7-5C, top I_m record). Conversely, adding either tetrodotoxin (TTX) or saxitoxin (STX)—which we discuss below—abolishes the inward I_{Na} and reveals the isolated outward I_K (see Fig. 7-5C, bottom I_m record). TEA, TTX, and STX are cationic molecules

that act as specific ion channel blockers. Millimolar concentrations of TEA block the outer entrance of certain neuronal K^+ channels, and nanomolar concentrations of TTX (or STX) block the outer entrance of neuronal Na^+ channels. Biophysical evidence suggests that these particular molecules act by binding in the outer vestibule of their respective channels, thus occluding the channel pore to permeant ions. Therefore, the terms *channel block* and *blocking agent* are often used to describe their effect.

Voltage Dependence of Na^+ and K^+ Currents

The ability to use specific inhibitors to resolve separate pathways for Na^+ and K^+ currents in excitable membranes makes it possible to characterize how these ionic currents depend on V_m . [Figure 7-6A](#) illustrates an idealized family of records of total membrane current (I_m) recorded from a myelinated nerve axon. In each case, V_m was initially clamped to -60 mV and then rapidly shifted to a more positive value. The five traces in [Figure 7-6A](#) show the current evoked by depolarizations to -45 , -30 , 0 , $+30$, and $+60$ mV. By repeating the same experiment in the presence of TEA or TTX, one can obtain the unique time course and voltage dependence of I_{Na} and I_K .

FIGURE 7-6 Voltage dependence of ionic currents. **A**, The top panels show the time course of the total ionic current. These data are from a voltage-clamp experiment on a frog node of Ranvier. Sudden shifting of V_m from a holding potential of -60 mV to -45 , -30 , 0 , $+30$, and $+60$ mV elicits ionic currents that depend on V_m . **B**, These results are comparable to those in **A**, except that TEA abolished the outward K^+

currents, leaving the Na^+ current. Notice that the peak Na^+ current varies with V_m . **C**, These results are comparable to those in **A**, except that TTX abolished the inward Na^+ currents, leaving the K^+ current. Notice that the peak K^+ current varies with V_m . **D**, The blue curve is a plot of peak Na^+ currents from experiments that are similar to those in **B**. The green curve is a plot of peak K^+ currents from experiments that are similar to those in **C**. Notice that both the Na^+ and K^+ currents are linear or ohmic in the positive voltage range. In a more negative V_m range, the Na^+ current exhibits negative resistance; that is, the magnitude of the current becomes more negative rather than more positive as V_m increases in the positive direction. (**A–C**, Data from Hille B: Common mode of action of three agents that decrease the transient change in sodium permeability in nerves. *Nature* 210:1220–1222, 1966; and Hille B: The selective inhibition of delayed potassium currents in nerve by tetraethylammonium ions. *J Gen Physiol* 50:1287–1302, 1967; **D**, data from Cole KS, Moore JW: Ionic current measurements in the squid giant axon membrane. *J Gen Physiol* 44:123–167, 1960.)

The time course of I_{Na} obtained in the presence of TEA to block K^+ channels is distinctly biphasic (see [Fig. 7-6B](#)). Immediately after a depolarizing voltage step to a V_m of -30 mV, for example, the inward I_{Na} (downward going) reaches a “peak” value and then returns to zero. The initial phase of this time course (before the peak) is called **activation**, and the later phase (after the peak) is called **inactivation**.

In contrast to the time course of I_{Na} , a depolarizing voltage step to a V_m of $+60$ mV, for example, causes the outward I_{K} to activate with a clear delay that gives rise to a sigmoidal time course (see [Fig. 7-6C](#)). Moreover, I_{K} takes longer than I_{Na} to reach its maximal value, which is then sustained. Thus, I_{K} does not show significant inactivation on the same rapid time scale as does I_{Na} .

If we plot the peak Na^+ and K^+ currents obtained at each of the clamped voltages in [Figure 7-6B and C](#) against the clamped voltages, we obtain the two I - V relationships shown in [Figure 7-6D](#). Because the currents in [Figure 7-6B and C](#) represent the activity of many individual ion channels, the plots in [Figure 7-6D](#) are **macroscopic current-voltage relationships**. The I - V relationship for K^+ is the more straightforward of the two. If we step V_m from -60 mV to increasingly more positive values, the peak I_{K} is outward and increases with voltage in a monotonic fashion, as expected from Ohm's law ($\Delta I = \Delta V/R$). Because such nerve K^+ channels pass current in the outward direction and activate with a time delay (see [Fig. 7-6C](#)) under physiological conditions, the term **delayed-rectifier K^+ current** (or delayed outwardly rectifying K^+ channel) has been coined to describe them. We discuss this delayed outwardly rectifying K^+ current and the K^+ channel responsible for it in more detail below.

The voltage dependence of the peak Na^+ current is biphasic. Stepping V_m from -60 mV to more positive values at first causes I_{Na} to become increasingly negative (i.e., inward) and then reach a peak. This portion of the Na^+ I - V relationship is sometimes referred to as the negative resistance region because the negative slope corresponds to an anomalous or negative resistance value according to Ohm's law ($\Delta I = \Delta V/R$). At more positive values of V_m , the peak I_{Na} reverses direction and becomes more positive, with a nearly linear or ohmic dependence on voltage. 🍷N7-5

N7-5

Ohmic I - V Curve

Contributed by Ed Moczydlowski

According to Ohm's law ($I = V/R$), the I - V relationship is a straight line if $1/R$ (i.e., the conductance) is constant. The slope is positive. For a simple electrical circuit consisting of a resistor and a voltage source, the line passes through the origin (i.e., $I = 0$ when $V = 0$). However, if the Na^+ current (I_{Na}) were

ohmic (i.e., we assume that the $[Na^+]$ is the same on both sides of the membrane), I_{Na} is zero when the driving force ($V_m - E_{Na}$) is zero (see Equation 7-2 on p. 180 of the text). Therefore, the I - V plot for an Na^+ current passes through the x-axis at the equilibrium potential for Na^+ (E_{Na}).

In real-life situations, the I - V curve for Na^+ currents is much more complicated, following the Goldman-Hodgkin-Katz current equation, as discussed in **N6-8**.

Macroscopic Na^+ and K^+ currents result from the opening and closing of many channels

The complex macroscopic I - V relationships of the Na^+ and K^+ currents (see [Fig. 7-6D](#)) reflect the single channel conductance and gating of Na^+ and K^+ channels. The pore of an open channel is expected to have a linear or ohmic I - V relationship:

$$i_X = g_X(V_m - E_X) \quad (7-2)$$

Here, i_x is the single channel current and g_x is the single channel conductance. We already introduced a similar relationship as [Equation 6-15](#). [Figure 7-7A](#) illustrates the predicted linear behavior of single channel currents as a function of V_m for hypothetical Na^+ and K^+ channels. Assuming an Na^+ reversal potential (E_{Na}) of +50 mV, the Na^+ current is zero at a V_m of +50 mV. Similarly, with an E_K of -80 mV, the K^+ current is zero at a V_m of -80 mV. Assuming a unitary conductance of 20 pS for each channel, the two I - V relationships have the same slope. Note that these idealized single channel I - V plots for Na^+ and K^+ approximate the shape of the macroscopic peak I - V relationships of [Figure 7-6D](#) for the positive V_m range (i.e., in the right upper quadrant of [Fig. 7-6D](#)). In this V_m range, both the Na^+ and K^+ channels through which the currents flow are maximally activated at the peaks of their respective time courses. Thus, the macroscopic peak I - V relationships (see [Fig. 7-6D](#)) are nearly linear in this range, just as they would be for idealized, fully open channels (see [Fig. 7-7A](#)).

A SINGLE-CHANNEL I-V RELATIONSHIPS

B VOLTAGE DEPENDENCE OF SINGLE-CHANNEL OPEN PROBABILITIES

C RECONSTRUCTED I-V RELATIONSHIPS

FIGURE 7-7 Microscopic basis of macroscopic I - V relationships. **A**, The blue line represents the I - V relationship of an idealized open Na^+ channel. The green line represents the I - V relationship of an idealized open K^+ channel. Because the channels are assumed always to be fully open (i.e., the conductance does not change with voltage), the current through them is linear or ohmic. **B**, The blue curve shows the open probability of Na^+ channels. The equation in the inset will generate this curve if the values $z_{Na} = 6.5$ and $V_{0.5} = -50 \text{ mV}$ are inserted. The green curve shows the open probability of K^+ channels. The equation in the inset will generate this curve if the values $z_K = 5.3$ and $V_{0.5} = -30 \text{ mV}$ are

inserted. **N7-6 C**, We can obtain a reasonable estimate for the macroscopic Na^+ current and the macroscopic K^+ current by multiplying the single channel current in **A**, the P_o in **B**, and the number of channels (N). We assume that there are 100 Na^+ and 100 K^+ channels.

However, in the negative voltage range, the macroscopic peak I - V relationships for Na^+ and K^+ in [Figure 7-6D](#) deviate from the linear (or ohmic) behavior in [Figure 7-7A](#). Why, as the voltage is made more negative, does the inward Na^+ current fail to increase further and even decrease (negative resistance)? Similarly, why, as the voltage becomes more negative, does the outward K^+ current fall to zero long before the voltage reaches an E_K of -80 mV? The answer is that the probability that the Na^+ and K^+ channels are “open” (P_o)—and therefore able to conduct current—depends on voltage. We introduced the concept of open probability on [page 156](#). To see why V_m might affect P_o , we consider a simplified model.

Assume that a channel protein molecule may exist in either of two conformational states, closed (C) and open (O), and that these two conformational states are in equilibrium with one another:

The equilibrium constant K_{eq} for this reaction is the ratio of the concentrations of open to closed channels, which can also be expressed as the ratio of the probability that the channel is open (P_o) to the probability that the channel is closed (P_c):

$$K_{eq} = \frac{[\text{Open}]}{[\text{Closed}]} = \frac{P_o}{P_c}$$

(7-3)

In the case of voltage-gated channel proteins, V_m changes affect K_{eq} and thus the distribution of channels between the open and closed states. **N7-6** The probability of a channel's being open depends on V_m according to a Boltzmann distribution (see [Fig. 7-7B](#)). Accordingly, if the valence (z) of the voltage-sensing part of the channel protein (i.e., the “gating charge”) is positive, the probability of channel opening should increase from 0 to 1 in a sigmoid fashion as V_m becomes more positive. [Figure 7-7B](#) shows the behavior of P_o for hypothetical Na^+ and K^+ channels that simulate Na^+ and K^+ channels in real cells.

N7-6

Boltzmann Distribution of Voltage-Dependent Gating for Ion Channel Proteins

Contributed by Ed Moczydlowski

If a channel can exist only in a closed or open conformation, the sum of the channel's open probability (P_o) and closed probability (P_c) must be 1, so that the equilibrium constant K_{eq} is

$$K_{\text{eq}} = \frac{[\text{Open}]}{[\text{Closed}]} = \frac{P_o}{P_c} = \frac{P_o}{1 - P_o}$$

(NE 7-1)

The first two equalities in the above equation are the same as Equation 7-3 in the text.

According to statistical mechanics, the relative probability that the channel is in the open versus the closed state (P_o/P_c) is determined by the difference in free energy (ΔG) between the open state (G_o) and closed state (G_c) of the channel. By applying the **Boltzmann distribution**—a law of physical chemistry that describes the statistical distribution of states or chemical species in a chemical equilibrium—we find that

$$\frac{P_o}{P_c} = \frac{P_o}{1 - P_o} = \exp \left[\frac{-\Delta G}{k_B T} \right]$$

(NE 7-2)

Here, k_B is the Boltzmann constant ($1.381 \times 10^{-23} \text{ J K}^{-1}$) and T is the absolute temperature. According to Equation NE 7-2, when half of the channels are open and half are closed (i.e., $P_o = 0.5$ and $P_o/P_c = 1$), ΔG must be zero. In other words, if the energy of the open state is the same as the energy of the closed state, there ought to be an equal number of channels in each state. The free energy ΔG for opening a voltage-gated channel may be thought of as a sum of two terms, a chemical free-energy difference (ΔG_{chem}) and an electrical free-energy difference (ΔG_{elec}). The ΔG_{chem} term describes the difference in free energy between the open and closed conformational states of a *single* channel protein in the absence of an applied electric field. The ΔG_{elec} term describes the energy expended when an electrically charged portion of the channel protein molecule is moved by the electric field as the channel opens. Thus, the total change in free energy for opening a voltage-gated channel is the sum of the chemical and electrical terms:

$$\Delta G = \Delta G_{\text{chem}} + \Delta G_{\text{elec}}$$

(NE 7-3)

Note that this equation is similar to Equation 5-6, which we introduced to describe the electrochemical potential difference (i.e., $\Delta \tilde{\mu}_X$) for a *mole* of ions X. **ON5-3** The difference is that, here, we are applying Equation NE 7-3 to a *single* channel molecule. We already saw in Chapter 5 that the electrical term for a mole of X is the product zFV_m , where z is the valence and F is the charge on a mole of particles. Likewise, the electrical term ΔG_{elec} for a single molecule is the product of the valence (z) of the moving portion of the channel protein (the “voltage sensor”), the elementary charge ($e_0 = 1.602 \times 10^{-19}$ coulomb) and the applied membrane voltage, V_m . Thus,

$$\Delta G = \Delta G_{\text{chem}} + ze_0 V_m$$

(NE 7-4)

Note that ze_0V_m is the energy required to move the charge of the channel's “voltage sensor” across the electric field of the whole membrane.

In deriving an expression for P_o , it is helpful to express ΔG_{chem} in electrical terms. As noted above, when half the channels are open and half are closed (i.e., $P_o = P_c = 0.5$), ΔG is zero. Equation NE 7-4 thus becomes

$$\begin{aligned} 0 &= \Delta G_{\text{chem}} + ze_0V_{0.5} \\ \Delta G_{\text{chem}} &= -ze_0V_{0.5} \end{aligned}$$

(NE 7-5)

Here, $V_{0.5}$ is the voltage at which P_o is 0.5. Combining Equations NE 7-4 and NE 7-5, we have

$$\begin{aligned} \Delta G &= -ze_0V_{0.5} + ze_0V_m \\ \Delta G &= ze_0(V_m - V_{0.5}) \end{aligned}$$

(NE 7-6)

Equation NE 7-6 may be substituted into Equation NE 7-2 and rearranged to yield the following expression for the dependence of open probability on voltage:

$$P_o = \frac{1}{1 + \exp \left[\frac{-ze_0(V_m - V_{0.5})}{k_B T} \right]}$$

(NE 7-7)

The above equation appears in the text as the inset to Figure 7-7B.

To summarize, Figure 7-7A shows that once a single channel is open, the current flowing through the open channel is linearly related to V_m . Figure 7-7B shows that the likelihood that the channel is open depends on V_m in a sigmoid fashion. The actual macroscopic current (I_X) depends on the number of channels (N) in the area of membrane being sampled, the open probability, and the single channel current, as we already pointed out in Equation 6-21:

$$I_X = NP_o i_X$$

(7-4)

Thus, we can use Equation 7-4 to compute the macroscopic currents (I) contributed by our hypothetical Na^+ and K^+ channels. We merely multiply the number of channels (which we assume to be 100 for both cations), the open probability for Na^+ and K^+ channels in Figure 7-7B, and the single channel currents for Na^+ and K^+ in Figure 7-7A. If we compare the resulting hypothetical I_{Na} and I_{K} curves in Figure 7-7C, which are based on a simple theory, with actual data on macroscopic I - V relationships (see Fig. 7-6D),

we see that this model provides a reasonable description of voltage-sensitive ionic currents.

The Hodgkin-Huxley model predicts macroscopic currents and the shape of the action potential

Even before the concepts of single channels and channel proteins emerged, [Hodgkin and Huxley in 1952](#) formulated voltage-dependent and time-dependent parameters to predict the ionic currents that underlie the action potential of the squid giant axon. Hodgkin and Huxley defined a series of three dimensionless parameters, n , m , and h , each of which can have a value between 0 and 1. The activation parameter n describes the probability that the K^+ channels are open ([Fig. 7-8A](#)). The activation parameter m describes the probability that the Na^+ channels are open (see [Fig. 7-8B](#), blue curve). Because Hodgkin and Huxley observed that the Na^+ current **inactivates**, they introduced the inactivation parameter h to describe this process (see [Fig. 7-8B](#), violet curve).

FIGURE 7-8 Voltage-dependent parameters of the HH model and their use in predicting the shape of the action potential. **A**, The n parameter describes the probability that each of four “particles” in the K^+ channel is in the proper state for channel opening. It is believed that these four particles are the gates of the four K^+ channel subunits. The parameter plotted here is the value of n at infinite time. **B**, The m parameter describes the probability that each of three particles in the Na^+ channel is in the proper state for channel opening. The h parameter describes the probability that an inactivation particle is *not* in the proper state for inactivating the Na^+ channel. Thus, a high h favors the open state of the channel. The parameters plotted

here are the values of m and h at infinite time. **C**, Hodgkin and Huxley used data similar to those in **A** and **B** to compute the time course of an action potential in the squid giant axon. **D**, The actual data are very similar to the computed action potential in **C**. (Data from Hodgkin AL, Huxley AF: A quantitative description of membrane current and its application to conduction and excitation in nerve. J Physiol 117:500–544, 1952.)

Hodgkin and Huxley developed an equation for total membrane current (I_m) and used it to predict the shape of the action potential in the squid giant axon.  **N7-7** Figure 7-8C shows their *predicted* action potential, which is triggered by a brief depolarization. Figure 7-8D shows an actual recording. The close agreement between the Hodgkin-Huxley (HH) theory and experimental results indicates that this model provides a reasonable description of nerve excitation. The fundamental observation of Hodgkin and Huxley was that an increase in Na^+ conductance causes the upswing or depolarizing phase of the action potential as V_m rapidly approaches E_{Na} , whereas inactivation of Na^+ conductance and delayed activation of K^+ conductance underlie the repolarization of V_m to its resting value near E_K . The importance of the HH model in electrophysiology is that it was the first analysis to accurately describe the time course and voltage dependence of ionic currents that occur during an action potential.

N7-7

Classical Hodgkin-Huxley Model of the Action Potential

Contributed by Ed Moczydlowski

The HH analysis follows basic principles similar to the simple two-state (i.e., closed-open) model of single channel gating that we described in Equation 7-3. The HH analysis provides a description of macroscopic currents for Na^+ (I_{Na}) and K^+ (I_K), but relates these macroscopic currents not to single channel currents but to the maximal conductance of the membrane to Na^+ (\bar{G}_{Na}) or K^+ (\bar{G}_K). In the single channel/Boltzmann model,  **N7-6** these maximal conductances would be achieved when P_o is 1. Thus, \bar{G}_{Na} or \bar{G}_K would be the product of the single channel conductance (g_{Na} or g_K) and the number of open channels (N). In the HH analysis, the probability of observing the maximal conductance is described by three empirical voltage-sensitive parameters, m and h for the Na^+ conductance and n for the K^+ conductance. Like P_o in the single channel/Boltzmann model, m , h , and n vary between 0 and 1. The original HH equations for macroscopic K^+ and Na^+ current are

$$I_K = n^4 \bar{G}_K (V_m - E_K)$$

(NE 7-8)

$$I_{\text{Na}} = m^3 h \bar{G}_{\text{Na}} (V_m - E_{\text{Na}})$$

(NE 7-9)

Here, V_m is the membrane potential, E_K is the equilibrium potential for K^+ , and E_{Na} is the equilibrium potential for Na^+ .

Hodgkin and Huxley used the parameter n to describe the probability (which varies from 0 to 1) that

an activating “particle” or gate is in a permissive configuration for K^+ channel opening. However, they found it necessary to use the fourth power of n to account for the sigmoid-shaped time dependence (or lag phase) for K^+ -current activation. The molecular interpretation of this n^4 dependence is that four independent activation (or gating) particles must be in a permissive state for a single channel to open.

Similarly, the m^3 parameter in Equation NE 7-9 is the probability of Na^+ channel opening. In molecular terms, this m^3 dependence states that three independent gating particles must be in a permissive configuration for opening to occur. In order to account for the inactivation phase of the Na^+ current, Hodgkin and Huxley proposed that the channel has a separate inactivation gate described by the parameter h in Equation NE 7-9. The h parameter is defined as the probability (from 0 to 1) that the channel is *not* inactivated. Thus, when m and h are both 1, the current is maximal.

The n , m , and h probability parameters of the HH model depend on V_m according to a Boltzmann distribution function like that in **EN7-6**. The green curve in Figure 7-8A shows the steady-state dependence of the n parameter (which governs \bar{G}_K) on V_m , as derived by Hodgkin and Huxley. Because this parameter is measured at infinite time, it is represented as n_∞ . Figure 7-8B shows the same for the two steady-state parameters that govern \bar{G}_{Na} , m_∞ (blue curve) and h_∞ (red curve). The dependence of n_∞ and m_∞ on V_m determines the voltage range for activation of the K^+ and Na^+ currents, respectively. The h_∞ parameter for inactivation of the Na^+ current spans a voltage range that is more negative than activation described by the m_∞ parameter. Thus, any voltage capable of activating the Na^+ channel also promotes inactivation. The reason Na^+ channels are able to open first, before closing, is that once a depolarization is initiated, activation occurs *faster* than inactivation. (Note that the m_∞ and h_∞ parameters describe m and h at infinite time and make no statement about how rapidly m reaches m_∞ , or h reaches h_∞ !)

In their analysis of the squid axon action potential, Hodgkin and Huxley modeled the axon membrane as an equivalent electrical circuit that included \bar{G}_K and \bar{G}_{Na} —which we have just discussed—as well as a leak component (\bar{G}_L)—which corresponds to unspecified ohmic background conductance attributable to other types of K^+ channels and Cl^- channels—and a membrane capacitance (C_m). The HH theory predicts that the total membrane current (I_m) is a sum of the capacitive current and the various ionic currents (see Equation 6-19 in the text). For the HH model,

$$I_m = C_m(dV_m/dt) + \bar{G}_K n^4 (V_m - E_K) + \bar{G}_{Na} m^3 h (V_m - E_{Na}) + \bar{G}_L (V_m - E_L)$$

(NE 7-10)

Hodgkin and Huxley used this equation to predict the shape of the action potential in the squid giant axon. A comparison of their prediction (see Fig. 7-8C) with an actual record of an action potential from the squid giant axon (see Fig. 7-8D) shows that their theory does a very good job of describing this phenomenon.

In addition to delineating the basis of the action potential waveform, the HH model also explains threshold behavior and the refractory period. For an action potential to fire, an external stimulus must depolarize the membrane above threshold to activate a sufficient number of Na^+ channels. The external stimulus can come from an electrode, a synaptic event, or propagation of a depolarizing wave along the cell membrane. What determines whether a stimulus will be sufficient to reach the threshold V_m for firing

of an action potential? The number of Na^+ channels activated by the stimulus is determined by the voltage dependence of the *activation* process (i.e., m parameter). Opposing the local depolarization that is produced by the current flowing through these Na^+ channels are current losses that occur because of passive spread of the current through intracellular and extracellular fluid (see the discussion of cable theory on pp. 201–203). Also opposing depolarization is the hyperpolarizing effect of currents through any open K^+ or Cl^- channels in the membrane. Thus, the **threshold** is the level of depolarization at which the depolarizing effect of the open Na^+ channels becomes sufficiently self-reinforcing to overcome these opposing influences. Once threshold is reached, further activation of Na^+ channels rapidly drives V_m toward E_{Na^+} .

The basis of the **absolute refractory period**, the time during which a second action potential cannot occur under any circumstances, is *Na^+ channel inactivation*. In other words, it is impossible to recruit a sufficient number of Na^+ channels to generate a second spike unless previously activated Na^+ channels have recovered from inactivation (i.e., h parameter), a process that takes several milliseconds. The **relative refractory period**, during which a stronger than normal stimulus is required to elicit a second action potential, depends largely on delayed *K^+ channel opening* (i.e., n parameter). In other words, for a certain period after the peak of the action potential, the increased K^+ conductance tends to hyperpolarize the membrane, so a stronger depolarizing stimulus is required to activate the population of Na^+ channels that in the meantime have recovered from inactivation.

Another key feature of the HH model is that it implies that V_m activates a channel by inducing the movement of an electrically charged gating particle or voltage sensor across the membrane. Physically, this gating could occur by the movement of a charged portion of the channel protein through all or part of the transmembrane electrical field or by the reorientation of an electrical dipole (a neutral structure with positive and negative polarity) within the electrical field of the membrane. Thus, the HH model correctly predicted that activation of a voltage-gated Na^+ channel or K^+ channel should be accompanied by a small movement of gating charge, which should produce a **gating current**.  **N7-8** This prediction was satisfied in 1973 when Armstrong and Bezanilla recorded a very small, rapid outward current that is activated by depolarization in a voltage-clamped squid axon in which the ionic current of the Na^+ channels is completely blocked by TTX (see Fig. 7-5C, bottom I_m record). This tiny, transient gating current is almost finished by the time that the slower K^+ current begins to flow. The properties of such gating currents account for the voltage dependence of channel activation kinetics. Although the key features of the HH theory are correct, modern patch-clamp studies of single Na^+ and K^+ channels have revealed that the kinetics of channel gating are much more complicated than originally assumed. Such complexity is to be expected inasmuch as the conformational dynamics of large protein molecules cannot generally be described adequately by simple models that incorporate only a few discrete states.

N7-8

Evidence for Gating Currents

Contributed by Emile Boulpaep, Walter Boron

Two groups of investigators, working on two different preparations, nearly simultaneously discovered the gating currents predicted 2 decades earlier by Alan Hodgkin and Andrew Huxley. In a paper published in March 1973, Martin Schneider and W. Knox Chandler demonstrated the presence of a gating current for Na^+ channels in frog skeletal muscle. In a paper published in April 1973, Clay Armstrong and

Pancho Bezanilla demonstrated the presence of a gating current for Na^+ channels in squid giant axons.

Physiology of Voltage-Gated Channels and Their Relatives

A large superfamily of structurally related membrane proteins includes voltage-gated and related channels

Voltage-gated Na^+ channels, Ca^{2+} channels, and K^+ channels are part of a superfamily of channel proteins called the **voltage-gated-like (VGL) ion channel superfamily** (see [Table 6-2](#)). This superfamily also includes structurally related channels that are not strictly activated by voltage. [Figure 7-9](#) shows a dendrogram based on an analysis of evolutionary relationships of the minimal pore regions of 143 human channels belonging to the VGL superfamily. Major branches of the tree define groups of related channel genes present in the human genome. In this section, we discuss how structural relationships among these proteins determine their physiological functions.

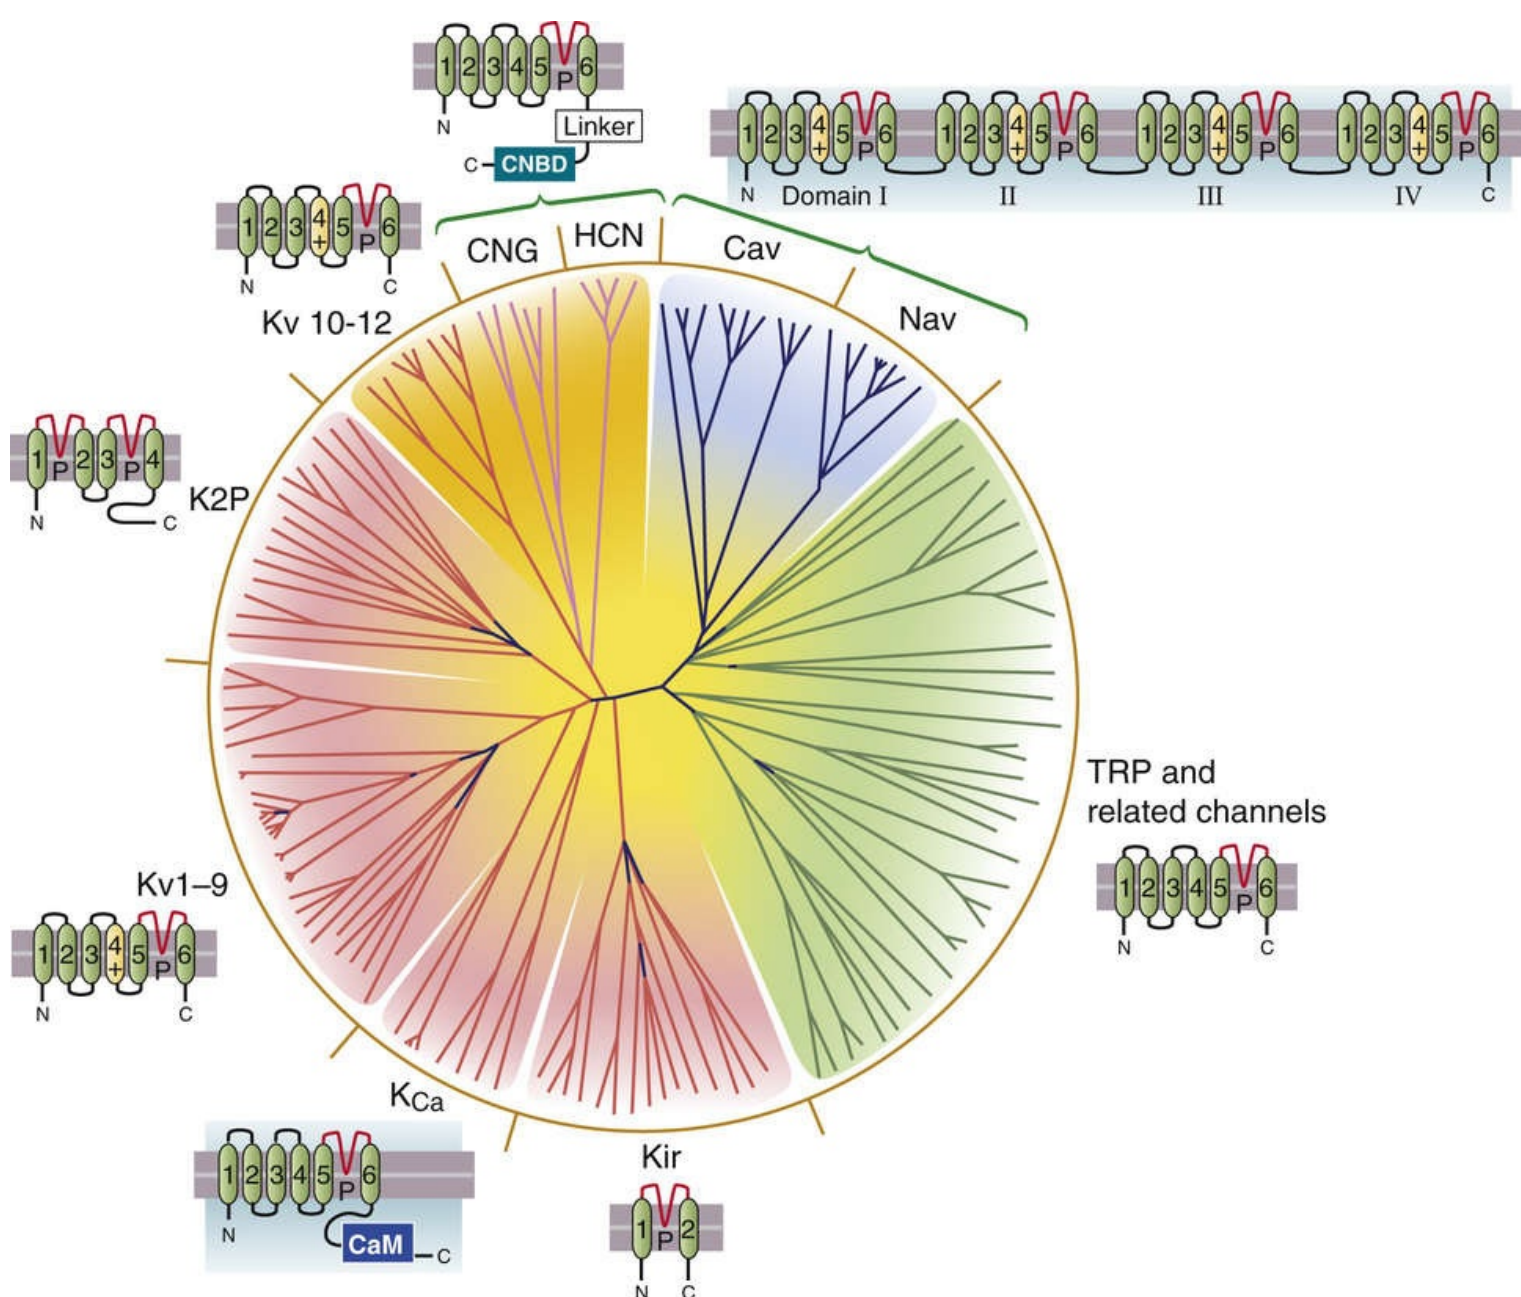

FIGURE 7-9 Family tree of hypothetical evolutionary relationships among voltage-gated cation channels represented in the human genome, based on sequences of the pore domain. This dendrogram of the superfamily of VGL channels (see Table 6-2) shows distinct branches colored to indicate various tetrameric K⁺ channels (Kv, K_{Ca}, Kir, K2P) in red, CNG and HCN channels in pink, and TRP channels in green. CaM, calmodulin; CNBD, cyclic nucleotide-binding domain. A separate branch includes the pseudotetrameric Cav and Nav channels in blue. (Data from Yu FH, Catterall WA: The VGL-chanome: A protein superfamily specialized for electrical signaling and ionic homeostasis. *Sci STKE* 2004:re15, 2004.)

Initial progress toward biochemical characterization of the voltage-gated ion channels responsible for the action potential began with the discovery of naturally occurring, specific, high-affinity neurotoxins such as TTX and STX and their use as biochemical probes. Tritium-labeled derivatives of TTX and STX were prepared chemically and used in radioligand-binding assays to directly measure the number of voltage-gated Na⁺ channels in excitable tissues.

The electroplax organ of the electric eel *Electrophorus electricus*  **N7-9** proved to be a convenient source of tissue for the first successful biochemical purification of the Na⁺ channel protein by William Agnew and coworkers in 1978. These Na⁺ channels consist of a large glycosylated α subunit of ~200 kDa that contains the TTX-binding site. Reconstitution experiments revealed that the α subunit—by itself—is the channel-forming protein that mediates ionic selectivity for Na⁺, voltage-dependent gating, and

pharmacological sensitivity to various neurotoxins. Similar approaches with skeletal muscle and brain led to the identification of analogous mammalian Na⁺ channel α subunits, which are protein products of related genes.

N7-9

Electroplax Organ of the Electric Eel

Contributed by Ed Moczydlowski

The electroplax organ of the electric eel (*Electrophorus electricus*) is composed of specialized cells called **electrocytes** that are an evolutionary adaptation of skeletal muscle cells. The innervated membrane face of the electrocytes contains a high density of both **nicotinic acetylcholine receptors** and voltage-gated Na⁺ **channels**. Thus, this tissue is a rich source of both proteins. Indeed, for both proteins, this tissue played a key role in the purification, biochemical characterization, reconstitution into lipid membranes, and physiological characterization.

In addition to the α subunit, the functional complex of the rat skeletal muscle Na⁺ channel contains a 38-kDa subunit, and the rat brain Na⁺ channel contains both a 33- and a 36-kDa subunit. These smaller **β subunits** of mammalian Na⁺ channels contain a single transmembrane span and appear to play an accessory role in modulating channel gating or channel expression. In humans, four genes (*SCN1B* to *SCN4B*) encode β subunits— β_1 to β_4 —that preferentially associate with different α subunits in different tissues.

Molecular biological studies of voltage-gated channels began in 1984 with the cloning of the *Electrophorus* Na⁺ **channel** α subunit by the laboratory of Shosaku Numa. These investigators used antibodies raised against the purified α subunit to screen a complementary DNA (cDNA) library, and they isolated the cDNA encoding the electroplax Na⁺ channel. In addition, direct sequencing of channel peptides provided partial amino-acid sequence information for confirmation. Similar strategies led to the purification and cloning of voltage-gated Ca²⁺ **channel** proteins from skeletal muscle and brain tissue. The primary sequence of the α_1 subunit of the Ca²⁺ channel is structurally homologous to the α subunit of the Na⁺ channel.

Whereas a biochemical approach was used to discover Na⁺ and Ca²⁺ channels, the initial breakthrough in the molecular biology of K⁺ **channels** came with the study of *Shaker* mutants of the fruit fly *Drosophila*. These mutants are called Shaker because their bodies literally shake under the influence of ether anesthesia. This phenotype is due to defective voltage-gated K⁺ channels. The laboratory of L.Y. Jan and Y.N. Jan, and those of O. Pongs and M. Tanouye, used molecular genetic techniques to identify and clone the first K⁺ channel genes in 1987.

For voltage-gated K⁺ channels, plots based on the hydropathy index of each amino acid (see [Table 2-1](#)) typically reveal six distinct peaks of hydrophobicity ([Fig. 7-10A](#)), corresponding to transmembrane segments S1 to S6—a conserved structural feature of all voltage-gated K⁺ channels. Transmembrane segments S1 to S6 have an α -helical secondary structure and are connected by cytoplasmic and extracellular linker regions (see [Fig. 7-10B](#)).

FIGURE 7-10 Membrane topology model of a single subunit of a voltage-gated K^+ channel. **A**, This voltage-dependent K^+ channel, a member of the Shaker family (Kv1.1), has six transmembrane segments (S1 to S6) with a high hydropathy index. Each of these six segments (highlighted in green or yellow) is presumed to traverse the membrane completely. In addition, the channel also has a smaller region (highlighted in red) with a somewhat lower hydropathy index, termed the P region. **B**, This topology model is based on the hydropathy data in **A**. The six membrane-spanning segments are assumed to be α helices. The S4 segment (highlighted in yellow) has a large number of positively charged lysine and arginine residues and is part of the voltage-sensing domain that comprises the entire S1 to S4 region. S5 and S6—as well as the intervening P region—comprise the S5-P-S6 pore domain (see Fig. 7-11). **N7-13** (Data from Shen NV, Pfaffinger PJ: Conservation of K^+ channel properties in gene subfamilies. In Peracchia C [ed]: Handbook of Membrane Channels: Molecular and Cellular Physiology. New York, Academic Press, 1994, pp 5–16.)

Extensive mutagenesis studies on cloned channel genes have associated various channel functions and binding properties with particular domains. The amino-terminal part of the channel, including the S1 to S4 transmembrane segments, forms a **voltage-sensing domain** (see Fig. 7-10B). The **S4 segment** has four to seven arginine or lysine residues that occur at every third S4 residue in voltage-gated K^+ , Na^+ , and Ca^{2+} channels. The positively charged S4 segment acts as the **voltage sensor** for channel activation by moving outward when the membrane depolarizes. This movement causes the four S6 helices—which form the inner lining of the pore—to bend away from the pore axis, thereby opening the channel.

The extracellular linker region between the S5 and S6 segments is termed the **P region** (for pore region) and contains residues that form the binding sites for toxins and external blocking molecules such as TEA. The **pore domain** formed by S5-P-S6 is the minimal structure required to form an ion-conducting pore for this class of channels (see Fig. 7-10B). The P region also contains conserved residues that form the **selectivity filter**, which determines the ionic selectivity for permeant cations. **N7-10**

N7-10

Selectivity Filter

Contributed by Ed Moczydlowski

Evidence from mutational and structural analysis has revealed the basic mechanism by which voltage-gated K⁺, Na⁺, and Ca²⁺ channels discriminate permeant ions. In the case of Kv K⁺ channels, four selective binding sites for K⁺ are formed within cages of eight oxygen atoms from the *peptide backbone* and hydroxyl groups of Thr (see Table 2-1 for amino-acid code). In Ca²⁺ channels, the carboxyl groups from the *side chains* of four negatively charged Glu residues—called the **EEEE locus**—form two binding sites for Ca²⁺. Na⁺ channels have a selectivity filter similar to that of Ca²⁺ channels, but contain a conserved **DEKA locus**, consisting of Asp, Glu, Lys, and Ala residues.

Since the discovery and recognition of diverse genes belonging to the voltage-gated channel superfamily, structural-biological studies have substantially advanced our understanding of the three-dimensional structure of certain channel proteins.  **N7-11** In 1998, a major breakthrough in elucidating the structure of ion channel proteins occurred when MacKinnon and colleagues reported the crystal structure of a bacterial K⁺ channel protein called KcsA. This work revealed the three-dimensional structure of a protein that contained segments analogous to the S5-P-S6 part of voltage-gated channels, which forms the ion conduction pathway. For his work on the structural biology of ion channels, Roderick MacKinnon shared the 2003 Nobel Prize in Chemistry.  **N7-12**

Crystal Structures of Ion Channel Proteins

Contributed by Ed Moczydlowski

The accompanying table summarizes data for 12 ion channel proteins that have been crystallized.

Crystal Structures of Ion Channel Proteins							
Channel	Summary Notes	PDB Structure File	References	Resolution	Open/Closed	GenBank Accession	Species
1. KcsA	First crystal structure of a tetrameric K ⁺ channel pore domain revealing the basis of K ⁺ selectivity. Recognized with the 2003 Nobel Prize in Chemistry.	1BL8	Doyle et al: Science 280:69–77, 1998	3.2 Å	Closed	GI:61226909	<i>Streptomyces lividans</i>
KcsA high resolution	Higher-resolution KcsA structure complexed with Fab antibody fragments showing the location of 7 binding sites for K ⁺ .	1K4C	Zhou et al: Nature 414:43–48, 2001	2.0 Å	Closed	GI:17942556	
KcsA full length	Structure of full-length KcsA showing the cytoplasmic 4-helix bundle that was missing in previous structures.	3EFF	Uysal et al: Proc Natl Acad Sci U S A 106:6644–6649, 2009	3.8 Å	Closed	GI:226887747	
2. KirBac1.1	Crystal structure of a tetrameric prokaryotic inward-rectifier K ⁺ channel. Shows the location of negatively charged residues in the cytoplasmic C-terminal vestibule domain that play a role in intracellular block by Mg ²⁺ and polyamines.	1P7B	Kuo et al: Science 300:1922–1926, 2003	3.65 Å	Closed	GI:33357898	<i>Burkholderia pseudomallei</i>
3. KirBac1.3-Kir3.1 chimera	Structure of a tetrameric inward-rectifier K ⁺ channel chimera with a prokaryotic pore domain and a cytoplasmic vestibule domain of Kir3.1 from mouse. Shows location of positively charged residues at the intracellular membrane interface that play a role in PIP ₂ lipid activation.	2QKS	Nishida et al: EMBO J 26:4005–4015, 2007	2.20 Å	Closed	GI:158430248	<i>Burkholderia xenovorans</i> (KirBac1.3) and <i>Mus musculus</i> (Kir3.1)
4. Kir2.2	Kir channel from chicken is 90% identical to human ortholog. Possible binding sites for Mg ²⁺ are identified from crystals grown in the presence of various inorganic cations. Additional structures show location of PIP ₂ lipid-binding sites.	3JYC 3SPI 3SPC	Tao et al: Science 326:1668–1674, 2009 Hansen et al: Nature 477:495–498, 2011	3.1 Å		GI:283807125	<i>Gallus gallus</i>

5. Kv1.2	First structure of a tetrameric mammalian voltage-gated K ⁺ channel showing the structure of the voltage-sensor domains and the cytoplasmic β subunit.	2A79	Long et al: Science 309:897–903; 309:903–908, 2005	2.9 Å	Open	GI:25742772	<i>Rattus norvegicus</i>
6. KvAP	Structure of a tetrameric voltage-gated K ⁺ channel from a thermophilic archaeobacterium with voltage sensors in a non-native conformation.	1ORQ 1ORS	Jiang et al: Nature 423:33–41, 2003	3.2 Å	Open	GI:38605092	<i>Aeropyrum pernix</i>
	Additional structure of KvAP with information on variable orientation of the pore domain to the loosely adherent voltage-sensor domains.	2A0L	Lee et al: Proc Natl Acad Sci U S A 102:15441–15446, 2005	3.9 Å	Open	GI:82407656	
7. MthK	Structure of a tetrameric prokaryotic Ca ²⁺ -activated K ⁺ channel showing the intracellular gating ring composed of two RCK domains.	1LNQ	Jiang et al: Nature 417:515–522; 417:523–526, 2002	3.3 Å	Open	GI:21542150	<i>Methanobacterium thermoautotrophicum</i>
8. BK _{Ca} channel	Structure of intracellular gating ring of the large-conductance human Ca ²⁺ -activated K ⁺ channel (HSlo, BK _{Ca}) provides insight into the mechanism of Ca ²⁺ activation.	3MT5 3NAF	Yuan et al: Science 329:182–186, 2010 Wu et al: Nature 466:393–397, 2010	3.0 Å		GI:297787762 GI:299856894 GI:408358007	
9. NaK	Structure of a tetrameric prokaryotic Na ⁺ ,K ⁺ -nonselective cation channel with a TVGDG (named for the five single-letter amino-acid codes) selectivity filter resembling that of cyclic nucleotide-gated channels.	2AHZ	Shi et al: Nature 440:570–574, 2006	2.8 Å	Closed	GI:229042533	<i>Bacillus cereus</i>
	High-resolution structures of NaK channel in the open state revealing changes involved in gating of the pore. Complexes with different inorganic cations reveal mechanisms involved in ion selectivity.	3E86 3E8H 3E8F 3E8B 3E89 3E83 3E8G	Alam & Jiang: Nat Struct Mol Biol 16:30–34; 16:35–41, 2009	1.8 Å	Open	GI:218766679	
10. TRAAK (TWIK-related arachidonic acid-stimulated K ⁺ channel)	Structure of a dimeric two-pore K ⁺ -leak channel activated by arachidonic acid and mechanical deformation of the membrane. Structure shows a unique 35-Å-tall helical cap topping the extracellular entrance to the pore creating a bifurcated entryway for K ⁺ .	3UM7	Brohawn et al: Science 335:436–441, 2012	3.8 Å	Open	GI:374977794	<i>Homo sapiens</i>
11. NaAb	Structure of a prokaryotic tetrameric homolog of voltage-gated Na ⁺ -selective channels shows features of the selectivity filter that distinguish Nav and Cav channels from K ⁺ channels. Additional structures show changes associated with inactivation gating.	3RVY 3RVZ 3RW0 4EKW	Payandeh et al: Nature 475:353–358, 2011 Payandeh et al: Nature 486:135–139, 2012	2.7 Å	Closed	GI:339961372	<i>Arcobacter butzleri</i>
12. NavRh	Structure of bacterial tetrameric homolog of voltage-gated Na ⁺ channels showing details of ion selectivity and inactivation gating.	4DXW	Zhang et al: Nature 486:130–134, 2012	3.05 Å	Closed	GI:388326721	alpha proteobacterium, Rickettsiales species

Roderick MacKinnon

For more information about Roderick MacKinnon and the work that led to his Nobel Prize, visit <http://nobelprize.org/chemistry/laureates/2003/index.html> (accessed October 2014).

In 2005, the MacKinnon laboratory solved the structure of a mammalian voltage-gated K⁺ channel containing both the S1 to S4 voltage-sensing domain and the S5-P-S6 pore domain (Fig. 7-11). N7-13

A TOP VIEW OF TETRAMER**B LATERAL VIEW OF TETRAMER****C LATERAL VIEW OF ONE MONOMER**

FIGURE 7-11 Crystal structure of the mammalian K^+ channel, Kv1.2, at a resolution of 2.9 Å. **A**, Four α subunits of the channel, each in a different color, viewed from the extracellular side. A K^+ ion is shown in the central open pore. **B**, Side view of the four α and four β subunits of the channel, each in a different color, with extracellular solution on the top and intracellular solution on the bottom. The transmembrane domain (TM) of each α subunit is preceded by an $-NH_2$ terminus (T1 domain). The T1 domain is located over the intracellular entryway to the pore but allows access of K^+ ions to the pore through side portals. The T1 domain is also a docking platform for the oxidoreductase β subunit. Each β subunit is colored according to the α subunit it contacts. **C**, Side view of one α subunit and adjacent β subunit. Transmembrane segments are labeled S1 to S6. Tetramers of segments S5, pore helix, and S6 constitute the conduction pore in the shape of an inverted “teepee.” The selectivity filter lies in the wide portion (extracellular end) of the teepee. Helices S1 to S4 constitute the voltage sensors that are connected by a linker helix (S4-S5) to the pore. The PVP sequence (Pro-Val-Pro) on S6 is critical for gating. N7-13

Crystal Structures of a Vertebrate K^+ Channel

Contributed by Ed Moczydlowski

In 2005, the MacKinnon laboratory solved the crystal structure of a rat voltage-gated K^+ channel called Kv1.2, which is homologous to the *Drosophila* Shaker channel and human Kv1 K^+ channels that function in repolarization of nerve and muscle action potentials. This structure, which shows the channel in an open state, reveals that the S1 to S4 domain containing the voltage-sensing S4 element is spatially separated from the K^+ pore domain (S5-P-S6). The tetrameric Kv1.2 channel has a pinwheel shape when viewed from the extracellular surface (see Fig. 7-11A). The central square portion of the Kv1.2 pinwheel is the pore—formed by the assembly of four S5-P-S6 pore domains, one from each monomer—and closely resembles the *entire* bacterial KcsA **N7-22** channel. The four wings of the pinwheel correspond to the four S1 to S4 voltage-sensor domains. The four Kv1.2 monomers (yellow, green, blue, and red in Fig. 7-11A) form an interlinked assembly in which the S1 to S4 voltage-sensing domain of any given monomer lies closest to the S5-P-S6 domain of an adjacent monomer.

A lateral view of Kv1.2 shows an intracellular T1 domain formed by the four N-terminal segments of the channel (see Fig. 7-11B). The T1 domain of Kv channels is also called the **tetramerization domain** because it helps assemble and maintain the tetrameric structure of the channel. This view also shows four separately attached intracellular β subunits (see p. 183). These β subunits of Kv channels are part of a

separate gene family of soluble accessory proteins with structural homology to oxidoreductase enzymes. Certain variants of both the T1 domain and β subunits may contain an N-terminal inactivation peptide that produces the rapid N-type inactivation (ball-and-chain mechanism) of some Kv channels by plugging the intracellular entrance to the pore.

Figure 7-11C shows a lateral view of a single Kv1.2 monomer in an open configuration as well as a single β subunit. On depolarization, the S4 segment moves within the membrane toward the extracellular side of the membrane. This mechanical movement of the S4 segment shifts an α -helical S4-S5 linker, causing a bending of the S6 transmembrane α helix from a linear configuration in the closed state to a curved configuration in the open state of the channel shown. Thus, voltage-dependent channel activation is an electromechanical coupling mechanism.

Other important features of K^+ channel function are revealed by crystal structures (not shown) of a Kir2.2 inward-rectifier K^+ channel from chicken and the C-terminal intracellular gating ring of the BK_{Ca} (KCa1.1) large-conductance Ca^{2+} -activated K^+ channel. Kir2.2 structures show the location of the PIP₂ lipid-binding site in the inner leaflet of the lipid bilayer at the interface between the pore domain and the cytoplasmic domain. PIP₂ stabilizes the interaction of these two protein domains to favor opening of the channel, corresponding to the mechanism of activation of Kir channels by PIP₂.

Crystal structures (not shown) of the intracellular gating ring domain of the human BK_{Ca} channel show a tetrameric assembly of two tandem C-terminal **regulator of K^+ conductance domains** (RCK1 and RCK2 domains). A region of the RCK2 domain rich in Asp residues called the **calcium bowl** forms four Ca^{2+} binding sites, one from each BK_{Ca} channel subunit. Binding of Ca^{2+} to these sites located at the interface between RCK domains facilitates conformational changes of the gating ring that favor channel opening. Detailed structural analyses of channel proteins help us to understand how genetic defects and drugs affect channel function.

Crystal Structure of the KcsA K^+ Channel

Contributed by Ed Moczydlowski

In 1998, the laboratory of Roderick MacKinnon at Rockefeller University used x-ray diffraction to solve the three-dimensional crystal structure of a membrane protein known as KcsA. KcsA is the protein product of a gene from the actinomycete bacterium *Streptomyces lividans*. KcsA is homologous to the S5-P-S6 region of the Shaker K^+ channel and is known to function as a K^+ channel in planar bilayer membranes. KcsA lacks the S1 to S4 voltage-sensing region and consists of a pore-forming domain equivalent to that of the vertebrate inward-rectifier K^+ channel gene family (Kir), which we discuss in this chapter. As is the case for the Shaker-type K^+ channels, KcsA is a homotetramer. The P-region

sequence of KcsA is very similar to the P region of the Shaker K⁺ channel, which contains amino-acid residues critical for K⁺ selectivity, as well as extracellular sensitivity to blockade by TEA and charybdotoxin. The accompanying eFigure 7-1 shows a ribbon diagram representation of the structure of KcsA, in one view looking down from the top of the membrane (see eFig. 7-1A) and in a second view looking from the side (see eFig. 7-1B). Each of the four monomer subunits of the protein is shown in a different color. Starting from the intracellular N terminus, the first transmembrane span (“outer helix,” corresponding to Shaker S5) forms an α helix that serves as the periphery of the channel. After crossing the membrane to the extracellular side, the peptide backbone then forms a loop that corresponds to the **P region**. The first half of this loop is a short α helix that folds back a short distance into the plane of the membrane and then immediately exits the extracellular side of the membrane. In the tetrameric complex that constitutes the channel protein, this latter portion of the P loop forms a narrow tunnel-like region called the **ion selectivity filter**. After exiting the extracellular face of the membrane, the peptide backbone turns again to form a third α helix (“inner helix,” corresponding to Shaker S6) that crosses the membrane to the intracellular side. The four inner helices of the tetramer form the scaffold of the ion channel pore. These four inner helices are tilted in a remarkable flower-like configuration that has also been compared to four poles of an inverted teepee tent dwelling.

The KcsA structure reveals the molecular basis for the K⁺ selectivity of K⁺ channel pores. The selectivity filter region is lined not by the side chains of amino acids, but rather by four rings of carbonyl oxygen atoms contributed by the peptide backbone of four amino-acid residues in the P region. K⁺ ions in the 12-Å-long selectivity filter (near the extracellular surface of the channel) are bound in a cage by coordination to oxygen atoms contributed by each of the four subunits. This cage is just the right size for a K⁺ ion. A smaller Na⁺ ion would fit too loosely, so its binding in the cage would not be energetically favorable in comparison to its binding to water in its normal hydrated state. eFigure 7-1C is a cutaway surface view of the pore showing the location of three K⁺ ions in the crystal structure. Up to seven distinct binding sites for K⁺ have been identified in high-resolution studies of the KcsA pore. The presence of multiple K⁺ ions in the pore is consistent with the results of many electrophysiological studies, which suggest that multiple K⁺ ions move through the channel in single file.

For his work on the structural biology of ion channels, Roderick MacKinnon shared the 2003 Nobel Prize in Chemistry. 🏆N7-12

FIGURE 7-1 Structure of the *Streptomyces* K⁺ channel (KcsA). **A**, KcsA is a homotetramer. Each monomer is represented in a different color and contains only two membrane-spanning elements, which is analogous to the S5-P-S6 portion of Shaker-type K⁺ channels. **B**, The side view more clearly shows the P region, which is very similar to the P region of the Shaker K⁺ channel. The P region appears to form the selectivity filter of the channel. **C**, This cut-away view of the pore shows three K⁺ ions. The top two K⁺ ions are bound in a tight cage that is formed by the peptide backbones of the P regions of each of the four channel subunits. (Data from Doyle DA, Morais Cabral J, Pfuetzner RA, et al: The structure of the potassium channel: Molecular basis of K⁺ conduction and selectivity. *Science* 280:69–77, 1998.)

Figure 7-12 shows a comparison of the predicted membrane-folding diagrams of three families of voltage-gated channels: Na⁺, Ca²⁺, and K⁺ channels. The channel-forming subunit of each type of channel is called the α subunit for Na⁺ and K⁺ channels and the α_1 subunit for Ca²⁺ channels. Accessory subunits include β_1 and β_2 for Na⁺ channels; α_2 , δ , β , and γ , for Ca²⁺ channels; and β for K⁺ channels.

A Na⁺ CHANNEL

B Ca²⁺ CHANNEL

C K⁺ CHANNEL

FIGURE 7-12 Subunit structure and membrane-folding models of voltage-gated channels. **A**, A voltage-gated Na⁺ channel (Nav) is made up of a pseudo-oligomeric α subunit as well as membrane-spanning β_1 and β_2 subunits. **B**, A voltage-gated Ca²⁺ channel (Cav) is made up of a pseudo-oligomeric α_1 subunit as well as an extracellular α_2 subunit, a cytoplasmic β subunit (not shown in left panel), and membrane-spanning γ and δ subunits. Note that the domains I to IV of the Nav and Cav α subunits are homologous to a single subunit of a voltage-gated K⁺ channel (see **C**). **C**, A voltage-gated K⁺ channel is made up of four α subunits as well as four cytoplasmic β subunits (not shown in left panel). (Data from Isom LL, De Jongh KS, Catterall WA: Auxiliary subunits of voltage-gated ion channels. *Neuron* 12:1183–1194, 1994.)

The α subunit of Na⁺ channels (see Fig. 7-12A) and the α_1 subunit of Ca²⁺ channels (see Fig. 7-12B) consist of four internally homologous repeats—domains I, II, III, and IV—each containing an S1 to S6 motif composed of the S1 to S4 voltage-sensing domain and the S5-P-S6 pore domain. In contrast, voltage-gated K⁺ channels (see Fig. 7-12C) are homotetramers of four identical α subunits (see p. 162),

whereas Na^+ and Ca^{2+} channels are pseudotetramers. Molecular evolution of the pseudotetrameric I to IV domain structure of Na^+ and Ca^{2+} channels is believed to have occurred by consecutive gene duplication of a primordial gene encoding a structure similar to the basic S1 to S6 motif of K^+ channels.

Na^+ channels generate the rapid initial depolarization of the action potential

Because the equilibrium potential for Na^+ and Ca^{2+} is in the positive voltage range for normal cellular ionic gradients, channels that are selectively permeable to these ions mediate electrical depolarization. However, prolonged cellular depolarization is an adverse condition inasmuch as it results in sustained contraction and rigor of muscle fibers, cardiac dysfunction, and abnormally elevated levels of intracellular Ca^{2+} , which leads to cell death. Thus, it is critical that Na^+ and Ca^{2+} channels normally reside in a closed conformation at the resting membrane potential. Their opening is an intrinsically transient process that is determined by the kinetics of channel activation and inactivation.

The primary role of voltage-gated Na^+ channels is to produce the initial depolarizing phase of fast action potentials in neurons and skeletal and cardiac muscle. The selectivity of Na^+ channels for Na^+ is much higher than that for other alkali cations. The permeability ratio of Na^+ relative to K^+ ($P_{\text{Na}}/P_{\text{K}}$) lies in the range of 11 to 20 under physiological conditions. Voltage-gated Na^+ channels are virtually impermeable to Ca^{2+} and other divalent cations under normal physiological conditions.

Although Na^+ channels do not significantly conduct Ca^{2+} ions across the cell membrane, the voltage dependence of Na^+ channel gating is nevertheless dependent on the extracellular Ca^{2+} concentration ($[\text{Ca}^{2+}]_o$). If $[\text{Ca}^{2+}]_o$ is progressively increased above the normal physiological level, the voltage activation range of Na^+ channels progressively shifts to more positive voltages. In [Figure 7-13](#) this change is represented as a shift in the P_o versus V_m relationship. Similarly, if $[\text{Ca}^{2+}]_o$ is decreased, the voltage activation range is shifted to more negative voltages. This phenomenon has important clinical implications because a negative shift corresponds to a **reduced voltage threshold** for action potential firing and results in hyperexcitability and spontaneous muscle twitching. Similarly, a positive voltage shift of Na^+ channel gating corresponds to decreased electrical excitability (i.e., the threshold is now farther away from resting V_m), resulting in muscle weakness. Thus, metabolic disorders that result in abnormal plasma $[\text{Ca}^{2+}]$, such as hypoparathyroidism (low $[\text{Ca}^{2+}]$) and hyperparathyroidism (high $[\text{Ca}^{2+}]$), can cause marked neurological and neuromuscular symptoms. The mechanism of this voltage shift in Na^+ channel gating by extracellular divalent cations such as Ca^{2+} is thought to involve an alteration in the transmembrane electrical field that is sensed by the channel protein. Presumably, this effect is caused by Ca^{2+} binding or electrostatic screening of negative charges at the membrane surface.

FIGURE 7-13 Effect of extracellular Ca^{2+} concentration on Na^+ channel activation. High $[\text{Ca}^{2+}]_o$ shifts the P_o versus V_m to more positive voltages (i.e., less excitable). Thus, *hypocalcemia* leads to *hyperexcitability*.

Humans have 10 homologous genes (Table 7-1) that encode the pore-forming α subunit of **voltage-gated Na^+ channels (Navs)**. The isoforms encoded by these genes are expressed in different excitable tissues and can be partially discriminated on the basis of their sensitivity to TTX. Four of the isoforms (Nav1.1, 1.2, 1.3, and 1.6) are differentially expressed in various regions of the brain. Nav1.4 and Nav1.5 are the major isoforms in skeletal and cardiac muscle, respectively. A divergent Na^+ channel gene Nax (*SCN7A*) functions as a homeostatic sensor of plasma $[\text{Na}^+]$ in circumventricular organs of the brain (see pp. 284–285).

TABLE 7-1

Na^+ Channel α Subunits

CHANNEL PROTEIN	HUMAN GENE	TISSUE	SENSITIVITY TO TTX (MOLAR)
Nav1.1	<i>SCN1A</i>	CNS, PNS, heart	10^{-9}
Nav1.2	<i>SCN2A</i>	CNS	10^{-9}
Nav1.3	<i>SCN3A</i>	CNS, PNS, heart	10^{-9}

Erythromelalgia or Primary Erythermalgia

Contributed by Ed Moczydlowski

Certain defects in the human gene *SCN9A*, which encodes the peripheral nerve Na^+ channel Nav1.7, result in a variety of syndromes that alter pain perception. The absence of functional expression of this channel by nonsense mutation results in complete insensitivity to pain. Various single amino-acid

replacements due to missense mutations of the channel gene result in gain-of-function syndromes that lead to heightened and severe sensitivity to pain known as primary erythromalgia or **erythromalgia** (from the Greek *erythros* [red] + *melos* [limb] + *algos* [pain]) and **paroxysmal extreme pain disorder**. These findings suggest that Nav1.7 may be a good target in the search for new drugs for the treatment of pain.

Na⁺ channels are blocked by neurotoxins and local anesthetics

Studies of the mechanism of action of neurotoxins have provided important insight into channel function and structure. The guanidinium **toxins** TTX and STX (see Fig. 7-5C) are specific blocking agents of Na⁺ channels that act on the extracellular side of the cell membrane.

TTX is produced by certain bacteria and is accumulated in tissues of various marine invertebrates, amphibians, and fish. The viscera of the *Fugu* pufferfish consumed in Japan often contain lethal amounts of TTX. The flesh of such fish must be carefully prepared to prevent food poisoning.

STX is produced by specific species of marine dinoflagellates that are responsible for “red tide” in the ocean as well as by freshwater cyanobacteria, which can poison ponds and rivers. It is the agent responsible for paralytic shellfish poisoning, which is caused by human ingestion of toxic shellfish that have accumulated STX-producing plankton. Death from TTX and STX intoxication, which ultimately results from respiratory paralysis, can be prevented by the timely initiation of mechanical ventilation.

Venomous marine snails of the *Conus* genus produce a variety of peptides that target ion channels. The **μ-conotoxins**  **N7-14** block muscle Na⁺ channels by binding near the external binding site for TTX and STX.

N7-14

Effects of μ-Conotoxin

Contributed by Ed Moczydlowski

The μ-conotoxins are specific blockers of the subtype of voltage-gated Na⁺ channels that are present in adult skeletal muscle (Nav1.4). This conclusion can be verified by performing a simple electrophysiological experiment on a “nerve-muscle” preparation consisting of a motor nerve and the attached skeletal muscle fibers. The approach is to record the membrane potential of a muscle fiber membrane while artificially stimulating the preparation with a brief electrical depolarization applied either to the nerve or directly to the muscle. In a normal preparation, either stimulus is able to evoke a muscle action potential. However, in a preparation exposed to μ-conotoxin, one observes no response

when stimulating the *muscle fiber* directly but observes a graded postsynaptic potential in the end-plate region when stimulating the *nerve* directly. This latter response demonstrates that μ -conotoxin does not affect either the motor nerve or the neuromuscular junction (e.g., the nicotinic acetylcholine receptor at the motor end plate).

TTX, STX, and μ -conotoxins are important pharmacological probes because they can be used to functionally discriminate among several distinct isoforms of Na^+ channels (see [Table 7-1](#)). Other important neurotoxins that act on Na^+ channels include batrachotoxin (a steroidal alkaloid from certain tropical frogs and birds), various plant alkaloids (veratridine, grayanotoxin, aconitine), natural plant insecticides (pyrethrins), brevetoxins (cyclic polyethers from dinoflagellates), α and β scorpion peptide toxins, and peptide toxins from tarantulas. Some of these neurotoxins are stimulatory, acting primarily by altering gating kinetics, so that the Na^+ channels are open at voltages in which Na^+ channels are normally closed or inactivated. Others block the channel by stabilizing the voltage sensor in the resting (i.e., channel-closed) conformation.

Local anesthetics are a large group of synthetic drugs that are generally characterized by an aromatic moiety linked to a tertiary amine substituent via an ester or amide linkage ([Fig. 7-14A](#)). Drug development of local anesthetics began in the late 1800s with the recognition by Karl Koller and Sigmund Freud that the plant alkaloid **cocaine** numbs sensation in the tongue and suppresses eye movement during ophthalmological procedures, in addition to having psychoactive effects on the central nervous system (CNS). Attempts to synthesize safer alternatives to cocaine led to **procaine**, which mimics the local anesthetic effect of cocaine without the CNS effects.

A STRUCTURES OF SOME LOCAL ANESTHETICS

B USE DEPENDENCE OF INHIBITION BY LIDOCAINE

FIGURE 7-14 Effect of local anesthetics. **A**, The three clinically useful local anesthetics shown here are synthetic analogs of the plant alkaloid cocaine. **B**, In the presence of lidocaine, the relative Na^+ current decays with time during repetitive stimulation. However, the inhibition becomes more pronounced as the rate of stimulation increases from 1/s to 8/s; these findings demonstrate use-dependent inhibition. (Data from Hille B: Local anesthetics: Hydrophilic and hydrophobic pathways for the drug-receptor reaction. *J Gen Physiol* 69:497–515, 1977.)

Local anesthetics that are used clinically, such as procaine, **lidocaine**, and **tetracaine**, reversibly block nerve impulse generation and propagation by inhibiting voltage-gated Na^+ channels. The action of these drugs is “use dependent,” which means that inhibition of Na^+ current progresses in a time-dependent manner with increasing repetitive stimulation or firing of action potentials (see Fig. 7-14B). **Use dependence** occurs because the drug binds most effectively only after the Na^+ channel has already opened. This use-dependent action of the drug further enhances inhibition of nerve impulses at sites where

repetitive firing of action potentials takes place. Local anesthetics are widely used to control pain during dental procedures, many types of minor surgery, and labor in childbirth.

Box 7-1

Genetic Defects of Voltage-gated Na⁺ Channels

A diverse spectrum of human genetic diseases has been mapped to inheritable defects in the α -subunit genes for voltage-gated Na⁺ channels (see Table 7-1). Genetic diseases have been linked to five different Nav genes: SCN4A (Nav1.4) expressed in skeletal muscle, SCN5A expressed in the heart (Nav1.5), and three genes—SCN1A (Nav1.1), SCN2A (Nav1.2), and SCN9A (Nav1.7)—expressed in central and peripheral neurons.

One disorder of skeletal muscle resulting from mutations in Nav1.4 is called **hyperkalemic periodic paralysis (HYPP or HyperPP)** because muscle weakness is triggered by an elevation in serum [K⁺] that may occur after vigorous exercise or ingestion of foods rich in K⁺. A second Nav1.4-linked muscle disorder is called **paramyotonia congenita (PC)**. This form of periodic paralysis may be induced in affected individuals by exposure to cold temperature and results in symptoms of myotonia (muscle stiffness) associated with abnormal repetitive firing of muscle action potentials.

Long QT syndromes comprise a diverse number of inherited defects in heart rhythm that can lead to sudden death from cardiac arrhythmias, including ventricular fibrillation. Long QT refers to lengthening of the duration of the cardiac action potential as measured by the QT interval on the electrocardiogram (see p. 506). One form of these syndromes, classified as LQT3, is the result of a deletion of three amino acids, Δ KPQ, in the linker region between repetitive domains III and IV of the Nav1.5 heart Na⁺ channel. Many other LQT3 mutations of Nav1.5 have been mapped in affected families. Genetic defects in various cardiac K⁺ channels also cause long QT syndromes as described in Box 7-3.

Mutations in two different Nav channels expressed in the brain result in syndromes called **generalized epilepsy with febrile seizures plus (GEFS+; Nav1.1)** and **infantile epileptic encephalopathy (Nav1.2)**.

Certain defects in Nav1.7 in peripheral nerves result in a variety of syndromes that alter pain perception (**nociception**). Various single amino-acid replacements in Nav1.7 result in syndromes of heightened and severe sensitivity to pain—**primary erythralgia (PE)** or **familial erythromelalgia**  **N7-21** (from the Greek *erythros* [red] + *melos* [limb] + *algos* [pain]) and **paroxysmal extreme pain disorder (PEPD)**. Conversely, the *absence* of functional expression of this channel by nonsense mutation prevents action potential firing in sensory afferent nociceptive neurons, resulting in a complete inability to perceive pain—**channelopathy-associated insensitivity to pain (CIP)**. Thus, the development of drugs that selectively block Nav1.7 channels could lead to a new class of pain medications.

Figure 7-15 illustrates the location of various Nav mutations mapped onto a membrane topology diagram of a generic Nav channel. Most of these Nav mutations cause hyperexcitability of nerve or muscle due to altered voltage-dependent gating kinetics, resulting in excessive or prolonged channel opening.

FIGURE 7-15 Na^+ channel mutations in human genetic diseases. The topology diagram shows a few examples of locations of mutations mapped in three Na^+ channel genes for six human genetic channelopathy diseases. Symbols show sites on a generic Na^+ channel α subunit. All these disease mutations are missense mutations resulting in amino-acid changes or deletions except for channelopathy-associated insensitivity to pain, which is due to nonsense mutations that result in lack of functional Nav1.7 expression. (Data from Catterall WA: Cellular and molecular biology of voltage-gated sodium channels. *Physiol Rev* 72:S15–S48, 1992; Ashcroft FM: Ion Channels and Disease, Academic Press, 2000; and Drenth JPH, Waxman S: Mutations in sodium-channel gene SCN9A cause a spectrum of human genetic pain disorders. *J Clin Invest* 117:3606–3609, 2007.)

Ca^{2+} channels contribute to action potentials in some cells and also function in electrical and chemical coupling mechanisms

Ca^{2+} channels play important roles in the depolarization phase of certain action potentials, in coupling electrical excitation to secretion or muscle contraction, and in other signal-transduction processes. Because $[\text{Ca}^{2+}]_o$ is $\sim 1.2 \text{ mM}$, whereas resting $[\text{Ca}^{2+}]_i$ is only $\sim 10^{-7} \text{ M}$, a huge gradient favors the passive influx of Ca^{2+} into cells. At the relatively high $[\text{Ca}^{2+}]_o$ that prevails under physiological conditions, voltage-gated Ca^{2+} channels are highly selective for Ca^{2+} , with permeability to Ca^{2+} being ~ 1000 -fold greater than permeability to Na^+ . Other alkaline earth divalent cations such as Sr^{2+} and Ba^{2+} also readily permeate Ca^{2+} channels and are often used as substitute ions for recording the activity of Ca^{2+} channels in electrophysiological studies. However, if $[\text{Ca}^{2+}]_o$ is experimentally reduced to a *nonphysiological* level of $< 10^{-6} \text{ M}$ with the use of chelating agents, Ca^{2+} channels can also conduct large currents of monovalent alkali cations, such as Na^+ and K^+ . Thus, in terms of its intrinsic ionic selectivity, the Ca^{2+} channel is functionally similar to the Na^+ channel, except that high-affinity binding of Ca^{2+} in the pore effectively prevents permeation of all other physiological ions except Ca^{2+} .

The mechanism of this extraordinary selectivity behavior is based on ion-ion interactions within the selectivity filter of the pore. **N7-10** For the Ca^{2+} channel to conduct current, at least two Ca^{2+} ions must bind simultaneously. This general mechanism, referred to as **multi-ion conduction**, also applies to many other classes of ion channels, notably K^+ channels. Multi-ion conduction generally plays an important role

in determining the permeation properties of channels with a high ionic selectivity, such as Ca^{2+} and K^{+} channels.

Voltage-gated Ca^{2+} channels contribute to the depolarizing phase of **action potentials** in certain cell types. Notably, the gating of voltage-gated Ca^{2+} channels is slower than that of Na^{+} channels. Whereas Na^{+} channels are most important in initiating action potentials and generating rapidly propagating spikes in axons, Ca^{2+} channels often give rise to a more sustained depolarizing current, which is the basis for the long-lived action potentials in cardiac cells, smooth-muscle cells, secretory cells, and many types of neurons.

The exquisite selectivity of Ca^{2+} channels under physiological conditions endows them with special roles in **cellular regulation**. When activated by a depolarizing electrical stimulus or a signal-transduction cascade, these Ca^{2+} channels mediate an influx of Ca^{2+} that raises $[\text{Ca}^{2+}]_i$. Thus, in serving as a major gateway for Ca^{2+} influx across the plasma membrane, Ca^{2+} channels not only contribute to membrane depolarization but also play a role in signal transduction because Ca^{2+} is an important second messenger (see p. 60).

Ca^{2+} channels also play a pivotal role in a special subset of signal-transduction processes known as excitation-contraction coupling and excitation-secretion coupling. **Excitation-contraction (EC) coupling** refers to the process by which an electrical depolarization at the cell membrane leads to cell contraction, such as the contraction of a skeletal muscle fiber. In EC coupling of skeletal muscle (see p. 229), one class of plasma-membrane Ca^{2+} channel that is located in the transverse tubule membrane of skeletal muscle serves as the voltage sensor and forms a direct mechanical linkage to intracellular Ca^{2+} -release channels that are located in the sarcoplasmic reticulum (SR) membrane. In contrast, Ca^{2+} channels play a different role in EC coupling in cardiac muscle, where Ca^{2+} channels in the plasma membrane mediate an initial influx of Ca^{2+} . The resultant increase in $[\text{Ca}^{2+}]_i$ triggers an additional release of Ca^{2+} stored in the SR by a process known as Ca^{2+} -induced Ca^{2+} release (see pp. 242–243).

Excitation-secretion (ES) coupling is the process by which depolarization of the plasma membrane causes release of neurotransmitters in the nervous system and the secretion of hormones in the endocrine system. Such processes require an increase in $[\text{Ca}^{2+}]_i$ to trigger exocytosis of synaptic and secretory vesicles.

In keeping with the diverse roles of Ca^{2+} channels, the human genome contains 10 distinct genes (Table 7-2) for the channel-forming α_1 subunit of **voltage-gated Ca^{2+} channels (Cavs)**. Molecular studies have also identified four accessory subunits of Ca^{2+} channels: α_2 , δ , β , and γ (see Fig. 7-12B). A single gene gives rise to the α_2 and δ subunits, which are separated by proteolytic cleavage. Coexpression studies show that these accessory subunits can greatly influence the kinetics, voltage sensitivity, and peak currents exhibited by various α_1 channel subunits. Table 7-2 shows that the genetic diversity is mirrored by a diversity of Ca^{2+} currents in various cell types.

TABLE 7-2

Properties and Classification of Ca²⁺ Channel α Subunits

	CHANNEL				
PROPERTY	L	T	N	P/Q	R
Kinetics	Long duration	Transient	Intermediate to long duration	Intermediate to long duration	Intermediate duration
Voltage activation	High threshold (> -30 mV)	Low threshold (< -30 mV)	High threshold (> -30 mV)	High threshold (> -30 mV)	High threshold (> -30 mV)
Pharmacology	Blocked by DHPs	Less sensitive to DHPs	Insensitive to DHPs, blocked by ω-conotoxin GVIA	Insensitive to DHPs, blocked by ω-agatoxin IVA	Insensitive to DHPs, ω-conotoxin GVIA, and ω-agatoxin IVA
Location	Heart, skeletal muscle, neurons, vascular smooth muscle, uterus, neuroendocrine cells	Sinoatrial node of heart, brain neurons	Presynaptic terminals, dendrites, and cell bodies of neurons	Cerebellar Purkinje's and granule cells, cell bodies of central neurons	Cerebellar granule cells, neurons
Function	EC coupling in skeletal muscle, link membrane depolarization to intracellular Ca signalling	Repetitive firing of action potentials in heart and many neurons	Exocytotic neurotransmitter release	Exocytotic neurotransmitter release	Exocytotic neurotransmitter release
Channel protein (gene)	Cav1.1 (<i>CACNA1S</i>) Cav1.2 (<i>CACNA1C</i>) Cav1.3 (<i>CACNA1D</i>) Cav1.4 (<i>CACNA1F</i>)	Cav3.1 (<i>CACNA1G</i>) Cav3.2 (<i>CACNA1H</i>) Cav3.3 (<i>CACNA1I</i>)	Cav2.2 (<i>CACNA1B</i>)	Cav2.1 (<i>CACNA1A</i>)	Cav2.3 (<i>CACNA1E</i>)

Ca²⁺ channels are characterized as L-, T-, P/Q-, N-, and R-type channels on the basis of kinetic properties and inhibitor sensitivity

An example of the functional diversity of Ca²⁺ channels is illustrated in [Figure 7-16](#), which shows two different types of voltage-gated Ca²⁺ channels that have been identified in cardiac ventricular cells by the patch-clamp technique. If the cell-attached patch, initially clamped at -50 mV, is suddenly depolarized to +10 mV, currents appear from a large-conductance (18 to 25 pS), slowly inactivating Ca²⁺ channel (see [Fig. 7-16A](#)). However, if the same patch is initially clamped at -70 mV and depolarized to only -20 mV, currents appear instead from a small-conductance (8 pS), rapidly inactivating Ca²⁺ channel (see [Fig. 7-16B](#)). These two types of Ca²⁺ channel are, respectively, named **L-type** (for long-lived) and **T-type** (for transient) channels. T-type channels are activated at a lower voltage threshold (more negative than -30 mV) than are other types of Ca²⁺ channels and are also inactivated over a more negative voltage range. These characteristics of T-type channels permit them to function briefly in the initiation of action potentials and to play a role in the repetitive firing of cardiac cells and neurons. Other types of Ca²⁺ channels, including L-, N-, P/Q-, and R-type channels, which are activated at a higher voltage threshold (more positive than -30 mV), mediate the long-lived plateau phase of slow action potentials and provide a more substantial influx of Ca²⁺ for contractile and secretory responses. N-, P/Q-, and R-type Ca²⁺ channels appear to mediate the entry of Ca²⁺ into certain types of presynaptic nerve terminals and thus play an important role in facilitating the release of neurotransmitters.

Box 7-2

Consequences of Genetically Defective Ca²⁺ Channels

Given their significance in excitation-contraction and excitation-secretion coupling, mutations resulting in dysfunctional voltage-gated Ca²⁺ channels would be expected to have many adverse physiological consequences. Here we describe Cav defects that perturb cardiac and neurological function. Cav mutations and related autoimmune disorders that specifically affect muscle are the focus of Box 9-1.

The L-type Cav1.2 channel is highly expressed in the heart but also in many other tissues. Mutations in the human *CACNA1C* gene for Cav1.2 are linked to two distinct genetic channelopathies: Timothy syndrome (LQT8) and a form of Brugada syndrome. **Timothy syndrome** is inherited in an autosomal dominant pattern with common features of syndactyly (fused fingers), autism, and **long QT** arrhythmia. The arrhythmia apparently reflects a gain of function resulting from defective Cav inactivation. **Brugada syndrome**, which also carries a risk of sudden cardiac death, is recognized by an abnormal pattern on electrocardiogram characterized by an elevated ST segment and shortened QT interval (see Fig. 21-7), or so-called **short QT**. Defects in at least six different human genes are linked to Brugada-like symptoms. However, loss-of-function Brugada mutations in the Cav1.2 channel cause defective trafficking of this channel, reducing Ca^{2+} -current density in the heart.

The Cav1.4 L-type channel is highly expressed in the retina and is genetically linked to visual disorders. One form of **X-linked congenital stationary night blindness** is due to mutations in the *CACANA1F* gene that result in nonfunctional Cav1.4 channels. The consequence is reduced sustained transmitter release by photoreceptor cells in the dark (see Fig. 15-11).

Amino-acid variations in the human *CACNA1H* gene for the Cav3.2 T-type Ca^{2+} channel are associated with various forms of epilepsy. These symptoms appear to reflect a gain of function that enhances Ca^{2+} current. Genetic syndromes linked to defects in Cav3.2 include a variety of idiopathic generalized epilepsies such as **juvenile myoclonic epilepsy**, **generalized tonic-clonic seizures**, and **generalized epilepsy with febrile seizures**.

The P/Q-type Cav2.1 channel, expressed in cerebellar Purkinje cells, is the culprit in diverse CNS movement disorders (**ataxia**) and migraine syndromes. Mutations in the *CACNA1A* gene for Cav2.1 variously cause **episodic ataxia type 2 (EA2)**, **spinocerebellar ataxia type 6**, and **familial hemiplegic migraine**. Symptoms of EA2 result from Cav2.1 mutations that decrease Ca^{2+} current, whereas the other two disorders stem from mutations that increase Ca^{2+} entry. Discovery of the genetic origin of such diseases has led to the realization that delicate perturbations of Ca^{2+} channel activity can have profound consequences on proper function of the human nervous system.

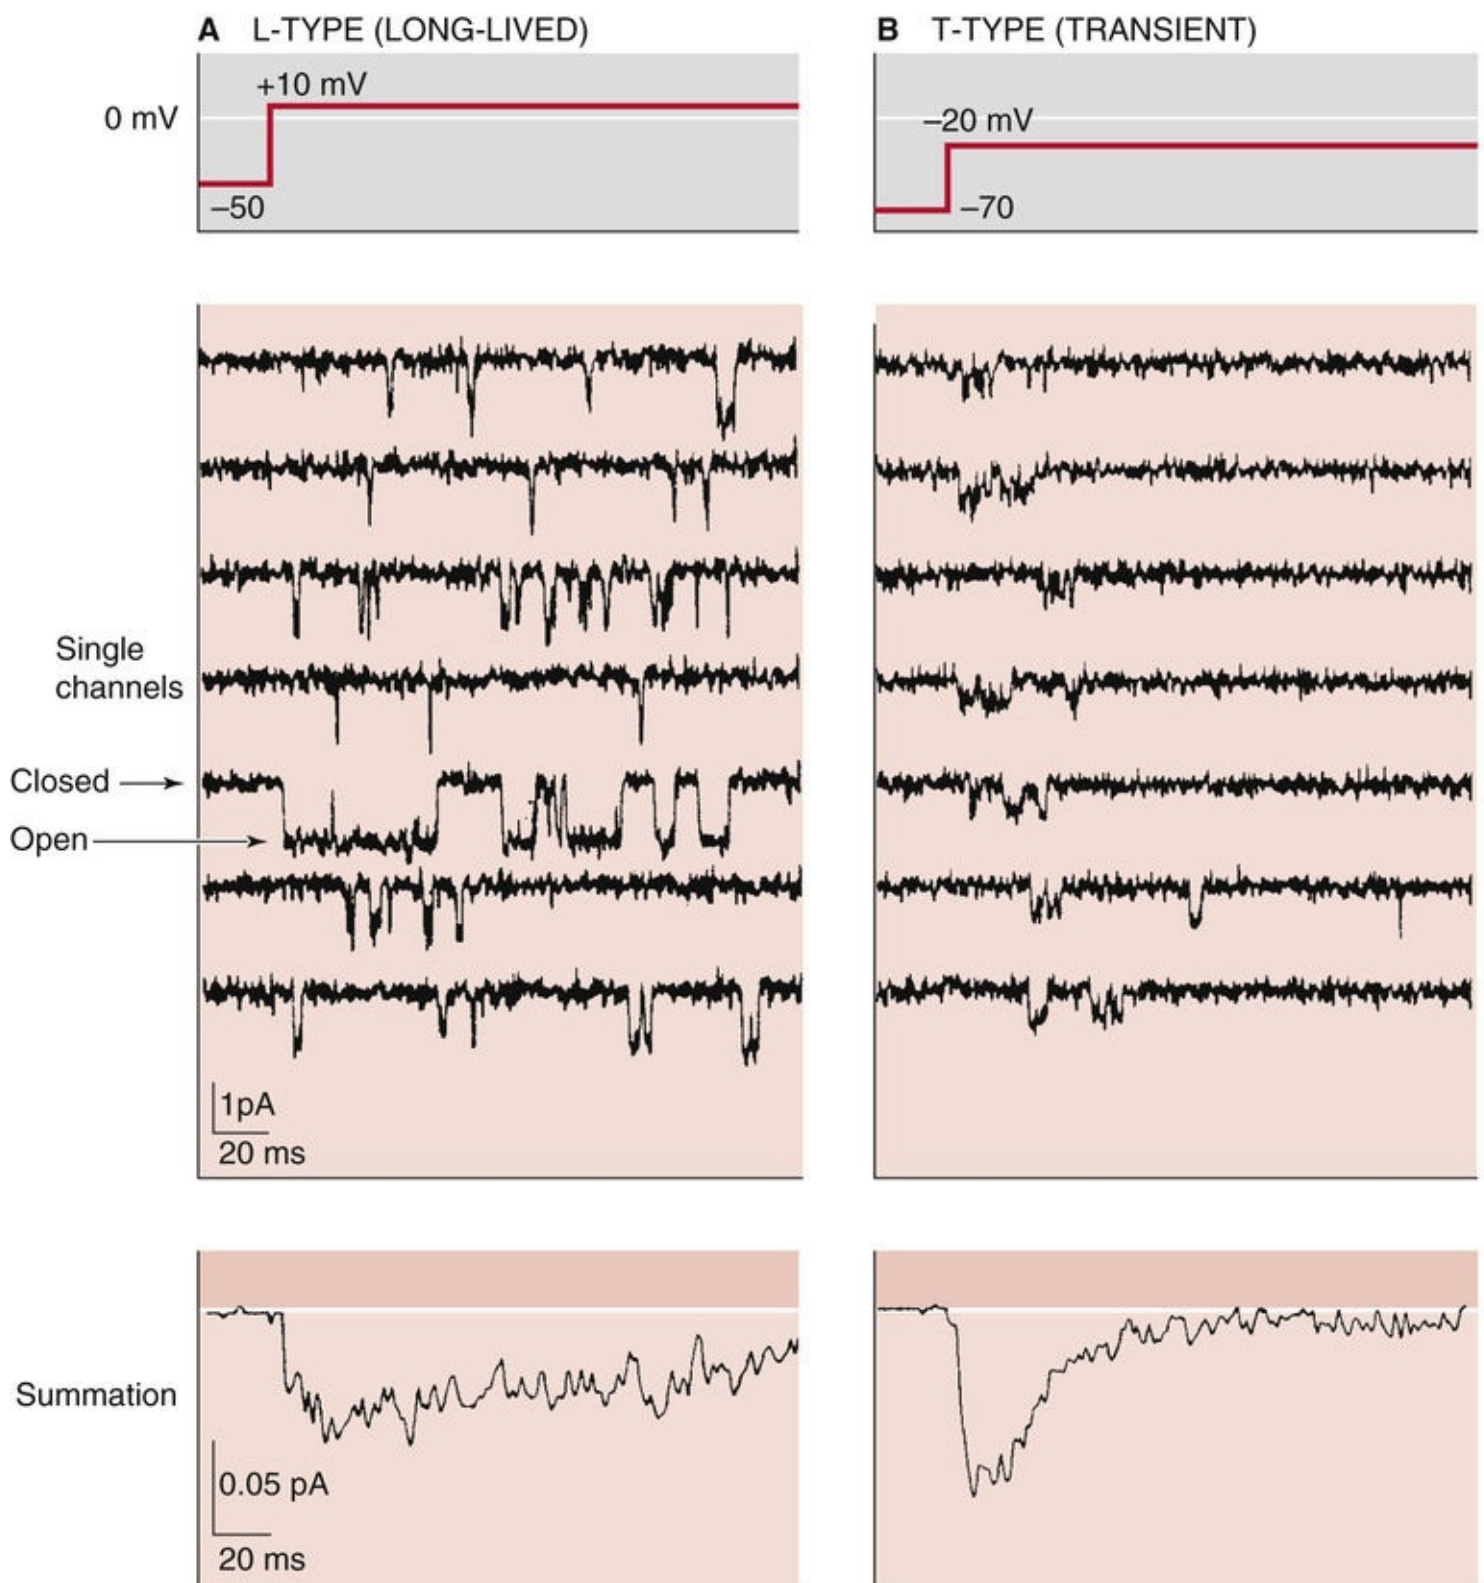

FIGURE 7-16 Current records from two types of Ca^{2+} channel. **A**, Data from an experiment using cell-attached patches on guinea pig ventricular myocytes are shown. These currents are carried by Ba^{2+} through L-type Ca^{2+} channels, which conduct Ba^{2+} even better than Ca^{2+} . Shown in the middle panel are seven single channel current records obtained during and after a shift of the cytosolic voltage from -50 to $+10$ mV. Channel activity (i.e., downward deflections) begins only after depolarization and continues more or less at the same level throughout the depolarization. The lower panel shows the average of many records that are similar to those shown in the middle panel. **B**, The experiments yielding the data shown for T-type Ca^{2+} channels are identical in design to those in **A**, except for the depolarizing step. Again, channel activity begins only after depolarization (*middle panel*). However, channel activity is transient, waning during a sustained depolarization, as confirmed by the average current shown in the lower panel. (Data from Nilius B, Hess P, Lansman JB, Tsien RW: A novel type of cardiac calcium channel in ventricular cells. *Nature* 316:443–446, 1985.)

In addition to discrimination on the basis of gating behavior, Ca^{2+} channel isoforms can also be distinguished by their sensitivity to different drugs and toxins (see [Table 7-2](#)). **Ca^{2+} channel blockers** are an important group of therapeutic agents. [Figure 7-17](#) shows the structures of representatives of three different classes of Ca^{2+} channel blockers: 1,4-dihydropyridines (DHPs), phenylalkylamines, and benzothiazepines. These synthetic compounds are available for treatment of cardiovascular disorders such as angina pectoris (see [Box 24-1](#)), hypertension, and various arrhythmias and also have potential applications in the treatment of CNS conditions such as cerebral vasospasm and epileptic seizure.

A 1,4-DIHYDROPYRIDINES

B PHENYLALKYLAMINES

C BENZOTHAZEPINES

FIGURE 7-17 Antagonists and agonists of L-type Ca^{2+} channels. **A**, 1,4-Dihydropyridines. One DHP, nitrendipine, is an antagonist; another, Bay K8644, is an agonist. **B**, Phenylalkylamines. Verapamil is an antagonist. **C**, Benzothiazepines. Diltiazem is an antagonist.

DHPs such as nitrendipine selectively block L-type Ca^{2+} channels. Phenylalkylamines (e.g., verapamil) and benzothiazepines (e.g., diltiazem) also inhibit L-type Ca^{2+} channels; however, these other two classes of drugs act at sites that are distinct from the site that binds DHPs. Particular DHP derivatives, such as Bay K8644, actually *enhance* rather than inhibit Ca^{2+} channel currents. DHPs can have the contrasting effects of either inhibitors (antagonists) or activators (agonists) because they act not by plugging the channel pore directly but by binding to a site composed of transmembrane helices S5 and S6 in domain III and S6 in domain IV. Drug binding in this region probably induces various conformational changes in channel structure and thereby perturbs Ca^{2+} permeation and gating behavior.

Other molecules useful in discriminating Ca^{2+} channel isoforms are present in the venom of the marine snail *Conus geographus* and the funnel web spider *Agelenopsis aperta*. The snail produces a peptide called ω -conotoxin GVIA, which selectively blocks N-type Ca^{2+} channels. The spider produces the peptide ω -agatoxin IVA, which selectively blocks P/Q-type Ca^{2+} channels. In contrast, an R-type neuronal Ca^{2+} channel is resistant to these two peptide toxins.

The summary of the basic properties of L-, T-, N-, P/Q-, and R-type Ca^{2+} channels contained in [Table 7-2](#) indicates their presumed correspondence to 10 known genes that encode α_1 subunits.

K^+ channels determine resting potential and regulate the frequency and termination of action potentials

K^+ channels are the largest and most diverse family of voltage-gated ion channels. Humans have at least

79 distinct genes encoding K^+ channels, characterized by a K^+ -selective S5-P-S6 pore domain (see [Fig. 7-10](#)). Ion conduction through most types of K^+ channels is very selective for K^+ according to the permeability sequence $K^+ > Rb^+ > NH_4^+ \gg Cs^+ > Li^+, Na^+, Ca^{2+}$. Under normal physiological conditions, the permeability ratio P_K/P_{Na} is >100 , and Na^+ can block many K^+ channels. Some K^+ channels can pass Na^+ current in the complete absence of K^+ . This characteristic is analogous to the behavior of Ca^{2+} channels, which can pass Na^+ and K^+ currents in the absence of Ca^{2+} .

Given such strong K^+ selectivity and an equilibrium potential near -80 mV, the primary role of K^+ channels in excitable cells is to oppose the action of excitatory Na^+ and Ca^{2+} channels and stabilize the resting state. Whereas some K^+ channels are major determinants of the resting potential, other K^+ channels mediate the repolarizing phase and shape of action potentials, control firing frequency, and define the bursting behavior of rhythmic firing. Such functions are broadly important in regulating the strength and frequency of all types of muscle contraction, in terminating transmitter release at nerve terminals, in attenuating the strength of synaptic connections, and in coding the intensity of sensory stimuli. Finally, in epithelia, K^+ channels also function in K^+ absorption and secretion.

Before understanding the molecular nature of K^+ channels, electrophysiologists classified K^+ currents according to their functional properties and gating behavior, grouping macroscopic K^+ currents into four major types:

1. **Delayed outward rectifiers**
2. **Transient outward rectifiers** (A-type currents)
3. **Ca^{2+} -activated K^+ currents**
4. **Inward rectifiers**

These four fundamental K^+ currents are the macroscopic manifestation of five distinct families of genes (see [Table 6-2](#), family No. 2):

1. **Kv channels** (voltage-gated K^+ channels related to the Shaker family)
2. **Small- and intermediate-conductance K_{Ca} channels** (Ca^{2+} -calmodulin-activated K^+ channels), including SK_{Ca} and IK_{Ca} channels
3. **Large-conductance K_{Ca} channels** (Ca^{2+} -activated BK_{Ca} channels and related Na^+ - and H^+ - activated K^+ channels)
4. **Kir channels** (inward-rectifier K^+ channels)
5. **K2P channels** (two-pore K^+ channels)

In the next three sections, we discuss the various families of K^+ channels and their associated macroscopic currents.

The Kv (or Shaker-related) family of K^+ channels mediates

both the delayed outward-rectifier current and the transient A-type current

The K^+ current in the HH voltage-clamp analysis of the squid giant axon (see [pp. 177–178](#)) is an example of a **delayed outward rectifier**. [Figure 7-18A](#) shows that this current activates with a sigmoidal lag phase (i.e., it is *delayed* in time, as in [Fig. 7-6C](#)). [Figure 7-18B](#) is an I - V plot of peak currents obtained in experiments such as that presented in [Figure 7-18A](#) and shows that the outward current rises steeply at positive voltages (i.e., it is an *outward* rectifier).

A DELAYED ACTIVATION OF Kv CHANNELS

B OUTWARD RECTIFICATION OF Kv CHANNELS

Peak K current (I_K)

C A-TYPE OUTWARD RECTIFIER: SMALL CURRENT

D A-TYPE OUTWARD RECTIFIER: LARGE CURRENT

E DIFFERENCES IN GATING KINETICS AMONG Kv-TYPE DELAYED OUTWARD RECTIFIERS

F INACTIVATION OF Kv-TYPE CHANNELS

FIGURE 7-18 Outwardly rectifying K^+ channels. **A**, Note that in a voltage-clamp experiment, a depolarizing step in V_m activates the current, but with a delay. **B**, The current-voltage relationship is shown for a delayed outwardly rectifying K^+ channel, as in **A**. **C**, This A-type K^+ current is active at relatively negative values of V_m and tends to hyperpolarize the cell. In a spontaneously spiking neuron, a low level of the A-type current allows V_m to rise relatively quickly toward the threshold, which produces a relatively short interspike interval and thus a high firing rate. **D**, In a spontaneously spiking neuron, a high level of the A-type current causes V_m to rise relatively slowly toward the threshold, which produces a relatively long interspike interval and thus a low firing rate. **E**, Four different types of K^+ channels (Kv1.1, Kv1.2, Kv1.3, and Kv1.4) from mammalian brain and expressed in *Xenopus* oocytes show activation and inactivation kinetics during steps of V_m from -80 mV to 0 mV. The left panels, at high time resolution, show that some of these channels activate more slowly than others. The right panels, at a longer time scale, show that inactivation gradually speeds up from Kv1.1 to Kv1.4. **F**, The left panel shows N-type inactivation, so called because the N or amino terminus of the protein is essential for inactivation. Each of the four subunits is thought to have an N-terminal “ball” tethered by a “chain” that can swing into place to block the pore. The right panel shows a variant in which certain β subunits can provide the ball and chain for Kv channel α subunits that themselves lack this capability at their N termini. (Data from Stühmer W, Ruppersberg JP, Schroter KH, et al: Molecular basis of functional diversity of voltage-gated potassium channels in mammalian brain. *EMBO J* 8:3235–3244, 1989.)

A second variety of K^+ current that is also outwardly rectifying is the **transient A-type** K^+ current. This current was first characterized in mollusk neurons, but similar currents are common in the vertebrate nervous system. A-type currents are activated and inactivated over a relatively rapid time scale. Because their voltage activation range is typically more negative than that of other K^+ currents, they are activated in the negative V_m range that prevails during the afterhyperpolarizing phase of action potentials. In neurons that spike repetitively, this A-type current can be very important in determining the interval between successive spikes and thus the timing of repetitive action potentials. For example, if the A-type current is small, V_m rises relatively quickly toward the threshold, and consequently the interspike interval is short and the firing frequency is high (see [Fig. 7-18C](#)). However, if the A-type current is large, V_m rises slowly toward the threshold, and therefore the interspike interval is long and the firing frequency is low (see [Fig. 7-18D](#)). Because the nervous system often encodes sensory information as a frequency-modulated signal, these A-type currents play a critical role.

The channels responsible for both the delayed outward-rectifier and the transient A-type currents belong to the **Kv channel family** (where v stands for voltage-gated). The prototypic protein subunit of these channels is the Shaker channel of *Drosophila* (see [Fig. 7-12C](#)). All channels belonging to this family contain the conserved S1 to S6 core that is characteristic of the Shaker channel (see [Fig. 7-10](#)), but may differ extensively in the length and sequence of their intracellular N-terminal and C-terminal domains. The voltage-sensing element in the S4 segment underlies activation by depolarization; the S4 segment actually moves outward across the membrane with depolarizing voltage, thus increasing the probability of the channel's being open. **ON7-13**

The Kv channel family has multiple subclasses (see [Table 6-2](#), family No. 2). Individual members of this Kv channel family, whether in *Drosophila* or humans, exhibit profound differences in gating kinetics that are analogous to delayed-rectifier (slow activation) or A-type (rapid inactivation) currents. For example, [Figure 7-18E](#) shows the macroscopic currents of four subtypes of rat brain Kv1 (or Shaker) channels heterologously expressed in frog oocytes. All of these Kv1 channel subtypes (Kv1.1 to Kv1.4) exhibit sigmoidal activation kinetics when examined on a brief time scale—in the millisecond range (left side of [Fig. 7-18E](#)). That is, these channels display some degree of “delayed” activation. Different Kv channels exhibit different rates of activation. Thus, these currents can modulate action potential duration by either keeping it *short* (e.g., in nerve and skeletal muscle) when the delayed rectifier turns on quickly

or keeping it *long* (e.g., in heart) when the delayed rectifier turns on slowly.

Box 7-3

Congenital and Drug-Induced Cardiac Arrhythmias Linked to K⁺ Channels

Congenital Long QT Syndromes

As discussed in Box 7-1, congenital cardiac abnormality in some people results in lengthening of the QT interval of the electrocardiographic signal—long QT syndrome—which corresponds to a prolonged cardiac action potential. Affected children and young adults can exhibit an arrhythmic disturbance of the ventricular heartbeat that results in sudden death. As we have already seen in Box 7-1, one form of a long QT syndrome—LQT3—involves gain-of-function mutations of the cardiac Na⁺ channel Nav1.5 (*SCN5A*) that prolong Na⁺ channel opening. However, at least six forms of long QT syndrome—LQT1, LQT2, LQT5, LQT6, LQT7, and LQT13—are caused by loss-of-function mutations in cardiac K⁺ channels (see Table 6-2, family No. 2) or their accessory proteins.

LQT1 is due to mutations in the *KCNQ1* gene encoding KvLQT1, a 581-residue protein belonging to the Kv family of voltage-gated K⁺ channels. Another form of this disease, **LQT2**, involves mutations in the *KCNH2* gene encoding HERG (for human ether-à-go-go) which is related to the gene defective in the *ether-à-go-go Drosophila* mutation, in which flies convulsively shake under ether anesthesia. Both KvLQT1 and HERG K⁺ channels participate in repolarization of the human cardiac action potential (see p. 488). KvLQT1 mediates the slowly activating delayed-rectifier component (I_{Ks}) of cardiac action potential repolarization; HERG mediates the rapidly activating repolarization component (I_{Kr}). Both LQT1 and LQT2 result from loss-of-function effects associated with decreased K⁺ channel expression in cardiac myocytes.

KvLQT1 associates with minK, a small, single-span membrane protein encoded by the *KCNE1* gene. minK modulates the gating kinetics of KvLQT1, and mutations in minK cause **LQT5**. Three other human proteins closely related to minK are known as MiRP1, MiRP2, and MiRP3 (minK-related proteins)—the products of the genes *KCNE2*, *KCNE3*, and *KCNE4*, respectively. MiRP1 associates with HERG, and mutations in MiRP1 are linked to **LQT6**.

Two other K⁺ channel genes also cause long QT syndromes. Mutations in Kir2.1, encoded by the gene *KCNJ2*, cause **LQT7**, whereas mutations in GIRK4, encoded by *KCNJ5*, cause **LQT13**.

Acquired Long QT Syndrome

The HERG channel is notorious for its sensitivity to blockade by many classes of therapeutic drugs, including antihistamines (e.g., terfenadine), antipsychotics (e.g., sertindole), and gastrointestinal drugs (e.g., cisapride). Blockade of HERG can readily mimic the genetic condition of LQT2. The promiscuous drug sensitivity of the HERG K⁺ channel appears to result from particular structural features of the internal aspect of the channel pore that favor binding of many hydrophobic small molecules. People who have natural variations in ion channel genes that cause a subclinical propensity for long QT intervals or who have deficiencies in drug-metabolizing enzymes appear to be especially at risk. Many drugs have been banned or limited for therapeutic use because of the risk of HERG channel block. Today all new drugs proposed for clinical use must first undergo screening for HERG blockade in order to prevent deaths by acquired long QT syndrome.

Kv1 channels also differ markedly in their *inactivation* kinetics when observed over a long time scale—in the range of seconds (right side of [Fig. 7-18E](#)). Kv1.1 exhibits little time-dependent inactivation (i.e., the current is sustained throughout the stimulus). On the other hand, the Kv1.4 channel completely inactivates in <1 second. Kv1.2 and Kv1.3 show intermediate behavior.

How are Kv channels inactivated? The structural basis for one particular type of K⁺ channel inactivation, known as **N-type inactivation**, is a stretch of ~20 amino-acid residues at the N terminus of some fast-inactivating Kv channels. This domain acts like a ball to block or to plug the internal mouth of the channel after it opens; the result is inactivation (see [Fig. 7-18F](#)). Thus, this process is also known as the **ball-and-chain mechanism** of K⁺ channel inactivation. Particular kinds of β subunits that are physically associated with some isoforms of Kv channels have structural elements that mimic this N-terminal ball domain and rapidly inactivate K⁺ channel α subunits that lack their own inactivation ball domain (see [Fig. 7-11](#)). Many K⁺ channels also exhibit a second, slower **C-type inactivation**, which appears to involve a constriction of the outer mouth of the pore.

Various delayed-rectifier K⁺ channels are blocked by either internal or external application of quaternary ammonium ions such as **TEA** (see [Fig. 7-5C](#)). Many transient A-type K⁺ currents are inhibited by another organic cation, **4-aminopyridine (4-AP)**, which effectively shifts the action potential threshold in the negative direction and also prolongs action potentials by inhibiting repolarization. Both effects promote the propagation of action potentials through demyelinated regions of axons, which is why 4-AP has been approved for treatment of symptoms of multiple sclerosis (see [Box 12-1](#)). Two distinct families of peptide toxins—**charybdotoxins** of scorpion venom and **dendrotoxins** of mamba snake venom—discriminate particular subtypes of Kv and K_{Ca} channels, depending on the particular amino acids present in the P region. Such toxins cause nerve and muscle hyperexcitability, resulting in paralysis of envenomated victims.

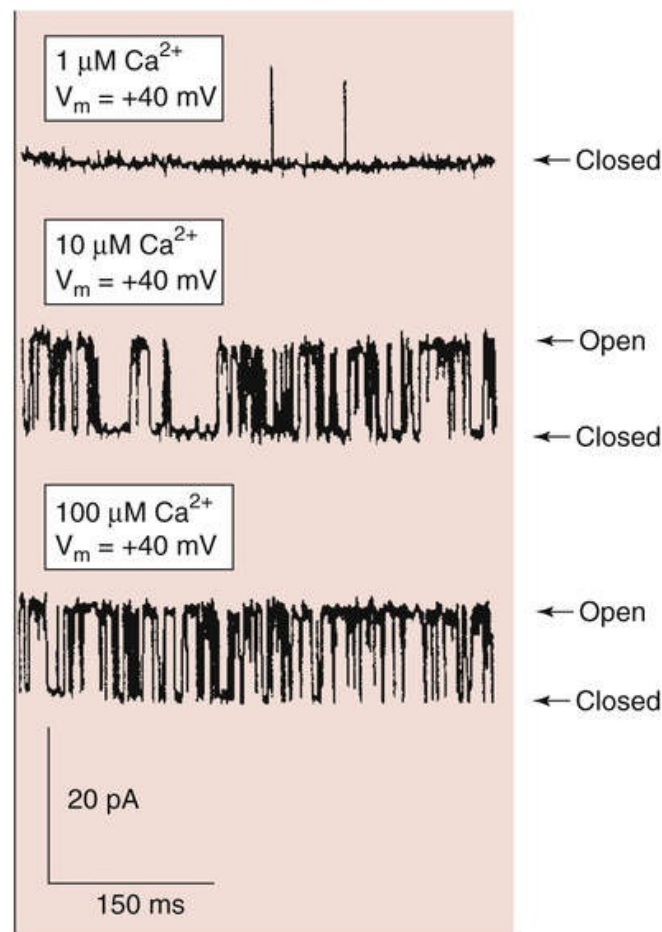

Two families of K_{Ca} K⁺ channels mediate Ca²⁺-activated K⁺ currents

Ca²⁺-activated K⁺ channels—K_{Ca} channels—are present in the plasma membrane of cells in many different tissues. A particular type of K_{Ca} channel is shown in [Fig. 7-19A](#); this is called **BK_{Ca}** (for “big” K_{Ca}) or the maxi-K_{Ca} channel because it has a large unitary conductance (~300 pS). In patch-clamp experiments, all K_{Ca} channels are easily recognized because the open probability of individual channels increases with increasing [Ca²⁺] on the *intracellular* surface of the membrane patch (see [Fig. 7-19B](#) for BK_{Ca}). In addition, the *P*_o of BK_{Ca} increases with positive voltage (see [Fig. 7-19C](#)).  **N7-15** [Figure 7-19D](#) shows how increasing [Ca²⁺]_i causes a negative or leftward shift in the *P*_o versus *V*_m plot for BK_{Ca} channels. Thus, at negative voltages, the binding of Ca²⁺ to the **regulator of conductance of K⁺ (RCK)** domains causes BK_{Ca} channels to be open when they otherwise would be closed.

D COMBINED EFFECTS OF CHANGING V_m AND $[Ca^{2+}]_i$

FIGURE 7-19 Large-conductance Ca^{2+} -activated K^+ channels (BK_{Ca}). **A**, Topology of BK_{Ca} channels.

B, Shown are data from an experiment on BK_{Ca} channels that are expressed in *Xenopus* oocytes and studied by using a patch pipette in an inside-out configuration. V_m is always held at +40 mV and the $[Ca^{2+}]_i$ on the cytosolic side of the patch varies from 1 to 10 to 100 μM . Note that channel activity increases with increasing $[Ca^{2+}]_i$. **C**, The experiment is the same as in **B** except that when V_m is held at -60 mV, there is very little channel activity. On the other hand, when V_m is +80 mV, both channels in the patch are open most of the time. **D**, Combined effects of changing V_m and $[Ca^{2+}]_i$. Shown is a plot of relative open probability (P_o) of the K_{Ca} channels versus V_m at three different levels of Ca^{2+} . The data come from experiments such as that in **B**. (Data from Butler A, Tsunoda S, McCobb DP, et al: mSlo, a complex mouse gene encoding "maxi" calcium-activated potassium channels. Science 261:221–224, 1993.)

The BK_{Ca} Channel

Contributed by Ed Moczydlowski

The BK_{Ca} channel was discovered by cloning and sequencing the *Slowpoke* gene of *Drosophila*. The BK_{Ca} channel-forming α subunit—activated by intracellular Ca^{2+} —consists of a conserved S1 to S6 motif, an extra S0 transmembrane segment at the amino terminus, and a unique C-terminal intracellular domain of ~850 residues, consisting of two RCK domains. The RCK domains contain Ca^{2+} -binding sites involved in channel activation (see Table 6-2, family No. 2, as well as Fig. 7-19).

Because BK_{Ca} channels—like Kv channels—have a voltage-sensing domain that is analogous to S4, they are also activated by positive voltage.

Besides the plasma membrane, BK_{Ca} channels are also present in the inner mitochondrial membrane of cardiac myocytes, where they exert a cardioprotective role under conditions of ischemia. Hypoxia increases the open probability of this channel, which would lead to an efflux of K^+ from the mitochondrial matrix into the cytosol; this efflux would tend to maintain a relatively high cytosolic $[\text{K}^+]$ and help to maintain a relatively negative resting potential.

In principle, K_{Ca} channels provide a stabilizing mechanism to counteract repetitive excitation and intracellular Ca^{2+} loading. K_{Ca} channels mediate the afterhyperpolarizing phase of action potentials (see Fig. 7-1A) in cell bodies of various neurons. They have also been implicated in terminating bursts of action potentials in bursting neuronal pacemaker cells. Thus, the gradual increase in $[\text{Ca}^{2+}]_i$ that occurs during repetitive firing triggers the opening of K_{Ca} channels, which results in hyperpolarization and a quiescent interburst period that lasts until intracellular Ca^{2+} accumulation is reversed by the action of Ca pumps (see p. 118). K_{Ca} channels are also present at high density in many types of smooth-muscle cells, where they appear to contribute to the relaxation of tension by providing a hyperpolarizing counterbalance to Ca^{2+} -dependent contraction. In a number of nonexcitable cells, K_{Ca} channels are activated during cell swelling and contribute to regulatory volume decrease (see pp. 131–132).

In addition to the BK_{Ca} channel and the related Na^+ - and H^+ -activated K^+ channels, there is another K^+ channel gene family that includes small- and intermediate-conductance Ca^{2+} -activated K^+ channels, respectively termed SK_{Ca} and IK_{Ca} (see Table 6-2, family No. 2). Unlike BK_{Ca} channels, the closely related IK_{Ca} and SK_{Ca} channels are voltage *insensitive* and are activated by the Ca^{2+} -binding protein calmodulin (see p. 60). In some cells, SK_{Ca} and IK_{Ca} channels participate in action potential repolarization and afterhyperpolarization, thus regulating action potential firing frequency. IK_{Ca} also functions in the activation of lymphocytes.

The Kir K^+ channels mediate inward-rectifier K^+ currents, and K2P channels may sense stress

In contrast to the delayed rectifiers and A-type currents—which are *outwardly* rectifying K^+ currents—the inward-rectifier K^+ current (also known as the anomalous rectifier) actually conducts more K^+ current in the *inward* direction than in the outward direction. Such inwardly rectifying, steady-state K^+ currents have been recorded in many types of cells, including heart, skeletal muscle, and epithelia. Physiologically,

these channels help clamp the resting membrane potential close to the K^+ equilibrium potential and prevent excessive loss of intracellular K^+ during repetitive activity and long-duration action potentials. In epithelial cells, these inwardly rectifying K^+ currents are important because they stabilize V_m in the face of electrogenic ion transporters that tend to depolarize the cell (see [Chapter 5](#)).

The channel-forming subunits of the **inward-rectifier (Kir)** K^+ channel family are relatively small proteins (~400 to 500 residues) that do not contain the complete S1 to S6 core domain found in the Kv and K_{Ca} channel families. However, the Kir channels do have a conserved pore domain similar to the S5-P-S6 segment of Kv channels ([Fig. 7-20A](#)).  **N7-13** The conserved P region is the most basic structural element that is common to all K^+ channels. The absence of an S1 to S4 voltage-sensing domain in Kir channels is consistent with their lack of steeply voltage-dependent activation.

FIGURE 7-20 Inwardly rectifying K^+ channels. **A**, This family of channels has only two membrane-spanning segments that correspond to the S5-P-S6 domain of the voltage-gated K^+ channels. **B**, The GIRK1 channels—a particular type of Kir channel—were expressed in *Xenopus* oocytes and studied by use of a patch pipette in the inside-out configuration. V_m was clamped to values between -100 mV and $+60$ mV, and $[Mg^{2+}]$ was 2.5 mM on the cytosolic side. Note that channel activity increases at more negative voltages but the channel is virtually inactive at positive voltages. **C**, The I - V plot shows that there is inward rectification only in the presence of Mg^{2+} on the cytosolic side. In the absence of Mg^{2+} , the I - V relationship is nearly linear or ohmic. **D**, As shown in the left panel, cytosolic Mg^{2+} occludes the channel pore and prevents the exit of intracellular K^+ . However, even in the presence of Mg^{2+} , extracellular K^+ can move into the cell by displacing the Mg^{2+} . (Data from Kubo Y, Reuveny E, Slesinger PA, et al: Primary structure and functional expression of a rat G protein-coupled muscarinic potassium channel. *Nature* 364:802–806, 1993.)

Figure 7-20B shows a series of single channel currents from a particular type of Kir channel, with equal concentrations of K^+ on both sides of the membrane and Mg^{2+} on the cytosolic side. Under these conditions, the channel conducts K^+ current only in the inward direction. An I - V plot derived from such data (see Fig. 7-20C) shows typical inward rectification of the unitary current. At negative values of V_m , the inward current decreases linearly as voltage becomes more positive, and no outward current is present at positive values of V_m . However, when Mg^{2+} is omitted from the cytosolic side of the membrane, the channel exhibits a linear or **ohmic I - V curve** even over the positive range of V_m values. Thus, the inward rectification in this example is due to **intracellular block** of the channel by Mg^{2+} . Selective

inhibition of outward K^+ current in the presence of intracellular Mg^{2+} results from voltage-dependent binding of this divalent metal ion. Positive internal voltage favors the binding of Mg^{2+} to the inner mouth of this channel (see [Fig. 7-20D](#)), as would be expected if the Mg^{2+} binding site is located within the transmembrane electrical field. Because Mg^{2+} cannot permeate the channel, it acts as a blocker of outward K^+ current. However, negative values of V_m pull the Mg^{2+} out of the channel. Moreover, incoming K^+ tends to displace any remaining Mg^{2+} . Thus, the Kir channel favors K^+ influx over efflux. Under physiological conditions, intracellular cationic polyamines such as spermine and spermidine [N7-16](#) block outward movements through Kir channels in a fashion similar to Mg^{2+} and largely account for the Kir rectification. In skeletal muscle, the Kir2.1 channel (see [Table 6-2](#), family No. 2) appears to function in K^+ re-uptake from the T-tubule system during prolonged periods of muscle contraction associated with a rise in extracellular $[K^+]$ and muscle fatigue.

N7-16

Spermine and Spermidine

Contributed by Ed Moczydlowski

Spermine and spermidine are important regulators of numerous processes associated with cell growth. These polyamines modulate the activity of many cation channels in addition to having the blocking effect on Kir channels described here.

The Kir family of K^+ channels exhibits various modes of regulation. One Kir subfamily (the G protein–activated inwardly rectifying K^+ channels or **GIRKs**) is regulated by the $\beta\gamma$ subunits of heterotrimeric **G proteins** (see [pp. 51–66](#)). For example, stimulation of the vagus nerve slows the heartbeat because the vagal neurotransmitter acetylcholine binds to postsynaptic muscarinic receptors in the heart that are coupled to G proteins. The binding of acetylcholine to muscarinic receptors causes the release of G-protein $\beta\gamma$ subunits, which diffuse to a site on neighboring GIRK channels to activate their opening. The resulting increase in outward K^+ current hyperpolarizes the cardiac cell, [N7-17](#) thereby slowing the rate at which V_m approaches the threshold for firing action potentials and lowering the heart rate. GIRK channels are also activated by the membrane phospholipid phosphatidylinositol 4,5-bisphosphate (PIP_2). Thus, G protein–coupled receptors that activate phospholipase C lead to the release of PIP_2 , thereby activating GIRK channels.

N7-17

Hyperpolarization by Activation of GIRKs

Contributed by Ed Moczydlowski

Even though Kir channels pass current better in the inward than outward direction, the membrane potential (V_m) is typically never more negative than E_K . Thus, *net* inward K^+ current does not occur physiologically. As a result, the activation of GIRK channels hyperpolarizes cardiac cells by increasing K^+ conductance or outward K^+ current.

Another subfamily of Kir K^+ channels known as **K_{ATP} channels** are directly regulated by adenine

nucleotides. K_{ATP} channels are present in the plasma membrane of many cell types, including skeletal muscle, heart, neurons, insulin-secreting β cell of the pancreas, and renal tubule. These channels are inhibited by intracellular ATP and activated by ADP in a complex fashion. They are believed to provide a direct link between cellular metabolism, on the one hand, and membrane excitability and K^+ transport, on the other. For example, if cellular ATP levels fall because of oxygen deprivation, opening of such channels hyperpolarizes the cell to suppress Ca^{2+} influx and firing of action potentials, and further reduce energy expenditure. Pancreatic β cells respond to an increase in plasma [glucose] by elevating their uptake of glucose and, thus, glucose metabolism and the cytoplasmic ATP/ADP ratio. This increased ratio inhibits enough K_{ATP} channels to cause a small depolarization, which in turn activates voltage-gated Ca^{2+} channels, resulting in Ca^{2+} -dependent insulin secretion (see [pp. 1039–1041](#)).

K_{ATP} channels are the target of a group of antidiabetic drugs called **sulfonylureas** that include tolbutamide and glibenclamide. Sulfonylureas are used in the treatment of type 2 (or non-insulin-dependent) diabetes mellitus because they inhibit pancreatic K_{ATP} channels and stimulate insulin release. Another chemically diverse group of drugs (e.g., pinacidil and cromakalim) called K^+ channel openers activate K_{ATP} and BK_{Ca} channels. Such K^+ channel openers may have therapeutic potential in light of their ability to relax various types of smooth muscle. The ability of sulfonylurea drugs to inhibit K_{ATP} channels depends on an accessory subunit called the **sulfonylurea receptor (SUR)**. This protein is a member of the ATP-binding cassette family of proteins (see [pp. 119–120](#)), which include two nucleotide-binding domains.

The most recently discovered family of K^+ channels is that of the two-pore or **K2P** channels, which consist of a tandem repeat of the basic Kir topology (see [Fig. 6-20F](#)). Because the monomeric subunit of K2P channels contains two linked S5-P-S6 pore domains, a dimer of the monomer contains four S5-P-S6 pores and thereby forms a functional channel. K2P channels have been implicated in the genesis of the resting membrane potential. K^+ channels encoded by the 15 human genes for K2P channels may be activated by various chemical and physical signals including PIP_2 , membrane stretch, heat, high intracellular pH, and general anesthetics. These channels are thought to be involved in a wide range of sensory and neuronal functions.

Propagation of Action Potentials

The propagation of electrical signals in the nervous system involves local current loops

The extraordinary functional diversity of ion channel proteins provides a large array of mechanisms by which the membrane potential of a cell can be changed to evoke an electrical signal or biochemical response. However, channels alone do not control the spread of electrical current. Like electricity in a copper wire, the passive spread of current in biological tissue depends on the nature of the conducting and insulating medium. Important factors include geometry (i.e., cell shape and tissue anatomy), electrical resistance of the aqueous solutions and cell membrane, and membrane capacitance. Furthermore, the electrotonic spread of electrical signals is not limited to excitable cells.

Efficient propagation of a change in V_m is essential for the *local* integration of electrical signals at the level of a single cell and for the *global* transmission of signals across large distances in the body. As we discussed above in this chapter (see Fig. 7-2), *action potentials* propagate in a regenerative manner without loss of amplitude as long as the depolarization spreads to an adjacent region of excitable membrane and does so with sufficient strength to depolarize the membrane above its threshold. However, many types of *nonregenerative*, subthreshold potentials also occur and spread for short distances along cell membranes. These **graded responses**, which we also discussed above, contrast with the all-or-nothing nature of action potentials. Such nonregenerative signals include **receptor potentials** generated during the transduction of sensory stimuli and **synaptic potentials** generated by the opening of agonist-activated channels.

With a graded response, the greater the stimulus, the greater the voltage change. For example, the greater the intensity of light that is shined on a mammalian photoreceptor cell in the retina, the greater the hyperpolarization produced by the cell. Similarly, the greater the concentration of acetylcholine applied at a postsynaptic neuromuscular junction, the greater the resulting depolarization (i.e., synaptic potential). Just as subthreshold voltage responses produced by current injections into a cell through a microelectrode decline by passive **electrotonic** spread, graded signals dissipate over distances of a few millimeters and thus have only local effects. In contrast, action potentials—actively generated by above-threshold depolarization—can propagate over a meter via nerve axons.

Electrotonic spread of voltage changes along the cell occurs by the flow of electrical current that is carried by ions in the intracellular and extracellular medium along pathways of the least electrical resistance. Both depolarizations and hyperpolarizations of a small area of membrane produce **local circuit currents**. Figure 7-21A illustrates how the transient voltage change that occurs during an action potential at a particular active site results in local current flow. The cytosol of the active region, where the membrane is depolarized, has a slight excess of positive charge compared with the adjacent inactive regions of the cytosol, which have a slight excess of negative charge.  **N7-18** This charge imbalance within the cytosol causes currents of ions to flow from the electrically excited region to adjacent regions of the cytoplasm. Because current always flows in a complete circuit along pathways of least resistance, the current spreads longitudinally from positive to negative regions along the cytoplasm, moves outward across membrane conductance pathways (“leak channels”), and flows along the extracellular medium back to the site of origin, thereby closing the current loop. Because of this flow of current (i.e., positive charge), the region of membrane immediately adjacent to the active region becomes more depolarized,

and V_m eventually reaches threshold. Thus, an action potential is generated in this adjacent region as well. Nerve and muscle fibers conduct impulses in both directions if an inactive fiber is excited at a central location, as in this example. However, if an action potential is initiated at one end of a nerve fiber, it will travel only to the opposite end and stop because the refractory period prevents backward movement of the impulse (see p. 302). Likewise, currents generated by subthreshold responses migrate equally in both directions.

FIGURE 7-21 Local current loops during action potential propagation. **A**, In an unmyelinated axon, the ionic currents flow at one instant in time as a result of the action potential (“active” zone). In the “inactive” zones that are adjacent to the active zone, the outward currents lead to a depolarization. If the membrane is not in an absolute refractory period and if the depolarization is large enough to reach threshold, the immediately adjacent inactive zones will become active and fire their own action potential. In the more distant inactive zones, the outward current is not intense enough to cause V_m to reach threshold. Thus, the magnitudes of the outward currents decrease smoothly with increasing distance from the active zone. **B**, In this example, the “active” zone consists of a single node of Ranvier. As an action potential conducts along a myelinated axon, the ionic current flows only through the nodes, which lack myelin and have a very high density of Na^+ channels. Ionic current does not flow through the internodal membrane because of the high resistance of myelin. Rather, as an action potential fires at a *node*, the resistance-capacitance properties of the adjacent *internodal* membrane (see Fig. 6-11) give rise to charge displacement across this *internodal* membrane—that is, a *capacitive current*—that actually is responsible for conducting the action potential through the internodal region. As a result, the current flowing down the axon is conserved, and the current density at the nodes is very high, triggering an action potential at the next node. Thus, the regenerative action potential propagates in a “saltatory” manner by jumping from node to node.

To generate a membrane potential, there must be a tiny separation of charge across the membrane. How large is that charge? Imagine that we have a spherical cell with a diameter of 10 μm . If $[\text{K}^+]_{\text{i}}$ is 100 mM and $[\text{K}^+]_{\text{o}}$ is 10 mM, the V_{m} according to the Nernst equation would be -61.5 mV (or -0.0615 V) for a perfectly K^+ -selective membrane at 37°C . What is the charge (Q) on 1 cm^2 of the “plates” of the membrane capacitor? We assume that the specific capacitance is $1 \mu\text{F}/\text{cm}^2$. From Equation 6-13 in the text, we know that

$$Q = CV$$

(NE 7-11)

where Q is measured in coulombs (C), C is in farads (F), and V is in volts (V). Thus,

$$\begin{aligned} Q &= (1 \times 10^{-6} \text{ F cm}^{-2}) \times (0.0615 \text{ V}) \\ &= 61.5 \times 10^{-9} \text{ C cm}^{-2} \end{aligned}$$

(NE 7-12)

The Faraday is the charge of 1 mole of univalent ions—or 96,480 C  N6-12. To determine how many moles of K^+ we need to separate in order to achieve an electrical charge of $61.5 \times 10^{-9} \text{ C cm}^{-2}$ (i.e., the Q in the previous equation), we merely divide Q by the faraday. Because V_{m} is negative, the cell needs to lose K^+ :

$$\begin{aligned} \text{K}^+ \text{ deficit per cm}^2 \text{ of membrane} &= \frac{\left(\frac{61.5 \times 10^{-9} \text{ C}}{\text{cm}^2} \right)}{\left(\frac{96,480 \text{ C}}{\text{mole}} \right)} \\ &= 6.37 \times 10^{-13} \text{ moles cm}^{-2} \end{aligned}$$

(NE 7-13)

The surface area for a spherical cell with a diameter of 10 μm is $3.14 \times 10^{-6} \text{ cm}^2$. Therefore,

$$\begin{aligned}\text{Total K}^+ \text{ deficit per cell} &= \frac{6.37 \times 10^{-13} \text{ moles}}{\text{cm}^2} \times \frac{3.14 \times 10^{-6} \text{ cm}^2}{1} \\ &= 2.0 \times 10^{-18} \text{ moles}\end{aligned}$$

(NE 7-14)

The volume of this cell is 0.52×10^{-12} L. Given a $[\text{K}^+]_i$ of 100 mM,

$$\begin{aligned}\text{Total K}^+ \text{ content of cell} &= (0.1 \text{ mole/L}) \times (0.52 \times 10^{-12} \text{ L}) \\ &= 0.52 \times 10^{-13} \text{ moles}\end{aligned}$$

(NE 7-15)

What fraction of the cell's total K^+ content represents the charge separated by the membrane?

$$\begin{aligned}\text{Fraction of cell K}^+ &= \frac{\text{K}^+ \text{ deficit of cell}}{\text{Total K}^+ \text{ content of cell}} \\ &= \frac{2.0 \times 10^{-18} \text{ moles}}{0.52 \times 10^{-13} \text{ moles}} \\ &= 4 \times 10^{-5} \text{ or } 0.004\%\end{aligned}$$

(NE 7-16)

Thus, in the process of generating a V_m of -61.5 mV, our hypothetical cell needs to lose only 0.004% of its total K^+ content to charge the capacitance of the cell membrane.

Myelin improves the efficiency with which axons conduct action potentials

The flow of electrical current along a cylindrical nerve axon has often been compared with electrical flow through an undersea cable. Similar principles apply to both types of conducting fiber. An underwater cable is designed to carry an electrical current for long distances with little current loss; therefore, it is constructed of a highly conductive (low-resistance) metal in its core and a thick plastic insulation wrapped around the core to prevent loss of current to the surrounding seawater. In contrast, the axoplasm of a nerve fiber has much higher resistance than a copper wire, and the nerve membrane is inherently electrically leaky because of background channel conductance. Therefore, in a biological fiber such as a nerve or muscle cell, some current is passively lost into the surrounding medium, and the amplitude of the signal rapidly dissipates over a short distance.

Animal nervous systems use two basic strategies to improve the conduction properties of nerve fibers: (1) increasing the diameter of the axon, thus decreasing the internal resistance of the cable; and (2) myelinating the fibers, which increases the electrical insulation around the cable. As **axon diameter** increases, the conduction velocity of action potentials increases because the internal resistance of the axoplasm is inversely related to the internal cross-sectional area of the axon. Unmyelinated nerve fibers

of the invertebrate squid giant axon (as large as $\sim 1000\ \mu\text{m}$ in diameter) are a good example of this type of size adaptation. These nerve axons mediate the escape response of the squid from its predators and can propagate action potentials at a velocity of $\sim 25\ \text{m/s}$.

In vertebrates, **myelination** of smaller-diameter ($\sim 1\text{-}$ to $5\text{-}\mu\text{m}$) nerve axons serves to improve the efficiency of impulse propagation, especially over the long distances that nerves traverse between the brain and the extremities. Axons are literally embedded in myelin, which consists of concentrically wound wrappings of the membranes of certain glial cells (see pp. 292–293). The thickness of the myelin sheath may amount to 20% to 40% of the diameter of a nerve fiber, and the sheath may consist of as many as 300 membrane layers. The glial cells that produce myelin are called Schwann cells in the periphery and oligodendrocytes in the brain. Because resistors in series add directly and capacitors in series add as the sum of the reciprocal, the insulating resistance of a myelinated fiber with 300 membrane layers is increased by a factor of 300 and the capacitance is decreased to $1/300$ that of a single membrane. This large increase in membrane resistance minimizes loss of current across the leaky axonal membrane and forces the current to flow longitudinally along the inside of the fiber.

In myelinated peripheral nerves, the myelin sheath is interrupted at regular intervals, forming short ($\sim 1\text{-}\mu\text{m}$) uncovered regions called **nodes of Ranvier**. The length of the myelinated axon segments between adjacent unmyelinated nodes ranges from 0.2 to 2 mm. In mammalian axons, the density of voltage-gated Na^+ channels is very high at the nodal membrane, whereas K^+ channels are localized in the paranodal regions flanking each node. The unique anatomy of myelinated axons results in a mode of impulse propagation known as **saltatory conduction**. Current flow that is initiated at an excited node flows directly to adjacent nodes with little loss of transmembrane current through the internode region (see Fig. 7-21B). In other words, the high membrane resistance in the internode region effectively forces the current to travel from node to node.

The high efficiency of impulse conduction in such axons allows several adjacent nodes in the same fiber to fire an action potential virtually simultaneously as it propagates. Thus, saltatory conduction in a myelinated nerve can reach a very high velocity, up to $130\ \text{m/s}$. The action potential velocity in a myelinated nerve fiber can thus be several-fold greater than that in a giant unmyelinated axon, even though the axon diameter in the myelinated fiber may be more than two orders of magnitude smaller. During conduction of an action potential in a myelinated axon, the intracellular regions between nodes also transiently depolarize as a result of capacitative current. However, no transmembrane current flows in these internodal regions, and therefore no dissipation of ion gradients occurs. The nodal localization of Na^+ channels conserves ionic concentration gradients that must be maintained at the expense of ATP hydrolysis by the Na-K pump.

The cable properties of the membrane and cytoplasm determine the velocity of signal propagation

Using the analogy of a nerve fiber as an underwater cable, **cable theory** allows one to model the pathways of electrical current flow along biomembranes. The approach is to use circuit diagrams that were first employed to describe the properties of electrical cables. Figure 7-22A illustrates the equivalent circuit diagram of a cylindrical electrical cable or membrane that is filled and bathed in a conductive electrolyte solution. The membrane itself is represented by discrete elements, each with a transverse membrane resistance (r_m) and capacitance (c_m) connected in parallel (a representation we used above, in Fig. 6-11A). Consecutive membrane elements are connected in series by discrete resistors, each of which

represents the electrical resistance of a finite length of the external medium (r_o) or internal medium (r_i). The parameters r_m , c_m , r_o , and r_i refer to a unit length of axon (Table 7-3).

A EQUIVALENT-CIRCUIT MODEL

B DISTRIBUTION OF CURRENT FLOW

C VOLTAGE DECAY

FIGURE 7-22 Passive cable properties of an axon. **A**, The axon is represented as a hollow, cylindrical “cable” that is filled with an electrolyte solution. All of the electrical properties of the axon are represented by discrete elements that are expressed in terms of the length of the axon. r_i is the resistance of the internal medium. Similarly, r_o is the resistance of the external medium. r_m and c_m are the membrane resistance and capacitance per discrete element of axon length. **B**, When current is injected into the axon, the current flows away from the injection site in both directions. The current density smoothly decays with increasing distance from the site of injection. **C**, Because the current density decreases with distance from the site of current injection in **B**, the electrotonic potential (V) also decays exponentially with distance in both directions. V_o is the maximum change in V_m that is at the site of current injection.

TABLE 7-3
Cable Parameters 📌N7-19

PARAMETER	UNITS	DEFINITION OR RELATIONSHIP
r_m	$\Omega \times \text{cm}$	Membrane resistance (per unit length of axon)
r_o	Ω/cm	Extracellular resistance (per unit length of axon)
r_i	Ω/cm	Intracellular resistance (per unit length of axon)
c_m	$\mu\text{F}/\text{cm}$	Membrane capacitance (per unit length of axon)
$R_m = r_m \times 2\pi a$	$\Omega \times \text{cm}^2$	Specific membrane resistance (per unit area of membrane)
$R_i = r_i \times \pi a^2$	$\Omega \times \text{cm}$	Specific internal resistance (per unit cross-sectional area of axoplasm)
$C_m = c_m/(2\pi a)$	$\mu\text{F}/\text{cm}^2$	Specific membrane capacitance (per unit area of membrane)

a , Radius of the axon.

How do the various electrical components of the cable model influence the electrotonic spread of current along an axon? To answer this question, we inject a steady electrical current into an axon with a microelectrode to produce a constant voltage (V_0) at a particular point ($x = 0$) along the length of the axon (see Fig. 7-22B). This injection of current results in the longitudinal spread of current in both directions from point $x = 0$. The voltage (V) at various points along the axon decays exponentially with distance (x) from the point of current injection (see Fig. 7-22C), according to the following equation:

$$V = V_0e^{-x/\lambda}$$

(7-5)

The parameter λ has units of *distance* and is referred to as the **length constant** or the **space constant**. One length constant away from the point of current injection, V is $1/e$, or $\sim 37\%$ of the maximum value of V_0 . The decaying *currents* that spread away from the location of a current-passing electrode are called **electrotonic currents**. Similarly, the passive spread of subthreshold *voltage* changes away from a site of origin is referred to as electrotonic spread, unlike the regenerative propagation of action potentials.

The length constant depends on the three resistance elements in Figure 7-22A: 📌N7-19

$$\lambda = \sqrt{\frac{r_m}{r_o + r_i}}$$

(7-6)

N7-19

Resistance and Capacitance Units for Cable Properties

Contributed by Emile Boulpaep, Walter Boron

The purpose of this webnote is to justify the units given in the first four rows of Table 7-3. Our approach is to present these four electrical units per unit length of axon and then to show how these units make sense when we calculate the resistance or capacitance of an entire axon.

The **longitudinal resistances** of the intracellular fluid (r_o) and extracellular fluids (r_i) are expressed in units of ohms per centimeter. In each case, we can think of the total resistance of either the intra- or

extracellular fluid as being the resistance of a stack of resistors in *series*—each resistor representing 1 cm of fluid length along the axis of the cable. Thus, the total resistance of either the intra- or extracellular fluid (in ohms) increases in proportion to increasing fiber length (in centimeters), and the proportionality factor is the longitudinal resistance of each of the N segments (in ohms per centimeter):

$$\text{Total resistance} = (\text{Individual resistance}) \times N$$

Because each N is in fact 1 cm,

$$\begin{aligned} \text{Total resistance} &= \frac{\text{ohm}}{\text{cm}} \times \text{cm} \\ &= \text{ohm} \end{aligned}$$

(NE 7-17)

The **transverse membrane resistance (r_m)** is expressed in the units ohms \times centimeters. We can think of the total resistance of the membrane as being the resistance of a stack of resistors in *parallel*—each resistor representing the membrane resistance of a segment of axon that is 1 cm long. Because the N resistors are arranged in parallel,

$$\frac{1}{\text{Total resistance}} = \sum^N \frac{1}{\text{Individual resistance}}$$

Rearranging,

$$\text{Total resistance} = \frac{\text{Individual resistance}}{N}$$

(NE 7-18)

Finally, inserting the units for the individual resistance, and realizing that each N is in fact 1 cm, we obtain

$$\text{Total resistance} = \frac{\text{ohm} \times \text{cm}}{\text{cm}} = \text{ohm}$$

(NE 7-19)

One way to think of this is that a longer section of axon membrane has more channels, a greater total conductance, and thus a lower total resistance.

The **membrane capacitance (c_m)** has the units microfarads per centimeter. We can think of the total capacitance of the membrane as being the capacitance of a stack of capacitors in *parallel*—each capacitor representing the membrane capacitance of a segment of axon that is 1 cm long. Because the N

capacitors are arranged in parallel,

$$\text{Total capacitance} = (\text{Individual capacitance}) \times N$$

Because each N is in fact 1 cm,

$$\begin{aligned} \text{Total capacitance} &= \left(\frac{\text{farad}}{\text{cm}} \right) \times \text{cm} \\ &= \text{farad} \end{aligned}$$

(NE 7-20)

Thus, just as longitudinal resistances in *series* summate, membrane capacitances in *parallel* summate; both are thus expressed per unit length.

We can simplify this expression by noting that internal resistance is much larger than external resistance, so the contribution of r_o to the denominator can be ignored. Thus,

$$\lambda = \sqrt{\frac{r_m}{r_i}}$$

(7-7)

The significance of the length constant is that it determines how far the electrotonic spread of a local change in membrane potential can extend to influence neighboring regions of membrane. The longer the length constant, the farther down the axon a voltage change spreads.

How does the diameter of an axon affect the length constant? To answer this question, we must replace r_m and r_i (expressed in terms of axon length) in Equation 7-7 with the **specific resistances** R_m and R_i (expressed in terms of the area of axon membrane or cross-sectional area of axoplasm). Making the substitutions according to the definitions in Table 7-3, we have **N7-20**

$$\lambda = \sqrt{\frac{aR_m}{2R_i}}$$

(7-8)

N7-20

Units of the “Length Constant”

Contributed by Emile Boulpaep, Walter Boron

In our discussion of cable properties in the text, we presented Table 7-3, which summarizes the units of

cable parameters in two ways: (1) **resistance per unit length** (top three rows in Table 7-3) and (2) **specific resistance** (fifth and sixth rows in Table 7-3).

Resistance per Unit Length

In the text, we presented Equation 7-6 (shown here as Equation NE 7-21):

$$\lambda = \sqrt{\frac{r_m}{r_o + r_i}}$$

(NE 7-21)

The above equation uses *resistance per unit length*. If we substitute the appropriate units from Table 7-3 into the above equation, we obtain

$$\lambda = \sqrt{\frac{r_m}{r_o + r_i}} = \sqrt{\frac{\text{ohm} \times \text{cm}}{\text{ohm/cm}}} = \sqrt{\text{cm}^2} = \text{cm}$$

(NE 7-22)

Thus, the length constant has units of distance (centimeters).

Specific Resistance

In the text, we presented Equation 7-8 (shown here as Equation NE 7-23):

$$\lambda = \sqrt{\frac{aR_m}{2R_i}}$$

(NE 7-23)

The above equation uses *specific resistance*. If we substitute the appropriate units from Table 7-3 into the preceding equation, we obtain

$$\lambda = \sqrt{\frac{(\text{cm}) \times (\text{ohm} \times \text{cm}^2)}{(\text{ohm} \times \text{cm})}} = \sqrt{\text{cm}^2} = \text{cm}$$

(NE 7-24)

Thus, the length constant again has units of distance (centimeters).

Thus, the length constant (λ) is directly proportional to the square root of the axon radius (a). [Equation 7-8](#) confirms basic intuitive notions about what makes an efficiently conducting electrical cable:

1. The greater the specific membrane resistance (R_m) and cable radius, the greater the length constant and the less the loss of signal.
2. The greater the resistance of the internal conductor (R_i), the smaller the length constant and the greater

the loss of signal.

These relationships also confirm measurements of length constants in different biological preparations. For example, the length constant of a squid axon with a diameter of ~ 1 mm is ~ 13 mm, whereas that of a mammalian nerve fiber with a diameter of ~ 1 μm is ~ 0.2 mm.

So far, we have been discussing the *spatial* spread of voltage changes that are stable in *time*. In other words, we assumed that the amount of injected current was steady. What happens if the current is not steady? For example, what happens at the beginning of a stimulus when we (or a physiological receptor) first turn the current “on”? To answer these questions, we need to know how rapidly V_m changes in time at a particular site, which is described by a second cable parameter called the membrane **time constant** (τ_m). Rather than determining the spread of voltage changes in space, as the length constant does, the time constant influences the spread of voltage changes in *time* and thus the *velocity* of signal propagation. We previously discussed the time constant with respect to the time course of the change in V_m caused by a stepwise pulse of current (see [Fig. 6-12A](#)). Because the membrane behaves like an RC circuit, the voltage response to a square current pulse across a small piece of membrane follows an exponential time course with a time constant that is equal to the product of membrane resistance and capacitance:

$$\tau_m = R_m \cdot C_m$$

(7-9)

We introduced this expression above as [Equation 6-17](#). The shorter the time constant, the more quickly a neighboring region of membrane will be brought to threshold and the sooner the region will fire an action potential. Thus, the shorter the time constant, the faster the speed of impulse propagation and vice versa. In contrast, conduction velocity is directly proportional to the length constant. The greater the length constant, the further a signal can spread before decaying below threshold and the greater the area of membrane that the stimulus can excite. These relationships explain why, in terms of relative conduction velocity, a high-resistance, low-capacitance *myelinated* axon has a distinct advantage over an *unmyelinated* axon of the same diameter for all but the smallest axons (<1 μm in diameter; see [p. 302](#)).

In summary, the cable parameters of length constant and time constant determine the way in which graded potentials and action potentials propagate over space and time in biological tissue. These parameters are in turn a function of material properties that include resistance, capacitance, and geometric considerations. The dependence of impulse conduction velocity on fiber diameter has been studied experimentally and analyzed theoretically for unmyelinated and myelinated nerve axons. For *unmyelinated* axons, conduction velocity increases roughly with the square root of the axon's diameter, just as the length constant increases with the square root of the axon's diameter or radius (see [Equation 7-8](#)). In contrast, the conduction velocity of *myelinated* fibers is a linear function of diameter and increases ~ 6 m/s per 1- μm increase in outer diameter. Thus, a mammalian myelinated axon with an outer diameter of ~ 4 μm has roughly the same impulse velocity as a squid giant axon with a diameter of 500 μm ! However, for myelinated fibers with a very small diameter (<1 μm), the adverse effect of high internal resistance of the axoplasm predominates, and conduction is slower than in unmyelinated axons of the same outer diameter. For outer diameters that are greater than ~ 1 μm , the increased membrane resistance and reduced capacitance caused by myelination result in much faster conduction velocities.

The physiological importance of myelin in action potential propagation is most dramatically illustrated

in the pathology that underlies human demyelinating diseases such as **multiple sclerosis**. This disease is an autoimmune disorder in which the myelin sheath surrounding CNS axons is progressively lost (see [Box 12-1](#)). Gradual demyelination is responsible for an array of neurological symptoms that involve various degrees of paralysis and altered or lost sensation. As myelin is eliminated, the loss of membrane resistance and increased capacitance mean that propagated action potentials may ultimately fail to reach the next node of Ranvier and thus result in nerve blockage.

CHAPTER 8

Synaptic Transmission and the Neuromuscular Junction

Edward G. Moczydlowski

The ionic gradients that cells maintain across their membranes provide a form of stored electrochemical energy that cells can use for electrical signaling. The combination of a resting membrane potential of -60 to -90 mV and a diverse array of voltage-gated ion channels allows excitable cells to generate action potentials that propagate over long distances along the surface membrane of a *single* nerve axon or muscle fiber. However, another class of mechanisms is necessary to transmit such electrical information from cell to cell throughout the myriad of neuronal networks that link the brain with sensory and effector organs. Electrical signals must pass across the specialized gap region between two apposing cell membranes that is called a **synapse**. The process underlying this cell-to-cell transfer of electrical signals is termed **synaptic transmission**. Communication between cells at a synapse can be either electrical or chemical. Electrical synapses provide direct electrical continuity between cells by means of gap junctions, whereas chemical synapses link two cells together by a chemical **neurotransmitter** that is released from one cell and diffuses to another.

In this chapter we introduce the general principles of synaptic transmission and then focus mainly on synaptic transmission between a motor neuron and a skeletal muscle fiber. This interface between the motor neuron and the muscle cell is called the neuromuscular junction. In [Chapter 13](#), we expand upon this topic with a focus on synaptic transmission between neurons in the central nervous system (CNS).

Mechanisms of Synaptic Transmission

Electrical continuity between cells is established by electrical or chemical synapses

Once the concept of bioelectricity had taken hold among physiologists of the 19th century, it became clear that the question of how electrical signals flow between cells posed a fundamental biological problem. Imagine that two cells lie side by side without any specialized device for communication between them. Furthermore, imagine that a flat, $20\text{-}\mu\text{m}^2$ membrane area of the first, or **presynaptic**, cell is separated—by 15 nm—from a similar area of the second, or **postsynaptic**, cell. In his classic book on electrophysiology, Bernard Katz calculated that a voltage signal at the presynaptic membrane would suffer 10,000-fold attenuation in the postsynaptic membrane. A similar calculation based on the geometry and cable properties of a typical nerve-muscle synapse suggests that an action potential arriving at a nerve terminal could depolarize the postsynaptic membrane by only 1 μV after crossing the synaptic gap—an attenuation of 10^5 . Clearly, the evolution of complex multicellular organisms required the development of special synaptic mechanisms for electrical signaling to serve as a workable means of intercellular communication.

Two competing hypotheses emerged in the 19th century to explain how closely apposed cells could communicate electrically. One school of thought proposed that cells are directly linked by microscopic connecting bridges that enable electrical signals to flow directly. Other pioneering physiologists used pharmacological observations to infer that cell-to-cell transmission was chemical in nature. Ultimate resolution of this question awaited both the development of electron microscopic techniques, which permitted visualization of the intimate contact region between cells, and further studies in neurochemistry, which identified the small organic molecules that are responsible for neurotransmission. By 1960, accumulated evidence led to the general recognition that cells use *both* direct electrical and indirect chemical modes of transmission to communicate with one another.

The essential structural element of intercellular communication, the synapse, is a specialized point of contact between the membranes of two different but connected cells. Electrical and chemical synapses have unique morphological features, distinguishable by electron microscopy. One major distinction is the distance of separation between the two apposing cell membranes. At **electrical synapses**, the adjacent cell membranes are separated by $\sim 3\text{ nm}$ and appear to be nearly sealed together by a plate-like structure that is a fraction of a micrometer in diameter. Freeze-fracture images of the intramembrane plane in this region reveal a cluster of closely packed intramembranous particles that represent a **gap junction**. As described, a gap junction corresponds to planar arrays of connexons, each of which is made up of six connexin monomers (see [Fig. 6-18](#)). The multiple connexons from apposing cells physically connect the two cells together via multiple aqueous channels.

In contrast to those of the gap junction, the apposing cell membranes of the **chemical synapse** are separated by a much larger distance of $\sim 30\text{ nm}$ at a neuronal chemical synapse and up to 50 nm at the vertebrate nerve-muscle synapse. An additional characteristic of a chemical synapse is the presence of numerous synaptic vesicles on the side of the synapse that initiates the signal transmission, termed the *presynaptic* side. These vesicles are sealed, spherical membrane-bound structures that range in diameter from 40 to 200 nm and contain a high concentration of chemical neurotransmitter.

The contrasting morphological characteristics of electrical and chemical synapses underline the

contrasting mechanisms by which they function ([Table 8-1](#)). Electrical synapses pass voltage changes directly from one cell to another across the low-resistance continuity that is provided by the connexon channels. On the other hand, chemical synapses link two cells by the diffusion of a chemical transmitter across the large gap separating them. Key steps in chemical neurotransmission include release of transmitter from synaptic vesicles into the synaptic space, diffusion of transmitter across the cleft of the synapse, and activation of the postsynaptic cell by binding of transmitter to a specific receptor protein on the postsynaptic cell membrane.

TABLE 8-1
Summary of Properties of Electrical and Chemical Synapses

		CHEMICAL	
	ELECTRICAL	IONOTROPIC	METABOTROPIC
Agonist	None	e.g., ACh	e.g., ACh
Membrane protein	Connexon	Receptor/channel	Receptor/G protein
Delay in transmission	Instantaneous	~1 ms	Seconds to minutes

Direct evidence for the existence of chemical synapses actually predated the experimental confirmation of electrical synapses. The foundations of synaptic physiology can be traced to early studies of the autonomic nervous system. Early in the 1900s, researchers noted that adrenal gland extracts, which contain epinephrine (or adrenaline), elicit physiological effects (e.g., increases in heart rate and blood pressure) that are similar to those elicited by stimulation of sympathetic nerve fibers. In 1904, Thomas R. Elliot proposed that sympathetic nerves might release a substance analogous to epinephrine—later identified as norepinephrine—that would function in chemical transmission between a nerve and its target organ.

Subsequent studies by Otto Loewi suggested that the vagus nerve, which is parasympathetic, produces a substance responsible for depression of the heartbeat. His classic 1921 experiment is widely cited as the first definitive evidence for chemical neurotransmission. Loewi used an ingenious bioassay to test for the release of a chemical substance by the vagus nerve. He repeatedly stimulated the vagus nerve of a cannulated frog heart and observed a slowing of the heartbeat. At the same time, he collected the artificial saline that emerged from the ventricle of this overstimulated heart. When he later applied the collected fluid from the vagus-stimulated heart to a different heart, he observed that this perfusate slowed the second heart in a manner that was identical to direct vagal stimulation. He also later identified the active compound in the perfusion fluid, originally called *Vagusstoff*, as acetylcholine (ACh).

Efforts by Henry Dale and coworkers to understand the basis of neurotransmission between motor nerves and skeletal muscle culminated in the identification of ACh as the endogenous excitatory neurotransmitter. Thus, the inherent complexity of chemical synaptic transmission was evident from these earliest investigations, which indicated that the same neurotransmitter (ACh) could have an inhibitory action at one synapse (vagus nerve–heart) and an excitatory action at another synapse (motor nerve–skeletal muscle). For their work on nerve transmission across chemical synapses, Otto Loewi and Henry Dale received the Nobel Prize in Physiology or Medicine in 1936. 🏆[N8-1](#)

N8-1

Sir Henry H. Dale and Otto Loewi

Contributed by Emile Boulpaep, Walter Boron

The recognition of norepinephrine and ACh as the principal neurotransmitters of the autonomic nervous system led to the classification of peripheral nerve terminals and their synapses as either adrenergic or cholinergic, corresponding to their dependence on these two transmitters.

Dale and Loewi shared the 1936 Nobel Prize in Physiology or Medicine for their research on the chemical transmission of impulses. For more information about these investigators and the work that led to their Nobel Prize, visit <http://www.nobel.se/medicine/laureates/1936/index.html> (accessed October 2014).

Electrical synapses directly link the cytoplasm of adjacent cells

Whereas overwhelming support for chemical synaptic transmission accumulated in the first half of the 20th century, the first direct evidence for electrical transmission came much later from electrophysiological recordings of a crayfish nerve preparation. In 1959, Furshpan and Potter used two pairs of stimulating and recording electrodes to show that depolarization of a presynaptic nerve fiber (the crayfish abdominal nerve) resulted in excitation of a postsynaptic nerve cell (the motor nerve to the tail muscle) with virtually no time delay. In contrast, chemical synapses exhibit a characteristic delay of ~1 ms in the postsynaptic voltage signal after excitation of the presynaptic cell. The demonstration of an electrical synapse between two nerve membranes highlighted an important functional difference between electrical and chemical synapses—immediate signal propagation (electrical) versus briefly delayed communication (chemical) via the junction.

An electrical synapse is a true structural connection formed by connexon channels of gap junctions that link the cytoplasm of two cells (Fig. 8-1). These channels thus provide a low-resistance path for electrotonic current flow and allow voltage signals to flow with little attenuation and no delay between two or more coupled cells. Many types of gap junctions pass electrical current with equal efficiency in both directions—these are termed **reciprocal synapses**. In other words, the current passing through the gap junction is ohmic; it varies linearly with the transjunctional voltage (i.e., the V_m difference between the two cells). However, the crayfish synapse described by Furshpan and Potter allows depolarizing current to pass readily in only one direction, from the presynaptic cell to the postsynaptic cell. Such electrical synapses are called **rectifying synapses** to indicate that the underlying junctional conductance is voltage dependent. Studies of cloned and expressed connexins have shown that the voltage dependence of electrical synapses arises from unique gating properties of different connexin isoforms. Some isoforms are voltage dependent; others are voltage independent. Intrinsic rectification can also be altered by the formation of a gap junction that is composed of two hemichannels, each made up of a different connexin monomer. Such hybrid connexins are called heterotypic channels.

FIGURE 8-1 An electrical synapse. An electrical synapse consists of one or more gap junction channels permeable to small ions and molecules (see Fig. 6-18).

Chemical synapses use neurotransmitters to provide electrical continuity between adjacent cells

By their very nature, chemical synapses are inherently rectifying or polarized. They propagate current in one direction: from the presynaptic cell that releases the transmitter to the postsynaptic cell that contains the receptors that recognize and bind the transmitter. However, the essentially vectorial nature of chemical synaptic transmission belies the possibility that the postsynaptic cell can influence synapse formation or transmitter release by the presynaptic cell. Studies of synapse development and regulation have shown that postsynaptic cells also play an active role in synapse formation. In the CNS, postsynaptic cells may also produce retrograde signaling molecules, such as nitric oxide (see pp. 315–317), that diffuse back into the presynaptic terminal and modulate the strength of the synaptic connection. Furthermore, the presynaptic membrane at many synapses has receptors that may either inhibit or facilitate the release of transmitter. Thus, chemical synapses should be considered a unidirectional pathway for signal propagation that can be modulated by bidirectional chemical communication between two interacting cells.

The process of chemical transmission can be summarized by the following series of steps (Fig. 8-2):

Step 1: Neurotransmitter molecules are packaged into synaptic vesicles. Vesicular transporters concentrate neurotransmitters inside the vesicle using the energy of an H^+ electrochemical gradient.

Step 2: An action potential, which involves voltage-gated Na^+ and K^+ channels (see [pp. 176–177](#)), arrives at the presynaptic nerve terminal.

Step 3: Depolarization opens voltage-gated Ca^{2+} channels, which allows Ca^{2+} to enter the presynaptic terminal.

Step 4: The increase in intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) triggers the fusion of synaptic vesicles with the presynaptic membrane. As a result, packets (quanta) of transmitter molecules are released into the synaptic cleft.

Step 5: The transmitter molecules diffuse across the synaptic cleft and bind to specific receptors on the membrane of the postsynaptic cell.

Step 6: The binding of transmitter activates the receptor, which in turn activates the postsynaptic cell.

Step 7: The process is terminated by (a) enzymatic destruction of the transmitter (e.g., hydrolysis of ACh by acetylcholinesterase), (b) uptake of transmitter into the presynaptic nerve terminal or into other cells by Na^+ -dependent transport systems, or (c) diffusion of the transmitter molecules away from the synapse.

FIGURE 8-2 A chemical synapse. Synaptic transmission at a chemical synapse can be thought of as occurring in seven steps as shown.

The molecular nature of chemical synapses permits enormous diversity in functional specialization and regulation. Functional diversity occurs at the level of the transmitter substance, receptor protein, postsynaptic response, and subsequent electrical and biochemical processes. Many different small molecules are known—or proposed—to serve as neurotransmitters (see pp. 314–322). These molecules include both small organic molecules, such as norepinephrine, ACh, serotonin (5-hydroxytryptamine [5-HT]), glutamate, gamma-aminobutyric acid (GABA), and glycine, and peptides such as endorphins and enkephalins.

Neurotransmitters can activate ionotropic or metabotropic receptors

Neurotransmitter receptors transduce information by two molecular mechanisms: some are ligand-gated ion channels and others are G protein–coupled receptors (see pp. 51–66). Several neurotransmitter molecules—such as ACh, glutamate, serotonin, GABA, and glycine—serve as ligands (agonists) for both types of receptors. Agonist-gated receptors that are also ion channels are known as **ionotropic receptors**. Receptors coupled to G proteins are called **metabotropic receptors** because their activation initiates a metabolic process involving GTP.

Ionotropic and metabotropic receptors determine the ultimate functional response to transmitter release. Activation of an ionotropic receptor causes rapid opening of ion channels. This channel activation, in turn, results in depolarization or hyperpolarization of the postsynaptic membrane, depending on the ionic selectivity of the conductance change. Activation of a metabotropic G protein–linked receptor results in the production of active α and $\beta\gamma$ subunits, which initiate a wide variety of cellular responses by direct interaction with either ion channel proteins or other second-messenger effector proteins. By their very nature, ionotropic receptors mediate fast ionic synaptic responses that occur on a millisecond time scale, whereas metabotropic receptors mediate slow, biochemically mediated synaptic responses in the range of seconds to minutes.

Figure 8-3 compares the basic processes mediated by two prototypic ACh receptors (AChRs): (1) the ACh-activated ion channel at the neuromuscular junction of skeletal muscle, an ionotropic receptor also known as the **nicotinic** AChR (see Fig. 8-3A), and (2) the G protein–linked AChR at the atrial parasympathetic synapse of the heart, a metabotropic receptor also known as the **muscarinic** AChR (see Fig. 8-3B). The nicotinic versus muscarinic nomenclature is *pharmacological* based on whether the AChR is activated by nicotine or muscarine, two natural products that behave like agonists. In the case of the ionotropic (nicotinic) receptor, opening of the AChR channel results in a transient increase in permeability to Na^+ and K^+ , which directly produces a brief depolarization that activates the muscle fiber. In the case of the metabotropic (muscarinic) receptor, activation of the G protein–coupled receptor opens an inward-rectifier K^+ channel, or GIRK (see pp. 197–198) via $\beta\gamma$ subunits released from an activated heterotrimeric G protein. Enhanced opening of these GIRKs produces membrane hyperpolarization and leads to inhibition of cardiac excitation (see p. 492). These two receptor types provide the molecular explanation for the puzzling observations of early physiologists that ACh (*Vagusstoff*) activates skeletal muscle but inhibits heart muscle.

A IONOTROPIC RECEPTOR**B METABOTROPIC RECEPTOR**

FIGURE 8-3 Ionotropic and metabotropic AChRs. **A**, Nicotinic AChR (ionotropic), which is a ligand-gated channel on the postsynaptic membrane. In a skeletal muscle, the end result is muscle contraction. **B**, Muscarinic AChR (metabotropic), which is coupled to a heterotrimeric G protein. In a cardiac muscle, the end result is decreased heart rate. Note that the presynaptic release of ACh is similar here and in **A**.

Synaptic Transmission at the Neuromuscular Junction

Neuromuscular junctions are specialized synapses between motor neurons and skeletal muscle

The chemical synapse between peripheral motor nerve terminals and skeletal muscle fibers is the most intensely studied synaptic connection in the nervous system. Even though the detailed morphology and the specific molecular components (e.g., neurotransmitters and receptors) differ considerably among different types of synapses, the basic electrophysiological principles of the neuromuscular junction are applicable to many other types of chemical synapses, including neuronal synaptic connections in the brain, to which we will return in [Chapter 13](#). In this chapter, we focus on the neuromuscular junction in discussing the basic principles of synaptic transmission.

Motor neurons with cell bodies located in the ventral horn of the spinal cord have long axons that branch extensively near the point of contact with the target muscle ([Fig. 8-4](#)). Each axon process innervates a separate fiber of skeletal muscle. The whole assembly of muscle fibers innervated by the axon from one motor neuron is called a **motor unit**.

FIGURE 8-4 Vertebrate neuromuscular junction or motor end plate. A motor neuron, with its cell body in the ventral horn of the spinal cord, sends out an axon that progressively bifurcates to innervate several muscle fibers (a motor unit). The neuron contacts a muscle fiber at exactly one spot called a neuromuscular junction or motor end plate. The end plate consists of an arborization of the nerve into many presynaptic terminals, or boutons, as well as the specializations of the postsynaptic membrane. A high-magnification view of a bouton shows that the synaptic vesicles containing the neurotransmitter ACh cluster and line up at the active zone of the presynaptic membrane. The active zones on the presynaptic membrane are directly opposite the secondary postsynaptic clefts that are created by infoldings of the postsynaptic membrane (postjunctional folds). Depolarization of the bouton causes the vesicles to fuse with the presynaptic membrane and to release their contents into the synaptic cleft. The ACh molecules must diffuse at least 50 nm before reaching nicotinic AChRs. Note the high density of AChRs at the crests of the postjunctional folds. The activity of the released ACh is terminated mainly by an AChE. The bouton reloads its discharged synaptic vesicles by resynthesizing ACh and transporting this ACh into the vesicle via an ACh-H exchanger. CoA, coenzyme A.

Typically, an axon makes a single point of synaptic contact with a skeletal muscle fiber, midway along the length of the muscle fiber. This specialized synaptic region is called the **neuromuscular junction** or the **end plate** (see [Fig. 8-4](#)). An individual end plate consists of a small tree-like patch of unmyelinated nerve processes that are referred to as terminal arborizations. The bulb-shaped endings that finally contact the muscle fiber are called **boutons**. Schwann cells are intimately associated with the nerve terminal and form a cap over the face of the nerve membrane that is located away from the muscle membrane. The postsynaptic membrane of the skeletal muscle fiber lying directly under the nerve terminal is characterized by extensive invaginations known as **postjunctional folds**. These membrane infoldings greatly increase the surface area of the muscle plasma membrane in the postsynaptic region. The intervening space of the **synaptic cleft**, which is ~50 nm wide, is filled with a meshwork of proteins and proteoglycans that are part of the extracellular matrix. A particular region of the muscle basement membrane called the synaptic basal lamina contains various proteins (e.g., collagen, laminin, agrin) that mediate adhesion of the neuromuscular junction and play important roles in synapse development and regeneration. The synaptic basal lamina also contains a high concentration of the enzyme **acetylcholinesterase (AChE)**, which ultimately terminates synaptic transmission by rapidly hydrolyzing free ACh to choline and acetate.

Electron micrographs of the bouton region demonstrate the presence of numerous spherical synaptic vesicles, each with a diameter of 50 to 60 nm. The cell bodies of motor neurons in the spinal cord produce these vesicles, and the microtubule-mediated process of fast axonal transport (see [p. 25](#)) translocates them to the nerve terminal. The quantal nature of transmitter release (described below in more detail) reflects the fusion of individual synaptic vesicles with the plasma membrane of the presynaptic terminal. Each synaptic vesicle contains 6000 to 10,000 molecules of ACh. The ACh concentration in synaptic vesicles is ~150 mM. ACh is synthesized in the nerve terminal—outside the vesicle—from choline and acetyl coenzyme A by the enzyme **choline acetyltransferase**. The ACh moves into the synaptic vesicle via a specific ACh-H exchanger, which couples the inward transport of ACh to the efflux of H⁺. Energetically, this process is driven by the vesicular proton electrochemical gradient (positive voltage and low pH inside), which in turn is produced by a vacuolar-type H pump fueled by ATP (see [pp. 118–119](#)). The nerve terminal also contains numerous mitochondria that produce the ATP required to fuel energy metabolism.

The process of fusion of synaptic vesicles and release of ACh occurs at differentiated regions of the presynaptic membrane called **active zones**. In electron micrographs, active zones appear as dense spots over which synaptic vesicles are closely clustered in apposition to the membrane. High-resolution images of active zones reveal a double linear array of synaptic vesicles and intramembranous particles. These zones are oriented directly over secondary *postsynaptic* clefts that lie between adjacent postjunctional folds. Molecular localization studies have shown that the density of ionotropic (nicotinic) AChRs is very high at the crests of postjunctional folds. Examination of the detailed microarchitecture of the neuromuscular synapse thus reveals a highly specialized structure for delivery of neurotransmitter molecules to a precise location on the postsynaptic membrane.

ACh activates nicotinic AChRs to produce an excitatory end-plate current

Electrophysiological experiments on muscle fibers have characterized the electrical nature of the postsynaptic response at the muscle end plate. [Figure 8-5](#) illustrates results obtained from a classic

experiment performed by Fatt and Katz in 1951. Their work is the first description of how stimulation of the motor nerve affects the membrane potential (V_m) at the postsynaptic region (i.e., muscle cell) of the neuromuscular junction. Nerve stimulation normally drives the V_m of the muscle above threshold and elicits an action potential (see [p. 173](#)). However, Fatt and Katz were interested not in seeing the action potential but in studying the small graded electrical responses that are produced as ACh binds to receptors on the muscle cell membrane. Therefore, Fatt and Katz greatly reduced the response of the AChRs by blocking most of them with a carefully selected concentration of *d*-tubocurarine, which we discuss below. 🟡N8-2 They inserted a KCl-filled microelectrode into the end-plate region of a frog sartorius muscle fiber. This arrangement allowed them to measure tiny changes in V_m at one location of the muscle cell called the neuromuscular junction or NMJ.

FIGURE 8-5 EPPs elicited at the frog neuromuscular junction by stimulation of the motor neuron. The magnitude of the excitatory postsynaptic potential is greatest near the end plate and decays farther away. (Data from Fatt P, Katz B: An analysis of the end-plate potential recorded with an intracellular electrode. *J Physiol* 115:320–370, 1951.)

Tubocurarine

For more information about tubocurarine, visit

<http://www.portfolio.mvm.ed.ac.uk/studentwebs/session2/group12/tubocura.htm> (accessed October 2014).

When Fatt and Katz electrically excited the motor nerve axon, they observed a transient depolarization in the muscle membrane after a delay of a few milliseconds. The delay represents the time required for the release of ACh, its diffusion across the synapse, and activation of postsynaptic AChRs. The positive voltage change follows a biphasic time course: V_m rapidly rises to a peak and then more slowly relaxes back to the resting value, consistent with an exponential time course. This signal, known as the **end-plate potential (EPP)**, is an example of an **excitatory postsynaptic potential**. It is produced by the transient opening of AChR channels, which are selectively permeable to monovalent cations such as Na^+ and K^+ . The increase in Na^+ conductance drives V_m to a more positive value in the vicinity of the end-plate region. In this experiment, curare blockade allows only a small number of AChR channels to open, so that the EPP does not reach the threshold to produce an action potential. If the experiment is repeated by inserting the microelectrode at various distances from the end plate, the amplitude of the potential change is successively diminished and its peak is increasingly delayed. This decrement with distance occurs because the EPP originates at the end-plate region and spreads away from this site according to the passive cable properties (see pp. 201–203) of the muscle fiber. Thus, the EPP in Figure 8-5 is an example of a propagated graded response. However, without the curare blockade, more AChR channels would open and a larger EPP would ensue, which would drive V_m above threshold and consequently trigger a regenerating action potential (see p. 173).

What ions pass through the AChR channels during generation of the EPP? This question can be answered by the same voltage-clamp technique **N7-4** that was used to study the basis of the action potential (see Fig. 7-5B). Figure 8-6A illustrates the experimental preparation for a two-electrode voltage-clamp experiment in which the motor nerve is stimulated while the muscle fiber in the region of its end plate is voltage-clamped to a chosen V_m . The recorded current, which is proportional to the conductance change at the muscle end plate, is called the **end-plate current (EPC)**. The EPC has a characteristic time course that rises to a peak within 2 ms after stimulation of the motor nerve and falls exponentially back to zero (see Fig. 8-6B). The time course of the EPC corresponds to the opening and closing of a population of AChR channels, governed by the rapid binding and disappearance of ACh as it diffuses to the postsynaptic membrane and is hydrolyzed by AChE.

A EXPERIMENTAL PREPARATION

B END-PLATE CURRENTS OBTAINED AT VARIOUS HOLDING POTENTIALS

C I-V RELATIONSHIP FOR PEAK END-PLATE CURRENT

FIGURE 8-6 EPCs obtained at different membrane potentials in a voltage-clamp experiment. **A**, Two-electrode voltage clamp is used to measure the EPC in a frog muscle fiber. The tips of the two

microelectrodes are in the muscle fiber. **B**, The six records represent EPCs that were obtained while the motor nerve was stimulated and the postsynaptic membrane was clamped to V_m values of -120 , -91 , -68 , -37 , $+24$, and $+38$ mV. Notice that the peak current reverses from inward to outward as the holding potential shifts from -37 to $+24$ mV. **C**, The reversal potential is near 0 mV because the nicotinic AChR has a poor selectivity for Na^+ versus K^+ . (Data from Magleby KL, Stevens CF: The effect of voltage on the time course of end-plate current. J Physiol 223:151–171, 1975.)

As shown in [Figure 8-6B](#), when the muscle fiber is clamped to a “holding potential” of -120 mV, we observe a large inward current (i.e., the EPC). This inward current decreases in magnitude as V_m is made more positive, and the current reverses direction to become an outward current at positive values of V_m . A plot of the peak current versus the clamped V_m shows that the reversal potential for the EPC is close to 0 mV (see [Fig. 8-6C](#)). Because the EPC specifically corresponds to current through AChR channels, this reversal potential reflects the ionic selectivity of these channels when extracellular Na^+ and K^+ concentrations ($[\text{Na}^+]_o$ and $[\text{K}^+]_o$) are normal.

By varying the concentrations of the extracellular ions while monitoring the shift in the reversal potential of the EPC, researchers found that the AChR channel is permeable to Na^+ , K^+ , and Ca^{2+} but not to anions such as Cl^- . Because of its low extracellular concentration, the current attributable to Ca^{2+} is small under physiological conditions and its contribution to reversal potential can be ignored. **N8-3** By plugging the values for the various cations into the Goldman-Hodgkin-Katz voltage equation (see [Equation 6-9](#)), one can obtain the permeability of the AChR channel to various alkali monovalent ions relative to Na^+ permeability. The result is the following sequence of relative permeability: 0.87 (Li^+), 1.00 (Na^+), 1.11 (K^+), and 1.42 (Cs^+). This weak ionic selectivity stands in marked contrast to typical voltage-gated Na^+ channels, which have $P_{\text{Na}}/P_{\text{K}}$ ratios of ~ 20 , and voltage-gated K^+ channels, which have $P_{\text{K}}/P_{\text{Na}}$ ratios of >100 . On this basis, the ionotropic (nicotinic) AChR channel at the muscle end plate is often classified as a **nonselective cation channel**. Nevertheless, the weak ionic selectivity of the AChR is well suited to its basic function of raising V_m above the threshold of about -50 mV, which is necessary for firing of an action potential. When the nicotinic AChR channel at the muscle end plate opens, the normally high resting permeability of the muscle plasma membrane for K^+ relative to Na^+ falls so that Na^+ and K^+ become equally permeant and V_m shifts to a value between E_{K} (approximately -80 mV) and E_{Na} (approximately $+50$ mV).

N8-3

Contribution of Ca^{2+} to the Resting Membrane Potential

Inspired by Jack Rose, Idaho State University

Contributed by Emile Boulpaep, Walter Boron

Equation 6-9 in the text (shown here as Equation NE 8-1) is the **Goldman-Hodgkin-Katz (GHK) voltage equation**:

$$V_{\text{rev}} = \frac{RT}{F} \ln \left(\frac{P_{\text{K}}[\text{K}^+]_o + P_{\text{Na}}[\text{Na}^+]_o + P_{\text{Cl}}[\text{Cl}^-]_i}{P_{\text{K}}[\text{K}^+]_i + P_{\text{Na}}[\text{Na}^+]_i + P_{\text{Cl}}[\text{Cl}^-]_o} \right)$$

Of course, we could insert additional terms for other cations besides K^+ and Na^+ ; for example, if we included Ca^{2+} , the equation would look something like the following*:

$$V_{\text{rev}} = \frac{RT}{F} \ln \left(\frac{P_K[K^+]_i + P_{Na}[Na^+]_i + P_{Ca}[Ca^{2+}]_i + P_{Cl}[Cl^-]_o}{P_K[K^+]_o + P_{Na}[Na^+]_o + P_{Ca}[Ca^{2+}]_o + P_{Cl}[Cl^-]_i} \right)$$

A typical value for $[Ca^{2+}]_i$ would be 10^{-7} M or 0.0001 mM, and a typical value for $[Ca^{2+}]_o$ would be 1.2 mM. Thus, even though the concentration *ratio* for Ca^{2+} across the plasma membrane is large, this ratio per se has no bearing on the GHK equation. What counts here are the magnitudes of the product $P_{Ca}[Ca^{2+}]$, which are generally small compared to the other terms in both the numerator and denominator. Thus, Ca^{2+} makes very little contribution to V_m in the resting state. However, if we were to reduce the size of the other terms in either the numerator or denominator, the Ca^{2+} would begin to matter.

*The GHK equation has dropped the z (valence) term, as if all ions were monovalent. In order to insert Ca^{2+} into this simple equation, we treat the ion as if it were monovalent, which is clearly not the case. Thus, this equation merely serves to make the point that Ca^{2+} contributes very little to V_m because of the small magnitude of the product of permeability and concentration.

As we shall see in [Chapter 13](#), which focuses on synaptic transmission in the CNS, similar principles hold for the generation of postsynaptic currents by other types of agonist-gated channels. For example, the receptor-gated channels for serotonin and glutamate are cation selective and give rise to *depolarizing excitatory postsynaptic potentials*. In contrast, the receptor-gated channels for glycine and GABA are anion selective and drive V_m in the hyperpolarizing direction, toward the equilibrium potential for Cl^- . These *hyperpolarizing* postsynaptic responses are called **inhibitory postsynaptic potentials**.

The nicotinic AChR is a member of the pentameric Cys-loop receptor family of ligand-gated ion channels

The molecular nature of the nicotinic AChR channel was revealed by studies that included protein purification, amino-acid sequencing of isolated subunits, molecular cloning, and cryoelectron microscopy. Purification of the receptor was aided by the recognition that the electric organs of certain fish are a particularly rich source of the nicotinic AChR. In the electric eel and torpedo ray, the electric organs are embryologically derived from skeletal muscle. The torpedo ray can deliver large electrical discharges by summing the simultaneous depolarizations of a stack of many disk-like cells called electrocytes. These cells have the skeletal muscle isoform of the nicotinic AChR, which is activated by ACh released from presynaptic terminals.

The purified torpedo AChR consists of four subunits (α , β , γ , and δ) in a pentameric stoichiometry of $2\alpha:1\beta:1\gamma:1\delta$ ([Fig. 8-7](#)). Each subunit has a molecular mass of ~ 50 kDa and is homologous to the other subunits. The primary sequences of nicotinic AChR subunits are $\sim 90\%$ identical between the torpedo ray and human.

FIGURE 8-7 Structure of the *Torpedo* nicotinic AChR. The nicotinic AChR receptor is a heteropentamer with the subunit composition of $\alpha_2\beta\gamma\delta$. These subunits are homologous to one another, and each has four membrane-spanning segments (M1 to M4). (For view from above, data from N Unwin: Refined structure of the nicotinic receptor at 4 Å resolution. J Mol Biol 346:968-989, 2005.) **N8-14**

N8-14

Structure of the Nicotinic Acetylcholine Receptor

Contributed by Ed Moczydlowski

The nicotinic acetylcholine receptors (AChRs), which are all ligand-gated ion channels, come in two major subtypes, N_1 and N_2 . The N_1 nicotinic AChRs are at the neuromuscular junction, whereas the N_2 AChRs are found in the autonomic nervous system (on the postsynaptic membrane of the postganglionic sympathetic and parasympathetic neurons) and in the CNS. Both N_1 and N_2 are ligand-gated ion channels activated by ACh or nicotine. However, whereas the N_1 receptors at the neuromuscular junction are stimulated by decamethonium and preferentially blocked by *d*-tubocurarine and α -bungarotoxin, the autonomic N_2 receptors are stimulated by tetramethylammonium, blocked by hexamethonium, but resistant to α -bungarotoxin. When activated, N_1 and N_2 receptors are both permeable to Na^+ and K^+ , with the entry of Na^+ dominating. Thus, the nicotinic stimulation leads to rapid depolarization.

The nicotinic AChRs in skeletal muscle and autonomic ganglia are heteropentamers. That is, five nonidentical protein subunits surround a central pore, in a rosette fashion. **N6-20** Because the five subunits are not identical, the structure exhibits *pseudosymmetry*, rather than true symmetry. There are at least ten α subunits (α_1 to α_{10}) and four β subunits (β_1 to β_4). As we will see below, the basis for these differences is a difference in subunit composition.

The **N_1 receptors** have different subunit compositions depending upon location and developmental

stage. The subunit composition of $\alpha_2\beta\gamma\delta$ is found in fetal skeletal muscle, as well as the nonjunctional regions of denervated adult skeletal muscle. The electric organ of the electric eel (*Torpedo*), from which the channel was first purified, has the same subunit composition. The subunit composition of $\alpha_2\beta\epsilon\delta$ is found at the neuromuscular junction of adult skeletal muscle. Here, the ϵ subunit replaces the γ subunit. In both the $\alpha_2\beta\gamma\delta$ and $\alpha_2\beta\epsilon\delta$ pentamers, the α subunits are of the α_1 subtype and the β subunits are of the β_1 subtype.

In the *Torpedo* N₁ AChRs, the α , β , γ , and δ subunits have polypeptide lengths of 437 to 501 amino acids. eFigure 8-1 shows side and top views of this AChR.

FIGURE 8-1 Three-dimensional view of the *Torpedo* or human fetal nicotinic AChR channel. (Data from Toyoshima C, Unwin N: Ion channel of acetylcholine receptor reconstructed from images of postsynaptic membranes. *Nature* 336:247–250, 1988.)

The **N₂ receptors** in the nervous system, like those in muscle, are heteromers, probably heteropentamers. N₂ receptors use α₂ to α₁₀ and β₂ to β₄.

Nicotinic Receptors		
Receptor Type	Agonists	Antagonists
N ₁ Nicotinic ACh	ACh (nicotine, decamethonium)	<i>d</i> -tubocurarine α-bungarotoxin
N ₂ Nicotinic ACh	ACh (nicotine, tetramethylammonium)	Hexamethonium

Ligand-Binding Sites of the Nicotinic AChRs

Contributed by Ed Moczydlowski

New insight into molecular details of the extracellular agonist-binding domain of AChR has been

obtained from the x-ray crystal structure of an ACh-binding protein (AChBP) from *Lymnaea stagnalis*, a freshwater snail. AChBP is a soluble protein of 229 residues that is homologous to the amino-terminal region of nicotinic AChR and other members of the pentameric ligand-gated channel superfamily. As shown in Figure 3 of the paper by Brejc and colleagues, the crystal structure demonstrates that AChBP is formed as a radially symmetrical homopentamer of the monomer subunit with the agonist-binding site located between the five subunit interfaces. The tertiary structure of a single monomer subunit of AChBP features ten β strands folded into a β sandwich. The snail AChBP specifically binds many of the same agonist and antagonist molecules as AChR, including ACh, carbamylcholine, nicotine, *d*-tubocurarine, and α -bungarotoxin. AChBP serves as a particularly good homology model for the structure of nicotinic receptors in the mammalian nervous system that are formed as homopentamers of α subunits.

AChRs of normal adult *muscle fibers* are present in high density in the junctional folds of the postsynaptic membrane. However, in developing muscle fibers of the mammalian embryo and in denervated fibers of adult skeletal muscle, AChRs are also widely distributed in the membrane outside the end-plate region. The two types of AChRs, called junctional and nonjunctional receptors, have different functional properties. The unitary conductance of nonjunctional receptors is ~50% larger and the single channel lifetime is longer in duration than that of junctional receptors. The basis for this phenomenon is a difference in subunit composition. The *nonjunctional* (or fetal) receptors are a pentameric complex with a subunit composition of $\alpha_2\beta\gamma\delta$ in mammals, just as in the electric organ of the torpedo ray. For the *junctional* AChR in adult skeletal muscle, substitution of an ϵ subunit for the fetal γ subunit results in a complex with the composition $\alpha_2\beta\epsilon\delta$.

The functional properties of the two types of receptors have been studied in preparations of *Xenopus* oocytes that coexpress the cloned subunits. [Figure 8-8A](#) shows patch-clamp recordings of single ACh-activated channels in oocytes that had been injected with mRNA encoding either α , β , γ , δ or α , β , ϵ , δ . Measurements of currents at different voltages yielded single channel current-voltage (*I-V*) curves (see [Fig. 8-8B](#)) showing that the channel formed with the ϵ subunit had a unitary conductance of 59 picosiemens (pS), whereas that formed with the γ subunit had a conductance of 40 pS. The mean lifetime of single channel openings at 0 mV was 1.6 ms for ϵ -type and 4.4 ms for γ -type receptors, which closely corresponds to values found in native fetal and adult muscle, respectively. The different functional properties of junctional and nonjunctional nicotinic AChRs presumably reflect their specialized roles in synaptic transmission versus development and synapse formation.

A SINGLE CHANNEL CURRENTS

B I-V RELATIONSHIPS

FIGURE 8-8 Properties of fetal and adult AChRs from skeletal muscle. **A**, The results of patch-clamp experiments, with the patch pipettes in the outside-out configuration and the patch exposed to $0.5 \mu\text{M}$ ACh, are summarized. In the upper panel, recordings are from *Xenopus* oocytes that expressed the fetal AChR, which has the subunit composition $\alpha_2\beta\gamma\delta$. In the lower panel, the oocytes expressed the adult AChR, which has the subunit composition $\alpha_2\beta\epsilon\delta$. Notice that the mean open times are greater for the fetal form, whereas the unitary currents are greater for the adult form. **B**, The two lines summarize data that are similar to those shown in **A**. The single channel conductance of the adult form (59 pS) is higher than that of the fetal form (40 pS). (Data from Mishina M, Takai T, Imoto K, et al: Molecular distinction between fetal and adult forms of muscle acetylcholine receptor. *Nature* 321:406–411, 1986.)

Humans have ten genes (*CHRNA1* to *CHRNA10*) that encode homologous α subunits α_1 to α_{10} of nicotinic ACh-activated receptors (see Fig. 6-200). Humans also have four genes (*CHRNA1* to *CHRNA4*) that encode β subunits β_1 to β_4 , as well as separate genes encoding γ , δ , and ϵ subunits. The skeletal muscle receptor comprises two α_1 subunits, one β_1 , one δ , and one ϵ in the adult receptor but one γ in the fetal receptor. Various heteromeric combinations of the other α subunits (α_2 to α_{10}) and β subunits (β_2 to β_4)

produce a diverse array of functional receptor isoforms in neurons. Whereas muscle AChRs can be activated only by high concentrations of **nicotine**, the neuronal $(\alpha_4)_2(\beta_2)_3$ AChR isoform in the CNS and autonomic ganglia has the highest affinity for nicotine and is responsible for the behavioral and addictive effects of nicotine in tobacco. The α subunits α_1 , α_7 , and α_9 bind a snake venom protein called α -bungarotoxin (see [p. 226](#)) from the Taiwanese banded krait.

The nicotinic AChRs belong to the **pentameric Cys-loop receptor family** of ligand-gated ion channels (see [Table 6-2](#), family No. 11), so named because they contain a highly conserved pair of disulfide-bonded cysteine residues. This family also contains three other classes of agonist-activated channels, those activated by **serotonin** (5-HT₃ receptor), glycine (GlyR), and **GABA** (GABA_A receptor). As is the case for the AChRs, the 5-HT₃ receptor channels are permeable to cations and thus produce excitatory currents. In contrast, glycine-activated and GABA_A channels are permeable to anions such as Cl⁻ and produce inhibitory currents. [Figure 8-9](#) shows examples of macroscopic and unitary Cl⁻ currents mediated by glycine-activated and GABA_A channels. Cloned genes encoding subunits of these receptor channels encode proteins that are homologous to AChR subunits. Their primary amino-acid sequences share a common arrangement of M1, M2, M3, and M4 transmembrane segments, as described above for the nicotinic AChR (see [Fig. 8-7](#)). Sequence analysis of these genes indicates that they evolved from a common ancestor. The basis for cation versus anion selectivity appears to reside solely within the M2 segment. Mutation of only three residues within the M2 segment of a cation-selective α subunit of a neuronal nicotinic AChR is sufficient to convert it to an anion-selective channel activated by ACh.

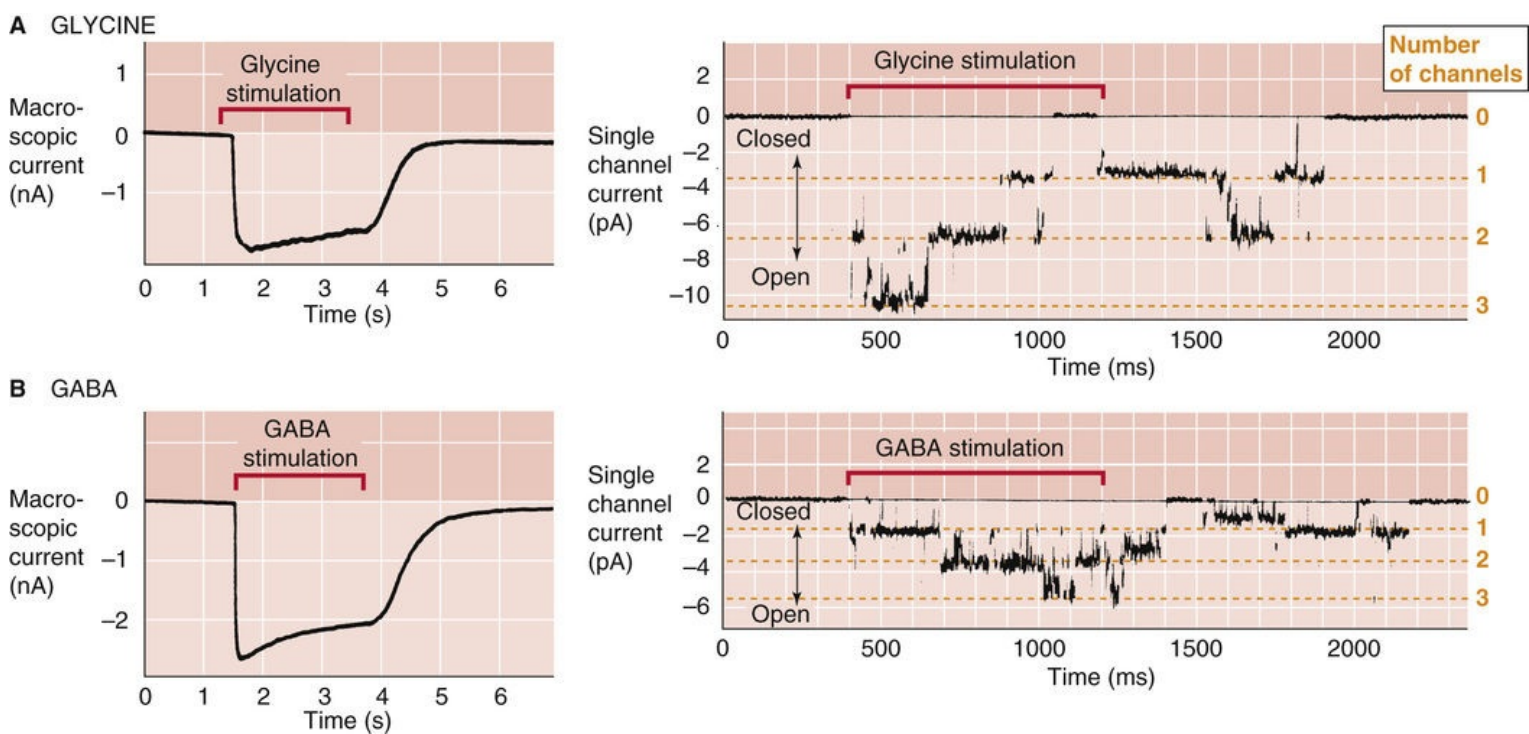

FIGURE 8-9 Currents activated by glycine and GABA. **A**, These data are from experiments performed on cultured mouse spinal cord neurons using patch-clamp techniques. The left panel shows the macroscopic Cl^- current, which is measured in the whole-cell configuration and carried by glycine receptor (GlyR) channels when exposed to glycine. The right panel shows single channel currents that are recorded using the outside-out patch configuration. In both scenarios, the holding potential was -70 mV. **B**, The left panel shows the macroscopic Cl^- current that is carried by GABA_A receptor channels when exposed to GABA. The right panel shows single channel currents. (Data from Bormann J, Hamill OP, Sakmann B: Mechanism of anion permeation through channels gated by glycine and γ -aminobutyric acid in mouse spinal neurones. *J Physiol* 385:243–286, 1987.)

Activation of AChR channels requires binding of two ACh molecules

The EPC is the sum of many single channel currents, each representing the opening of a single AChR channel at the neuromuscular junction. Above we described the random opening and closing of an idealized channel in a two-state model in which the channel could be either closed or open (see [p. 181](#)):

In the case of an *agonist*-activated channel, such as the AChR channel, binding of an agonist to the channel in its closed state favors channel opening. This gating process may be represented by the following kinetic model:

In this two-step scheme, the closed state (C) of the channel must bind one molecule of the agonist ACh to form a closed agonist-bound channel (AC) before it can convert to an open agonist-bound channel (AO). However, studies of the dependence of the probability of channel opening on agonist concentration indicate that binding of *two* molecules of ACh is required for channel opening. This feature of nicotinic receptor gating is described by the following modification of [Equation 8-2](#):

The kinetics of channel opening are important for understanding the mechanism by which certain channel inhibitors work. For example, a competitive antagonist such as *d*-tubocurarine prevents the binding of the agonist ACh to each of its two sites. However, many noncompetitive antagonists of the AChR channel, including some local anesthetics, act by entering the lumen of the channel and blocking the flow of ionic current. [Figure 8-10A](#) shows the results of a patch-clamp experiment in which a single AChR channel opened and closed in response to its agonist, ACh. After the addition of QX-222, an analog of the local anesthetic agent lidocaine (see [pp. 187–189](#)), to the extracellular side, the channel exhibits a rapidly flickering behavior. This flickering represents a series of brief interruptions of the open state by numerous closures (see [Fig. 8-10B](#)). This type of flickering block is caused by rapid binding and unbinding of the anesthetic drug to a site in the mouth of the *open* channel. When the drug binds, it blocks the channel to the flow of ions (A₂B). Conversely, when the drug dissociates, the channel becomes unblocked (A₂O):

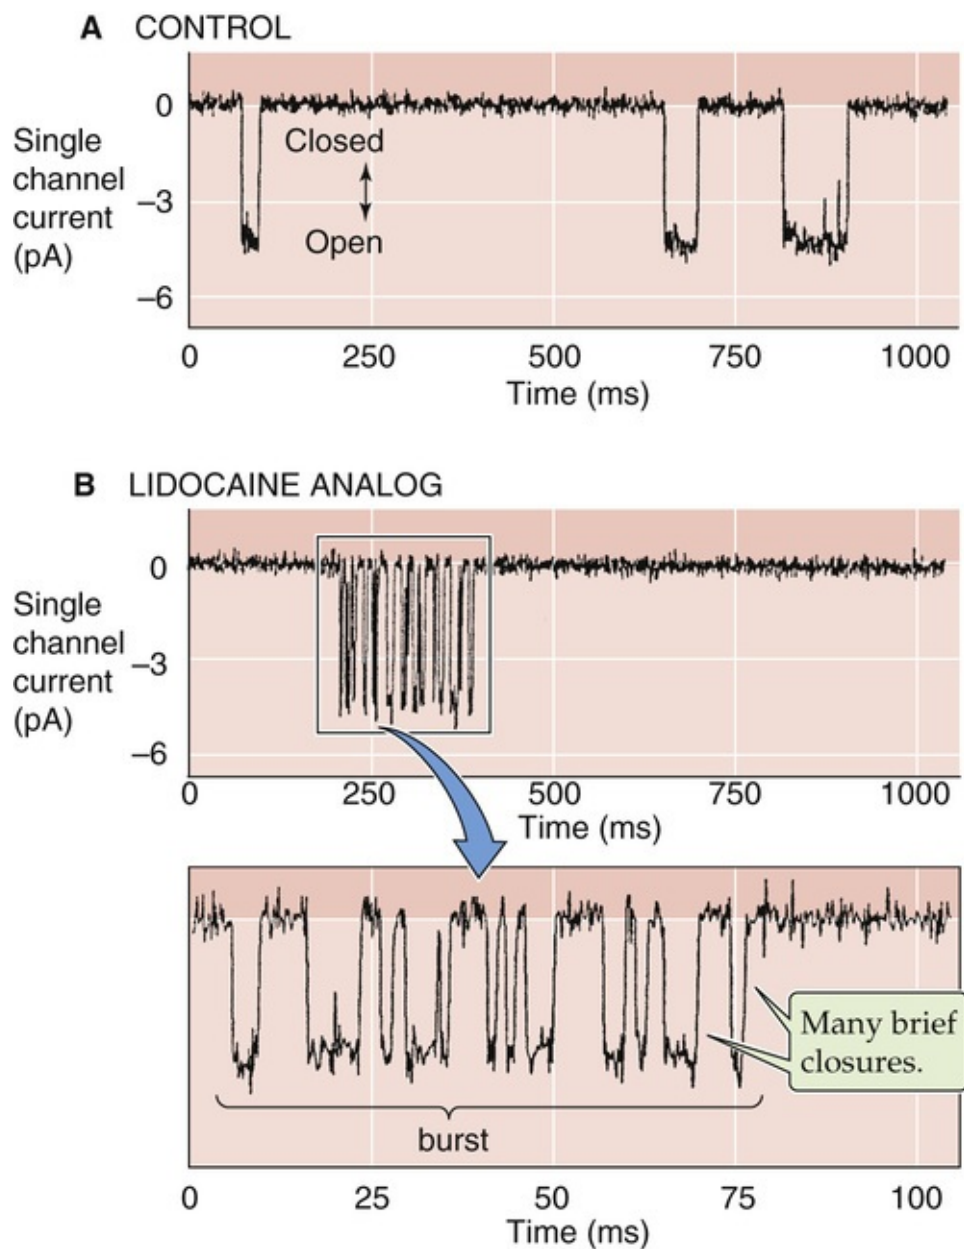

FIGURE 8-10 Effect of a local anesthetic on the AChR. **A**, Single channel recording of nicotinic AChR expressed in a *Xenopus* oocyte. The patch was in the outside-out configuration, and the holding potential was -150 mV. The continuous presence of $1\text{ }\mu\text{M}$ ACh caused brief channel openings. **B**, Recordings from an experiment similar to that in **A** except that, in addition to the ACh, the lidocaine analog QX-222 ($20\text{ }\mu\text{M}$) was present at the extracellular surface of the receptor channel. Note that the channel opening is accompanied by rapid flickering caused by many brief channel closures. The time scale of the lower panel is expanded 10-fold. (Data from Leonard RJ, Labarca CG, Charney P, et al: Evidence that the M2 membrane-spanning region lines the ion channel pore of the nicotinic receptor. *Science* 242:1578–1581, 1988.)

Channel blockers are often used as molecular tools to study the mechanism of ion permeation. For example, studies with the blocker QX-222—in combination with site-directed mutagenesis—helped to localize the blocker binding site on the M2 transmembrane segment, thus identifying residues that line the aqueous pore.

Miniature EPPs reveal the quantal nature of transmitter release from the presynaptic terminals

Under physiological conditions, an action potential in a presynaptic motor nerve axon produces a depolarizing postsynaptic EPP that peaks at a level ~ 40 mV more positive than the resting V_m . This large signal results from the release of ACh from only about 200 synaptic vesicles, each containing 6000 to

10,000 molecules of ACh. The neuromuscular junction is clearly designed for excess capacity inasmuch as a single end plate is composed of numerous synaptic contacts (~1000 at the frog muscle end plate), each with an active zone that is lined with dozens of mature synaptic vesicles. Thus, a large inventory of ready vesicles ($>10^4$), together with the ability to synthesize ACh and to package it into new vesicles, allows the neuromuscular junction to maintain a high rate of successful transmission without significant loss of function as a result of presynaptic depletion of vesicles or ACh.

The original notion of a vesicular mode of transmitter delivery is based on classic observations of EPPs under conditions of reduced ACh release. In 1950, Fatt and Katz observed an interesting kind of electrophysiological “noise” in their continuous high-resolution recordings of V_m with a microelectrode inserted at the end-plate region of a frog muscle fiber. Their recordings from resting muscle fibers that were not subjected to nerve stimulation revealed the occurrence of tiny depolarizations of ~0.4 mV that appeared at random intervals. These small depolarizations were blocked by the AChR antagonist curare and they increased in size and duration with application of the AChE inhibitor neostigmine. Because the spontaneous V_m fluctuations also exhibited a time course similar to that of the normal EPP, they were named **miniature end-plate potentials** (also known as MEPPs or minis). These observations suggested that even in the absence of nerve stimulation, there is a certain low probability of transmitter release at the presynaptic terminal, resulting in the opening of a small number of AChRs in the postsynaptic membrane. An examination of the size of individual MEPPs suggested that they occur in discrete multiples of a unitary amplitude. This finding led to the notion that ACh release is *quantized*, with the quantal event corresponding to ACh release from one synaptic vesicle.

Another way of studying the quantal release of ACh is to stimulate the presynaptic motor neuron and to monitor V_m at the end plate under conditions in which the probability of ACh release is greatly decreased by lowering $[Ca^{2+}]_o$ and increasing $[Mg^{2+}]_o$. Low $[Ca^{2+}]_o$ decreases Ca^{2+} entry into the presynaptic terminal (see Fig. 8-2, step 3). High $[Mg^{2+}]_o$ partially blocks the presynaptic Ca^{2+} channels and thus also decreases Ca^{2+} entry. Therefore, the consequence of either decreased $[Ca^{2+}]_o$ or increased $[Mg^{2+}]_o$ is a fall in $[Ca^{2+}]_i$ in the presynaptic terminal, which reduces transmitter release and thus the amplitude of the EPP (Fig. 8-11). Del Castillo and Katz exploited this suppression of transmitter release under conditions of low $[Ca^{2+}]_o$ and high $[Mg^{2+}]_o$ to observe the V_m changes caused by the quantal release of transmitter.

Figure 8-12A shows seven superimposed records of MEPPs that were recorded from a frog muscle fiber during seven repetitive trials of nerve stimulation under conditions of reduced $[Ca^{2+}]_o$ and elevated $[Mg^{2+}]_o$. The records are aligned at the position of the nerve stimulus artifact. The amplitudes of the peak responses occur in discrete multiples of ~0.4 mV. Among the seven records were one “nonresponse,” two responses of ~0.4 mV, three responses of ~0.8 mV, and one response of ~1.2 mV. One of the recordings also revealed a spontaneous MEPP with a quantal amplitude of ~0.4 mV that appeared later in the trace. Del Castillo and Katz proposed that the macroscopic EPP is the sum of many unitary events, each having a magnitude of ~0.4 mV (see Fig. 8-12B). Microscopic observation of numerous vesicles in the synaptic terminal naturally led to the hypothesis that a single vesicle releases a relatively fixed amount of ACh and thereby produces a unitary MEPP. According to this view the quantized MEPPs thus correspond to the fusion of discrete numbers of synaptic vesicles: 0, 1, 2, 3, and so on.  **N8-5**

FIGURE 8-11 Effect of extracellular Ca^{2+} and Mg^{2+} on EPPs. The data obtained by stimulating the motor neuron and monitoring the evoked subthreshold EPP show that the EPP is stimulated by increasing levels of Ca^{2+} but inhibited by increasing levels of Mg^{2+} . (Data from Dodge FAJr, Rahaminoff R: Cooperative action of calcium ions in transmitter release at the neuromuscular junction. *J Physiol* 193:419–432, 1967.)

A MINIATURE END-PLATE POTENTIALS (MEPPs)

B DISTRIBUTION OF MEPP AMPLITUDES

FIGURE 8-12 Evoked and spontaneous MEPPs. **A**, The investigators recorded V_m in frog skeletal muscle fibers that were exposed to extracellular solutions having a $[Ca^{2+}]$ of 0.5 mM and $[Mg^{2+}]$ of 5 mM. These values minimize transmitter release, and therefore it was possible to resolve the smallest possible MEPP, which corresponds to the release of a single synaptic vesicle (i.e., 1 quantum). The investigators stimulated the motor neuron seven consecutive times and recorded the evoked MEPPs. In one trial, the stimulus evoked no response (0 quanta). In two trials, the peak MEPP was about 0.4 mV (1 quantum). In three others, the peak response was about 0.8 mV (2 quanta). Finally, in one, the peak was about 1.2 mV (3 quanta). In one case, a MEPP of the smallest magnitude appeared spontaneously. **B**, The histogram summarizes data from 198 trials on a cat neuromuscular junction in the presence of 12.5 mM extracellular Mg^{2+} . The data are in bins with a width of 0.1 mV. The distribution has eight peaks. The first represents stimuli that evoked no responses. The other seven represent stimuli that evoked MEPPs that were roughly

integral multiples of the smallest MEPP. The curve overlying each cluster of bins is a gaussian or “normal” function and facilitates calculation of the average MEPP for each cluster of bins. The peak values of these gaussians follow a Poisson distribution. (Data from Magleby KL: Neuromuscular transmission. In Engel AG, Franzini-Armstrong C [eds]: *Myology: Basic and Clinical*, 2nd ed. New York, McGraw-Hill, 1994, pp 442–463.)

N8-5

Quantal Nature of Transmitter Release

Contributed by Ed Moczydlowski

The quantal nature of transmitter release can be expressed *quantitatively* by postulating that a nerve terminal contains a population of N quanta or vesicles and that each has a finite probability (P) of releasing under any given set of conditions. Thus, the mean number (m) of quanta released after any single nerve impulse is

$$m = N \times P$$

Figure 8-12B in the text illustrates the results of an experiment very similar to that producing the data shown in Figure 8-12A, except that the investigators—Boyd and Martin—repeated the nerve stimulation 198 times, rather than 7 times as in Figure 8-12A. In each case, Boyd and Martin recorded the magnitude of the MEPP and placed it into a “bin” that was 0.1 mV wide. Thus, if they observed a MEPP of 1.23 mV, they placed it into the 1.2 bin. Figure 8-12B, a histogram summarizing the results of the 198 nerve-evoked responses, shows a series of peaks. The peak at 0 mV corresponds to the 18 trials in which the nerve stimulus evoked no end-plate potential. The peaks labeled I, II, III, and so on correspond to MEPPs that are multiples of the unit event—which is 0.4 mV—at amplitudes of 0.4 mV, 0.8 mV, 1.2 mV, and so forth. Thus, peak I corresponds to 1 quantum released, peak II corresponds to 2 quanta released, and so on.

If we sum up all the MEPPs in the 198 trials, we see that the total change in V_m was 184 mV. Dividing by 198 produces the mean amplitude of the MEPPs, 0.93 mV. If we assume a unitary response of 0.4 mV, 0.93 mV corresponds to 2.3 quanta, which is the m in Equation NE 8-3. Thus, on average, a nerve impulse produces a MEPP of 0.93 mV, which corresponds to the release of 2.3 quanta. However, in any given nerve impulse, the actual MEPP—if we could measure it with perfect accuracy—must correspond to an integral number of quanta released ($x = 0, 1, 2, 3, \dots$). Of course, because of noise and inaccuracies in the measuring system, Boyd and Martin also measured MEPPs that corresponded to *nonintegral* numbers of quanta. The y-axis in Figure 8-12B gives the number of times Boyd and Martin observed a given MEPP, out of the total of 198 observations. The seven bell-shaped or gaussian curves in Figure 8-12B represent the probability of releasing 1, 2, 3, 4, 5, 6, or 7 quanta.

Because each bin is 0.1 mV wide, and because the unitary MEPP is 0.4 mV, Boyd and Martin added up 0.4/0.1 or four consecutive bins to obtain the number of observations (n_x) corresponding to the release of x quanta, out of the total of 198 observations (n_{total}). For example, for $x = 0$ quanta, n_0 was 18; for $x = 1$ quantum, n_1 was 44; the second column in eTable 8-1 in this webnote gives the number of events observed (n_x) for each number of quanta x (listed in the first column). The probability (p_x) that we saw x quanta being released after a single nerve impulse is

eTABLE 8-1

Poisson Distribution of Quanta Released During Nerve Stimulation

Number of Quanta (x)	Number of Events Observed (n _x)	Probability Observed	Probability Predicted
0	18	0.091	0.100
1	44	0.222	0.231
2	55	0.278	0.265
3	36	0.182	0.203
4	25	0.126	0.117
5	12	0.061	0.054
6	5	0.025	0.021
7	2	0.010	0.007
8	1	0.005	0.002

$$p_x = \frac{n_x}{n_{total}}$$

Thus, for $x = 0$, p_0 would be 18/198 or 0.091; for $x = 1$, p_1 would be 44/198 or 0.222; the other values are given in the third column of eTable 8-1.

How do these observed values agree with those predicted by probability theory? Probability theory predicts that p_x should follow a **Poisson distribution**:

$$p_x = \frac{m^x}{x!} e^{-m}$$

Note that m in this equation is once again the mean number of quanta released per nerve impulse, 2.3 in our example. This theory assumes that the underlying probability of vesicle release (P in Equation NE 8-3) is very small and that the population of replenishable vesicles (N in Equation NE 8-3) is very large. The fourth column of eTable 8-1 shows that the p_x predicted by Equation NE 8-5 is very nearly the same as the observed p_x for each number of quanta.

We can also check the agreement of the data with the theory by testing whether the observed number of blank records (0-mV events) can predict the mean number (m) of quanta released after any single nerve impulse. According to Equation NE 8-5, when $x = 0$,

$$p_0 = \frac{m^0}{0!} e^{-m} = \frac{1}{1} e^{-m} = e^{-m}$$

or
$$\ln p_0 = -m$$

Because p_0 is 18/198 or 0.091, the m value that we compute from Equation NE 8-6 is 2.4 quanta. This value is very close to the measured mean of 2.3 quanta. Findings such as these have provided strong support for the quantal theory of neurotransmitter release at the neuromuscular junction.

Direct sensing of extracellular transmitter also shows quantal release of transmitter

Instead of using the postsynaptic AChR as a biological detector of quantum release, one can use a microscopic electrochemical sensor to measure neurotransmitter levels directly. [Figure 8-13](#) shows results from an experiment in which a fine carbon-fiber electrode was placed very close to the presynaptic terminal membrane of a leech neuron that uses serotonin as its only neurotransmitter. The carbon fiber is an electrochemical detector of serotonin (see [Fig. 8-13A](#)); the current measured by this electrode corresponds to four electrons per serotonin molecule oxidized at the tip. Stimulation of the leech neuron to produce an action potential also elicits an oxidation current, as measured by the carbon fiber, that corresponds to the release of serotonin. At a $[\text{Ca}^{2+}]_o$ of 5 mM, the current is large and composed of many small spikes (see [Fig. 8-13B](#), top). On the other hand, reducing $[\text{Ca}^{2+}]_o$ to 1 mM—presumably reducing Ca^{2+} influx into the nerve terminal and thus reducing the number of quanta released—reveals individual spikes of serotonin release. The release spikes come in two sizes, small and large (see [Fig. 8-13B](#), bottom), corresponding to two separate classes of synaptic vesicles that are evident on electron micrographs. Injection of the cell with tetanus toxin, which blocks the release of synaptic vesicles, abolishes the serotonin release spikes. Thus, the spikes represent genuine events of synaptic exocytosis.

A EXPERIMENTAL PREPARATION

B SEROTONIN RELEASE

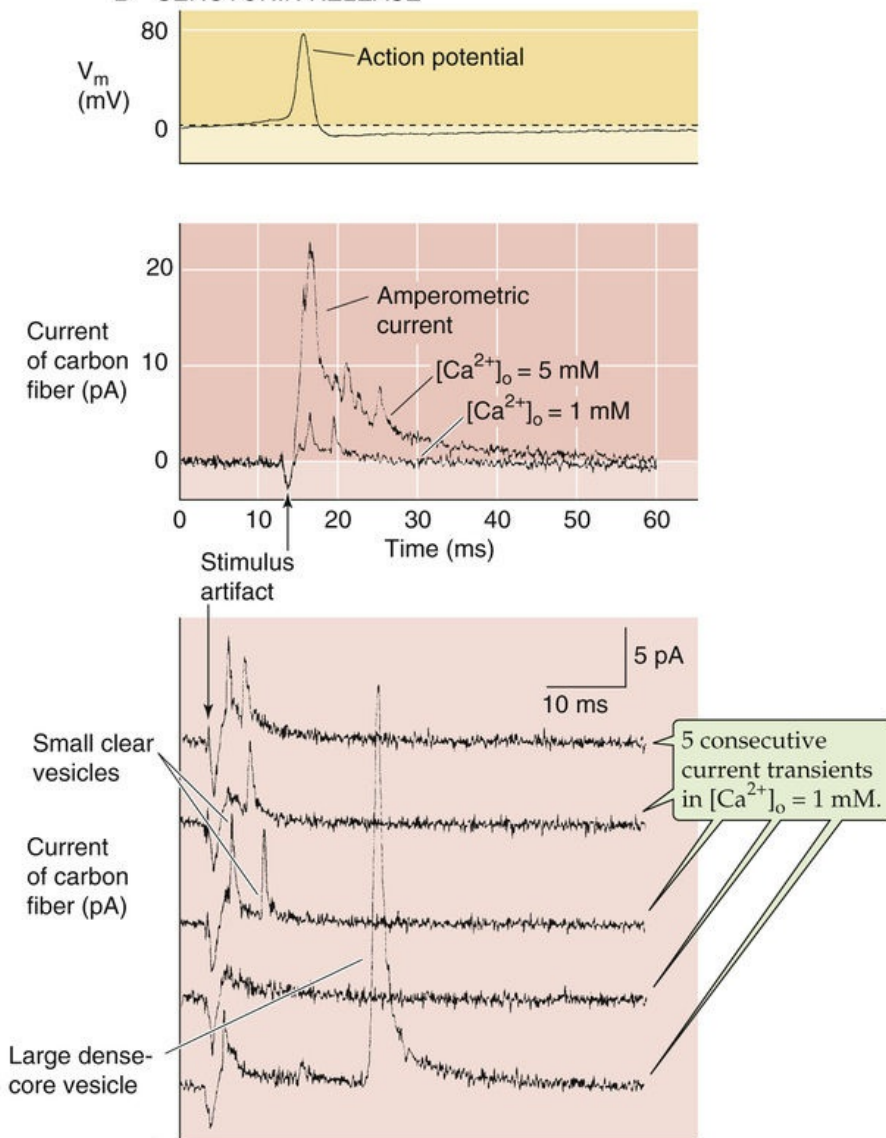

FIGURE 8-13 Detection of serotonin that is released from synaptic vesicles. **A**, The serotonin that is released from a synaptic terminal of a leech neuron can be detected electrochemically by use of a carbon-fiber microelectrode. The current carried by the carbon fiber increases with the amount of serotonin that is released, reflecting the oxidation of serotonin molecules on the surface of the carbon fiber. **B**, The top panel shows the action potential recorded from the stimulated motor neuron. The middle panel shows the evoked serotonin release (measured as a current) at both a $[Ca^{2+}]_o$ of 5 mM (high level of serotonin release) and a $[Ca^{2+}]_o$ of 1 mM (lower level of release). The bottom panel shows results of five consecutive trials at a $[Ca^{2+}]_o$ of 1 mM and illustrates that the release of serotonin can occur in either small quanta or very large quanta. These two sizes of quanta correspond to small clear vesicles and large dense-core vesicles, both of which can be observed by electron microscopy. (Data from Bruns D, Jahn R: Real-time measurement of transmitter release from single synaptic vesicles. *Nature* 377:62–65, 1995.)

The nearly immediate appearance of the small release spikes after electrical stimulation of the cell shows that this type of vesicular release is extremely rapid. From the height and duration of the small and large spikes in [Figure 8-13B](#), one can estimate the amount of electrical charge and thus the number of serotonin molecules oxidized at the carbon fiber per spike. A unitary *small* event corresponds to the release of ~4700 serotonin molecules, whereas a unitary *large* event corresponds to the release of 15,000 to 300,000 serotonin molecules. Thus, the amount of serotonin released by the small synaptic vesicles of the leech neuron is about half the number of ACh molecules contained in a synaptic vesicle at the frog neuromuscular junction. These and other observations of the synaptic function of nerve-muscle and nerve-nerve synapses have led to the conclusion that *chemical neurotransmission operates by a fundamentally similar mechanism* at many types of synapses in different animal species (see [Chapter 13](#)).

Short-term or long-term changes in the relative efficiency of neurotransmitter release can increase or decrease the *strength* of a particular synapse and thereby give rise to an alteration in behavior. Three types of synaptic modulation occur at the neuromuscular junction, and they differ in how they affect the quantal release of neurotransmitter:  **N8-7**

N8-7

Modulation of Quantal Release

Contributed by Ed Moczydlowski

As discussed in  **N8-5**, the quantal nature of transmitter release can be expressed *quantitatively* by postulating that a nerve terminal contains a population of N quanta or vesicles and that each has a finite probability (P) of releasing under any given set of conditions. Thus, the mean number (m) of quanta released after any single nerve impulse is

$$m = N \times P$$

As noted in the text, **facilitation** is a *short-lived* enhancement of the postsynaptic potential in response to a *brief* increase in the frequency of nerve stimulation. One way facilitation may occur is by a transient increase in the mean number of quanta per nerve stimulus, corresponding to an increase in the m parameter of Equation NE 8-7.

Potentialiation is a *long-lived* and pronounced increase in transmitter release that occurs after a *long* period of high-frequency nerve stimulation. This effect can last for minutes after the conditioning stimulus. Potentialiation may be caused by a period of intense nerve firing, which increases $[Ca^{2+}]_i$ in the presynaptic terminal and thus increases the probability of exocytosis (the P parameter in Equation NE 8-7).

Synaptic **depression** is a *transient* decrease in the efficiency of transmitter release—and, consequently, a reduction in the postsynaptic potential—in response to a period of frequent nerve stimulation. Depression may result from a temporary depletion of transmitter-loaded vesicles in the presynaptic terminal—that is, a reduction in the number of available quanta, corresponding to the parameter N in Equation NE 8-7.

Thus, these three temporal changes in synaptic strength and efficiency appear to reflect changes at different steps of synaptic transmission. Similar modulation of synaptic strength in the CNS provides a mechanistic paradigm for understanding how individual nerve terminals may “learn.”

Facilitation is a *short-lived* enhancement of the EPP in response to a *brief* increase in the frequency of nerve stimulation. One way that facilitation may occur is by a transient increase in the mean number of quanta per nerve stimulus.

Potentialiation (or post-tetanic potentialiation) is a *long-lived* and pronounced increase in transmitter release that occurs after a *long* period of high-frequency nerve stimulation. This effect can last for minutes after the conditioning stimulus. Potentialiation may be caused by a period of intense nerve firing, which increases $[Ca^{2+}]_i$ in the presynaptic terminal and thus increases the probability of exocytosis.

Synaptic **depression** is a *transient* decrease in the efficiency of transmitter release and, consequently, a reduction in the EPP in response to a period of frequent nerve stimulation. Depression may result from temporary depletion of transmitter-loaded vesicles from the presynaptic terminal, that is, a reduction in

the number of available quanta. Thus, these three temporal changes in synaptic strength and efficiency appear to reflect changes at different steps of synaptic transmission. Similar modulation of synaptic strength in the CNS provides a mechanistic paradigm to understand how individual nerve terminals may “learn” and “remember” (see p. 328).

Synaptic vesicles package, store, and deliver neurotransmitters

The physiology of synaptic vesicles in the nervous system is a variation on the universal theme used by endocrine or secretory cells in animals from the most primitive invertebrates up to mammals (see pp. 35–37). Many proteins involved in synaptic vesicle movement and turnover are related to those involved in intracellular membrane trafficking in almost all eukaryotic cells. This trafficking involves vesicular translocation from the endoplasmic reticulum to the Golgi network and fusion with the plasma membrane. Genetic analysis of the yeast secretory pathway has identified various gene products that are homologous to those associated with synaptic vesicles of higher vertebrates. Thus, the processes underlying synaptic function are inherently quite similar to cellular exocytosis and endocytosis.

As shown in Figure 8-14, **nascent synaptic vesicles** are produced in the neuronal cell body by a process similar to that in the **secretory pathway** (see pp. 34–35). The membrane proteins of synaptic vesicles are synthesized in the rough endoplasmic reticulum and are then directed to the Golgi network, where processing, maturation, and sorting occur. Nascent synaptic vesicles—which are, in fact, secretory vesicles—are then transported to the nerve terminal by **fast axonal transport** (see p. 25) mediated by the microtubule system, which also carries mitochondria to the terminal.

FIGURE 8-14 Synthesis and recycling of synaptic vesicles and their content.

Vesicles destined to contain *peptide* neurotransmitters travel down the axon with the presynthesized peptides or peptide precursors already inside. On arrival at the nerve terminal (see Fig. 8-14), the

vesicles—now called **dense-core secretory granules** (100 to 200 nm in diameter)—become randomly distributed in the cytoplasm of the terminal (see [p. 310](#)).

Vesicles destined to contain *nonpeptide* neurotransmitters (e.g., ACh) travel down the axon with no transmitter inside. On arrival at the nerve terminal (see [Fig. 8-14](#)), the vesicles take up the nonpeptide neurotransmitter, which is synthesized locally in the nerve terminal. These nonpeptide **clear synaptic vesicles** (40 to 50 nm in diameter) then attach to the actin-based cytoskeletal network. At this point, the mature clear synaptic vesicles are functionally ready for Ca^{2+} -dependent transmitter release and become docked at specific release sites in the **active zones** of the presynaptic membrane. After exocytotic fusion of the clear synaptic vesicles, endocytosis via clathrin-coated vesicles (see [pp. 40–42](#)) recovers membrane components and recycles them to an endosome compartment in the terminal. Synaptic vesicles may then be re-formed within the terminal for reuse in neurotransmission, or they may be transported back to the cell body for turnover and degradation.

The concentrative uptake of nonpeptide neurotransmitters into clear synaptic vesicles is accomplished by the combination of a vacuolar-type H-ATPase and various neurotransmitter transport proteins ([Fig. 8-15](#), top). The **vacuolar-type H pump** (see [pp. 118–119](#)) is a large, multisubunit complex that catalyzes the inward movement of H^+ into the vesicle, coupled to the hydrolysis of cytosolic ATP to ADP and inorganic phosphate. The resulting pH and voltage gradients across the vesicle membrane energize the uptake of neurotransmitters into the vesicle via three families of **neurotransmitter transport proteins** that mediate the exchange of neurotransmitters in the cytosol for H^+ in the vesicle (see [Table 5-4](#)). The SLC18 family includes members specific for monoamines (e.g., epinephrine, norepinephrine, dopamine, serotonin, histamine) and ACh. Members of the SLC17 family transport glutamate, and the SLC32 family handles GABA and glycine.

FIGURE 8-15 Model of fusion and exocytosis of synaptic vesicles. ● **N8-15** SNARE, SNAP receptor.

Proteins Involved in Fusion and Endocytosis of Synaptic Vesicles

Contributed by Ed Moczydlowski

SNAP stands for soluble NSF attachment protein.  **N8-8**

SNARE proteins are so-named because they act as receptors for SNAP. Thus, the acronym **SNARE** is a concatenation of **SNAP** and **RE**ceptor.

NSF stands for *N*-ethylmaleimide sensitive factor. It is a homohexameric ATPase enzyme that functions in the dissociation and recycling of SNARE complexes after vesicle fusion has occurred.

Synaptobrevin is also known as VAMP (vesicle-associated membrane protein).

Many proteins are involved in the fusion and recycling of synaptic vesicles (see [Fig. 8-15](#)). The **SNARE proteins** (see [p. 37](#)), which also participate in the secretory pathway, comprise the force-generating molecular machinery for membrane-membrane fusion. One SNARE protein—named **synaptobrevin** or VAMP—is a “v” SNARE because it is in the *vesicle* membrane. The two other SNARE proteins—one called syntaxin-1 and the other, SNAP-25 (synaptosome-associated protein, 25 kDa)—are “t” SNAREs because they are in the *target* (i.e., presynaptic) membrane. Synaptobrevin of the vesicle membrane and **syntaxin-1** of the presynaptic membrane are anchored in the presynaptic membrane by single membrane-spanning segments. On the other hand, the presynaptic **SNAP-25**—which exists as a dual-helix bundle—is tethered to the presynaptic membrane by palmitoyl lipid chains. In the next section, we discuss how the SNAREs produce fusion.

Synaptotagmin is a synaptic vesicle protein that has, at its cytosolic end, two repetitive domains that are homologous to the C2 domain of protein kinase C. It is the Ca^{2+} -sensor for exocytosis. **Rab3** is a member of a large family of low-molecular-weight GTP-binding proteins that appears to be universally involved in cellular membrane trafficking (see [p. 37](#)) via the binding and hydrolysis of GTP, and it also regulates synaptic release.

Neurotransmitter release occurs by exocytosis of synaptic vesicles

Although the mechanism by which synaptic vesicles fuse with the plasma membrane and release their contents is still not completely understood, we have working models (see [Fig. 8-15](#)) for the function of various key components and steps involved in synaptic vesicle release. These models are based on a variety of in vitro experiments. The use of specific toxins that act at nerve synapses and elegant functional studies of genetic mutants in *Drosophila*, *Caenorhabditis elegans*, and gene knockout mice have provided important information on the role of various components.

We have already introduced key proteins located in the synaptic vesicle, including the v-SNAREs synaptobrevin and the Ca^{2+} sensor synaptotagmin. We also have introduced the two t-SNAREs syntaxin-1

and SNAP-25 (see p. 37) in the target area of the presynaptic membrane. These are also essential for the fusion process. As discussed below on pages 224–225, tetanus toxin and certain botulinum toxins are endoproteases that cleave synaptobrevin, whereas other botulinum endoproteases cleave syntaxin-1 and SNAP-25. These toxins thus block the fusion of synaptic vesicles.  **N8-8**

N8-8

“SNAP” Nomenclature

Contributed by Emile Boulpaep, Walter Boron

Unfortunately, SNAP means different things to different people: “SNAP” in **SNAP-25** means “synaptosome-associated protein, 25 kDa,” and “SNAP” in **α-SNAP** means “soluble NSF-attachment protein.”

As summarized in Figure 8-15, after **docking** of the vesicle near the presynaptic membrane, Sec-1/Munc18, Munc13, and RIM catalyze assembly of the partial SNARE complex. The free helical ends of synaptobrevin, syntaxin, and SNAP-25 begin to coil around each other to form a four-helix bundle—the trans-SNARE complex—formed by four ~70-amino-acid SNARE helix motifs, one from synaptobrevin, one from syntaxin-1, and two from SNAP-25. The result, called **priming stage 1**, is a ternary SNARE complex with an extraordinarily stable rod-shaped structure of intertwined α helices. As the energetically favorable coiling of the three SNAREs continues in a zipper-like process, the vesicle membrane is pulled ever closer to the presynaptic membrane. Next, a cytosolic protein called **complexin** inserts into the trans-SNARE complex, preventing spontaneous fusion. The result is **priming stage 2**.

As Ca^{2+} enters through voltage-gated Ca^{2+} channels (see Table 7-2)—located in register with the active zone of the presynaptic membrane—it binds to multiple sites on the C2 domains of synaptotagmin. These Ca^{2+} -bound C2 domains promote the binding of synaptotagmin to acidic phospholipids in the presynaptic membrane and also displace the complexin, thereby reversing the block to fusion. These events trigger the actual membrane fusion event, accompanied by **fusion-pore opening** and the beginning of transmitter release. The role of the synaptotagmin as the Ca^{2+} sensor is supported by experiments with knockout mice and *Drosophila* mutants showing that the absence of the appropriate isoform of this protein results in impaired Ca^{2+} -dependent transmitter release.

Following **fusion completion**, as the plasma-membrane Ca-ATPase (PMCA) extrudes Ca^{2+} across the plasma membrane and as mitochondria take up Ca^{2+} , $[\text{Ca}^{2+}]_i$ rapidly falls, causing synaptotagmin to dissociate from the tightly wound SNARE complex. The soluble α -SNAP (soluble NSF attachment protein)  **N8-8** binds to the SNARE complex and promotes the binding of NSF (*N*-ethylmaleimide-sensitive factor, a homohexameric ATPase), which uses the energy of ATP hydrolysis to disassemble the SNAREs. The now-free synaptobrevin presumably undergoes recycling endocytosis, whereas the syntaxin and SNAP-25 on the presynaptic membrane are available for the next round of vesicle fusion.

The model just presented leaves unanswered some important questions. For example, what is the exact structure of the fusion pore detected by electrophysiological measurements as a primary event in membrane fusion? Also, precisely how do the many regulatory and scaffolding proteins control the numerous conformational changes that accompany the membrane fusion event? Physiologists are very interested in the details of synaptic vesicle fusion because regulation of the exocytotic process is a target for control of the strength of synaptic transmission and is undoubtedly involved in synaptic plasticity phenomena responsible for changes in animal behavior. For their work on vesicle trafficking, including

fusion of synaptic vesicle, James Rothman, Randy Schekman, and Thomas Südhof shared the Nobel Prize in Physiology or Medicine in 2013. 🌐N8-16

Re-uptake or cleavage of the neurotransmitter terminates its action

Effective transmission across chemical synapses requires not only release of the neurotransmitter and activation of the receptor on the postsynaptic membrane but also rapid and efficient mechanisms for removal of the transmitter. At synapses where ACh is released, this removal is accomplished by enzymatic destruction of the neurotransmitter. However, the more general mechanism in the nervous system involves re-uptake of the neurotransmitter mediated by specific high-affinity transport systems located in the presynaptic plasma membrane and surrounding glial cells. These secondary active transport systems use the normal ionic gradients of Na^+ , K^+ , H^+ , or Cl^- to achieve concentrative uptake of transmitter. Vertebrates have two distinct families of neurotransmitter transport proteins. The first family is characterized by a common motif of 12 membrane-spanning segments and includes transporters with specificity for catecholamines, serotonin, GABA, glycine, and choline. Energy coupling of transport in this class of systems is generally based on cotransport of the substrate with Na^+ and Cl^- . The second family is represented by transporters for the excitatory amino acids glutamate and aspartate; in these systems, substrate transport generally couples to cotransport of Na^+ and H^+ and to exchange of K^+ .

At the neuromuscular junction and other cholinergic synapses, immediate termination of the action of ACh is accomplished enzymatically by the action of AChE. Although AChE is primarily found at the neuromuscular junction, AChE activity can be detected throughout the nervous system. The enzyme occurs in a variety of physical forms. The **globular** or **G forms** exist as monomers, dimers, or tetramers of a common ~72-kDa glycoprotein catalytic subunit. These molecules can be found either in soluble form or bound to cell membranes via a GPI linkage (see p. 13) in which a post-translational modification attaches the C terminus of the protein to a glycolipid moiety. The **asymmetric** or **A forms** consist of one to three tetramers of the globular enzyme coupled via disulfide bond linkage to a collagen-like structural protein. The largest asymmetric form, which has 12 catalytic subunits attached to the collagen-like tail, is the major species located at the neuromuscular junction. The triple-helical, collagen-like tail attaches the asymmetric AChE complex to extracellular matrix components of the synaptic basal lamina. The various physical forms of AChE are a result of the alternative splicing that occurs in the transcription of a single AChE gene. 🌐N8-9

Acetylcholinesterase

Contributed by Ed Moczydlowski

The acetylcholinesterase (AChE) enzyme is an ellipsoidal globular protein, approximately 4.5 nm × 6.0 nm × 6.5 nm. It includes a central 12-stranded β sheet surrounded by 14 α-helical segments. The active site of the enzyme is composed of three residues (Ser200, His440, and Glu327) located on different loops. These residues are analogous to the Ser-His-Asp catalytic triad of serine proteases such as trypsin and chymotrypsin. This similarity is an example of convergent evolution, inasmuch as there is little structural similarity between the two types of enzymes. A unique aspect of the structure of AChE is that the active site of ACh hydrolysis is located at the bottom of a 2.0-nm-deep gorge (the **active site gorge**) that the substrate must enter by diffusion from the surface of the protein. The three-dimensional structure of the catalytic subunit of AChE from the electric ray, *Torpedo californica*, has been solved by x-ray crystallography.

In the first step of the enzymatic reaction (see Equation 8-5), the H from the hydroxyl of Ser200 becomes attached to the oxygen in the ester linkage of ACh, which results in the formation of choline and a tetrahedral acyl-enzyme intermediate at Ser200.

In the second step of Equation 8-5, the hydrolysis of the acyl-enzyme yields acetate and the free enzyme.

The enzyme AChE rapidly hydrolyzes ACh to choline and acetate in a two-step process:

In the first step of the reaction, the enzyme cleaves choline from ACh, which results in the formation of a transient intermediate in which the acetate group is covalently coupled to a serine group on the enzyme. The second step is the hydrolysis and release of this acetate as well as the recovery of free enzyme. The nerve terminal recovers the extracellular choline via a high-affinity Na⁺-coupled uptake system and uses it for the synthesis of ACh ([Box 8-1](#)).

Box 8-1

Diseases of Neuromuscular Transmission

The term *myasthenia* means muscle weakness (from the Greek *mys* + *asthenia*) and is generally used clinically to denote weakness in the absence of a CNS disorder, neuropathy, or primary muscle disease. Thus, myasthenia can be due to any one of a wide range of aberrations of neuromuscular transmission.

Myasthenia Gravis

Myasthenia gravis, one specific type of myasthenia and the most common adult form, affects 25 to 125 of every 1 million people. It can occur at any age but has a bimodal distribution, with peak incidences occurring among people in their 20s and 60s. Those affected at an early age tend to be women with hyperplasia of the thymus. Those who are older are more likely to be men with coexisting cancer of the thymus gland. The cells of the thymus possess nicotinic AChRs, and the disease arises as a result of antibodies directed against these receptors. The antibodies then lead to skeletal muscle weakness caused

in part by competitive antagonism of AChRs. Symptoms include fatigue and weakness of skeletal muscle. Two major forms of the disease are recognized: one that involves weakness of only the extraocular muscles and another that results in generalized weakness of all skeletal muscles. In either case, myasthenia gravis is typified by fluctuating symptoms, with weakness greatest toward the end of the day or after exertion. In severe cases, paralysis of the respiratory muscles can lead to death. Treatment directed at enhancing cholinergic transmission, alone or combined with thymectomy or immunosuppression, is highly effective in most patients.

Progress toward achieving an understanding of the cause of myasthenia gravis was first made when electrophysiological analysis of involved muscle revealed that the amplitude of the MEPP was decreased, although the frequency of quantal events was normal. This finding suggested either a defect in the postsynaptic response to ACh or a reduced concentration of ACh in the synaptic vesicles. A major breakthrough occurred in 1973, when Patrick and Lindstrom found that symptoms similar to those of humans with myasthenia developed in rabbits immunized with AChR protein purified from the electric eel. This finding was shortly followed by the demonstration of anti-AChR antibodies in human patients with myasthenia gravis and a severe reduction in the surface density of AChR in the junctional folds. The anti-AChR antibodies are directed against one or more subunits of the receptor, where they bind and activate complement and accelerate destruction of the receptors. The most common target of these antibodies is a region of the AChR α subunit called MIR (main immunogenic region).

Myasthenia gravis is now recognized to be an acquired autoimmune disorder in which the spontaneous production of anti-AChR antibodies results in progressive loss of muscle AChRs and degeneration of postjunctional folds. Treatment is aimed at either reducing the potency of the immunological attack or enhancing cholinergic activity within the synapse. Reduction of the potency of the immunological attack is achieved by the use of immunosuppressants (most commonly corticosteroids) or plasmapheresis (removal of antibodies from the patient's serum). Some patients with myasthenia gravis have a thymoma (a tumor of the thymus gland) that is often readily seen on routine chest radiographs. In these patients, removal of the thymoma leads to clinical improvement in nearly 75% of the cases. Enhancement of cholinergic activity is achieved via the use of AChE inhibitors; pyridostigmine is the most widely used agent. The dosage of these drugs must be carefully monitored to prevent *overexposure* of the remaining AChRs to ACh. Overexposure can lead to overstimulation of the postsynaptic receptors, prolonged depolarization of the postsynaptic membrane, inactivation of neighboring Na^+ channels, and thus synaptic blockade.

Congenital Myasthenic Syndrome

Congenital myasthenic syndrome (CMS) refers to a variety of inherited disorders, present at birth, that affect neuromuscular transmission in a variety of ways. Because specific cases can involve abnormal presynaptic release of ACh, AChE deficiency, or defective AChR function (without the presence of antireceptor antibodies), the signs and symptoms can also vary widely.

In 1995, an unusual example of a CMS disorder was traced to a mutation in the ϵ subunit of the human AChR. Single channel recordings from biopsy samples of muscle fibers of a young myasthenic patient revealed a profound alteration in AChR kinetics. The burst duration of AChR openings was greatly prolonged in comparison with that of normal human AChR channels. The patient had a mutation of threonine to proline at position 264 in the adult ϵ subunit of the AChR. This amino-acid residue corresponds to an evolutionarily conserved position in the M2 membrane-spanning segment, which is involved in formation of the channel pore. Thus, a human mutation in the pore region of the AChR protein results in failure of the channel to close normally, thereby causing excessive depolarization and

pathological consequences at the muscle end plate.

Many human mutations in α , β , δ , ϵ , and γ subunits of the nicotinic muscle AChR have since been characterized. These mutations have many different effects on AChR kinetics including *slow and fast channel syndromes* depending on where they occur in the receptor channel protein.

Lambert-Eaton Myasthenic Syndrome

Another condition characterized by progressive muscle weakness and fatigue is Lambert-Eaton myasthenic syndrome (LEMS; also called Lambert-Eaton syndrome), an impairment of presynaptic Ca^{2+} channels at motor nerve terminals. LEMS is an autoimmune disorder, most often seen in patients with certain types of cancer, such as small-cell lung carcinoma. In LEMS, antibodies attack Cav2.2 (*CACNA1B*), which reduces Ca^{2+} entry during the presynaptic action potential and thus reduces ACh release. LEMS differs from myasthenia gravis as follows: (1) LEMS primarily attacks the limb muscles, not the ocular and bulbar muscles. (2) In LEMS, repetitive stimulation of a particular muscle (which leads to a progressive rise in $[\text{Ca}^{2+}]_i$) causes a gradual increase in the amplitude of the **compound motor action potential (CMAP)** in the stimulated muscle—as measured using **electromyography (EMG)**  **N8-10**. In patients with myasthenia, repetitive stimulation leads to progressive lessening of the CMAP. Thus, repeated muscle stimulation leads to increasing contractile strength in patients with LEMS and to decreasing strength in patients with myasthenia.

N8-10

The Electromyogram and the Compound Motor Action Potential

Contributed by Walter Boron

An **electromyogram (EMG)** is a record obtained using an instrument called an electromyograph. The technique—called electromyography—is used to assess the electrical activity generated by excited skeletal muscle cells.

A **compound motor action potential (CMAP)** is the summation of many nearly simultaneous action potentials from many skeletal muscle fibers that are in the same vicinity. One would typically observe CMAPs during electromyography.

Toxins and Drugs Affecting Synaptic Transmission

Much of our knowledge of the synaptic physiology of the neuromuscular junction and the identities of its various molecular components have been derived from experiments using specific pharmacological agents and toxins that permit functional dissection of the system. [Figure 8-16](#) illustrates the relative synaptic location and corresponding pharmacology of AChE as well as several ion channels and proteins involved in exocytosis.

FIGURE 8-16 Pharmacology of the vertebrate neuromuscular junction. Many of the proteins that are involved in synaptic transmission at the mammalian neuromuscular junction are the targets of naturally occurring or synthetic drugs. The antagonists are shown as minus signs highlighted in red. The agonists are shown as plus signs highlighted in green.

Guanidinium neurotoxins such as tetrodotoxin prevent depolarization of the nerve terminal, whereas dendrotoxins inhibit repolarization

The action potential is the first step in transmission: a nerve action potential arriving at the terminal initiates the entire process. As discussed in [Chapter 7](#), the depolarizing phase of the action potential is mediated by voltage-dependent Na^+ channels that are specifically blocked by nanomolar concentrations of the small guanidinium neurotoxins **tetrodotoxin** and **saxitoxin** (see [Fig. 7-5C](#)). **N8-11**

N8-11

Blockade of Muscle Na^+ Channels

Contributed by Ed Moczydlowski

An action potential is not only the first but also the last step in transmission at the neuromuscular junction: the production of an action potential in the muscle fiber membrane signals the successful completion of synaptic transmission. As discussed above, action potentials, including those in muscle, can be blocked by TTX and STX. Selective blockade of the muscle action potential can be achieved with a unique toxin called **μ -conotoxin** (see p. 187), **N7-14** which is obtained from a marine snail (*Conus geographus*). μ -conotoxin is a 22-residue, basic peptide with a discoidal, star-like three-dimensional structure that is stabilized by three disulfide bonds. It is an especially potent blocker of the particular Nav1.4 isoform of the voltage-dependent Na^+ channel that is present in adult mammalian skeletal muscle, but it has little effect on the Na^+ channel isoforms of nerve or heart. If an intact nerve-muscle preparation is exposed to μ -conotoxin, stimulation of the nerve still evokes the release of ACh, but the muscle action potential is completely eliminated.

The mamba snake toxin **dendrotoxin** (see p. 196) has an effect that is precisely opposite that of tetrodotoxin: it facilitates the release of ACh that is evoked by nerve stimulation. Dendrotoxins are a family of ~59-residue proteins with three disulfide bonds that block certain isoforms of voltage-gated K^+ channels by binding to an extracellular site in the P-region domain with high affinity. These toxins reveal the important role of K^+ channels in terminating the process of transmitter release. Blockade of presynaptic K^+ channels by dendrotoxin inhibits repolarization of the presynaptic membrane, thereby prolonging the duration of the action potential and facilitating the release of transmitter in response to the entry of extra Ca^{2+} into the nerve terminal.

ω -Conotoxin blocks Ca^{2+} channels that mediate Ca^{2+} influx into nerve terminals, inhibiting synaptic transmission

The exocytotic fusion of mature synaptic vesicles positioned at presynaptic active zones and the subsequent release of ACh require the entry of Ca^{2+} into the nerve terminal. Ca^{2+} enters the presynaptic terminal through voltage-gated Ca^{2+} channels that are activated by the depolarization of an incoming action potential. One type of voltage-gated Ca^{2+} channel, the N-type isoform, has been localized to the region of the active zone of the frog neuromuscular junction. Voltage-clamp experiments demonstrate that a class of molluscan peptide toxins called **ω -conotoxins** (see p. 193) block N-type Ca^{2+} currents in a

virtually irreversible fashion. Exposure of a frog nerve-muscle preparation to ω -conotoxin thus inhibits the release of neurotransmitter. This effect is manifested as an abolition of muscle EPP when the preparation is stimulated via the nerve. The ω -conotoxins are 24 to 29 residues long and contain three disulfide bonds. Imaging with confocal laser scanning microscopy has shown that ω -conotoxin binds at highest density to voltage-dependent Ca^{2+} channels in the presynaptic nerve terminal, directly across the synaptic cleft from AChR channels. This observation implies that Ca^{2+} channels are located precisely at the active zones of synaptic vesicle fusion. This arrangement provides for focal entry and short-range diffusion of Ca^{2+} entering the nerve terminal to the exact sites involved in promoting Ca^{2+} -dependent transmitter release.

Bacterial toxins such as tetanus and botulinum toxins cleave proteins involved in exocytosis, preventing fusion of synaptic vesicles

Another class of neurotoxins that specifically inhibits neurotransmitter release includes the tetanus and botulinum toxins. These large-protein toxins (~150 kDa) are respectively produced by the bacteria *Clostridium tetani* and *Clostridium botulinum* (Box 8-2). *C. tetani* is the causative agent of **tetanus** (lockjaw), which is characterized by a general increase in muscle tension and muscle rigidity, beginning most often with the muscles of mastication. The reason for this paradoxical enhancement of muscle action is that the greatest effect of these toxins is to *inhibit* synaptic transmission by inhibitory neurons in the spinal cord, neurons that would normally *inhibit* muscle contraction. The result is hyperstimulation of skeletal muscle contraction. *C. botulinum* causes **botulism**, which is characterized by weakness and paralysis of skeletal muscle as well as by a variety of symptoms that are related to inhibition of cholinergic nerve endings in the autonomic nervous system.

Box 8-2

Clostridial Catastrophes

Botulism

Although hardly one of the most common causes of food poisoning today, botulism is still the example that many people cite when food-borne illnesses are discussed. The neurotoxin of *Clostridium botulinum* is considered the most toxic natural substance known. The median lethal dose is ~1 ng of toxin per kilogram of human body weight by intravenous exposure and 3-fold higher for inhalation exposure. The uptake into a presynaptic terminal of one molecule—with its cleavage of SNAREs—is theoretically sufficient to eliminate vesicle exocytosis in that terminal. The most common source of botulism is homemade foods. The spores of this organism can survive boiling temperatures for a number of hours, and if the cooked food is allowed to stand at room temperature for >16 hours, the clostridial spores can germinate and produce toxin. However, the toxin itself is readily denatured by prolonged heating at >60°C.

Symptoms of the illness may appear several hours to more than a week after ingestion, although most cases occur within 18 to 36 hours. Patients begin to complain of symptoms attributable to inhibition of synaptic vesicle release in the autonomic nervous system (see Chapter 14), such as dry mouth, double vision, and difficulty in swallowing and speaking, and later begin to experience gastrointestinal

complications, including vomiting, pain, and diarrhea. Symptoms attributable to inhibition of synaptic vesicle release at the neuromuscular junction, such as weakness and paralysis of the limbs, may soon follow; ultimately, paralysis of the respiratory muscles (see pp. 606–607) can be fatal. Prompt intervention with mechanical ventilation has reduced the mortality from botulism dramatically, and the figure today stands at about 20%. Almost all deaths occur among the first victims ingesting a contaminated food sample because the disease is not quickly recognized; those who fall victim later, when the diagnosis is much easier, do much better. Botulinum antitoxin formulated from equine antibodies is also available for acute treatment.

Tetanus

The disease tetanus is caused by a neurotoxin (tetanospasmin) produced by *Clostridium tetani*. The organism gains entry to its host via a cut or puncture wound. The toxin then travels along the peripheral nerves to the spinal cord, the major site of its attack. There, the toxin inhibits synaptic vesicle release by GABA and glycine interneurons (see p. 319) which normally inhibit firing of the motor neurons that, in turn, activate skeletal muscle. Thus, because the toxin suppresses inhibition of the normal reflex arc, muscle contraction leads to profound spasms, most characteristically of the jaw muscles but potentially affecting any muscle in the body. Symptoms can commence on the day of the injury or as long as 2 months later. Complications include respiratory arrest, aspiration pneumonia, rib fractures caused by the severe spasms, and a host of other pulmonary and cardiac manifestations.

Most people in the United States are protected from tetanus by childhood immunization with the DPT (diphtheria, pertussis, tetanus) vaccine.  **N8-12** Vaccination has reduced the number of cases of tetanus reported in the United States to only about 100 each year, almost all occurring in inadequately vaccinated individuals.

N8-12

DPT Vaccination

Contributed by Ed Moczydlowski

Most people in the United States are protected from tetanus by childhood immunization with the DPT (diphtheria, pertussis, tetanus) vaccine. However in recent years fear of side effects and rare allergic reactions has led some parents to reject DPT vaccination. Unvaccinated children may be at greater risk of these easily preventable diseases, whereas the risk of vaccination side effects is small in comparison.

In humans, infection by these bacteria can lead to death because the toxins that they synthesize are potent inhibitors of neurotransmitter release. This inhibition occurs because both tetanus and botulinum toxin proteins have zinc-dependent endoproteinase activity ([Table 8-2](#)). These toxins enter nerve terminals and specifically cleave three different SNARE proteins required for synaptic vesicle exocytosis. **Tetanus toxin** and **botulinum toxins** B, D, F, and G cleave the v-SNARE synaptobrevin (see [p. 219](#)), an integral membrane protein of the synaptic vesicle membrane. Botulinum toxins A and E cleave SNAP-25, whereas botulinum toxin C1 cleaves the t-SNAREs syntaxin-1 and SNAP-25.

TABLE 8-2
Neurotoxins That Block Fusion of Synaptic Vesicles

TOXIN	TARGET
Tetanus	Synaptobrevin
Botulinum B, D, F, G	Synaptobrevin
Botulinum A, E	SNAP-25
Botulinum C1	SNAP-25; syntaxin

These neurotoxins also have useful medical and cosmetic applications. For example, botulinum toxin is used to treat certain disorders characterized by muscle spasms and dystonias involving neurological movement disorders. Injection of a small amount of botulinum toxin into the eye muscles of a patient with strabismus (a condition in which both eyes cannot focus on the same object because of abnormal hyperactivity of particular eye muscles) is able to suppress aberrant muscle spasms and to restore normal vision. Since its approval by the U.S. Food and Drug Administration in 2002 for cosmetic applications, a commercial preparation of botulinum toxin known as Botox has been widely used for removal of frown lines and facial wrinkles. Local injections of Botox smooth wrinkles by paralysis of facial muscles, although care must be taken to prevent effects of the toxin away from the intended site. The benefits of such treatments may last for 3 to 6 months before regeneration of nerve terminals reinnervates the muscles causing the wrinkles.

Both agonists and antagonists of the nicotinic AChR can prevent synaptic transmission

The ionotropic (nicotinic) AChR channel located in the postsynaptic muscle membrane also has a rich and diverse pharmacology (see Fig. 8-16) that can be exploited for clinical applications as well as for elucidation of many functional aspects of the neuromuscular junction. Figure 8-17 shows the chemical structures of two classes of agents that act on the nicotinic AChR. These agents are classified as agonists or antagonists according to whether they activate opening of the channel or prevent its activation. Many **agonists** have a structure similar to that of the natural neurotransmitter ACh. In general, such agonists activate the opening of AChR channels with the same unitary conductance as those activated by ACh, but with different kinetics of channel opening and closing. The synthetic drugs **carbamylcholine** (or carbachol) and **succinylcholine** contain the choline moiety of ACh that is required for receptor activation. Carbamylcholine is a carbamyl ester of choline; succinylcholine (or succinylcholine) is a dimer of ACh molecules linked together via the acetyl methyl group. Both of these agents are resistant to hydrolysis by muscle AChE, but succinylcholine is susceptible to hydrolysis by plasma and liver esterases. This property allows prolonged activation of AChRs.

Carbamylcholine (carbachol)

Succinylcholine

Nicotine

ANTAGONISTS

d-Tubocurarine

Pancuronium

FIGURE 8-17 Agonists and antagonists of the nicotinic AChR.

Succinylcholine is used to produce sustained muscle relaxation or “flaccid paralysis,” which is useful in certain types of surgery and procedures such as tracheal intubation, in which it is important to prevent excitation and contraction of skeletal muscles. This paralytic action occurs because succinylcholine prolongs the opening of AChR channels and thereby depolarizes the muscle membrane in the vicinity of the end plate. Such depolarization results in initial repetitive muscle excitation and tremors, followed by relaxation secondary to **inactivation of Na⁺ channels** in the vicinity of the end plate. This effect prevents the spread of muscle action potentials beyond the end-plate region. On a longer time scale, such agents also lead to **desensitization of the AChR** to agonist, which further inhibits neuromuscular transmission.

Another important *agonist* acting on AChRs is **nicotine**, which we discussed on [pages 212–213](#). A classic example of a nicotinic AChR **antagonist** is *d*-tubocurarine (see [Fig. 8-17](#)), the active ingredient of curare, a poison extracted from plants of the genus *Strychnos*. The indigenous tribes of the Amazon region used curare to poison arrows for hunting. **d-Tubocurarine** [N8-2](#) is a competitive inhibitor of ACh binding to two activation sites on the α subunits of the AChR. This action leads to a *nondepolarizing* flaccid paralysis of skeletal muscle from inhibition of the nicotinic AChR, in contrast to the *depolarizing* flaccid paralysis produced by activating agonists such as succinylcholine. A hallmark of the action of *d*-

tubocurarine is that it can be reversed by an increase in concentration of the natural agonist ACh by binding competition. Such reversal can be achieved by a large increase in local ACh concentration, which can be produced indirectly by an inhibitor of AChE such as neostigmine (see [p. 226](#)).

[Figure 8-17](#) also shows the structure of **pancuronium**, which is a synthetic bis-quaternary ammonium steroid derivative. This drug is also useful for the production of neuromuscular blockade in surgery, and it is actually a more potent, selective competitive antagonist of the muscle nicotinic AChR than *d*-tubocurarine is.

Another class of nicotinic AChR inhibitors is a family of ~8-kDa proteins present in the venom of Elapidae snakes (e.g., cobras). These toxins include α -bungarotoxin (α -Bgt) and homologous α toxins, which bind very strongly to nicotinic receptors. The specific binding of α -Bgt to the nicotinic AChR of skeletal muscle is virtually irreversible. When α -Bgt binds to the nicotinic AChR, it obstructs the agonist binding site and prevents activation of the receptor by ACh. The radioiodinated derivative ^{125}I -labeled α -Bgt has been widely used as a ligand for purifying the nicotinic AChR from various tissues. Fluorescent derivatives of α -Bgt can also be used as specific labels for localizing AChRs at the muscle end plate. The same snake venom (from *Bungarus multicinctus*) that contains α -Bgt also contains a homologous protein toxin called κ -bungarotoxin (κ -Bgt). This toxin has little effect on nicotinic AChR channels at the neuromuscular junction, but it does inhibit AChR channels in neuronal tissue. The differential effect of α -Bgt and κ -Bgt on muscle and neuronal currents activated by both ACh and nicotine originally led to the recognition that pharmacologically distinct classes of nicotinic receptors exist in the CNS and in skeletal muscle. As we know today, the basis for these classes is the differential expression of multiple genes encoding various nicotinic AChR subunits (see [p. 213](#)).

Inhibitors of AChE prolong and magnify the EPP

A variety of inhibitors of anticholinesterase have been invaluable in defining the contribution of AChE to responses at the muscle end plate. Inhibition of AChE generally increases the amplitude and prolongs the duration of the postsynaptic response to ACh; thus, the enzyme plays an important role in limiting the excitatory action of ACh under normal physiological conditions. In the absence of ACh breakdown by AChE, the prolonged decay of the EPP reflects the underlying kinetics of activated receptors and slow depletion of the agonist in the vicinity of the junctional folds by diffusion of ACh.

The plant alkaloid **physostigmine** (also known as eserine) is the prototypic anticholinesterase ([Fig. 8-18](#)). **Neostigmine** (Prostigmin), a synthetic anti-AChE drug with chemical similarity to physostigmine, is used to treat myasthenia gravis (see [Box 8-1](#)). Both of these inhibitors—whose ester moieties resemble that of ACh—are slowly reversible. As shown in [Equation 8-5](#), when AChE reacts with its *normal* substrate (i.e., ACh), the resulting intermediate (i.e., acetyl-AChE) undergoes rapid hydrolysis to recycle AChE for its next round of catalysis. Reaction with physostigmine or neostigmine, however, produces a carbamylated form of AChE that undergoes hydrolysis at an extremely low rate, which eventually results in the release of the active enzyme. This slow hydrolysis explains why the effective half-lives of the drugs are on the order of several hours in humans.

Neostigmine (prostigmine)

IRREVERSIBLE

Diisopropylfluorophosphate (DFP)

O,O-dimethyl S-(1,2-dicarbethoxyethyl) phosphorodithioate (malathion)

FIGURE 8-18 Structures of AChE inhibitors.

Another important class of synthetic AChE inhibitors consists of **organophosphorus compounds**, which are *irreversible* inhibitors. These inhibitors are typified by **diisopropyl fluorophosphate (DFP)**; see Fig. 8-18). Such compounds react with the serine residue of AChE (see pp. 212–213) and form an essentially irreversible covalent modification of the enzyme. Such agents rank high among the most potent and lethal of toxic chemicals. Their devastating effect is due to excessive enhancement of cholinergic neurotransmission, mediated by both muscarinic and nicotinic receptor pathways throughout the body. For example, exposure to toxic organophosphorus agents results in the flaccid paralysis of respiratory muscles because of initial muscle stimulation followed by depolarization blockade. **N8-13** The lethality of these compounds dramatically underlines the essential role of AChE in terminating cholinergic

neurotransmission. Chemical warfare agents (i.e., “nerve gas,” such as sarin) are deadly, volatile forms of these compounds. Related compounds, such as malathion (see [Fig. 8-18](#)), which are relatively selective for insects, are widely used as agricultural insecticides.

N8-13

Depolarization Blockade

Contributed by Ed Moczydlowski

AChE inhibitors lead to an accumulation of ACh in the synaptic cleft, causing a sustained activation of the nicotinic AChR and thus a sustained depolarization of the postsynaptic membrane. Although the initial depolarization would lead to an action potential and muscle contraction, the sustained depolarization would prevent voltage-gated Na⁺ channels from recovering from inactivation. The result is a flaccid muscle paralysis.

A natural organophosphorus neurotoxin is produced by *Anabaena flos-aquae*, a toxic cyanobacterium (blue-green alga). Known as **anatoxin-a(s)**, this toxin is a potent inhibitor of AChE and is responsible for the poisoning of dogs and farm animals that drink from contaminated ponds. Another unusual class of natural inhibitors includes the **fasciculins**, a family of small-protein toxins present in mamba snake venom that inhibit AChE with very high affinity and specificity.

CHAPTER 9

Cellular Physiology of Skeletal, Cardiac, and Smooth Muscle

Edward G. Moczydlowski

The primary function of muscle is to generate force or movement in response to a physiological stimulus. The human body contains three fundamentally different types of muscle adapted to specialized functions. Skeletal muscle is responsible for the voluntary movement of bones that underlies locomotion and work production. Skeletal muscle also controls the breathing cycle of the lungs via contraction of the diaphragm and functions as a pump assisting return of the venous blood supply to the heart. Cardiac muscle is specific to the heart as the biomechanical pump driving the delivery of blood to the lungs and tissues. Smooth muscle provides mechanical control of organ systems such as the digestive, urinary, and reproductive tracts as well as the blood vessels of the circulatory system and the airway passages of the respiratory system.

Contraction of muscles is initiated either by a chemical neurotransmitter or paracrine factor or by direct electrical excitation. All muscles transduce chemical energy released by hydrolysis of ATP into mechanical work. The unique physiological role of each of the three basic muscle types dictates inherent differences in the rate and duration of contraction, metabolism, fatigability, and ability to regulate contractile strength. For example, both skeletal and cardiac muscle must be capable of rapid force development and shortening. However, skeletal muscle must be able to maintain contractile force for relatively long periods. Cardiac muscle contracts only briefly with each heartbeat but must sustain this rhythmic activity for a lifetime. Smooth muscle, like skeletal muscle, must be able to regulate contraction over a wide range of force development and elastic changes in the size of organs such as the urinary bladder and uterus. In some tissues (e.g., sphincters), smooth muscle sustains contraction without fatigue for very long periods. Despite these differences, the trigger for muscle contraction is the same for all three types of muscle: a rise in the free cytosolic Ca^{2+} concentration ($[\text{Ca}^{2+}]_i$).

This chapter describes the fundamental physiology of muscle excitation, the coupling of excitation to contraction, the molecular mechanism of contraction, the regulation of contraction, and the related issues of muscle diversity. We describe general molecular mechanisms shared by all muscle cells and contrast the unique features of skeletal, cardiac, and smooth muscle. Because molecular mechanisms specific to cardiac myocytes are best understood in the unique context of the heart as a pump, we discuss details of cardiac muscle physiology at greater depth in [Chapters 22](#).

Skeletal Muscle

Contraction of skeletal muscle is initiated by motor neurons that innervate motor units

The smallest contractile unit of skeletal muscle is a multinucleated, elongated cell called a **muscle fiber** or **myofiber** (Fig. 9-1). A bundle of linearly aligned muscle fibers forms a **fascicle**. In turn, bundles of fascicles form a muscle, such as the biceps. The whole muscle is contained within an external sheath extending from the tendons called the **epimysium**. Fascicles within the muscle are enveloped by a sheath called the **perimysium**. Single muscle fibers within individual fascicles are surrounded by a sheath called the **endomysium**. The highly organized architecture of skeletal muscle fibers and connective tissue allows skeletal muscle to generate considerable mechanical force in a vectorial manner. Beneath the endomysium surrounding each muscle fiber is the plasma membrane of the muscle cell called the **sarcolemma**. An individual skeletal muscle cell contains a densely arranged parallel array of cylindrical elements called **myofibrils**. Each myofibril is essentially an end-to-end chain of regular repeating units—or **sarcomeres**—that consist of smaller interdigitating filaments called **myofilaments**; these myofilaments contain both thin filaments and thick filaments (see pp. 25–28).

FIGURE 9-1 Structure of skeletal muscle, from muscle to myofibril.

All skeletal muscle is under voluntary or reflex control by **motor neurons** of the somatic motor system. Somatic motor neurons are efferent neurons with cell bodies located in the central nervous system (CNS). A single muscle cell responds to only a single motor neuron whose cell body—except for cranial nerves—resides in the ventral horn of the spinal cord. However, the axon of a motor neuron typically branches near its termination to innervate a few or many individual muscle cells. The group of muscle fibers innervated by all of the collateral branches of a single motor neuron is referred to as a **motor unit**. A whole muscle can produce a wide range of forces and a graded range of shortening by varying the number of motor units excited within the muscle. The **innervation ratio** of a whole skeletal muscle is defined as the number of muscle fibers innervated by a single motor neuron. Muscles with a small innervation ratio control fine movements involving small forces. For example, fine, high-precision movements of the extraocular muscles that control positioning movements of the eye are achieved via an innervation ratio of as little as ~ 3 muscle fibers per neuron. Conversely, muscles with a large innervation ratio control coarse movement requiring development of large forces. Postural control by the soleus muscle uses an innervation ratio of ~ 200 . The gastrocnemius muscle, which is capable of developing large forces required in athletic activities such as jumping, has innervation ratios that vary from ~ 100 to ~ 1000 .

As discussed on [pp. 208–210](#), a motor nerve axon contacts each muscle fiber near the middle of the fiber to form a synapse called the **neuromuscular junction**. The specialized region of sarcolemma in

closest contact with the presynaptic nerve terminal is called the **motor end plate**. Although skeletal muscle fibers can be artificially excited by direct electrical stimulation, physiological excitation of skeletal muscle always involves chemical activation by release of acetylcholine (ACh) from the motor nerve terminal. Binding of ACh to the nicotinic receptor gives rise to a graded, depolarizing **end-plate potential**. An end-plate potential of sufficient magnitude raises the membrane potential to the firing threshold and activates voltage-gated Na^+ channels (Navs) in the vicinity of the end plate, triggering an action potential that propagates along the surface membrane.

Action potentials propagate from the sarcolemma to the interior of muscle fibers along the transverse tubule network

As action potentials propagate along the surface membrane of skeletal and cardiac muscle fibers, they penetrate into the cell interior via radially oriented, tubular invaginations of the plasma membrane called **transverse tubules** or **T tubules** (Fig. 9-2). T tubules plunge into the muscle fiber and surround the myofibrils at two points in each sarcomere: at the junctions of the A and the I bands. A cross section through the A-I junction shows a complex branching array of T tubules penetrating to the center of the muscle cell and surrounding the individual myofibrils. Along its length the tubule associates with two **terminal cisternae**, which are specialized regions of the **sarcoplasmic reticulum (SR)**. The SR of muscle cells is a specialized version of the endoplasmic reticulum (ER) of noncontractile cells and serves as a storage organelle for intracellular Ca^{2+} . The combination of the T-tubule membrane and its two neighboring cisternae is called a **triad junction**, or simply a **triad**. 🍌N9-1

FIGURE 9-2 Transverse tubules and SR in skeletal muscle. The transverse tubules (T tubules) are extensions of the plasma membrane, penetrating the muscle cell at two points in each sarcomere: the junctions of the A and I bands.

N9-1

Diversity of Mechanisms for Excitation-Contraction Coupling in Skeletal, Cardiac, and Smooth Muscle

Contributed by Ed Moczydlowski

The process by which electrical “excitation” of the surface membrane triggers an increase of $[Ca^{2+}]_i$ in muscle is known as **excitation-contraction coupling** or EC coupling.

Membrane Invaginations ... Bringing the Depolarization into the Cell

Skeletal Muscle

The combination of the T-tubule membrane and its two neighboring cisternae is called a **triad** or **triad junction**; this structure plays a crucial role in the coupling of excitation to contraction in skeletal muscle.

Cardiac Muscle

Cardiac myocytes have a T-tubule network similar to that of skeletal muscle myofibers except that a single terminal cisterna of the SR forms a **dyad junction** with the T-tubule rather than a triad junction.

Furthermore, T-tubules of cardiac myocytes are located at the Z lines separating sarcomeres rather than at the A-I band junctions.

Smooth Muscle

Smooth muscle, in contrast, has more rudimentary and shallow invaginations of the plasma membrane called **caveolae** (see Fig. 9-15). Caveolae are considered to be a special form of membrane microdomain called **lipid rafts** that are enriched in glycosphingolipids and cholesterol and are involved in signal transduction. A peripheral SR compartment of smooth muscle encircles the plasma membrane in close proximity to the caveolae. A larger network of central SR runs along the long axis of the cell. The peripheral SR is involved in local Ca^{2+} release and interaction with plasma membrane ion channels that mediate electrical excitability, whereas the central SR has a greater role in delivering Ca^{2+} to intracellular myofilaments for contraction.

Source of Calcium

Although the ultimate intracellular signal that triggers and sustains contraction of skeletal, cardiac, or smooth-muscle cells is a rise in $[\text{Ca}^{2+}]_i$, the three types of muscle cells differ substantially in the detailed mechanism by which a depolarization of the sarcolemmal membrane results in a rise in $[\text{Ca}^{2+}]_i$. Ca^{2+} can enter the cytoplasm from the extracellular space through voltage-gated ion channels, or alternatively, Ca^{2+} can be released into the cytoplasm from the intracellular Ca^{2+} storage reservoir of the SR. Thus, both extracellular and intracellular sources may contribute to the increase in $[\text{Ca}^{2+}]_i$. However, the relative importance of these two sources of Ca^{2+} varies among the different muscle types.

Skeletal Muscle

In skeletal muscle, as noted in the text, the L-type Ca^{2+} channel (also known as the DHP receptor) in the T tubule directly couples to the SR Ca^{2+} -release channel (also known as the ryanodine receptor, RYR1), which leads to Ca^{2+} release from the SR and thus a rise in $[\text{Ca}^{2+}]_i$.

Cardiac and Smooth Muscle

In contrast to skeletal muscle, in heart and smooth muscle, Ca^{2+} influx via the voltage-gated Ca^{2+} channel Cav1.2 directly activates an RYR2 isoform, leading to Ca^{2+} release from the SR and raising $[\text{Ca}^{2+}]_i$. This mechanism of EC coupling known as **Ca^{2+} -induced Ca^{2+} release (CICR)** is quite different from the mechanical coupling mechanism of skeletal muscle. In heart and smooth muscle, colocalization of plasma membrane Cav channels with intracellular SR Ca^{2+} -release channels allows for close coupling of Ca^{2+} entry from the plasma membrane and Ca^{2+} -activation of RYR Ca^{2+} -release channels. In the CICR coupling mechanism, the action of Ca^{2+} can be considered as analogous to that of a neurotransmitter or chemical messenger that diffuses across a synapse to activate an agonist-gated channel, but in this case the synapse is the intracellular diffusion gap of ~ 15 nm between surface Cav channels and intracellular RYR channels on the SR membrane. The CICR mechanism serves as a robust amplification system whereby local influx of Ca^{2+} from small clusters of L-type Cav channels in the plasma membrane trigger the coordinated release of Ca^{2+} , the activation signal for myofilament contraction, from high-capacity internal Ca^{2+} stores of the SR.

In smooth muscle but not in cardiac muscle, other Ca^{2+} -activated ion channels (e.g., Ca^{2+} -activated K^+ channels, and Ca^{2+} -activated Cl^- channels) also participate in repolarization and regulation of contractile tone. Activation of smooth-muscle contraction also often involves the IP_3 receptor (IP_3R), another Ca^{2+} -release channel of the ER/SR membrane. In many smooth muscles, a variety of receptor agonists and

chemical mediators are coupled to activation of phospholipase C (PLC). PLC activation results in cleavage of PIP_2 (phosphatidylinositol 4,5-bisphosphate) and production of IP_3 , a chemical messenger that activates IP_3R -mediated Ca^{2+} release (see p. 60).

Depolarization of the T-tubule membrane results in Ca^{2+} release from the SR at the triad

The ultimate intracellular signal that triggers and sustains contraction of skeletal muscle cells is a rise in $[\text{Ca}^{2+}]_i$. Ca^{2+} can enter the cytoplasm from the extracellular space through voltage-gated ion channels or, alternatively, Ca^{2+} can be released into the cytoplasm from the intracellular Ca^{2+} storage reservoir of the SR. Thus, both extracellular and intracellular sources may contribute to the increase in $[\text{Ca}^{2+}]_i$. The process by which electrical “excitation” of the surface membrane triggers an increase of $[\text{Ca}^{2+}]_i$ in muscle is known as **excitation-contraction coupling** or EC coupling.

The propagation of the action potential into the T tubules of the myofiber depolarizes the triad region of the T tubules, as discussed in the previous section, thereby activating **L-type Ca^{2+} channels** (see pp. 190–193). These voltage-gated channels cluster in groups of four called tetrads (Fig. 9-3) and have a pivotal role as the **voltage sensor** EC coupling. Functional complexes of L-type Ca^{2+} channels contain the α_1 -subunit of the voltage-gated Ca^{2+} channel (i.e., Cav1.1) as well as the accessory α_2 - δ , β , and γ subunits (see Fig. 7-12B). The L-type Ca^{2+} channel is also often referred to as the **DHP receptor** because it is inhibited by a class of antihypertensive and antiarrhythmic drugs known as dihydropyridines or calcium channel blockers. Depolarization of the T-tubule membrane produces conformational changes in each of the four Cav1.1 channels of the tetrad, resulting in two major effects. First, the conformational changes open the Cav1.1 channel pore, which allows electrodiffusive Ca^{2+} entry. Second, and more importantly in skeletal muscle, the voltage-driven conformational changes in the four Cav1.1 channels mechanically activate each of the four directly coupled subunits of another channel—the Ca^{2+} -release channel located in the portion of the terminal cisternae of the SR membrane that faces the T tubule (see Fig. 9-3).

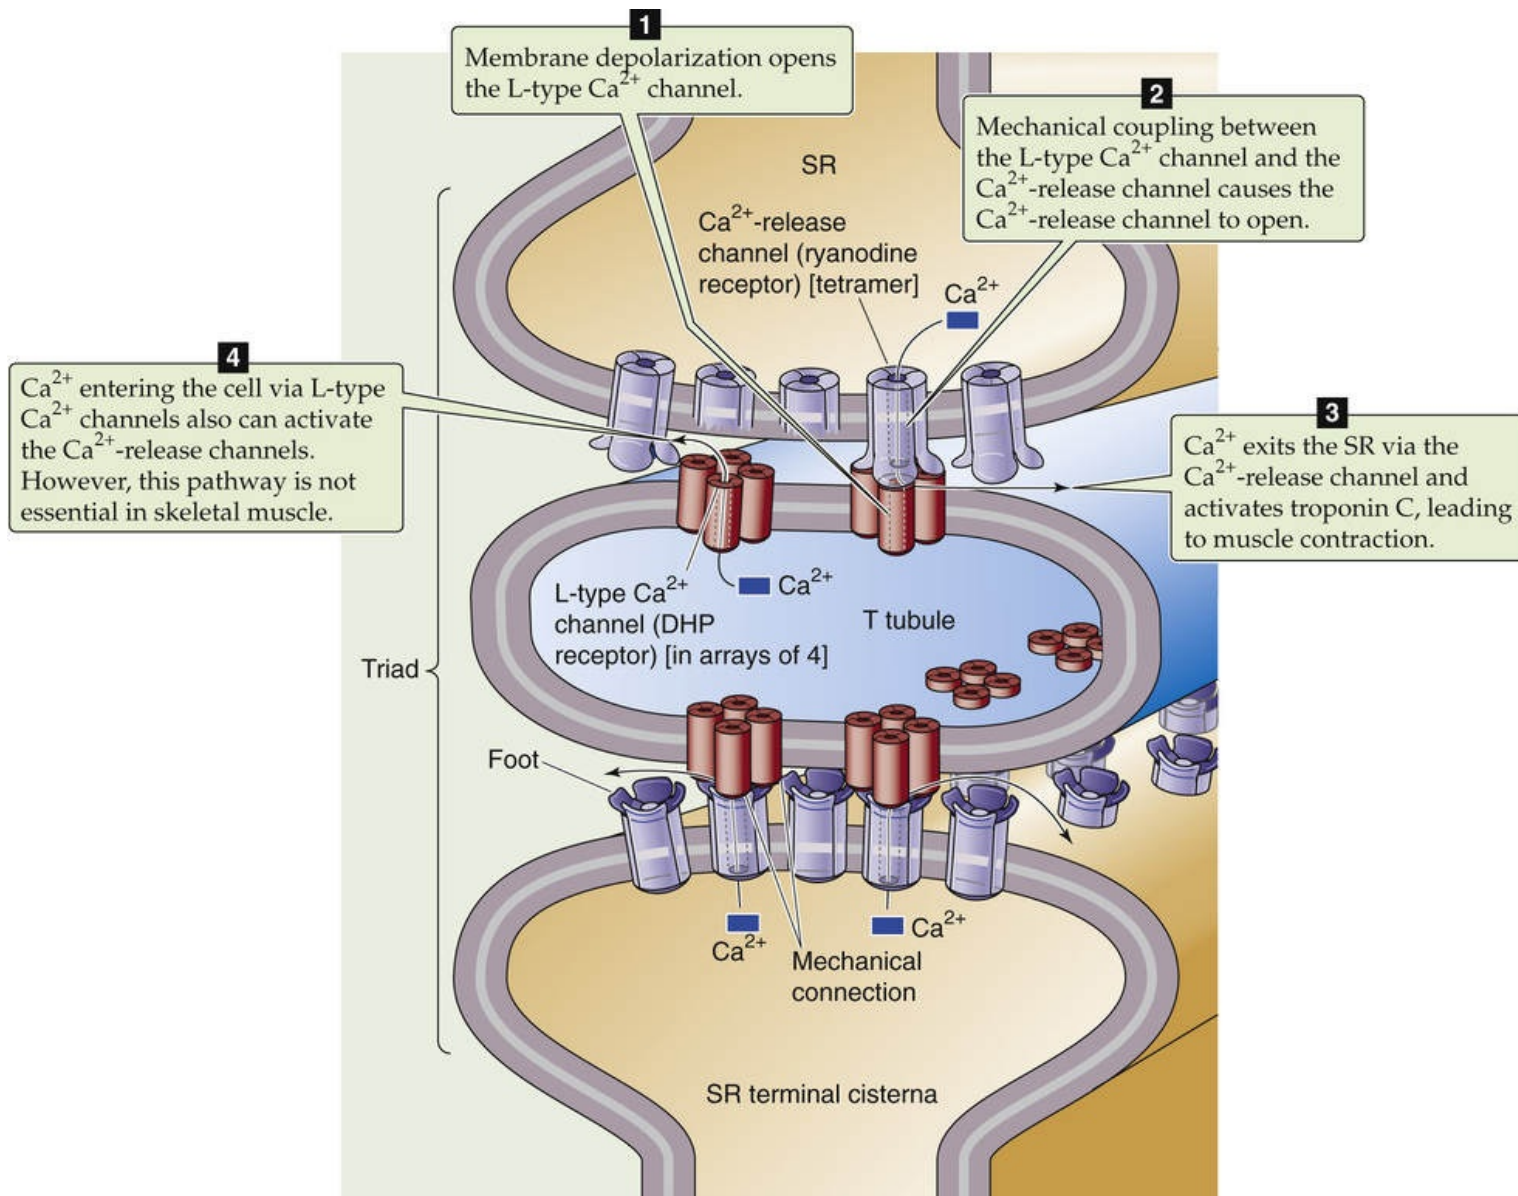

FIGURE 9-3 EC coupling in skeletal muscle. A tetrad of four L-type Cav channels on the T tubules faces a single RYR1 Ca^{2+} -release channel of the SR, so that each pseudotetrameric Cav channel interacts with the foot of one of the four subunits of the RYR. Note that every other RYR interacts with Cav channels along the T-tubule in a double checkerboard pattern. **N9-12**

The SR **Ca^{2+} -release channel** (see Fig. 6-20W) has a homotetrameric structure quite different from that of the T-tubule Cav1.1 channel. This SR Ca^{2+} -release channel is also known as the **ryanodine receptor (RYR)** because it is inhibited by the plant alkaloid *ryanodine*—an important tool in characterizing RYRs. In contrast, another plant alkaloid, *caffeine*, which is present in coffee, activates RYRs by increasing opening probability. **N9-2** RYRs are the largest known channel proteins, with a molecular mass of ~550 kDa for the monomer, or ~2.1 MDa for a homotetramer. Each of the four subunits of these channels has a large extension—also known as a foot—that projects into the cytosol (see Fig. 9-3).

N9-2

Caffeine

Contributed by Ed Moczydlowski

As noted on page 230 of the text, the plant alkaloid *caffeine*, which is present in coffee, activates RYRs by increasing opening probability. Caffeine is often used experimentally as a research tool to open RYRs and deplete SR Ca^{2+} stores in muscle, but this effect is not related to the potent CNS stimulant effects of caffeine, which are the result of its action as an antagonist of CNS adenosine receptors (see Fig 13-14B).

In skeletal muscle, where the Ca^{2+} -release channels are of the RYR1 subtype, RYR1 tetramers line up in two rows in the SR membrane. In the T-tubule membrane, half as many Cav1.1 channel tetrads are similarly aligned but are spaced such that they make intracellular contact with every other RYR1 in an alternating “double checkerboard” pattern. The monomer foot domain of each of the four RYR1 subunits is complementary to the cytoplasmic projection of one of the four Cav1.1 channels in a tetrad on the T tubule (see Fig. 9-3). The precise geometrical proximity of these two proteins as well as the ability of both DHP and ryanodine to block muscle contraction indicates that mechanical interactions between these two different Ca^{2+} channels underlie EC coupling in skeletal muscle. Further evidence for a direct physical interaction between Cav1.1 and RYR1 is the observation that many cycles of excitation and contraction can occur in complete absence of extracellular Ca^{2+} . Moreover, Cav1.1 channels in the closed state physically inhibit the opening of RYR1 channels and thereby prevent the spontaneous release of SR Ca^{2+} in the nonactivated, resting state. Thus, EC coupling in skeletal muscle is an electromechanical process involving a voltage-induced Ca^{2+} release mechanism.

After depolarization of the L-type Ca^{2+} channel on the T-tubule membrane and mechanical activation of

the Ca^{2+} -release channel in the SR, Ca^{2+} stored in the SR rapidly leaves through the Ca^{2+} -release channel. When imaged using a fluorescent Ca^{2+} indicator, the rapid and transient rise in local $[\text{Ca}^{2+}]_i$ —from clusters of RYR channels—appears as a **spark**.  **N9-3** This increase in $[\text{Ca}^{2+}]_i$ activates troponin C, initiating formation of cross-bridges between myofilaments, as described below. EC coupling in skeletal muscle thus includes the entire process we have just described, beginning with the depolarization of the T-tubule membrane to the initiation of the cross-bridge cycle of contraction.

N9-3

Calcium Sparks

Contributed by Ed Moczydlowski

The use of advanced fluorescent Ca^{2+} indicator dyes and confocal microscopy to image Ca^{2+} signaling in muscle cells has revealed a variety of elementary events observed as brief bursts of fluorescence corresponding to a transient and highly localized increase in intracellular Ca^{2+} . Detailed biophysical studies of these events, termed **Ca^{2+} sparks**, has helped to refine understanding of EC coupling in skeletal, cardiac, and smooth-muscle cells.

Ca^{2+} sparks were first characterized in cardiac myocytes and later also described in smooth muscle and skeletal muscle. Such spark events can be observed in resting cardiac myocytes loaded with a fluorescent Ca^{2+} dye indicator such as fluo-3 (eFig. 9-1A). The spark is a brief increase in fluorescence intensity corresponding to Ca^{2+} binding to the dye resulting from a local and rapid increase in Ca^{2+} concentration that rises to a peak within ~ 10 ms and decays within ~ 50 ms (see eFig. 9-1B). Such spontaneous sparks in cardiac myocytes are due to the small opening probability of SR RYR Ca^{2+} -release channels that depends upon $[\text{Ca}^{2+}]$ in the cytoplasm and SR lumen. Biophysical analysis indicates that a single spark event corresponds to the simultaneous opening of a cluster of Ca^{2+} -release channels, termed **calcium release units (CRUs)**, that may represent the opening of ~ 10 to 100 RYR channels, depending on the recording conditions and preparation. Although visual resolution of Ca^{2+} sparks generally requires low activation conditions of Ca^{2+} release, they can be observed in single cardiac myocytes activated by a depolarizing voltage pulse at the leading edge of a transient rise of $[\text{Ca}^{2+}]_i$ (see eFig. 9-1A).

eFigure 9-1C shows a series of Ca^{2+} sparks from a **cardiac myocyte** imaged by a *line scan* of a confocal microscope oriented along the long axis of the cell. The recording shows that synchronized voltage-activated Ca^{2+} sparks appear at the locations of T tubules at a spacing of ~ 1.8 μm apart. Such experiments have shown that the macroscopic or global increase in cytoplasmic $[\text{Ca}^{2+}]$ in muscle cells is the result of the stochastic summation of many individual spark events corresponding to localized bursts of intracellular Ca^{2+} release. Studies of Ca^{2+} sparks have also confirmed that voltage-activated mechanical coupling underlies EC mechanisms in skeletal muscle, whereas Ca^{2+} -induced Ca^{2+} release underlies these mechanisms in cardiac and smooth muscle.

Due to the tight voltage control of Ca^{2+} release and termination by brief ~ 2 -ms Na^+ action potentials in mammalian **skeletal muscle**, classical Ca^{2+} sparks in these striated muscle cells can be resolved only after strenuous exercise of the muscle and under certain nonphysiological and pathological conditions. This implies that spontaneous opening of RYRs in skeletal muscle is suppressed by mechanical linkage to Cav channels in the resting state and that mechanical EC coupling of mammalian skeletal muscle involves fine temporal and voltage control of Ca^{2+} release, which presumably facilitates precise control of many body movements.

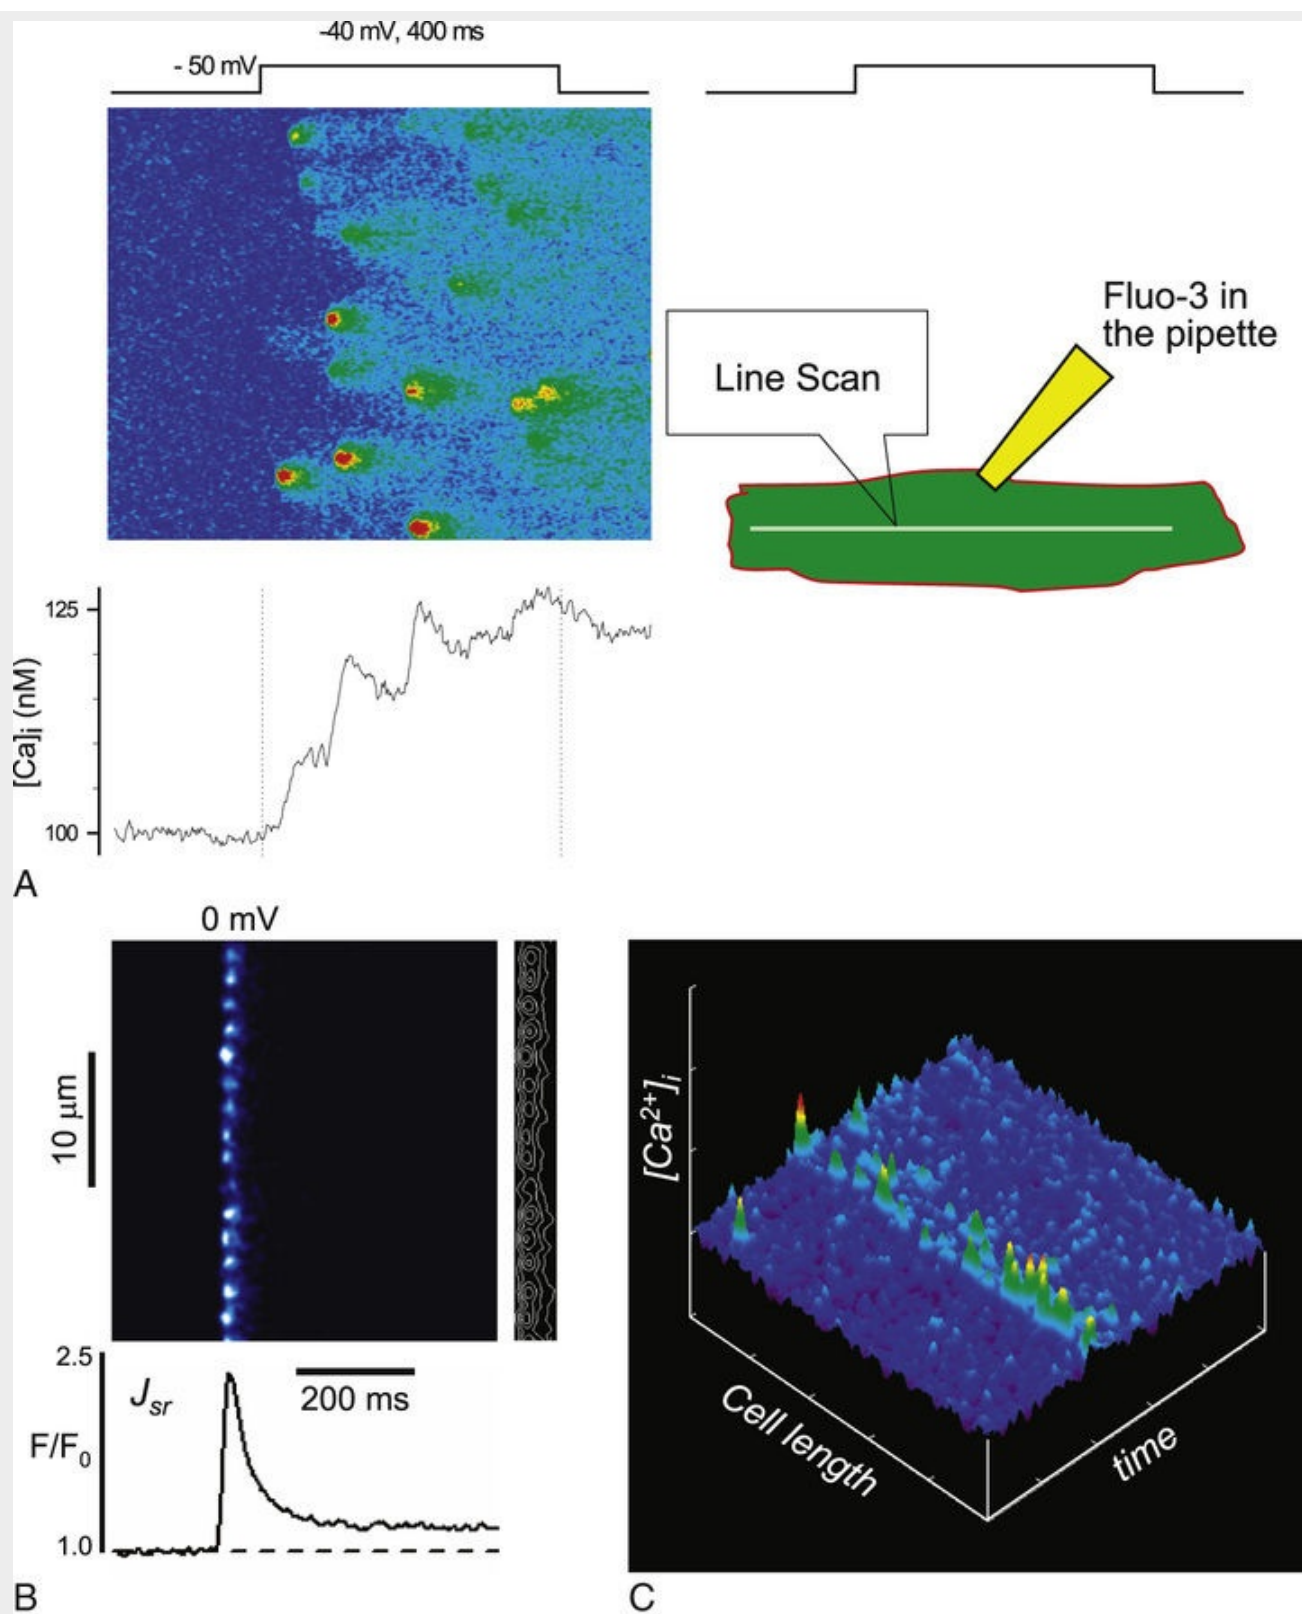

FIGURE 9-1 Calcium spark imaging in single cardiac ventricular myocytes. **A**, A recording was made from a myocyte under whole-cell voltage clamp with fluo-3 Ca^{2+} -imaging dye in the pipette (top right diagram). A line scan along the long dimension of the cell was imaged by confocal microscopy. Upon mild voltage depolarization from -50 to -40 mV for 400 ms, randomly appearing spark events (red-orange spots) are observed in the top left time course of the line scan. The lower trace shows the time course of total integrated intracellular Ca^{2+} , which increases in consecutive jumps corresponding to the appearance of Ca^{2+} sparks seen in the upper image. **B**, A myocyte loaded with 4 mM EGTA (ethylene glycol-bis(2-aminothylether)-N,N,N',N'-tetraacetic acid, or egtazic acid) and 1 mM Oregon Green 488 BAPTA-5N Ca^{2+} -imaging dye was imaged by confocal line scan as in **A**. Here the line scan was placed along a row of T tubules. Depolarization of the cell to 0 mV evoked a series of simultaneous Ca^{2+} spark events at the T-tubule spacing of ~ 1.8 μm . The lower trace shows the average time course of Ca^{2+} sparks corresponding to SR Ca^{2+} -release events. **C**, Surface plot of line-scan image from another myocyte

Although we have stressed that EC coupling in skeletal muscle primarily involves direct *mechanical* coupling between the L-type Ca^{2+} channel in the T-tubule membrane and the Ca^{2+} -release channel of the SR, **○N9-1** other mechanisms modulate the activity of RYR1. For example, RYR1 is subject to regulation by cytoplasmic Ca^{2+} , Mg^{2+} , ATP, and calmodulin (CaM) as well as protein kinases such as protein kinase A (PKA; see p. 57) and Ca^{2+} -calmodulin-dependent kinase II (CaMKII; see p. 60). In the fight-or-flight response (see p. 347), the sympathetic autonomic nervous system activates β -adrenergic receptors, causing PKA-mediated phosphorylation of RYR1 and other muscle proteins; this results in faster and larger increases in cytoplasmic Ca^{2+} , and thus stronger skeletal muscle contraction (**Box 9-1**).

Box 9-1

Defective EC Coupling in Muscle Due to Cav Channel Mutations

Ca^{2+} channels have been linked to a large variety of genetic defects of skeletal muscle. In mice, an interesting mutation results in **muscular dysgenesis**, or failure of normal skeletal muscle to develop. These mice lack a functional Ca^{2+} channel α_1 subunit in their skeletal muscle. They die shortly after birth, but their cultured muscle cells provide an assay system to investigate the mechanism of EC coupling. Contraction of such defective muscle cells can be rescued by expression of cloned genes for either the skeletal Cav1.1 (*CACNA1S* gene) or the cardiac Cav1.2 (*CACNA1C* gene) L-type Ca^{2+} channels. A key distinguishing feature of EC coupling in normal skeletal muscle versus cardiac muscle is the requirement for extracellular Ca^{2+} in cardiac muscle (see pp. 242–243) but not in skeletal muscle (see pp. 242–243). **○N9-1** Indeed, when the rescue is accomplished with skeletal Cav1.1, contraction *does not* require extracellular Ca^{2+} . On the other hand, when the rescue is accomplished with cardiac Cav1.2, contraction *does* require extracellular Ca^{2+} . Such studies provide strong support for the concept that EC coupling (1) in skeletal muscle involves direct mechanical coupling of Cav1.1 to the RYR1 but (2) in cardiac muscle involves Ca^{2+} entry through Cav1.2 channels, which causes Ca^{2+} -induced Ca^{2+} release (see pp. 242–243). Experiments with chimeric cardiac and skeletal Cav channel isoforms have shown that the intracellular linker region between domains II and III (see Fig. 7-12B) determines whether EC coupling is of the skeletal or cardiac type.

Hypokalemic periodic paralysis (not to be confused with *hyperkalemic* periodic paralysis, discussed in Box 7-1) is an autosomal dominant muscle disease of humans. Affected family members have a point mutation in the *CACNA1S* gene encoding the skeletal Cav1.1, located in transmembrane segment S4 of domain II. This finding explains the basis for a human disorder involving defective EC coupling of skeletal muscle.

Striations of skeletal muscle fibers correspond to ordered arrays of thick and thin filaments within myofibrils

Myofilaments are of two types: thick filaments composed primarily of a protein called myosin and thin

filaments largely composed of a protein called **actin** (see [pp. 25–28](#)). The **sarcomere** is defined as the repeating unit between adjacent Z disks or Z lines ([Fig. 9-4A, B](#)). A myofibril is thus a linear array of sarcomeres stacked end to end. The highly organized sarcomeres within skeletal and cardiac muscle are responsible for the striped or striated appearance of muscle fibers of these tissues as visualized by various microscopic imaging techniques. Thus, both skeletal muscle and cardiac muscle are referred to as **striated muscle**. In contrast, smooth muscle lacks striations because actin and myosin have a less regular pattern of organization in these myocytes.

B MODEL OF A SARCOMERE

C CROSS SECTIONS OF THIN AND THICK FILAMENTS

FIGURE 9-4 Structure of the sarcomere.

In striated muscle, **thin filaments**—composed of actin—are 5 to 8 nm in diameter and 1 μm in length. The plus end of the thin filaments attach to opposite faces of a dense disk known as the **Z disk** (see Fig. 9-4B), which is perpendicular to the axis of the myofibril and has the diameter of the myofibril. Cross-linking the antiparallel thin filaments at the Z disk are **α -actinin** proteins. Each α -actinin is a rod-shaped antiparallel homodimer, 35 nm long and belonging to the spectrin family of actin-binding proteins. Two large proteins, titin and nebulin, are also tethered at the Z disks, as are other diverse proteins thought to be involved in stretch sensing and signal communication to the nucleus. Not only do Z disks tether the thin filaments of a single myofibril together, but connections between the Z disks also tether each myofibril to its neighbors and align the Z disks and thus the sarcomeres. In summary, Z disks have an important protein-organizing and tension-bearing role in the sarcomere structure.

The **thick filaments**—composed of myosin—are 10 to 15 nm in diameter and, in striated muscle, 1.6 μm in length (see Fig. 9-4B). They lie between and partially interdigitate with the thin filaments. This partial interdigitation results in alternating light and dark bands along the axis of the myofibril. The light bands, which represent regions of the thin filament that do not overlap with thick filaments, are known as **I bands** because they are *isotropic* to polarized light as demonstrated by polarization microscopy. The Z disk is visible as a dark perpendicular line at the center of the I band. The dark bands, which represent the myosin filaments, are known as **A bands** because they are anisotropic to polarized light. When the A band is viewed in cross section where the thick and thin filaments overlap, six thin filaments (actin) are seen to surround each thick filament (myosin) in a tightly packed hexagonal array (see Fig. 9-4C). During contraction, the I bands (nonoverlapping region of actin) shorten, while the A bands (myosin) do not change in length. This observation led to the idea that an energy-requiring ratcheting mechanism causes the thick and thin filaments to slide past each other—the **sliding filament model** of muscle contraction.

Thin and thick filaments are supramolecular assemblies of protein subunits

Thin Filaments

The backbone of the thin filament is a right-handed, two-stranded helix of noncovalently polymerized **actin** molecules, forming filamentous or F-actin (Fig. 9-5A).  **N9-4** The fundamental unit is a supramolecular helix with a total of 13 molecules in the two strands and a length of ~36 nm. The muscle thin filament is an association of F-actin with two important regulatory actin-binding proteins: tropomyosin and the troponin complex.

F-Actin

Contributed by Ed Moczydlowski

Actin is perhaps the most abundant and highly conserved protein in eukaryotic cells. It is engaged in numerous protein-protein cytoskeletal interactions in the cytoplasm. The 43-kDa, 375-residue, soluble monomer form of actin is called G-actin. Aside from other cellular forms of cytoskeletal actin (see p. 25), there are three human isoforms of α -actin involved in muscle contraction that correspond to separate actin genes expressed in skeletal muscle (*ACTA1*), smooth muscle (*ACTA2*), and cardiac muscle (*ACTC1*). As noted beginning on pages 25–28, binding and hydrolysis of ATP controls polymerization of G-actin into the filamentous form of actin (F-actin) by sequential addition of actin monomers at the plus end of the molecule. Each actin molecule in F-actin interacts with four other actin molecules. The

fundamental unit is a supramolecular helix (a double strand) with a total of 13 molecules in the two strands, and a length of ~36 nm (see Fig. 9-5A).

The **tropomyosin** monomer of striated muscle is an α -helical protein of 284 amino acids, consisting of seven pseudo-repeats of ~40 residues along the length of the molecule. The pseudo-repeats of the monomer determine its linearly coiled shape and define the binding to seven actin monomers along the thin filament. Two tropomyosin monomers form a dimer aligned in parallel and wound about each other in a coiled-coil structure. Two such tropomyosin dimers flank each supramolecular helix of actin (see Fig. 9-5A). Overlapping head-to-tail contacts between two tropomyosin dimers produce two nearly continuous double-helical filaments that shadow the actin double helix. As we describe below, tropomyosin acts as a gatekeeper in regulating the binding of myosin head groups to actin.

Troponin or the **troponin complex** is a heterotrimer consisting of the following:

1. **Troponin T** (TnT or TNNT), which binds to a single molecule of tropomyosin
2. **Troponin C** (TnC or TNNC), which binds Ca^{2+} . Troponin C is closely related to another Ca^{2+} -binding protein, calmodulin (see p. 60).
3. **Troponin I** (TnI or TNNI), which binds to actin and inhibits contraction.

Thus, each troponin heterotrimer interacts with a single tropomyosin molecule, which in turn interacts with seven actin monomers. The troponin complex also interacts directly with the actin filaments. The coordinated interactions of troponin, tropomyosin, and actin allow the binding of actin and myosin to be regulated by changes in $[\text{Ca}^{2+}]_i$.

Thick Filaments

Like actin thin filaments, thick filaments are also an intertwined complex of proteins (see Fig. 9-5B). In fast skeletal muscle, the thick filament is a bipolar superassembly of several hundred **myosin II** molecules, which are part of a larger family of myosins (see p. 25). Myosin II is responsible for ATP-dependent force generation in all types of myocytes. The myosin II molecule is a pair of identical heterotrimers, each composed of a *myosin heavy chain* (MHC), and two myosin light chains (MLCs). One MLC is an *essential light chain* (ELC or MLC-1),  **N9-5** and the other is a *regulatory light chain* (RLC or MLC-2). Both the MHCs and MLCs vary among muscle types (Table 9-1).

[†]In normal adult ventricular muscle, α MHC is the dominant form.

N9-5

Muscle Myosin

Contributed by Ed Moczydlowski

For historical reasons, the parts of the myosin II molecule in muscle often have more than one name.

- **Myosin heavy chains (MHCs)** consist of the following:
 - The N-terminal head
 - A neck or lever (or lever arm) or linker or hinge
 - The C-terminal rod or tail
- **Essential myosin light chains (ELCs or MLC-1)** are also called *alkali chains*.
- **Regulatory myosin light chains (RLCs or MLC-2)**.

A **myosin heavy chain** molecule has ~2000 amino acids in three regions:  **N9-5** an N-terminal head region, a neck, and a C-terminal rod. The α -helical *rod* portions of two MHCs wrap around each other to form a dimer; these dimers self-assemble into thick filaments. At the *neck* regions, the two MHCs of the dimer flare apart, leading to the two globular *heads*. Each MHC head has, at its tip, several loops that bind actin and, at its middle, a nucleotide site for binding and hydrolyzing ATP.

The **essential light chain and regulatory light chain**—both structurally related to the CaM superfamily—bind to and mechanically stabilize the α -helical neck region. The phosphorylation of RLC by **myosin light-chain kinases (MLCKs)**—members of the CaMK family—enhances myosin cross-bridge

interactions. Phosphatases have the opposite effect. In skeletal muscle, this phosphorylation is an important mechanism for force potentiation. **Figure 9-6** illustrates how Ca^{2+} triggers the interaction between a thin filament and a myosin head group from a thick filament.

FIGURE 9-6 Role of Ca^{2+} in triggering the contraction of skeletal and cardiac muscle.

Running alongside the thick filaments of skeletal muscle is a protein named **titin**—the largest known protein, with ~25,000 amino acids (~3 MDa). The linear titin molecule spans one half the length of a

sarcomere, with its N terminus tethered in the Z disk and its C terminus in the **M line** (see Fig. 9-4B). Within the M line are other proteins that cross-link the antiparallel myosin molecules at the middle of the thick filament. Titin—the **elastic filament** of sarcomeres—includes ~300 immunoglobulin-like domains that appear to unfold reversibly upon stretch.

Nebulin is another large protein (600 to 900 kDa) of muscle that runs from the Z disk along the actin thin filaments. Nebulin interacts with actin and controls the length of the thin filament; it also appears to function in sarcomere assembly by contributing to the structural integrity of myofibrils.

During the cross-bridge cycle, contractile proteins convert the energy of ATP hydrolysis into mechanical energy

The fundamental process of skeletal muscle contraction involves a biochemical cycle, called the cross-bridge cycle, that occurs in six steps (Fig. 9-7). We start the cycle in the absence of both ATP and ADP, with the myosin head rigidly attached to an actin filament. In a corpse soon after death, the lack of ATP prevents the cycle from proceeding further; this leads to an extreme example of muscle rigidity—called rigor mortis—that is limited only by protein decomposition.

Step 1: ATP binding. ATP binding to the head of the MHC reduces the affinity of myosin for actin, which causes the myosin head to release from the actin filament. If all cross-bridges in a muscle were in this state, the muscle would be fully relaxed.

Step 2: ATP hydrolysis. The breakdown of ATP to ADP and inorganic phosphate (P_i) occurs on the myosin head; the products of hydrolysis are retained within the myosin active site. As a result of hydrolysis, the myosin head/neck pivots into a “cocked” position in which the head/neck are more colinear with the rod. This pivot causes the tip of the myosin head to move ~11 nm along the actin filament so that it now lines up with a new actin monomer two monomers farther along the actin filament.  **N9-6** If all cross-bridges in a muscle were in this state, the muscle would be fully relaxed.

N9-6

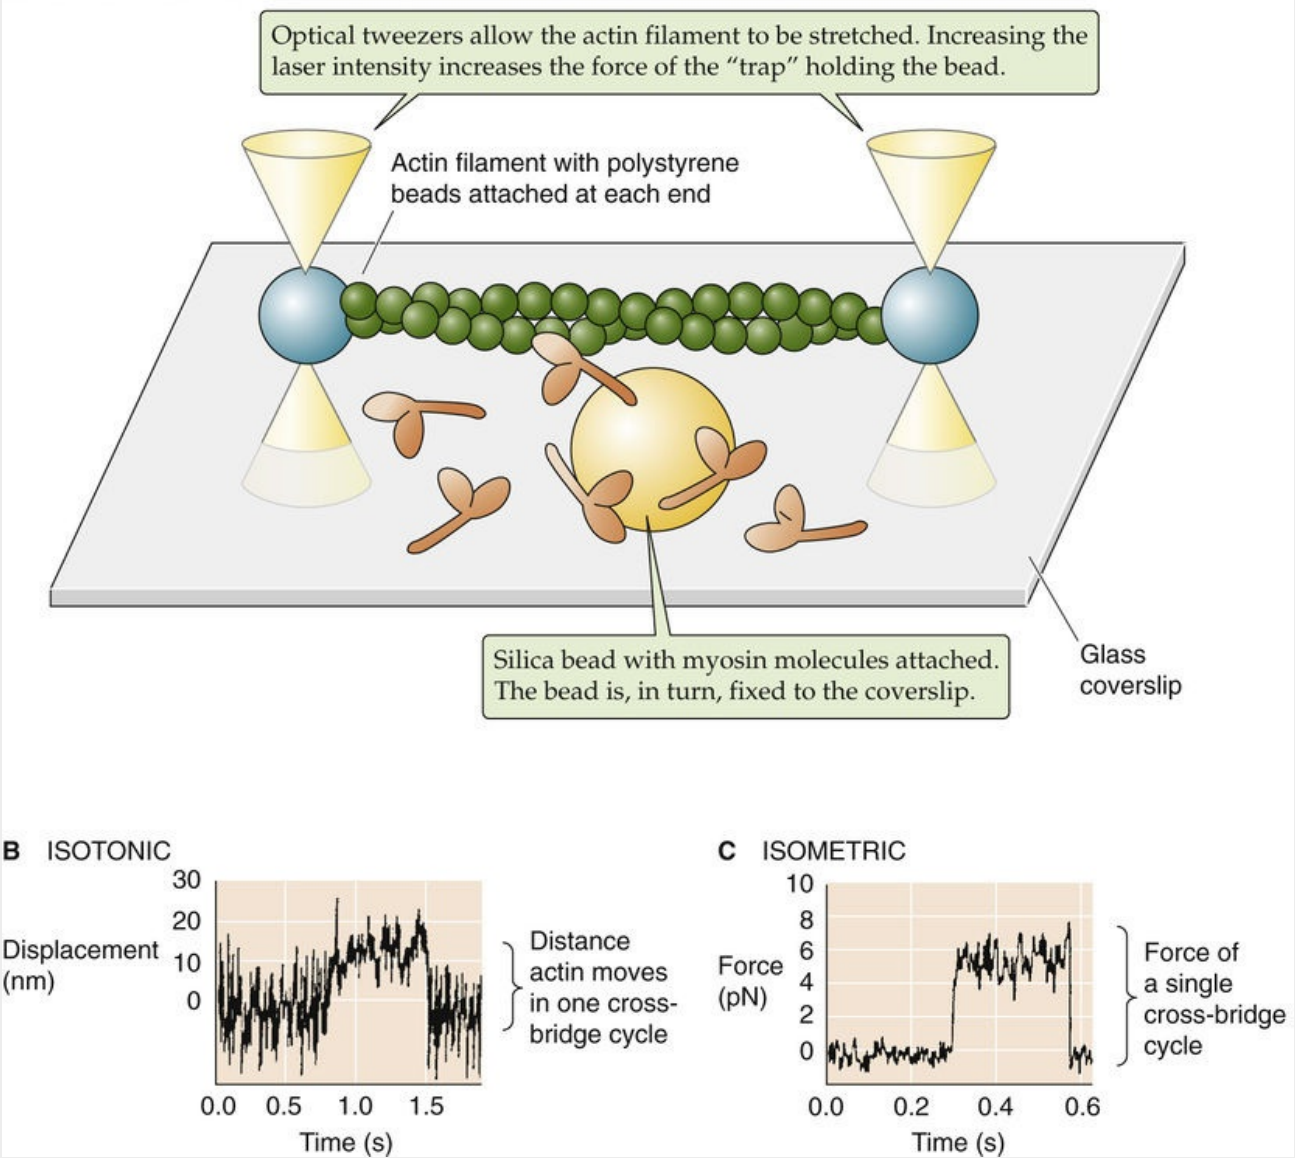

Measuring the Force of a Single Cross-Bridge Cycle

Contributed by Ed Moczydlowski

The force of a single cross-bridge cycle has been measured directly. Finer, Simmons, and Spudich used **optical tweezers** to manipulate a single actin filament and to place it in proximity to a myosin molecule immobilized on a bead (eFig. 9-2A). With the use of video-enhanced microscopy these investigators were able to detect movements of the actin filament as small as 1 nm. The optical tweezers could also exert an adjustable force opposing movement of the actin filament. When the tweezers applied only a small opposing force and the experiment was conducted in the presence of ATP, the researchers observed that the actin moved over the myosin bead in step-like displacements of 11 nm. This observation, made under “microscopically isotonic” conditions, suggests that the quantal displacement of a single cross-bridge cycle is ~11 nm (see eFig. 9-2B). When the tweezers applied a force sufficiently large to immobilize the actin filament, the investigators observed step-like impulses of force that averaged ~5 pN (see eFig. 9-2C). This observation, made under “microscopically isometric” conditions, suggests that the quantal force developed during a single cross-bridge cycle is ~5 pN. Interestingly, these isometric force

impulses lasted longer when the ATP concentration was lower. This last finding is consistent with the notion that ATP binding to myosin must occur to allow detachment of the cross-bridges (step 1 in the cycle in Fig. 9-7).

A EXPERIMENTAL PREPARATION

EFIGURE 9-2 Microscopic measurements of cross-bridge force and displacement. **A**, An actin filament is attached at each end to a polystyrene bead. The optical tweezers, a finely focused beam of laser light, can trap the bead at its focal point and physically move it. By adjusting the laser intensity, the experimenter can alter the strength of the trap (i.e., the force with which the bead is held). In this experiment, two optical tweezers were used to suspend the actin filament above a coverglass. Attached to this coverglass is a silica bead, and myosin molecules are bound to the bead. **B**, In an isotonic experiment, the force between the actin filament and the fixed myosin/silica bead is kept constant by use of a stable laser intensity. The experimenter measures, as a function of time, the displacement of the polystyrene bead away from the center of the trap. Thus, in one cross-bridge cycle, the myosin-actin interaction pulls the polystyrene bead ~11 nm away from the center of the trap. **C**, In an isometric experiment, the experimenter measures, as a function of time, the extra force that needs to be applied (i.e., increase in laser intensity) to keep the polystyrene bead at a fixed position near the center of the trap. Thus, in one cross-bridge cycle, the myosin-actin interaction exerts a force of ~5 pN. (Data from Finer JT, Mehta AD, Spudis JA: Characterization of single actin-myosin interactions. *Biophys J* 68:291s–296s, 1995.)

Step 3: Weak cross-bridge formation. The cocked myosin head now binds loosely to a new position on

the actin filament, scanning for a suitable binding site. Recall that six actin filaments surround each thick filament.

Step 4: Release of P_i from the myosin. Dissociation of P_i from the myosin head triggers an increased affinity of the myosin-ADP complex for actin—the strong cross-bridge state. The transition from weak to strong binding is the rate-limiting step in the cross-bridge cycle.

Step 5: Power stroke. A conformational change causes the myosin neck to rotate around the myosin head, which remains firmly fixed to the actin. This bending pulls the rod of the myosin, drawing the actin and myosin filaments past one another by a distance of ~ 11 nm. The myosin head/neck is now angled with respect to the rod. At the macroscopic level, this activity pulls the Z lines closer together and shortens the sarcomere, with concurrent force generation.

Step 6: ADP release. Dissociation of ADP from myosin completes the cycle, and the actomyosin complex is left in a rigid, “attached state.” The relative positions of the actin versus the myosin head, neck, and rod remain the same until another ATP molecule binds and initiates another cycle (step 1).

FIGURE 9-7 Cross-bridge cycle in skeletal and cardiac muscle. Each cycle advances the myosin head by two actin monomers, or ~11 nm.

The ADP-free myosin complex (“Attached State” in Fig. 9-7) would quickly bind ATP at the concentrations of ATP normally found within cells. Each round of the cross-bridge cycle consumes one molecule of ATP; we discuss the regeneration of ATP in muscle beginning on [pages 1208–1209](#). If unrestrained, this cross-bridge cycling would continue until the cytoplasm is depleted of ATP—rigor mortis.

The biochemical steps of the cross-bridge cycle reveal that $[ATP]_i$ does not regulate the cross-bridge cycle of actin-myosin interaction. In skeletal and cardiac muscle, temporal control of the cycle of contraction occurs at the third step by prevention of cross-bridge formation until the tropomyosin moves

out of the way in response to an increase in $[Ca^{2+}]_i$ —as we will see in the next section.

An increase in $[Ca^{2+}]_i$ triggers contraction by removing the inhibition of cross-bridge cycling

In skeletal, cardiac, and smooth muscle, an increase in $[Ca^{2+}]_i$ initiates and allows cross-bridge cycling to continue. During this excitatory increase, $[Ca^{2+}]_i$ may rise from its resting level of $<10^{-7}$ M to $>10^{-5}$ M. The subsequent decrease in $[Ca^{2+}]_i$ —discussed in the next section—is the signal to cease cross-bridge cycling and relax.

Regardless of the muscle type, Ca^{2+} exerts its effect by binding to *regulatory* proteins rather than directly interacting with contractile proteins. In the absence of Ca^{2+} , these regulatory proteins act in concert to inhibit actin-myosin interactions, thus inhibiting the contractile process. When Ca^{2+} binds to one or more of these proteins, a conformational change takes place in the regulatory complex that releases the inhibition of contraction. In both skeletal and cardiac muscle, the regulatory proteins form the **troponin complex**, which is composed of troponin C, troponin I, and troponin T. The **troponin T (TnT)** binds to tropomyosin, establishing the linkage between the troponin complex and tropomyosin.

In skeletal muscle, the TNNC2 subtype of **troponin C (TnC)** has two pairs of Ca^{2+} -binding sites. Two *high-affinity* sites—located on the C-lobe of TNNC2—are always occupied by Ca^{2+} or Mg^{2+} under physiological conditions. These sites on TNNC2 bind to **troponin I (TnI)**. On the other hand, two *low-affinity* sites—located on the N-lobe of TNNC2—bind and release Ca^{2+} as $[Ca^{2+}]_i$ rises and falls. At low $[Ca^{2+}]_i$, the N-lobe of TnC does not bind to TnI (see Fig. 9-6), which allows the TnI to bind to a particular spot on F-actin and thereby prevent the binding of myosin. At high $[Ca^{2+}]_i$, the N-lobe of TnC can now interact with TnI in such a way as to cause tropomyosin to translocate by 25 degrees on the F-actin surface, which allows the cocked myosin head group to interact weakly with actin (see Fig. 9-7, step 3 of the cross-bridge cycle). As long as $[Ca^{2+}]_i$ remains high and the tropomyosin is out of the way, cross-bridge cycling will continue indefinitely. 🟡N9-7

N9-7

Tropomyosin-Troponin Interactions—the “Functional Group” of the Thin Filament

Contributed by Ed Moczydlowski

As discussed in the text, **troponin** (which consists of troponin T, C, and I) interacts with one **tropomyosin** molecule, which in turn interacts with seven **actin** monomers (see Fig. 9-6). The region along a thin filament that falls under the control of a single troponin molecule is a **functional group**. However, overlap of troponin T onto the junction between two tropomyosin dimers (recall that the tropomyosin molecules stack end to end, with overlap, to create a continuous filament) may allow a single troponin complex to control—via the two tropomyosin dimers—a functional group of 14 or more actin molecules.

In the absence of Ca^{2+} , tropomyosin is bound in a position along the actin filament that blocks its interaction with myosin. When Ca^{2+} binds to the troponin complex, the tropomyosin shifts from its original position along the actin (eFig. 9-3, red area)—the **blocked off-state**—to a new position caused

by an azimuthal rotation of ~ 25 degrees on the F-actin surface (see eFig. 9-3, yellow area)—the **Ca²⁺-activated state**. This displacement enables myosin to bind to actin, which results in another ~ 10 -degree azimuthal movement of tropomyosin (see eFig. 9-3, green area); this shift allows myosin to engage in mechanical activity—the **fully activated state**.

EFIGURE 9-3 Model of the interaction of tropomyosin with actin illustrating the shift in position of tropomyosin from the off, myosin-blocked state (*red*), to the Ca²⁺-activated state (*yellow*), and to the fully activated state (*green*), which allows full interaction of the myosin head group. (Reprinted with permission from Brown JH, Zhou Z, Reshetnikova L, et al: Structure of the mid-region of tropomyosin: Bending and binding sites for actin. *Proc Natl Acad Sci U S A* 102[52]:18878–18883, 2005, Fig 4a. Copyright 2005 National Academy of Sciences, U.S.A.)

Termination of contraction requires re-uptake of Ca²⁺ into the SR

After the action potential in the skeletal muscle has subsided, Ca²⁺ must be removed from the **sarcoplasm** for contraction actually to cease and for relaxation to occur. Removal of Ca²⁺ from the sarcoplasm occurs by two mechanisms. Ca²⁺ may be extruded across the cell plasma membrane or sequestered within intracellular compartments ([Fig. 9-8](#)).

FIGURE 9-8 Mechanisms of Ca^{2+} removal from the cytoplasm.

The cell may extrude Ca^{2+} by use of either an **NCX** (Na-Ca exchanger, SLC8 family; see [p. 123](#)) or **PMCA** (plasma membrane Ca-ATPase or pump; see [p. 118](#)). Extrusion across the cell membrane, however, would eventually totally deplete the cell of Ca^{2+} and is therefore a minor mechanism for Ca^{2+} removal from the cytoplasm. Instead, Ca^{2+} re-uptake into the SR is the most important mechanism by which the cell returns $[\text{Ca}^{2+}]_i$ to resting levels. Ca^{2+} re-uptake by the SR is mediated by a **SERCA** (sarcoplasmic and endoplasmic reticulum Ca-ATPase or pump; see [p. 118](#)). [N9-8](#)

N9-8

SERCA Isoforms

Contributed by Emile Boulpaep, Walter Boron

SERCA is an acronym for sarcoplasmic and endoplasmic reticulum Ca-ATPase. The energy for **Ca** pumping comes from the hydrolysis of ATP. As discussed on page 126 in the text (also see [N5-10](#)), the Ca^{2+} -transporting protein is an $\text{E}_1\text{-E}_2$ (or P-type) ATPase that has a molecular weight of 110 kDa. Three different SERCA isoforms are known.

All of the SERCA isoforms (SERCA1, SERCA2, and SERCA3) are Ca-H exchange pumps. The

SERCA2 isoform may be expressed as two alternatively spliced variants. The SERCA1 isoform is expressed in fast-twitch skeletal muscle, which is a subtype of skeletal muscle fibers that contract rapidly (see Table 9-1). The SERCA2a isoform is found in slow-twitch skeletal muscle as well as cardiac and smooth muscle. The SERCA2b isoform is found in smooth-muscle cells; it is also heavily expressed in the ER of nonmuscle cells. Table 9-1 summarizes the distribution of the SERCA isoforms among muscle types.

Note that all of the SR Ca pumps (i.e., SERCAs) are distinct from the Ca pumps in the plasma membrane, which are known as PMCAs (see p. 126).

High $[Ca^{2+}]$ within the SR lumen inhibits the activity of SERCA, an effect attenuated by Ca^{2+} -binding proteins within the SR lumen. These Ca^{2+} -binding proteins buffer the $[Ca^{2+}]$ increase in the SR during Ca^{2+} re-uptake and thus markedly increase the Ca^{2+} storage capacity of the SR. The principal Ca^{2+} -binding protein in skeletal muscle, **calsequestrin (CSQ)**, is also present in cardiac and some smooth muscle. **Calreticulin** is a ubiquitous Ca^{2+} -binding protein that is found in particularly high concentrations within the SR of smooth muscle. These proteins have a tremendous capacity to bind Ca^{2+} , with up to 50 binding sites per protein molecule.

CSQ forms oligomers in the SR lumen and is highly localized to the region of the SR immediately beneath the triad junction, where it forms a complex with the Ca^{2+} -release channel and with two other RYR-anchoring proteins—junctin and triadin—and senses free $[Ca^{2+}]$ inside the SR. During high action potential frequency, SR Ca^{2+} content falls, and dissociation of Ca^{2+} from CSQ leads to deactivation of RYR, thereby preserving SR Ca^{2+} ([Box 9-2](#)).

Box 9-2

Malignant Hyperthermia and Central Core Disease—RYR Channelopathies

Malignant hyperthermia (MH) affects between 1 in 15,000 children and 1 in 50,000 adults undergoing anesthesia. It is a genetic disorder that may affect as many as 1 in 2000 to 3000 individuals in the general population. Affected individuals are at risk of a potentially life-threatening syndrome on exposure to particular inhalation anesthetic agents, especially halothane, sevoflurane, and desflurane. Administration of the muscle relaxant succinylcholine (see pp. 225–226) can also trigger or exaggerate MH. Onset of MH syndrome in the setting of the operating room is typified by the development of tachypnea (rapid breathing), low plasma $[O_2]$, high plasma $[CO_2]$, tachycardia (rapid heart rate), and *hyperthermia* (rising body temperature) as well as by rigidity, sweating, and dramatic swings in blood pressure. The patient's temperature may rise as rapidly as $1^\circ C$ every 5 minutes. The onset of MH is usually during anesthesia, but it can occur up to several hours later. If the condition is untreated, the patient will develop respiratory and lactic acidosis, muscle rigidity, and a breakdown of muscle tissue that leads to the release of K^+ and thus profound hyperkalemia. These episodes reflect a progressively severe hypermetabolic state in the muscle tissues. Fortunately, our evolving understanding of the pathophysiology of MH has led to the development of a therapeutic regimen that has greatly improved the once-dismal prognosis.

The major features of the syndrome—hyperthermia, muscle rigidity, and an increased metabolic rate—led early investigators to suggest that MH is a disease of abnormal regulation of muscle contraction. We now understand that uncontrolled Ca^{2+} release—somehow triggered by the administration of halothane and succinylcholine—causes excessive contraction and ATP hydrolysis. As muscle tries to replenish its

ATP stores, mitochondrial oxidative metabolism increases. Hyperthermia develops because of the heat liberated by these metabolic processes.

The incidence of MH is particularly high in swine, in which episodes are triggered by a variety of physical and environmental stresses (porcine stress syndrome). MH in animals has significant economic importance in view of the potential loss from fatal episodes and the devaluation of meat as a result of muscle destruction during nonfatal episodes.

When exposed to halothane, muscle biopsy samples from susceptible individuals develop more tension than fibers from normal individuals. In muscle fibers from both humans and a strain of swine susceptible to MH, Ca^{2+} -induced Ca^{2+} release from the SR is enhanced compared with that in fibers from unaffected subjects. Furthermore, caffeine, which causes the Ca^{2+} -release channels to open, induced greater contractions in fibers from susceptible subjects. Taken together, these observations suggested that MH results from an abnormality in the Ca^{2+} -release channel in the SR membrane.

In both humans and animals, inheritance of MH follows a mendelian autosomal dominant pattern. Approximately 200 mutations in the human RYR1 have been linked to MH and central core disease (discussed below). The mutations tend to cluster in three “hot spots” of the channel protein: the N-terminal, central, and C-terminal regions. Some of these mutations increase the sensitivity of the RYR1 to activation by halothane and caffeine. They may also act by a “gain-of-function” effect that promotes the constitutive leakage of Ca^{2+} from the SR. In swine, MH results from a single amino-acid substitution in RYR1 (cysteine for arginine at position 615), the skeletal muscle isoform. The analogous R614C substitution is present in some human kindreds as well. This substitution increases the open probability of the Ca^{2+} -release channel.

Therapy for MH involves intravenous administration of the drug dantrolene, cessation of anesthesia, and aggressive efforts aimed at cooling the body. **Dantrolene** is an effective therapeutic agent because it blocks RYR1, thus interrupting the otherwise uncontrolled release of SR Ca^{2+} and progression of muscle contractions. The drug can be given acutely in an effort to abort an ongoing attack or, in a person known to be at risk, it can be given before the initiation of anesthesia to prevent onset of the syndrome. Dantrolene treatment has decreased mortality due to MH from 80% to <10% today. Therapy also includes intravenous hydration and the judicious use of diuretics to keep the urine flowing; this lessens damage to the kidneys from the release of breakdown products, such as myoglobin from the damaged muscles. Sodium bicarbonate is given to counter the lactic acidosis, and patients may be mechanically hyperventilated to blow off the excess CO_2 . For patients known to be at risk of MH, alternative forms of pain suppression that can be safely used for necessary surgical procedures include nitrous oxide, propofol, opiates, and benzodiazepines. Local anesthetics such as lidocaine are also safe.

Despite the intensive protocol just outlined, MH is still regarded as an emergency in the operating room. The relatives of a patient with a documented history of one episode of MH should be carefully screened to see whether they, too, carry the inherited trait; many of the affected relatives may demonstrate baseline elevations in muscle enzyme levels in their blood (e.g., an increase in creatine kinase levels).

As noted above, mutations in RYR1 have also been linked to **central core disease (CCD)**, also called central core myopathy. CCD is a congenital autosomal dominant genetic condition defined by the histopathological appearance of so-called core regions within skeletal muscle cells that are devoid of mitochondria and are inactive with respect to oxidative metabolism. Symptoms of CCD include muscle weakness in young patients and skeletal abnormalities. Some CCD patients are also susceptible to MH.

Muscle contractions produce force under isometric

conditions and force with shortening under isotonic conditions

The total force generated by a muscle is the sum of the forces generated by many independently cycling actin-myosin cross-bridges. The number of simultaneously cycling cross-bridges depends substantially on the initial length of the muscle fiber and on the pattern or frequency of muscle cell stimulation. When muscle is stimulated to contract, it exerts a force tending to pull the attachment points at either end toward each other. This force is referred to as the **tension** developed by the muscle.

Two mechanical—and artificial—arrangements can be used to study force and length relationships in muscle contraction. In one, the attachment points are immobile, so that the muscle *length* is fixed. Here, stimulation causes an increase in tension, but no shortening. Because these contractions occur at constant length, they are referred to as **isometric contractions** (Fig. 9-9A). In the second arrangement, one of the two attachment points is mobile and tethered to a variable load, which tends to pull this mobile point away from the fixed one. Here, stimulation causes shortening, provided the tension developed by the muscle is greater than the opposing load. Because these shortenings occur at constant load, they are referred to as **isotonic contractions** (see Fig. 9-9B). 🟡N9-6 Both isometric and isotonic contractions can be examined at different initial muscle lengths. Moreover, they can be measured during individual muscle twitches evoked by single muscle action potentials as well as during other patterns of stimulation. Physical activity involves various combinations of isometric and isotonic contractions.

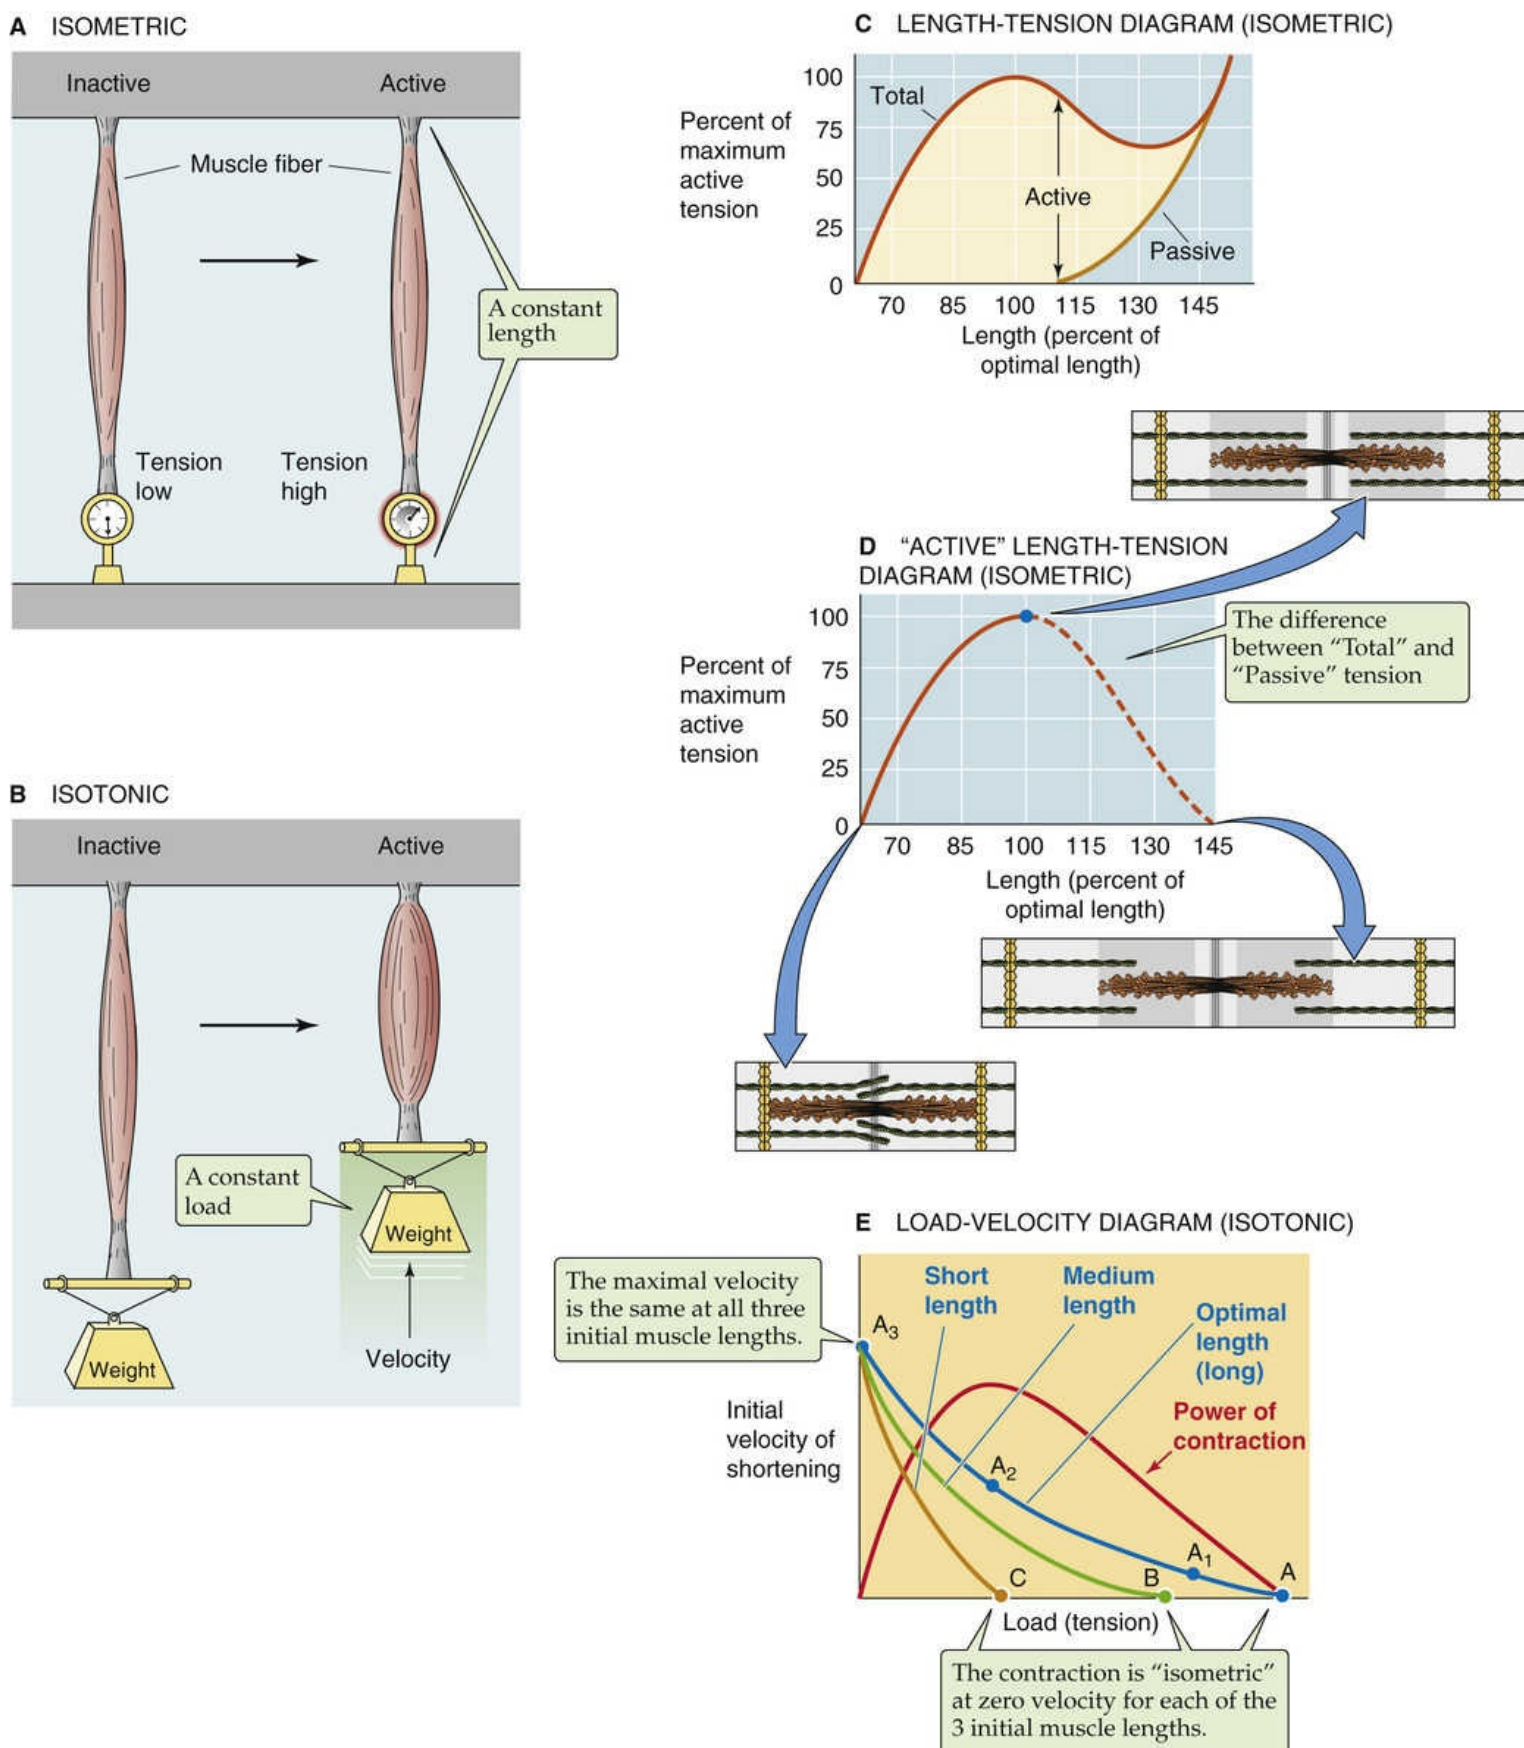

FIGURE 9-9 Isometric and isotonic contraction. **A**, Experimental preparation for study of muscle contraction under *isometric* conditions. **B**, Experimental preparation for study of muscle contraction under *isotonic* conditions. **C**, The "Passive" curve represents the tension that is measured at various muscle lengths before muscle contraction. The "Total" curve represents the tension that is measured at various muscle lengths during muscle contraction. Muscle length is expressed as the percent of "optimal" length; that is, the length at which active isometric tension is maximal. **D**, The active tension is the difference between the total and the passive tensions in **C**. **E**, Points A, A₁, A₂, and A₃ on the blue curve show that the velocity of muscle shortening is greater if the muscle lifts a lighter weight—it is easier to lift a feather (left side of each curve/low load) than to lift a barbell (right side of each curve/high load). The blue, green, and gold curves also show that for any given velocity of shortening, a longer muscle can develop a greater

Muscle length influences tension development by determining the degree of overlap between actin and myosin filaments

The *isometric* force of contractions depends on the initial length of the muscle fiber. Unstimulated muscle may be elongated somewhat by applying tension and stretching it. The tension measured before muscle contraction is referred to as **passive tension** (see Fig. 9-9C). Because muscle gets stiffer as it is distended, it takes increasing amounts of passive tension to progressively elongate the muscle cell. If at any fixed length (i.e., isometric conditions) the muscle is stimulated to contract, an additional **active tension** develops because of cross-bridge cycling. The total measured tension is thus the sum of the passive and active tension. This incremental or *active* tension—the difference between total tension and passive tension—is quite small when the muscle is less than ~70% of its normal resting length (see Fig. 9-9D). As muscle length increases toward its normal length, active tension increases. Active tension is maximal at an **optimal length** (blue point in Fig. 9-9D)—usually called L_0 —that is near the normal muscle length. Active tension decreases with further lengthening; thus, active tension is again small when the muscle is stretched beyond 150% of its normal resting length. Although the relationship between muscle length and tension has been best characterized for skeletal muscle, the tension of cardiac and smooth muscle also appears to depend on length in a similar manner.

This length-tension relationship is a direct result of the anatomy of the thick and thin filaments within individual sarcomeres (see Fig. 9-9D). As muscle length increases, the ends of the actin filaments arising from neighboring Z disks are pulled away from each other. When length is increased beyond 150% of the resting sarcomere length, the ends of the actin filaments are pulled beyond the ends of the myosin filaments. Under this condition, no interaction occurs between actin and myosin filaments and hence no active tension develops. As muscle length shortens from this point, actin and myosin filaments begin to overlap and tension can develop; the amount of tension developed corresponds to the degree of overlap between the actin and the myosin filaments. As the muscle shortens further, opposing actin filaments slide over one another and the ends of the myosin filaments and—with extreme degrees of shortening—eventually butt up against the opposing Z disks. Under these conditions, the spatial relationship between actin and myosin is distorted and active tension falls. The maximal degree of overlap between actin and myosin filaments, and hence maximal active tension, corresponds to a sarcomere length that is near its normal resting length.

At higher loads, the velocity of shortening is lower because more cross-bridges are simultaneously active

Under *isotonic* conditions, the velocity of shortening decreases as the applied load opposing contraction of the muscle fiber increases. This point is obvious; anyone can lift a single French fry much faster than a sack of potatoes. As shown for any of the three downward-sloping curves in Figure 9-9E—each of which represents a different initial length of muscle—there is an inverse relationship between velocity and load. Note that for isotonic contractions, the applied load is the same as the tension in the muscle.

The load (or tension)–velocity relationship is perhaps best understood by first considering the condition at points A, B, and C in Figure 9-9E, where—for each muscle length—we choose a different load that is just adequate to prevent shortening or lengthening (i.e., *isometric* conditions). Point A

represents the optimal length for supporting the largest isometric tension (represented by the blue point in Fig. 9-9D). Here, all available cross-bridges are engaged in resisting the opposing force, and none is left over to make the muscle shorten. If we could somehow decrease the number of engaged cross-bridges, the muscle would lengthen. On the other hand, starting at point A, if we decrease the load at the same initial muscle length, the number of cross-bridges already engaged is now more than needed to resist the opposing load. The extra cross-bridges are available to ratchet the thick myosin filaments over the thin actin filaments, but at a very low initial velocity (point A₁). Returning to the isometric condition at point A, if we were to reduce the lower load even more, then even more cross-bridges would be available for ratcheting the myosin over the actin, and the initial velocity would be even higher (point A₂). Again returning to the isometric condition at point A, if we make the load vanishingly small, the initial velocity is very high because the speed with which the thick and thin filaments slide over each other is limited only by the speed at which the cross-bridges can cycle. Viewed from a different perspective, as we increase velocity, the probability of actin-myosin interactions decreases, fewer cross-bridges are simultaneously active, and less tension develops.

Recall that the blue curve in Figure 9-9E applies to a single initial length of the muscle, that is, the *optimal length*. We already saw in Figure 9-9D that, starting at the optimal length, reducing initial muscle length causes isometric tension to fall. The points A, B, and C in Figure 9-9E restate this relationship: the shorter the initial length, the smaller the maximal load under zero-velocity conditions. As we decrease the load, starting from point B (green curve) or point C (brown curve), the initial velocity of shortening rises, as we saw for the blue curve. Note that all three curves extrapolate to the same initial maximal velocity at zero load. The explanation for this effect, as already noted, is that maximal velocity (at no load) depends on the maximal rate of cross-bridge turnover, not on the initial overlap of the thin and thick filaments.

The velocity-tension curve reveals an interesting relationship between muscle power and applied load. Muscle does measurable mechanical work only when it displaces a load. This mechanical **work (W)** is the product of load (*F*) and displacement (Δx). **Power (P)** is the rate at which work is performed, or work per unit time (Δt):

$$P = \frac{W}{\Delta t} = \frac{F \cdot \Delta x}{\Delta t}$$

(9-1)

Because velocity (*v*) is $\Delta x / \Delta t$, it follows that

$$P = F \cdot v$$

(9-2)

For a given load (*F*), we can calculate the power by reading the velocity (*v*) from the uppermost of the three blue load-velocity relationships in Figure 9-9E. Power is maximal at intermediate loads (where both *F* and *v* are moderate) and falls to zero at maximum load (where *v* = 0) and at zero load (where *F* = 0).

In a single skeletal muscle fiber, the force developed may be

increased by summing multiple twitches in time

At sufficiently low stimulation frequencies, the tension developed falls to the resting level between individual twitches (Fig. 9-10A). Single skeletal muscle twitches last between 25 and 200 ms, depending on the type of muscle. Although each twitch is elicited by a single muscle action potential, the duration of contraction is long compared with the duration of the exciting action potential, which lasts only several milliseconds. Because the muscle twitch far exceeds the duration of the action potential, it is possible to initiate a second action potential before a first contraction has fully subsided. When this situation occurs, the second action potential stimulates a twitch that is superimposed on the residual tension of the first twitch and thereby achieves greater isometric tension than the first (compare Fig. 9-10A and 9-10B). This effect is known as summation.

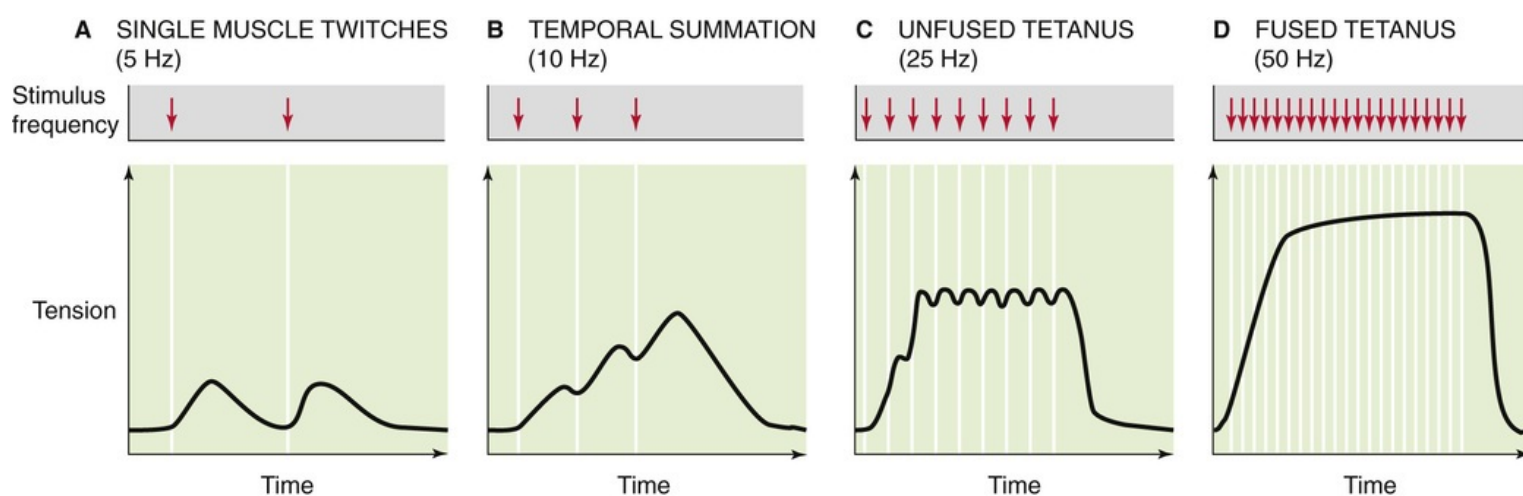

FIGURE 9-10 Frequency summation of skeletal muscle twitches.

If multiple action potentials occur close enough in time, the multiple twitches can summate and thus greatly increase the tension developed. Summation is more effective at increasing tension when the action potentials are grouped more closely in time, as in Figure 9-10C. In other words, tension is higher when action potentials are evoked at higher frequency. Because this type of tension enhancement depends on the frequency of muscle stimulation, it is referred to as **frequency summation**.

When the stimulation frequency is increased sufficiently, the individual twitches occur so close together in time that they fuse (see Fig. 9-10D) and cause the muscle tension to remain at a steady plateau. The state in which the individual twitches are no longer distinguishable from each other is referred to as **tetanus**. Tetanus arises when the time between successive action potentials is insufficient to return enough Ca^{2+} to the SR to lower $[\text{Ca}^{2+}]_i$ below a level that initiates relaxation. In fact, a sustained increase in $[\text{Ca}^{2+}]_i$ persists until the tetanic stimulus ceases. At stimulation frequencies above the **fusion frequency** that causes tetanus, muscle fiber tension increases very little.

In a whole skeletal muscle, the force developed may be increased by summing the contractions of multiple fibers

In addition to determining the frequency with which it stimulates a single muscle fiber, the CNS can control muscle force by determining the number of individual muscle fibers that it stimulates at a given time. As each additional motor-neuron cell body within the spinal cord is excited, those muscle fibers that

are part of the *motor unit* of that motor neuron are added to the contracting pool of fibers ([Fig. 9-11](#)). This effect is known as **multiple-fiber summation**. In general, smaller motor neurons serve motor units consisting of fewer individual muscle fibers. Because a given excitatory stimulus will generate a larger excitatory postsynaptic potential (see [p. 210](#)) in motor neurons with smaller cell bodies, the small motor units are recruited even with minimal neuronal stimulation. As neuronal stimulation intensifies, larger motor neurons innervating larger motor units are also recruited. The progressive recruitment of first small and then larger and larger motor units is referred to as the **size principle** (see [pp. 1204–1205](#)). The group of all motor neurons innervating a single muscle is called a **motor-neuron pool**.

FIGURE 9-11 The motor unit and the motor-neuron pool.

Multiple-fiber summation, sometimes referred to as **spatial summation**, is an important mechanism that allows the force developed by a whole muscle to be relatively constant in time. It is true that the CNS could direct the force to be relatively constant over time merely by driving a fixed number of motor units within the muscle to tetanus, where the force fluctuations are very small (see [Fig. 9-10D](#)). However, adding tetanic motor units would increase total muscle force by rather large individual increments. Instead, the CNS can activate individual motor units asynchronously so that some units are developing

tension while others are relaxing. Thus, whole-muscle force can be relatively constant with time, even when individual fibers are not stimulated to tetanus. Smooth, nontetanic contraction is essential for fine motor control.

Cardiac Muscle

Action potentials propagate between adjacent cardiac myocytes through gap junctions

Cardiac muscle and its individual myocytes have a morphological character different from that of skeletal muscle and its cells (Fig. 9-12). Cardiac myocytes are shorter, branched, and interconnected from end to end by structures called **intercalated disks**, visible as dark lines in the light microscope. The intercalated disks connecting the ends of adjoining cardiac myocytes contain **desmosomes** (see p. 45) that link adjacent cells mechanically and **gap junctions** (see pp. 158–159) that link cells electrically. Cardiac muscle thus acts as a mechanical and electrical syncytium of coupled cells, unlike skeletal muscle fibers, which are separate cells bundled together by connective tissue. Like skeletal muscle, cardiac muscle is striated (see pp. 232–233) and its sarcomeres contain similar arrays of thin and thick filaments.

FIGURE 9-12 Electrical coupling of cardiac myocytes.

Contraction of cardiac muscle cells is not initiated by neurons as in skeletal muscle but by electrical excitation originating from the heart's own **pacemaker**, the sinoatrial node. When an action potential is initiated in one cell, current flows through the gap junctions and depolarizes neighboring cells, producing self-propagating action potentials. Beginning on [page 483](#), we will consider cardiac electrophysiology in depth.

Cardiac myocytes receive synaptic input from autonomic neurons, but the sympathetic and parasympathetic divisions of the autonomic nervous system (see [Chapter 14](#)) use these synapses to *modulate* rather than to *initiate* electrical activity and contractile force of cardiac muscle.

Cardiac contraction requires Ca^{2+} entry through L-type Ca^{2+} channels

Whereas EC coupling in skeletal muscle does not require Ca^{2+} influx through L-type Ca^{2+} channels (see [pp. 190–193](#)), cardiac contraction has an *absolute requirement* for Ca^{2+} influx through these channels during the action potential. Cardiac myocytes have a T-tubule network similar to that of skeletal muscle myofibers except that a single terminal cisterna of the SR forms a **dyad junction** with the T-tubule rather than a triad junction. Furthermore, T-tubules of cardiac myocytes are located at the Z lines separating sarcomeres rather than at the A-I band junctions. Because the T-tubule lumen is an extension of the extracellular space, it facilitates the diffusion of Ca^{2+} from bulk extracellular fluid to the site of the L-type Ca^{2+} channels on the T-tubule membrane. Thus, the extracellular Ca^{2+} can simultaneously reach superficial and deep regions of the muscle. The increase in $[\text{Ca}^{2+}]_i$ resulting from Ca^{2+} influx through the L-type Ca^{2+} channels alone is not, however, sufficient to initiate contraction. Rather, this increase in $[\text{Ca}^{2+}]_i$ leads to an opening of the RYR Ca^{2+} -release channels in the SR membrane. The resulting release of Ca^{2+} from the SR amplifies the rise in $[\text{Ca}^{2+}]_i$ by a process known as **Ca^{2+} -induced Ca^{2+} release (CICR)**. Indeed, because the Ca^{2+} -release channels remain open for a longer period than do L-type Ca^{2+} channels, the contribution of CICR to the rise in $[\text{Ca}^{2+}]_i$ is greater than the flux contributed by the L-type Ca^{2+} channels of the T tubules. As noted above for skeletal muscle, single Ca^{2+} -release events from local clusters of RYR1 channels—known as **Ca^{2+} sparks**—are the unitary events underlying EC coupling in cardiac muscle. 🔥
N9-3 Summation of Ca^{2+} spark/CICR events, initially activated by membrane depolarization, results in a wave of increased $[\text{Ca}^{2+}]_i$ along the cell. 🔥**N9-9**

N9-9

Propagation of the $[\text{Ca}^{2+}]_i$ Wave in Cardiac Muscle

Contributed by Ed Moczydlowski

Although Ca^{2+} diffuses in the cytosol away from its SR release site, Ca^{2+} release at one site does not appear to be able to induce Ca^{2+} release from a neighboring SR Ca^{2+} -release channel. Thus, Ca^{2+} release events are not propagated along the myocyte. In fact, the SR Ca^{2+} -release channel does not appear to respond to generalized increases in cytoplasmic $[\text{Ca}^{2+}]_i$. Generalized cardiac muscle contractions occur as a result of the spatial and temporal summation of individual CICR events.

Beginning on [page 522](#), we consider cardiac EC coupling in depth.

Cross-bridge cycling and termination of cardiac muscle contraction are similar to the events in skeletal muscle

Cardiac muscle is similar to skeletal muscle in the interaction of the actin and myosin during cross-bridge cycling, the resynthesis of ATP, and the termination of contraction. However, there are a few important differences. For example, the regulatory protein **troponin C** (see [Fig. 9-6](#)) of cardiac muscle (TNNC1) binds three Ca^{2+} ions per molecule versus the four for TNNC2 in skeletal muscle (see [p. 237](#)). More importantly, in cardiac muscle, SR Ca-pump activity is inhibited by the regulatory protein **phospholamban (PLN)**. When PLN is phosphorylated by cAMP-dependent PKA, its ability to inhibit the SR Ca pump is lost. Thus, activators of PKA, such as the neurotransmitter epinephrine, may enhance the rate of cardiac myocyte relaxation. Beginning on [page 522](#), we consider cardiac contraction and relaxation in depth.

In cardiac muscle, increasing the entry of Ca^{2+} enhances the contractile force

Whereas frequency summation and multiple-fiber summation are important mechanisms for regulating the strength of skeletal muscle contractions, these mechanisms would not be consistent with the physiological demands of cardiac muscle. Because cardiac muscle must contract only once with each heartbeat and must fully relax between each contraction, frequency summation is precluded. Furthermore, the extensive electrical coupling between cardiac myocytes, as well as the requirement that cardiac muscle contract homogeneously, eliminates the potential for multiple-fiber summation. Therefore, the strength of cardiac muscle contraction must be regulated by modulating the contractile force generated during each individual muscle twitch. This type of regulation is an important part of the adaptive response to exercise and is mediated by norepinephrine, a neurotransmitter released by the sympathetic nervous system.

The contractile function in cardiac muscle is regulated either by modulating the magnitude of the rise in $[\text{Ca}^{2+}]_i$ or by altering the Ca^{2+} sensitivity of the regulatory proteins. Beginning on [page 539](#) (see [Tables 23-1](#) and [23-2](#)), we discuss the modulation of these events by the autonomic nervous system (see [Chapter 14](#)).

Smooth Muscle

Smooth muscles may contract in response to synaptic transmission or electrical coupling

Like skeletal muscle, smooth muscle receives synaptic input. However, the synaptic input to smooth muscle differs from that of skeletal muscle in two ways. First, the neurons are part of the autonomic nervous system rather than the somatic nervous system (see [Chapter 14](#)). Second, the neuron makes multiple synaptic contacts with a smooth-muscle cell in the form of a series of swellings called **varicosities** (see [pp. 340–341](#)) that contain the presynaptic machinery for vesicular release of transmitter. Each varicosity is close to the postsynaptic membrane of the smooth-muscle cell, but there is relatively little specialization of the postsynaptic membrane.

The mechanisms of intercellular communication between smooth-muscle cells vary more widely among tissues. There are two basic types of smooth-muscle tissues known as multiunit and single-unit smooth muscle. In **multiunit smooth muscle**, each smooth-muscle cell receives synaptic input but there is little intercellular electrical coupling between cells (i.e., few gap junctions). As a result, each smooth-muscle cell may contract independently of its neighbor. Thus, the term *multiunit* describes smooth muscle that behaves like multiple, independent cells or groups of cells ([Fig. 9-13A](#)). Multiunit smooth muscles are capable of fine control. Indeed, multiunit smooth muscle is found in the iris and ciliary body of the eye as well as the piloerector muscles of the skin.

FIGURE 9-13 Smooth-muscle organization. **A**, Multiunit. Each smooth-muscle cell receives its own synaptic input. **B**, Unitary. Only a few of the smooth-muscle cells receive direct synaptic input.

Unitary or single-unit smooth muscle (see [Fig. 9-13B](#)) is a group of cells that work as a syncytium because gap junctions provide electrical and chemical communication between neighboring cells. Direct electrical coupling allows coordinated contraction of many cells. Gap junctions also allow ions and small molecules to diffuse between cells, which gives rise to phenomena such as spreading Ca^{2+} waves among coupled cells. Unitary smooth muscle is the predominant smooth-muscle type within the walls of visceral

organs such as the gastrointestinal and urinary tracts, the uterus, and many blood vessels. In certain organs, adjacent smooth-muscle cells are physically connected by adhering junctions that provide mechanical stability to the tissue. Thus, unitary smooth muscle is often referred to as **visceral smooth muscle**. The functional size of the unit depends on the strength of intercellular coupling. For example, in the bladder, extensive coupling among cells defines large functional units, which allows the cells of the muscular wall of the bladder to contract in synchrony. On the other hand, the smooth-muscle cells of blood vessels couple to form smaller, independently functioning units that are more akin to multiunit smooth muscle. In fact, electrical coupling of smooth-muscle units exhibits a tissue-specific continuum from multiunit to unitary coupling.

Action potentials of smooth muscles may be brief or prolonged

Although action potentials initiate contraction in both skeletal and cardiac muscle, diverse changes in membrane potential (V_m) can either initiate or modulate contraction in smooth-muscle cells. Action potentials that are similar to those seen in skeletal muscle are observed in unitary smooth muscle and in some multiunit muscles. Like cardiac muscle cells, some smooth-muscle cells exhibit prolonged action potentials that are characterized by a prominent plateau phase. Still other smooth-muscle cells cannot generate action potentials at all. In these cells, V_m changes in a graded fashion (see pp. 174–176) rather than in the all-or-none manner of action potentials. The stimuli that produce a **graded response** of V_m include many circulating and local humoral factors as well as mechanical stimuli such as stretching of the cell. These graded V_m changes may be either hyperpolarizing or depolarizing; they sum temporally as well as spatially. If the summation of graded depolarizations brings V_m above threshold, action potentials will fire in electrically excitable smooth-muscle cells.

Action potentials—characteristic responses of unitary (visceral) smooth muscle—typically have a slower upstroke and longer duration (up to ~100 ms) than do skeletal muscle action potentials (~2 ms). The action potential in a smooth-muscle cell can be a simple spike, a spike followed by a plateau, or a series of spikes on top of slow waves of V_m (Fig. 9-14A). In any case, the depolarizing phase of the action potential reflects opening of L-type voltage-gated Ca^{2+} channels. The initial inward Ca^{2+} current further depolarizes the cell and thereby causes still more voltage-gated Ca^{2+} channels to open in positive-feedback fashion. Thus, some smooth-muscle cells exhibit the same type of regenerative all-or-none depolarization that is seen in skeletal muscle. However, the rate of rise of the action potential in smooth muscle is typically slower because Ca_v channels (see pp. 190–193) open more slowly than do Na_v channels (see pp. 187–189) of skeletal and cardiac muscle. Repolarization of the smooth-muscle cell is also relatively slow because L-type Ca_v Ca^{2+} channels exhibit prolonged openings and inactivate slowly. In addition, the slow repolarization reflects the delayed activation of voltage-gated K^+ channels and, in many cases, Ca^{2+} -activated K^+ channels, which depend on significant elevation of $[\text{Ca}^{2+}]_i$.

A TYPES OF SMOOTH-MUSCLE ACTION POTENTIALS

B GENERATION OF SLOW WAVES

FIGURE 9-14 Action potentials and slow waves in smooth muscle.

Some smooth-muscle cells also express fast voltage-gated Na^{+} channels. However, these channels do not appear to be necessary for generating an action potential but rather contribute to a greater rate of depolarization and thus the activation of voltage-gated Ca^{2+} channels.

In some types of unitary smooth muscle, repolarization is so delayed that the action potential waveform displays a prominent plateau lasting several hundred milliseconds—as in cardiac muscle. Plateau action

potentials occur in smooth muscle of the genitourinary tract, including the ureters, bladder, and uterus. The long plateau allows prolonged entry of Ca^{2+} , thereby elevating $[\text{Ca}^{2+}]_i$ and prolonging the contraction.

Some smooth-muscle cells spontaneously generate either pacemaker currents or slow waves

Although smooth-muscle cells undergo changes in V_m in response to neural, hormonal, or mechanical stimulation, many smooth-muscle cells are capable of initiating spontaneous electrical activity. In some tissues, this spontaneous activity results from **pacemaker currents**. In the intestine for example, special pacemaker cells called **interstitial cells of Cajal** initiate and control rhythmic contractions of the smooth-muscle layers. Pacemaker electrical activity arises from time- and voltage-dependent properties of ion channels that spontaneously produce either an increase in inward depolarizing currents (e.g., voltage-gated Ca^{2+} currents) or a decrease in outward hyperpolarizing currents (e.g., voltage-gated K^+ currents). If V_m reaches threshold, an action potential fires.

In other smooth-muscle cells, this spontaneous electrical activity results in regular, repetitive oscillations in V_m —and contractions—that occur at a frequency of several cycles per minute. These are referred to as **slow waves** (see [Fig. 9-14B](#)). One hypothesis regarding the origin of slow-wave potentials suggests that voltage-gated Ca^{2+} channels—active at the resting V_m —depolarize the cell enough to activate more voltage-gated Ca^{2+} channels. This activation results in progressive depolarization and Ca^{2+} influx. The increase in $[\text{Ca}^{2+}]_i$ activates Ca^{2+} -dependent K^+ channels, which leads to progressive hyperpolarization and eventual termination of the depolarization. These periodic depolarizations and $[\text{Ca}^{2+}]_i$ increases cause periodic tonic contractions of the smooth muscle. When the amplitude of the slow V_m waves is sufficient to depolarize the cell to threshold, the ensuing action potentials lead to further Ca^{2+} influx and phasic contractions.

Oscillations in intracellular ions (other than Ca^{2+}) or molecules may also explain spontaneous electrical activity. For example, increased $[\text{Ca}^{2+}]_i$ during an action potential might stimulate Na-Ca exchange and lead to a cyclic increase in $[\text{Na}^+]_i$ and thus an increase in the rate of Na^+ extrusion by the electrogenic Na-K pump. Alternatively, activation of G protein–coupled receptors may lead to the formation of inositol 1,4,5-trisphosphate (IP_3), thereby opening the IP_3 receptor (IP_3R) channel (see [Table 6-2](#), family No. 18) and releasing Ca^{2+} . The rise in $[\text{Ca}^{2+}]_i$ would be self-reinforcing because CICR via RYRs ([Fig. 9-15](#)) may propagate through the cell as a Ca^{2+} wave. However, high $[\text{Ca}^{2+}]_i$ levels inhibit RYR. The Ca^{2+} -release events ultimately terminate as high $[\text{Ca}^{2+}]_i$ inhibits RYR, SR Ca^{2+} stores become depleted, or re-uptake of Ca^{2+} into the SR occurs. The $[\text{Ca}^{2+}]_i$ increases may themselves lead to periodic electrical activity by stimulating Ca^{2+} -activated inward currents (e.g., Cl^- efflux) and outward currents (e.g., K^+ efflux; see below).

FIGURE 9-15 EC coupling in smooth muscle. PIP_2 , phosphatidylinositol 4,5-bisphosphate; PLA, phospholipase A; STIC, spontaneous transient inward current; STOC, spontaneous transient outward current.

Some smooth muscles contract without action potentials

Whereas generation of an action potential is essential for initiating contraction of skeletal and cardiac muscle, many smooth-muscle cells contract despite being unable to generate an action potential. As discussed above, V_m oscillations can lead to tonic contractions in the absence of action potentials. Action potentials usually do not occur in **multiunit** smooth muscle. For example, in the smooth muscle that regulates the iris of the eye, excitatory neurotransmitters such as norepinephrine and ACh cause a local depolarization—the **junctional potential**—which is similar to the end-plate potential in skeletal muscle (see p. 210). Junctional potentials spread electrotonically (i.e., in a graded fashion) throughout the muscle fiber, thereby altering V_m and triggering Ca^{2+} entry Ca^{2+} through L-type Cav channels. Graded changes in V_m may also modulate—by an unknown mechanism—the activity of the enzyme phospholipase C, which cleaves phosphoinositides to release the intracellular second messengers diacylglycerol (DAG) and IP_3 (see p. 58). Both second messengers are modulators of contractile force. In the absence of action potentials, some unitary smooth muscle, including some vascular smooth muscle, also contracts as a result of graded V_m changes.

Some smooth-muscle cells contract simply in response to extracellular agonists, with minimal depolarization and negligible Ca^{2+} entry from the outside. For example, a neurotransmitter can bind to a receptor, activate a G protein, and—via phospholipase C—lead to the generation of IP_3 , binding to IP_3R , and Ca^{2+} release from the SR.

In smooth muscle, both entry of extracellular Ca^{2+} and intracellular Ca^{2+} spark activate contraction

Whereas *striated* muscle has T tubules, *smooth* muscle has more rudimentary and shallow invaginations of the plasma membrane (see Fig. 9-15) called **caveolae** (see pp. 42–43). Smooth-muscle cells use three major pathways—not mutually exclusive—for producing the rise in $[\text{Ca}^{2+}]_i$ that triggers contraction (see Fig. 9-15): (1) Ca^{2+} entry through L-type Cav channels in response to depolarization, (2) Ca^{2+} release from the SR via RYR and IP_3R Ca^{2+} -release channels, and (3) Ca^{2+} entry through voltage-independent/store-operated channels.

Ca^{2+} Entry via Voltage-Gated Channels

Whether the smooth-muscle cell responds to graded depolarizations or action potentials, depolarization may produce a Ca^{2+} influx through L-type Cav channels.

Ca^{2+} Release from the SR

Sarcoplasmic Ca^{2+} release—seen as Ca^{2+} sparks (see pp. 242–243) if sufficiently robust—may occur by either of two mechanisms in smooth muscle: (1) Ca^{2+} entry through small clusters of the Cav1.2 variant of L-type channels, activating the RYR3 subtype of ryanodine receptors and causing CICR—a robust amplification of the Ca^{2+} signal; and (2) IP_3 activation of IP_3R . Ca^{2+} sparks in various smooth-muscle cells also may occur spontaneously due to random low-probability opening of RYR channels. Whereas the rise of $[\text{Ca}^{2+}]_i$ via CICR is a prominent aspect of cardiac muscle, the receptor-mediated IP_3 pathway is particularly significant for SR Ca^{2+} release in smooth muscle.

In smooth muscle, the relationship between the plasma membrane and the SR is not as regular as the triads (see p. 229) and dyads (see pp. 242–243) in striated muscle. At the level of the caveolae, a **peripheral SR compartment** encircles the invaginating plasma membrane—forming a gap of only 15 nm—facilitating Ca^{2+} diffusion and thus CICR. A larger network of **central SR** runs along the long axis of the cell, playing greater role in delivering Ca^{2+} to intracellular myofilaments for contraction.

In smooth muscle but not in cardiac muscle, the rise in $[\text{Ca}^{2+}]_i$ stimulates Ca^{2+} -activated ion channels other than RYR (e.g., Ca^{2+} -activated K^+ channels and Ca^{2+} -activated Cl^- channels) that participate in repolarization and regulation of contractile tone. 🎧N9-10

N9-10

STOCs and STICs in Smooth Muscle

Contributed by Ed Moczydlowski

Simultaneous imaging of Ca^{2+} spark events and electrophysiological recording from smooth-muscle cells has further revealed that individual Ca^{2+} -release spark events are often coupled to electrical signals at

the plasma membrane known as **STOCs (spontaneous transient outward currents)** and **STICs (spontaneous transient inward currents)**. STOCs and STICs are produced, respectively, by Ca^{2+} -activated K^+ channels and by Ca^{2+} -activated Cl^- channels at the plasma membrane that are directly activated by the pulse of Ca^{2+} released from SR stores by spark events (see Fig. 9-15).

Ca^{2+} -activated K^+ channels in the smooth-muscle plasma membrane include BK_{Ca} channels activated both by $[\text{Ca}^{2+}]_i$ and positive voltage as well as SK and IK channels activated by intracellular Ca^{2+} -CaM. Close reciprocal coupling between intracellular Ca^{2+} release and activation of Ca^{2+} -activated K^+ channels, particularly BK_{Ca} channels, is recognized as an important negative-feedback mechanism for control of excitability, contraction, and smooth-muscle tone, a term that describes the underlying state of contractile tension. Membrane hyperpolarization mediated by opening of BK_{Ca} channels is a negative-feedback response that protects smooth muscle from excessive excitation and contraction.

In most smooth-muscle cells, the Nernst potential for Cl^- (E_{Cl}) is on the order of -20 mV, which is significantly more positive than the typical smooth-muscle cell resting membrane potential of approximately -60 mV. In this situation, the Ca^{2+} -activated opening of Cl^- channels at membrane potentials more negative than E_{Cl} will depolarize the cell due to efflux of Cl^- (which is equivalent to inward movement of positive charge and physiologically defined as an inward current). Ca^{2+} -activated Cl^- channels of the anoctamin family (see Table 6-2, family No. 17) have recently been identified in smooth muscle, epithelia, and other cells. Inward current due to Cl^- efflux initiated by agonist-induced activation of IP_3Rs resulting in a global increase in $[\text{Ca}^{2+}]_i$ has been observed in many types of smooth-muscle cells. Since STIC responses depolarize V_m , they increase excitability and promote smooth-muscle contraction.

The ultimate consequences of changes in membrane potential, transmitter activation, and Ca^{2+} spark signaling in smooth muscle depend on complex interactions of ionic gradients and channels. For example, at very negative values of V_m , Ca^{2+} sparks can augment membrane depolarization by activation of Ca^{2+} -activated Cl^- current (STICs). The subsequent rise in V_m will subsequently activate L-type Cav channels to further enhance depolarization, Ca^{2+} entry, and muscle cell contraction. Eventually the opening of BK_{Ca} channels activated by positive voltage and the rise in $[\text{Ca}^{2+}]_i$ will hyperpolarize the cell, inhibit further Ca^{2+} entry, and lead to muscle cell relaxation. Complex sequences of such events associated with Ca^{2+} sparks, Ca^{2+} waves, and Ca^{2+} oscillations underlie the tonic and phasic behavior of Ca^{2+} signaling in smooth muscle.

Ca^{2+} Entry through Store-Operated Ca^{2+} Channels (SOCs)

In cells that lack Cav channels—including secretory epithelia, mast cells, and lymphocytes—depletion of Ca^{2+} from ER storage compartments may trigger Ca^{2+} influx through the plasma membrane, followed by the active uptake of this Ca^{2+} into the ER to replenish the Ca^{2+} store. This **Ca^{2+} -release-activated Ca^{2+} current (I_{CRAC})** underlies **capacitative Ca^{2+} entry**, also known as **store-operated Ca^{2+} entry (SOCE)**. Work on lymphocytes has identified three genes that encode the **Orai family of SOCs** (see Table 6-2, family No. 20 and Fig. 6-20X). **N9-13** Missense mutations in the human *ORAI1* gene eliminate the I_{CRAC} vital for lymphocyte activation, resulting in severe combined immunodeficiency syndrome (SCID).

Store-Operated Ca^{2+} Channels (SOCs)

Contributed by Emile Boulpaep, Walter Boron

Receptor-operated and store-operated Ca^{2+} channels are defined not by the structure of the channel but by their apparent physiological regulation.

Receptor-operated Ca^{2+} channels (ROCs)—also called “second messenger-operated channels”—mediate Ca^{2+} entry in response to stimulation of a G_q protein-coupled receptor (see Table 3-2) or a receptor tyrosine kinase (see p. 68) and subsequent increase in the activity of phospholipase C (see p. 58), such as $\text{PLC}\beta$ or $\text{PLC}\gamma$.

Store-operated Ca^{2+} channels (SOCs) mediate “capacitative” Ca^{2+} entry that is triggered by depletion of Ca^{2+} inside the endoplasmic reticulum. Thapsigargin, a specific inhibitor of the endoplasmic reticulum Ca^{2+} pump or SERCA, can cause depletion of the internal Ca^{2+} pool. As discussed on p. 247, one class of SOCs consists of the ORAI channels and their associated STIM proteins.

Although the ORAI channel and STIM proteins comprise a pathway for voltage-independent activation of SOC in **smooth muscle**, recent evidence suggests that the Ca^{2+} -permeable TRP channels (see Fig. 6-20I as well as p. 169)—**TRPC1** and **TRPC5**—may function as SOCs in mammalian portal-vein myocytes. Activation of these latter TRP channels in portal-vein smooth muscle appears to be coupled to IP_3 -mediated release of internal Ca^{2+} via mechanisms involving $\alpha 1$ -adrenergic receptor activation of a phospholipase C pathway that includes IP_3 , diacylglycerol, protein kinase C, and calmodulin. Further work is clearly needed to investigate the molecular basis of SOC channels in smooth muscle and the physiological functions of human ORAI channels.

In nonexcitable cells, the Orai channel is under the control of the Ca^{2+} -sensing **STIM** protein in ER membrane (see Fig. 9-15). When ER $[\text{Ca}^{2+}]$ is depleted, Ca^{2+} dissociates from a binding site on the N terminus of STIM, which causes STIM to aggregate in regions of the ER membrane that are closely associated with the plasma membrane. This STIM aggregation then triggers a direct interaction of the cytosolic C terminus of STIM with a coiled-coil domain on the cytosolic C terminus of Orai tetramers. The result is a clustering of Orai tetramers to form active Ca^{2+} channels that mediate Ca^{2+} influx across the plasma membrane and subsequent refilling of the ER stores. As ER $[\text{Ca}^{2+}]$ rises, Ca^{2+} again binds to the site on STIM, suppressing STIM aggregation, and halting SOCE.

SOCE is clearly involved in the Ca^{2+} -dependent regulation of smooth-muscle contraction. Many types of smooth muscle express STIM and Orai proteins. Ca^{2+} -permeable channels of the TRP family (see Table 6-2) are also present in smooth muscle and may be involved in SOCE. **N9-11**

SOCE in Skeletal Muscle

Contributed by Ed Moczydlowski

The possible role of SOCE in the physiology of other muscle cell types is also under active investigation. For example, skeletal muscle fibers express both the STIM and Orai proteins. Human mutations in the human *ORAI1* gene are associated with congenital myopathy, but the exact function of the gene product in muscle is unclear. Hypothetical proposed roles for plasma membrane entry of Ca^{2+} by the SOCE mechanism in skeletal muscle include supplementation of intracellular Ca^{2+} for activation of contraction, balancing of Ca^{2+} influx and depletion, and regulation of protein function at the triad junction.

Both Ca^{2+} release from the SR and the entry of Ca^{2+} via SOCE are voltage *independent*. These two mechanisms underlie **pharmacomechanical coupling**, a form of EC coupling in which intracellular release of Ca^{2+} is initiated by chemical activators rather than membrane voltage changes. Thus, a variety of drugs, excitatory neurotransmitters, and hormones can induce smooth-muscle contraction by these coupling mechanisms independently of action potential generation, as discussed in the previous section, and also independently of direct changes in $[\text{Ca}^{2+}]_i$, as discussed below.

Ca^{2+} -dependent phosphorylation of the myosin regulatory light chain activates cross-bridge cycling in smooth muscle

As we noted above, because smooth-muscle actin and myosin are not as highly organized as in skeletal and cardiac muscle, smooth muscle does not exhibit striations characteristic of skeletal and cardiac muscle. The actin filaments of smooth muscle are oriented mainly parallel or oblique to the long axis of the cell. Multiple actin filaments are joined at specialized locations in the cell called **dense bodies**, which contain α -actinin and are analogous to the filament-organizing Z lines of striated muscle. Dense bodies are found immediately beneath the cell membrane as well as within the interior of the myocyte. Thick filaments are interspersed among the thin filaments in smooth muscle and are far less abundant than in skeletal or cardiac muscle.

In contrast to the mechanism in striated muscle, an entirely different mechanism controls cross-bridge turnover in smooth muscle, where an increase in $[\text{Ca}^{2+}]_i$ initiates a slow sequence of biochemical events that ultimately increases the ATPase activity of the myosin (Fig. 9-16). The first step is the binding of four Ca^{2+} ions to **calmodulin (CaM)**, which is closely related to troponin C of striated muscle (see p. 233). Next, the Ca^{2+} -CaM complex activates an enzyme known as **myosin light chain kinase (MLCK)**, which in turn phosphorylates the regulatory light chain that is associated with each neck of the dimeric myosin II heavy chain (see pp. 233–234). Phosphorylation of the light chain causes a conformational change of the myosin head, which increases the angle between the head and neck domain of myosin and also increases its ATPase activity, allowing it to interact efficiently with actin and act as a molecular motor. Thus, in smooth muscle, CaM rather than troponin C is the Ca^{2+} -binding protein responsible for transducing the contraction-triggering increases in $[\text{Ca}^{2+}]_i$. Note that in smooth muscle, contraction cannot begin until MLCK increases the ATPase activity of myosin, which is a relatively slow, time-dependent process. In skeletal and cardiac muscle, on the other hand, the ATPase activity of the myosin head is constitutively high, and cross-bridge cycling begins as soon as tropomyosin moves out of the way.

FIGURE 9-16 Role of Ca^{2+} in triggering the contraction of smooth muscle.

In addition to activating *thick* filaments of smooth muscle, Ca^{2+} -CaM indirectly acts on the thin filaments to remove the tonic inhibition to actin-myosin interactions that are caused by steric hindrance. Two proteins, caldesmon and calponin, tonically inhibit the interaction between actin and myosin. Both are Ca^{2+} -CaM-binding proteins, and both bind to actin and tropomyosin. **Calponin**, which is found in a fixed stoichiometry with tropomyosin and actin (one calponin–one tropomyosin–seven actin monomers), tonically inhibits the ATPase activity of myosin. The Ca^{2+} -CaM complex not only activates MLCK (a CaMK; see p. 60) but also has two effects on calponin. First, Ca^{2+} -CaM binds to calponin. Second, Ca^{2+} -CaM activates CaMKII, which phosphorylates calponin. Both effects relieve calponin's inhibition of myosin's ATPase activity. **Caldesmon** is another regulatory protein of smooth muscle that appears to act like calponin by tonically inhibiting the actin-activated ATPase activity of myosin in smooth muscle. Caldesmon contains binding domains for actin, myosin, and tropomyosin, as well as Ca^{2+} -CaM. It appears to block the interaction of actin with myosin; however, the exact mechanism is controversial.

Although the steps of cross-bridge cycling in smooth muscle are similar to those in skeletal and cardiac muscle (see Fig. 9-7), smooth muscle controls the initiation of the cross-bridge cycle differently—at step 2 in Figure 9-7, where Ca^{2+} confers ATPase activity to the myosin head, as discussed before. Recall that the ATPase activity of striated muscle is always high and Ca^{2+} regulates the access of the myosin head to the actin. Another difference between smooth and striated muscle is that the frequency of cross-bridge cycling in smooth muscle is less than one tenth that in skeletal muscle. This variation reflects differences in the properties of myosin isoforms that are expressed in various cell types. Even though cross-bridge cycling occurs less frequently in smooth muscle, force generation may be as great or greater, perhaps because the cross-bridges remain intact for a longer period with each cycle. It is likely that this longer period during which the cross-bridges are intact reflects a lower rate of ADP release from the smooth-muscle isoform of myosin.

Termination of smooth-muscle contraction requires dephosphorylation of myosin light chain

Because Ca^{2+} triggers smooth-muscle contraction by inducing phosphorylation of the myosin regulatory light chain rather than by simple binding to troponin C as in striated muscle, merely restoring $[\text{Ca}^{2+}]_i$ to its low resting value does not produce muscle relaxation. Rather, relaxation of smooth muscle requires dephosphorylation of the myosin light chains (MLCs) by **myosin light chain phosphatase (MLCP)**. This

phosphatase is a heterotrimer consisting of subunits with molecular masses of 130, 20, and 37 kDa. The 130-kDa subunit confers specificity by binding to myosin; the 37-kDa protein is the catalytic subunit responsible for the dephosphorylating activity.

Smooth-muscle contraction may also occur independently of increases in $[Ca^{2+}]_i$

Whereas many excitatory stimuli rely on increases in $[Ca^{2+}]_i$ to evoke contraction, some stimuli appear to cause contraction without a measurable increase in $[Ca^{2+}]_i$. One mechanism by which excitatory stimuli might induce Ca^{2+} -independent contractions is by modulating the activity of contractile or regulatory proteins directly. Thus, the amount of force developed at any given $[Ca^{2+}]_i$ may vary. This force/ $[Ca^{2+}]_i$ ratio may be increased or decreased and is generally higher during pharmacomechanical activation than during depolarization-activated contractions. Because phosphorylation of the MLC is a major determinant of contractile force in smooth muscle, Ca^{2+} -independent contractions may result either from an increase in the rate of MLC phosphorylation by MLCK or from a decrease in the rate of MLC dephosphorylation by MLCP. One second-messenger system that can decrease the activity of phosphatases is protein kinase C (PKC; see pp. 60–61). Some excitatory stimuli are therefore capable of initiating smooth-muscle contraction by inducing IP_3 -mediated release of Ca^{2+} from intracellular stores as well as by producing PKC-mediated decreases in MLCP activity. These pathways are further examples of **pharmacomechanical coupling** (see p. 247).

In smooth muscle, increases in both $[Ca^{2+}]_i$ and the Ca^{2+} sensitivity of the contractile apparatus enhance contractile force

Unlike skeletal muscle, in which force development results from the summation of individual muscle *twitches*, individual smooth-muscle cells can maintain a sustained contraction that can be graded in strength over a wide range. Contractile force in smooth muscle largely depends on the relative balance between the phosphorylation and dephosphorylation of MLCs. The rate of MLC phosphorylation is regulated by the Ca^{2+} -CaM complex, which in turn depends on *levels of intracellular Ca^{2+}* . Smooth-muscle cells can regulate $[Ca^{2+}]_i$ over a wider range than skeletal and cardiac muscle for several reasons. First, smooth-muscle cells that do not generate action potentials—but rather exhibit graded V_m responses to neurotransmitters or hormones—are able to fine-tune Ca^{2+} influx via voltage-gated channels. Second, release of Ca^{2+} from intracellular stores may be modulated via neurotransmitter-induced generation of intracellular second messengers such as IP_3 . This modulation allows finer control of Ca^{2+} release than occurs in the SR Ca^{2+} -release channel by L-type Ca^{2+} channels in skeletal and cardiac muscle.

A second level of control over contractile force occurs by regulation of the Ca^{2+} sensitivity of proteins that regulate contraction. For example, inhibiting MLCP alters the balance between phosphorylation and dephosphorylation, in effect allowing a greater contraction at a lower $[Ca^{2+}]_i$. Some neurotransmitters act by inhibiting the phosphatase, which appears to occur via activation of G protein-coupled receptors. Another mechanism for governing the Ca^{2+} sensitivity of proteins that regulate contraction is alteration of the Ca^{2+} sensitivity of the MLCK. Phosphorylation of MLCK by several protein kinases—including PKA, PKC, and CaMK—decreases the sensitivity of MLCK to activation by the Ca^{2+} -CaM complex.

Smooth muscle maintains high force at low energy consumption

Smooth muscle is often called on to maintain high force for long periods. If smooth muscle consumed ATP at rates similar to those in striated muscle, metabolic demands would be considerable and the muscle would be prone to fatigue. Unlike striated muscle, however, smooth muscle is able to maintain high force at a low rate of ATP hydrolysis. This low energy consumption/high-tension state is referred to as the **latch state**. The latch state in smooth muscle is unique because high tension can be maintained despite a decrease in the degree of muscle activation by excitatory stimuli. As a result, force is maintained at a lower level of MLCK phosphorylation.

The mechanism underlying the latch state is not entirely known, although it appears to be due in large part to changes in the kinetics of actin-myosin cross-bridge formation and detachment. These changes may be a direct result of a decrease in the rate at which dephosphorylated cross-bridges detach. Tension is directly related to the number of attached cross-bridges. Furthermore, the proportion of myosin heads cross-bridged to actin is related to the ratio of attachment rates to detachment rates. Therefore, it is reasonable to expect that a decrease in the detachment rate would allow a greater number of cross-bridges to be maintained and would result in a lower rate of cross-bridge cycling and ATP hydrolysis. Thus, smooth muscle appears to be able to slow down cross-bridge cycling just before detachment, a feat that can be accomplished in skeletal muscle (see [Fig. 9-7](#)) only at low ATP levels (as in *rigor mortis*).

Diversity among Muscles

As we have seen, each muscle type (skeletal, cardiac, and smooth) is distinguishable on the basis of its unique histological features, EC coupling mechanisms, and regulation of contractile function. However, even within each of the three categories, muscle in different locations must serve markedly different purposes, with different demands for strength, speed, and fatigability. This diversity is possible because of differences in the expression of specific isoforms of various contractile and regulatory proteins (see [Table 9-1](#)).

Skeletal muscle is composed of slow-twitch and fast-twitch fibers

Some skeletal muscles must be resistant to fatigue and be able to maintain tension for relatively long periods, although they need not contract rapidly. Examples are muscles that maintain body posture, such as the soleus muscle of the lower part of the leg. In contrast, some muscles need to contract rapidly, yet infrequently. Examples are the extraocular muscles, which must contract rapidly to redirect the eye as an object of visual interest moves about.

Individual muscle fibers are classified as *slow twitch (type I)* or *fast twitch (type II)*, depending on their rate of force development. These fiber types are also distinguished by their histological appearance and their ability to resist fatigue.

Slow-twitch fibers ([Table 9-2](#)) are generally thinner and have a denser capillary network surrounding them. These **type I** fibers also appear red because of a large amount of the oxygen-binding protein **myoglobin** (see [pp. 648–649](#)) within the cytoplasm. This rich capillary network together with myoglobin facilitates oxygen transport to the slow-twitch fibers, which mostly rely on oxidative metabolism for energy. The metabolic machinery of the slow-twitch fiber also favors oxidative metabolism because it has low glycogen content and glycolytic-enzyme activity but a rich mitochondrial and oxidative-enzyme content. Oxidative metabolism is slow but efficient, which makes these fibers resistant to fatigue.

TABLE 9-2
Properties of Fast- and Slow-Twitch Muscle Fibers

	SLOW TWITCH	FAST TWITCH	FAST TWITCH
Synonym	Type I	Type IIa	Type IIx/IIb
Fatigue	Resistant	Resistant	Fatigable
Color	Red (myoglobin)	Red (myoglobin)	White (low myoglobin)
Metabolism	Oxidative	Oxidative	Glycolytic
Mitochondria	High	Higher	Fewer
Glycogen	Low	Abundant	High

Fast-twitch fibers differ among themselves with respect to fatigability. Some fast-twitch fibers are fatigue resistant (**type IIa**); they rely on oxidative metabolism and are quite similar to slow-twitch fibers with respect to myoglobin content (indeed, they are red) and metabolic machinery. One important difference is that fast-twitch oxidative fibers contain abundant glycogen and have a greater number of mitochondria than slow-twitch fibers do. These features ensure adequate ATP generation to compensate for the increased rate of ATP hydrolysis in fast-twitch fibers.

Other fast-twitch fibers are not capable of sufficient oxidative metabolism to sustain contraction.

Because these fibers must rely on the energy that is stored within glycogen (and phosphocreatine), they are more easily fatigable. Fatigable fast-twitch fibers (**type IIx/IIb**) have fewer mitochondria and lower concentrations of myoglobin and oxidative enzymes. Because of their low myoglobin content, type IIb muscle fibers appear white. They are, however, richer in glycolytic-enzyme activity than other fiber types are.

In reality, slow- and fast-twitch fibers represent the extremes of a continuum of muscle fiber characteristics. Moreover, each whole muscle is composed of fibers of each twitch type, with one twitch type predominating. The differences between fiber types derive in large part from differences in isoform expression of the various contractile and regulatory proteins (see [Table 9-1](#)).

Differences in the rate of contraction, for example, may be directly correlated with the maximal rate of myosin ATPase activity. The human genome database lists 15 *MYH* genes that encode **myosin heavy chains (MHCs)**. Expression of these genes and their splice variants differs among muscle types and with stage of development. Skeletal muscle expresses at least six *MYH* genes (*MYH1 to MYH4*, *MYH8*, *MYH13*). For the most part, a muscle fiber type expresses a single MHC type, the ATPase activity of which appears to correspond to the rate of contraction in that fiber type. Whereas most fibers express one MHC type, some fibers express a combination of two different types. These hybrid cells have rates of contraction that are intermediate between the two pure fiber types.

Differences in the rates and strength of contraction may also reflect differences in expression of types of **myosin light chains** or other components of the EC coupling, such as the **SR Ca pump** (i.e., the SERCA), calsequestrin, Ca^{2+} -release channels, and troponin C (see [Table 9-1](#)). Furthermore, some regulatory proteins, such as phospholamban, are expressed in certain muscle types (i.e., slow-twitch skeletal, cardiac, smooth) and not the others.

One particularly interesting feature of muscle differentiation is that fiber-type determination is not static. Through exercise training or changes in patterns of neuronal stimulation, alterations in contractile and regulatory protein isoform expression may occur. For example, it is possible for a greater proportion of fast-twitch fibers to develop in a specific muscle with repetitive training. It is even possible to induce cardiac-specific isoforms in skeletal muscle, given appropriate stimulation patterns.

The properties of cardiac cells vary with location in the heart

Just as skeletal muscle consists of multiple fiber types, so too does heart muscle. The electrophysiological and mechanical properties of cardiac muscle vary with their location (i.e., atria versus conducting system versus ventricles). Moreover, even among cells within one anatomical location, functional differences may exist between muscle cells near the surface of the heart (*epicardial cells*) and those lining the interior of the same chambers (*endocardial cells*). As in skeletal muscle, many of these differences reflect differences in isoform expression of the various contractile and regulatory proteins. Although some of the protein isoforms expressed in cardiac tissue are identical to those expressed in skeletal muscle, many of the proteins have cardiac-specific isoforms (see [Table 9-1](#)). The MHC in heart, for example, exists in two isoforms, α and β , which may be expressed alone or in combination.

The properties of smooth-muscle cells differ markedly among tissues and may adapt with time

When one considers that smooth muscle has a broad range of functions, including regulating the diameter of blood vessels, propelling food through the gastrointestinal tract, regulating the diameter of airways, and

delivering a newborn infant from the uterus, it is not surprising that smooth muscle is a particularly diverse type of muscle. In addition to being distinguished as unitary or multiunit muscle (see [p. 243](#)), smooth muscle in different organs diverges with respect to nerve and hormonal control, electrical activity, and characteristics of contraction.

Even among smooth-muscle cells within the same sort of tissue, important functional differences may exist. For example, vascular smooth-muscle cells within the walls of two arterioles that perfuse different organs may vary in their contractile response to various stimuli. Differences may even exist between vascular smooth-muscle cells at two different points along one arterial pathway.

The phenotype of smooth muscle within a given organ may change with shifting demands. The uterus, for example, is composed of smooth muscle—the **myometrium** (see [Fig. 56-2](#))—that undergoes remarkable transformation during gestation as it prepares for parturition. In addition to hypertrophy, greater coupling develops between smooth-muscle cells via the increased formation of gap junctions. The cells also undergo changes in their expression of contractile protein isoforms. Changes in the expression of ion channels and hormone receptors facilitate rhythmic electrical activity. This activity is coordinated across the myometrium by propagation of action potentials and increases in $[Ca^{2+}]_i$ via the gap junctions. These rhythmic, coordinated contractions develop spontaneously, but they are strongly influenced by the hormone oxytocin, levels of which increase just before and during labor and just after parturition.

These differences in smooth-muscle function among various tissues or even over the lifetime of a single cell probably reflect differences in protein composition. Indeed, in comparison to striated muscle, smooth-muscle cells express a wider variety of isoforms of contractile and regulatory proteins (see [Table 9-1](#)). This variety is a result of both multiple genes and variability among mRNA products of a gene (see [pp. 96–97](#)). This richness in diversity is likely to have important consequences for smooth-muscle cell function.

Smooth-muscle cells express a wide variety of neurotransmitter and hormone receptors

Perhaps one of the most impressive sources of diversity among smooth-muscle cells relates to differences in response to neurotransmitters, environmental factors, and circulating hormones. Smooth-muscle cells differ widely with respect to the types of cell-surface receptors that mediate the effects of these various mediators. In general, smooth-muscle cells each express a variety of such receptors, and receptor stimulation may lead to either contraction or relaxation. Many substances act via different receptor subtypes in different cells, and these receptor subtypes may act via different mechanisms. For example, whereas some neurotransmitter/hormone receptors may be ligand-gated ion channels (e.g., ATP-activated P2X receptor Ca^{2+} channel), other receptors are G protein–coupled receptors (e.g., adrenergic β_2 , muscarinic M_2) that either act directly on targets or act via intracellular second messengers (e.g., cAMP, cGMP, or IP_3 and DAG).

The list of neurotransmitters (see [Table 20-7](#)), hormones (see [Table 20-8](#)), and environmental factors (see [Table 20-9](#)) regulating the function of vascular smooth-muscle cells alone is vast. Identical stimuli, however, may result in remarkably different physiological responses by smooth muscle in different locations. For example, systemic arterial smooth-muscle cells relax when the oxygen concentration around them decreases, whereas pulmonary arterial smooth muscle contracts when local oxygen concentration decreases (see [p. 687](#)).

A summary comparison among muscle types is presented in [Table 9-3](#).

TABLE 9-3

Comparison of Properties among Muscle Types

	SKELETAL	CARDIAC	SMOOTH
Mechanism of excitation	Neuromuscular transmission (release of ACh, activating nicotinic ACh receptor)	Pacemaker depolarization, spread electrotonically via gap junctions	Synaptic transmission Agonist-activated receptors Electrical coupling Pacemaker potentials
Electrical activity of muscle cell	Action potential spikes	Action potential plateaus	Action potential spikes, plateaus Graded membrane potential changes Slow waves
Ca ²⁺ sensor	Troponin C	Troponin C	CaM
EC coupling	L-type Ca ²⁺ channel (Cav1.1, DHP receptor) in T-tubule membrane mechanically activates Ca ²⁺ -release channel (RYR1) in SR membrane	Ca ²⁺ entry via L-type Ca ²⁺ channel (Cav1.2, DHP receptor) triggers Ca ²⁺ -induced Ca ²⁺ release (sparks) via RYR2 in SR membrane	Ca ²⁺ entry via voltage-gated Ca ²⁺ channel, Cav1.2 Ca ²⁺ - or IP ₃ -mediated Ca ²⁺ release (sparks) via RYR3 or IP ₃ R1, IP ₃ R2, IP ₃ R3 in SR membrane Ca ²⁺ entry through SOCs via Orai and TRP channels
Terminator of contraction	Breakdown of ACh by acetylcholinesterase SR Ca ²⁺ uptake	Action potential repolarization SR Ca ²⁺ uptake	MLCP SR Ca ²⁺ uptake
Twitch duration	20–200 ms	200–400 ms	200 ms—sustained
Regulation of force	Frequency and multifiber summation	Regulation of calcium entry	Balance between MLCK phosphorylation and dephosphorylation Latch state
Metabolism	Oxidative, glycolytic	Oxidative	Oxidative

SECTION III

The Nervous System

OUTLINE

- Chapter 10 Organization of the Nervous System
- Chapter 11 The Neuronal Microenvironment
- Chapter 12 Physiology of Neurons
- Chapter 13 Synaptic Transmission in the Nervous System
- Chapter 14 The Autonomic Nervous System
- Chapter 15 Sensory Transduction
- Chapter 16 Circuits of the Central Nervous System

CHAPTER 10

Organization of the Nervous System

Bruce R. Ransom

The human brain is the most complex tissue in the body. It mediates behavior ranging from simple movements and sensory perception to learning, memory, and consciousness. It is the organ of the mind and accounts for the human capacity for invention, discovery, and language. Many of the brain's functions are poorly understood. In fact, the most prominent function of the human brain, its capacity to think, is hardly understood at all. Its capacity to reflect upon itself is a philosophical paradox. Our lack of knowledge about fundamental aspects of brain function stands in marked contrast to the level of comprehension that we have about the primary functions of other organ systems such as the heart, lungs, and kidneys. Nevertheless, tremendous strides have been made in the past few decades.

In this part of the book, we present the physiology of the nervous system in a manner that is intended to be complementary to texts on neurobiology and neuroanatomy. In this chapter, we review the basic cellular, developmental, and gross anatomy of the nervous system. In [Chapter 11](#), we discuss the fluid environment of the neurons in the brain, how this environment interacts with the rest of the extracellular fluid of the body, and the role of glial cells. [Chapters 12](#) and [13](#) focus on the broad physiological principles that underlie how the brain's cellular elements operate. Another major goal of this section is to provide more detailed information on those parts of the nervous system that play key roles in the physiology of other systems in the body. Thus, in [Chapter 14](#), we discuss the autonomic nervous system, which controls viscera such as the heart, lungs, and gastrointestinal tract. Finally, in [Chapters 15](#) and [16](#), we discuss the special senses and simple neuronal circuits.

The nervous system can be divided into central, peripheral, and autonomic nervous systems

The manner in which the nervous system is subdivided is somewhat arbitrary. All elements of the nervous system work closely together in a way that has no clear boundaries. Nevertheless, the traditional definitions of the subdivisions provide a useful framework for talking about the brain and its connections, and are important if only for that reason.

The **central nervous system (CNS)** consists of the brain and spinal cord ([Table 10-1](#)). It is covered by three “membranes”—the meninges. The outer membrane is the dura mater; the middle is the arachnoid; and the delicate inner membrane is called the pia mater. Within the CNS, some neurons that share similar functions are grouped into aggregations called **nuclei**. The CNS can also be divided into gray matter, which contains neuron cell bodies, and white matter, which is rich in myelin (see [pp. 199–201](#)).

TABLE 10-1
Subdivisions of the Nervous System

SUBDIVISION	COMPONENTS	SPECIAL FEATURES
Central	Brain (including CN II and retina) and spinal cord	Oligodendrocytes provide myelin Axons cannot regenerate
Peripheral	Peripheral ganglia (including cell bodies); sensory receptors; peripheral portions of spinal and cranial nerves (except CN II), both afferent and efferent	Schwann cells provide myelin Axons can regenerate
Autonomic	Selected portions of the CNS and PNS	Functionally distinct system

CN, cranial nerve.

The **peripheral nervous system (PNS)** consists of those parts of the nervous system that lie outside the dura mater (see [Table 10-1](#)). These elements include sensory receptors for various kinds of stimuli, the peripheral portions of spinal and cranial nerves, and all the peripheral portions of the autonomic nervous system. The **sensory** nerves that carry messages from the periphery to the CNS are termed **afferent nerves** (from the Latin *ad* + *ferens* [carrying toward]). Conversely, the peripheral **motor** nerves that carry messages from the CNS to peripheral tissues are called **efferent nerves** (from the Latin *ex* + *ferens* [carrying away]). **Peripheral ganglia** are groups of nerve cells concentrated into small knots or clumps that are located outside the CNS.

The **autonomic nervous system (ANS)** is that portion of the nervous system that regulates and controls visceral functions, including heart rate, blood pressure, digestion, temperature regulation, and reproductive function. Although the ANS is a functionally distinct system, it is anatomically composed of parts of the CNS and PNS (see [Table 10-1](#)). Visceral control is achieved by reflex arcs that consist of visceral afferent (i.e., sensory) neurons that send messages from the periphery to the CNS, control centers in the CNS that receive this input, and visceral motor output. Moreover, visceral afferent fibers typically travel together with visceral efferent fibers.

Each area of the nervous system has unique nerve cells and a different function

Nervous tissue is composed of neurons and neuroglial cells. **Neurons** vary greatly in their structure throughout the nervous system, but they all share certain features that tailor them for the unique purpose of electrical communication (see [Chapter 12](#)). Neuroglial cells, often simply called **glia**, are not primary signaling cells and have variable structures that are suited for their diverse functions (see [Chapter 11](#)).

The human brain contains ~10¹¹ neurons and slightly more glial cells. Each of these neurons may interact with thousands of other neurons, which helps explain the awesome complexity of the nervous system.

Few, if any, of the receptors, ion channels, or cells in the human brain are unique to humans. The unparalleled capabilities of the human brain are presumed to result from its unique patterns of connectivity and its large size.

The brain's diverse functions are the result of tremendous regional specialization. Different brain areas are composed of neurons that have special shapes, physiological properties, and connections. One part of the brain, therefore, cannot substitute functionally for another part that has failed. Any compensation of neural function by a patient with a brain lesion (e.g., a stroke) reflects enhancement of existing circuits or recruitment of latent circuits. A corollary is that damage to a specific part of the brain causes predictable symptoms that enable a clinician to establish the anatomical location of the problem, a key step in

diagnosis of neurological diseases.

Cells of the Nervous System

The neuron doctrine first asserted that the nervous system is composed of many individual signaling units—the neurons

In 1838, Schleiden and Schwann proposed that the nucleated cell is the fundamental unit of structure and function in both plants and animals. They reached this conclusion by microscopic observation of plant and animal tissues that had been stained to reveal their cellular composition. However, the brain proved to be more difficult to stain than other tissues, and until 1885, when Camillo Golgi introduced his silver-impregnation method, “the black reaction,” there was no clear indication that the brain is composed of individual cells. The histologist Santiago Ramón y Cajal worked relentlessly with the silver-staining method and eventually concluded that not only is nervous tissue composed of individual cells, but the anatomy of these cells also confers a functional polarization to the passage of nervous signals; the tapering branches near the cell body are the receptive end of the cell, and the long-axis cylinder conveys signals away from the cell. In the absence of any reliable physiological evidence, Ramón y Cajal was nevertheless able to correctly anticipate how complex cell aggregates in the brain communicate with each other.

The pathologist Heinrich von Waldeyer referred to the individual cells in the brain as neurons. He wrote a monograph in 1891 that assembled the evidence in favor of the cellular composition of nervous tissue, a theory that became known as the neuron doctrine. It is ironic that Golgi, whose staining technique made these advances possible, never accepted the neuron doctrine, and he argued vehemently against it when he received his Nobel Prize along with Ramón y Cajal in 1906. 🍷 **N10-1** The ultimate proof of the neuron doctrine was established by electron microscopic observations that definitively demonstrated that neurons are entirely separate from one another, even though their processes come into very close contact.

Nerve cells have four specialized regions: cell body, dendrites, axon, and presynaptic terminals

Neurons are specialized for sending and receiving signals, a purpose reflected in their unique shapes and physiological adaptations. The structure of a typical neuron can generally be divided into four distinct domains: (1) the cell body, also called the soma or perikaryon; (2) the dendrites; (3) the axon; and (4) the presynaptic terminals (Fig. 10-1). The shape and organelle composition of these domains depends strongly on their cytoskeleton, which consists of three fibrillary structures: neurofilaments (i.e., intermediate filaments; see p. 23), microtubules (see pp. 23–25), and thin filaments (see pp. 25–28). The cytoskeleton—especially the microtubules and thin filaments, is dynamic and imbues axons and dendrites with the capacity to change shape, a plasticity believed to participate in the synaptic alterations

associated with learning and memory.

Cell Body

As the name *perikaryon* implies, the cell body is the portion of the cell surrounding the nucleus. It contains much of the cell's complement of endoplasmic reticular membranes as well as the Golgi complex. The cell body appears to be responsible for many of the neuronal housekeeping functions, including the synthesis and processing of proteins.

Dendrites

These structures are tapering processes of variable complexity that arise from the cell body. Dendrites, and to a lesser extent the cell body, are the main areas for receiving information. Thus, their membranes are endowed with **receptors** that bind and respond to the neurotransmitters released by neighboring cells. The chemical message is translated by membrane receptors into an electrical or a biochemical event that influences the state of excitability or function of the receiving neuron. The cytoplasm of the dendrites contains dense networks of microtubules as well as extensions of the endoplasmic reticulum.

Axon

Perhaps the most remarkable feature of the neuron, the axon is a projection that arises from the cell body, like the dendrites. Its point of origin is a tapered region known as the **axon hillock**. Just distal to the cone-shaped hillock is an untapered, unmyelinated region known as the **initial segment**. This area is also called the spike initiation zone because it is where an action potential (see [p. 176](#)) normally arises as the result of the electrical events that have occurred in the cell body and dendrites. In contrast to the dendrites, the axon is thin, does not taper, and can extend for more than a meter. Because of its length, the typical axon contains much more cytoplasm than does the cell body, up to 1000 times as much. The neuron uses special metabolic mechanisms to sustain this unique structural component. The cytoplasm of the axon, the axoplasm, is packed with parallel arrays of microtubules and neurofilaments that provide structural stability and a means to rapidly convey materials back and forth between the cell body and the axon terminus. Axons are self-reliant in energy metabolism, taking up glucose and oxygen from their immediate environment to produce ATP. Specialized glial cells called oligodendrocytes contribute in complex ways to axon integrity (see [pp. 292–293](#)).

Axons are the message-sending portion of the neuron. The axon carries the neuron's signal, the action potential, to a specific target, such as another neuron or a muscle. Some axons have a special electrical insulation, called **myelin**, that consists of the coiled cell membranes of glial cells that wrap themselves around the nerve axon (see [pp. 292–293](#)). If the axon is *not* covered with myelin, the action potential travels down the axon by continuous propagation. On the other hand, if the axon is myelinated, the action potential jumps from one node of Ranvier (the space between adjacent myelin segments) to another in a process called saltatory conduction (see [pp. 200–201](#)). This adaptation greatly speeds impulse conduction.

Presynaptic Terminals

At its target, the axon terminates in multiple endings—the presynaptic terminals—usually designed for rapid conversion of the neuron's electrical signal into a chemical signal. When the action potential reaches the presynaptic terminal, it causes the release of chemical signaling molecules in a complex

process called synaptic transmission (see [Chapters 8 and 13](#)).

The junction formed between the presynaptic terminal and its target is called a chemical synapse. **Synapse** is derived from the Greek for “joining together” or “junction”; this word and concept were introduced in 1897 by the neurophysiologist Charles Sherrington, whose contributions led to a share of the 1932 Nobel Prize in Medicine or Physiology. 🍷 **N10-2** A synapse comprises the presynaptic terminal, the membrane of the target cell (postsynaptic membrane), and the space between the two (synaptic cleft). In synapses between two neurons, the presynaptic terminals primarily contact dendrites and the cell body. The area of the postsynaptic membrane is frequently amplified to increase the surface that is available for receptors. This amplification can occur either through infolding of the plasma membrane or through the formation of small projections called **dendritic spines**.

N10-2

Sir Charles Scott Sherrington

For more information about Sir Charles Scott Sherrington and the work that led to his Nobel Prize, visit <http://www.nobel.se/medicine/laureates/1932/index.html> (accessed October 2014).

The molecules released by the presynaptic terminals diffuse across the synaptic cleft and bind to receptors on the postsynaptic membrane. The receptors then convert the chemical signal of the transmitter molecules—either directly or indirectly—back into an electrical signal.

In many ways, neurons can be thought of as highly specialized *endocrine cells*. They package and store hormones and hormone-like molecules, which they release rapidly into the extracellular space by exocytosis (see [pp. 34–35](#)) in response to an external stimulus, in this case a nerve action potential. However, instead of entering the bloodstream to exert *systemic* effects, the substances secreted by neurons act over the very short distance of a synapse to communicate *locally* with a single neighboring cell (see [p. 47](#)).

In a different sense, neurons can be thought of as *polarized cells* with some of the properties of epithelial cells. Like epithelial cells, neurons have different populations of membrane proteins at each of the distinct domains of the neuronal plasma membrane, an arrangement that reflects the individual physiological responsibilities of these domains. Thus, the design of the nervous system permits information transfer across synapses in a selective and coordinated way that serves the needs of the organism and summates to produce complex behavior.

Synapses can undergo long-term changes based on certain patterns of prior activity. This **plasticity** (see [pp. 328–333](#)) is believed to underlie learning and memory.

The cytoskeleton helps compartmentalize the neuron and also provides the tracks along which material travels between different parts of the neuron

Neurons are compartmentalized in both structure and function. *Dendrites* are tapered, have limited length, and contain neurotransmitter receptor proteins in their membranes. *Axons* can be very long and have a high density of Na⁺ channels. *Dendrites* and the *cell body* contain messenger RNA, ribosomes, and a Golgi apparatus.

How does this compartmentalization come about? The molecular orientation of **microtubules** (see [pp.](#)

23–25) together with **microtubule-associated proteins (MAPs)** play important roles in dictating the vectorial transport of organelles and proteins. (Note that these MAPs are totally unrelated to the mitogen-activated protein [MAP] kinase; see [p. 69](#).) Two major classes of MAPs are found in the brain: high-molecular-weight proteins such as MAP-1 and MAP-2 and lower-molecular-weight tau proteins. Both classes of MAPs associate with microtubules and help link them to other cell components. MAP-2 is most abundant in dendrites, where it may assist in dendrite formation. **Tau proteins** are confined to axons; their suppression in cultured neurons prevents formation of the axon without altering formation of the dendrites. Hyperphosphorylated tau proteins can assemble into pathological aggregates called neurofibrillary tangles, which are a hallmark of **Alzheimer Disease**.

The polarization of microtubules (see [pp. 23–25](#)) helps to create remarkable morphological and functional divisions in neurons. In axons, microtubules assemble with their plus ends pointed away from the cell body; this orientation polarizes the flow of material into and out of the axon. The cytoskeletal “order” provided by the microtubules and the MAPs helps define what should or should not be in the axonal cytoplasm. In dendrites, microtubules do not have a consistent orientation, which gives dendrites a greater functional similarity to the soma and perhaps their tapered shape.

The neuron cell body is the main manufacturing site for the membrane proteins and membranous organelles that are necessary for the structural integrity and function of its processes. Axons have little or no intrinsic protein synthetic ability, whereas dendrites have some free ribosomes and are able to engage in limited protein production. The transport of proteins from the cell body all the way to the end of long axons is a challenging task. The neuron also has a second task: moving various material in the opposite direction, from presynaptic terminals at the end of the axon to the cell body. The neuron solves these problems by using two distinct mechanisms for moving material to the presynaptic terminals in an “anterograde” direction and a third mechanism for transport in the opposite or “retrograde” direction ([Table 10-2](#)).

TABLE 10-2
Features of Axoplasmic Transport

TRANSPORT TYPE	SPEED (mm/day)	MECHANISM	MATERIAL TRANSPORTED
Fast anterograde	~400	Saltatory movement along microtubules via the motor molecule kinesin (ATP dependent)	Mitochondria Vesicles containing peptides and other neurotransmitters, some degradative enzymes
Fast retrograde	~200–300	Saltatory movement along microtubules via the motor molecule MAP-1C (brain dynein, ATP dependent)	Degraded vesicular membrane Absorbed exogenous material (toxins, viruses, growth factors)
Slow (anterograde only)	0.2–8	Not clear; requires intact microtubules (ATP dependent)	Cytoskeletal elements (e.g., neurofilament and microtubule subunits) Soluble proteins of intermediary metabolism Actin

Fast Axoplasmic Transport

If the flow of materials from the soma to the distant axon terminus were left to the whims of simple diffusion, their delivery would be far too slow to be of practical use. It could take months for needed proteins to diffuse to the end of an axon, and the presynaptic terminals are high-volume consumers of these molecules. To overcome this difficulty, neurons exploit a rapid, pony express–style system of conveyance known as **fast axoplasmic transport** (see [Table 10-2](#)). Membranous organelles, including vesicles and mitochondria, are the principal freight of fast axoplasmic transport. The proteins (some associated with RNA), lipids, and polysaccharides that move at fast rates in axons do so because they have caught a ride with a membranous organelle (i.e., they are sequestered inside the organelle or bound

to or inserted into the organellar membrane). The peptide and protein contents of dense-core secretory granules, which are found in the presynaptic axonal terminals, are synthesized as standard secretory proteins (see [pp. 34–35](#)). Thus, they are cotranslationally inserted across the membranes of the rough endoplasmic reticulum and subsequently processed in the cisternae of the Golgi complex. They are shipped to the axon in the lumens of Golgi-derived carrier vesicles.

Organelles and vesicles, and their macromolecule payloads, move along **microtubules** (see [p. 23](#)) with the help of a microtubule-dependent motor protein called **kinesin** ([Fig. 10-2A](#)). The kinesin motor (see [p. 25](#)) is itself an ATPase that produces vectorial movement of its payload along the microtubule. This system can move vesicles down the axon at rates of up to 400 mm/day; variations in cargo speed simply reflect more frequent pauses during the journey. Kinesins always move toward the plus end of microtubules (i.e., away from the cell body), and transport function is lost if the microtubules are disrupted. The nervous system has many forms of kinesin that recognize and transport different cargo. It is not known how the motor proteins recognize and attach to their intended payloads.

FIGURE 10-2 Fast axoplasmic transport. ER, endoplasmic reticulum.

Fast Retrograde Transport

Axons move material back toward the cell body via a different motor protein called **brain dynein** (see p. 25) or **MAP-1C** (see Fig. 10-2B). Like kinesin, MAP-1C moves along microtubule tracks and is an ATPase (see Table 10-2). However, MAP-1C moves along microtubules in the opposite direction to kinesin (see Fig. 10-2C), though at a slightly slower pace. Retrograde transport provides a mechanism for target-derived growth factors, like nerve growth factor, to reach the nucleus of a neuron where they can influence survival. How this signal is transmitted up the axon has been a persistent question. It may be endocytosed at the axon's terminal and transported to the cell body in a "signaling endosome." The loss of ATP production in axons, as occurs with blockade of oxidative metabolism, causes fast axonal transport

in both the anterograde and retrograde directions to fail.

Slow Axoplasmic Transport

Axons also have a need for hundreds of other proteins, including cytoskeletal proteins and soluble proteins that are used as enzymes for intermediary metabolism. These proteins are delivered by a slow anterograde axoplasmic transport mechanism that moves material at a mere 0.2 to 8 mm/day, the nervous system's equivalent of snail mail. The slowest-moving proteins are neurofilament and microtubule subunits (0.2 to 1 mm/day). The mechanism of slow axoplasmic transport is not well understood, but molecular motors operating on microtubule tracks appear to be involved. In fact, the difference between slow and fast axonal transport may primarily be the number of transport *interruptions* during the long axonal journey.

Neurons can be classified on the basis of their axonal projection, their dendritic geometry, and the number of processes emanating from the cell body

The trillions of nerve cells in the CNS have great structural diversity. Typically, neurons are classified on the basis of where their axons go (i.e., where they “project”), the geometry of their dendrites, and the number of processes that emanate from the cell body ([Fig. 10-3](#)). The real significance of these schemes is that they have functional implications.

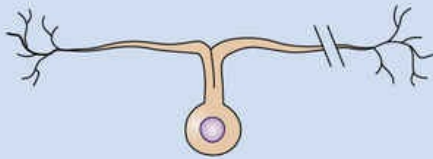

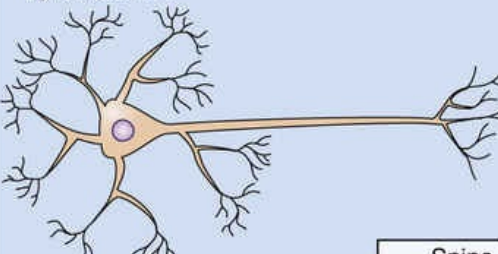

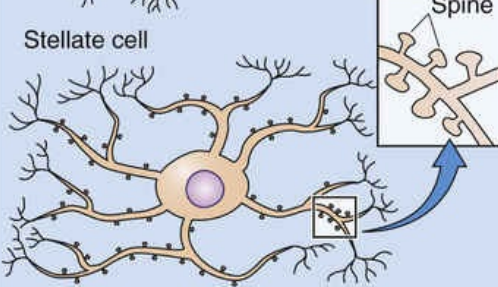

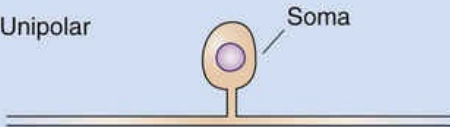

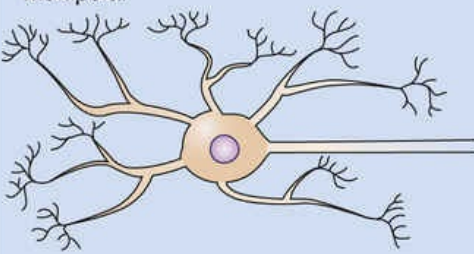

Basis for classification	Example	Functional implication	Structure
1. Axonal projection Goes to a distant brain area Stays in a local brain area	Projection neuron or Principal neuron or Golgi type I cell (cortical motor neuron)	Affects different brain areas	Dorsal root ganglion cell 
	Intrinsic neuron or Interneuron or Golgi type II cell (cortical inhibitory neuron)	Affects only nearby neurons	Retinal bipolar cell 
2. Dendritic pattern Pyramid-shaped spread of dendrites Radial-shaped spread of dendrites	Pyramidal cell (hippocampal pyramidal neuron)	Large area for receiving synaptic input; determines the pattern of incoming axons that can interact with the cell (i.e., pyramid-shaped)	Pyramidal cell 
	Stellate cell (cortical stellate cell)	Large area for receiving synaptic input; determines pattern of incoming axons that can interact with the cell (i.e., star-shaped)	Stellate cell 
3. Number of processes One process exits the cell body Two processes exit the cell body Many processes exit the cell body	Unipolar neuron (dorsal root ganglion cell)	Small area for receiving synaptic input: highly specialized function	Unipolar 
	Bipolar neuron (retinal bipolar cell)	Small area for receiving synaptic input: highly specialized function	Bipolar 
	Multipolar neuron (spinal motor neuron)	Large area for receiving synaptic input; determines the pattern of incoming axons that can interact with the cell	Multipolar 

FIGURE 10-3 Classification of neurons based on their structure.

Axonal Projection

Neurons with long axons that connect with other parts of the nervous system are called **projection neurons** (or principal neurons or Golgi type I cells). Each of these cells has a clearly defined axon that arises from the axon hillock located on the cell body or proximal dendrite and extends away from the cell body, sometimes for remarkable distances. Some neurons in the cortex, for example, project to the distal part of the spinal cord, a stretch of nearly a meter. All the other processes that a projection neuron has are dendrites. The other type of neuron that is defined in this way has all of its processes confined to one region of the brain. These neurons are called **interneurons** (or intrinsic neurons or Golgi type II cells). Some of these cells have very short axons, whereas others seem to lack a conventional axon altogether and may be referred to as *anaxonal*. The anaxonal neuron in the retina is called an amacrine cell (from the Greek for “no large/long fiber”).

Dendritic Geometry

A roughly pyramid-shaped set of dendritic branches characterizes **pyramidal cells**, whereas a radial pattern of dendritic branches defines **stellate cells**. This classification often includes mention of the presence or absence of dendritic spines—those small, protuberant projections that are sites for synaptic contact. All pyramidal cells appear to have spines, but stellate cells may have them (spiny) or may not (aspiny).

Number of Processes

Neurons can also be classified by the number of processes that extend from their cell bodies. The dorsal root ganglion cell is the classic **unipolar** neuron. The naming of the processes of primary sensory neurons, like the dorsal root ganglion cell, is often ambiguous. The process that extends into the CNS from this unipolar neuron is easily recognized as an axon because it carries information *away* from the cell body. On the other hand, the process that extends to sensory receptors in the skin and elsewhere is less easily defined. It is a typical axon in the sense that it can conduct an action potential, has myelin, and is characterized by an axonal cytoskeleton. However, it conveys information *toward* the cell body, which is usually the function of a dendrite. **Bipolar** neurons, such as the retinal bipolar cell, have two processes extending from opposite sides of the cell body. Most neurons in the brain are **multipolar**. Cells with many dendritic processes are designed to receive large numbers of synaptic inputs.

Most neurons in the brain can be categorized by two or more of these schemes. For example, the large neurons in the cortical area devoted to movement (i.e., the motor cortex) are multipolar, pyramidal, projection neurons. Similarly, a retinal bipolar cell is both an interneuron and a bipolar cell.

Glial cells provide a physiological environment for neurons

Glial cells are defined in part by what they lack: axons, action potentials, and synaptic potentials. They are more numerous than neurons and are diverse in structure and function. The main types of CNS glial cells are oligodendrocytes, astrocytes, and microglial cells. In the PNS, the main types of glial cells are satellite cells in autonomic and sensory ganglia, Schwann cells, and enteric glial cells. Glial function is discussed in [Chapter 11](#). Oligodendrocytes form the myelin sheaths of CNS axons, and Schwann cells myelinate peripheral nerves. Glial cells are involved in nearly every function of the brain and are far more than simply “nerve glue,” a literal translation of the name neuroglia (from the Greek *neuron* [nerve]

+ *glia* [glue]).

In depictions of the nervous system, the presence of glial cells is sometimes minimized or neglected altogether. Glia fills in almost all the space around neurons, with a narrow extracellular space left between neurons and glial cells that has an average width of only $\sim 0.02\ \mu\text{m}$. Glial cells have a major impact on the composition of the extracellular fluid, which in turn has a major impact on brain function, as we will see in [Chapter 11](#).

Box 10-1

Neural Modalities

The type of information, or neural **modality**, that a neuron transmits is classically categorized by three terms that refer to different attributes of the neuron.

1. The first category defines the *direction* of information flow.
 - **Afferent** (sensory): neurons that transmit information into the CNS from sensory cells or sensory receptors outside the nervous system. Examples are the dorsal root ganglion cell and neurons in the sensory nucleus of CN V.
 - **Efferent** (motor): neurons that transmit information out of the CNS to muscles or secretory cells. Examples are spinal motor neurons and motor neurons in the ANS.
2. The second category defines the *anatomical distribution* of the information flow.
 - **Visceral**: neurons that transmit information to or from internal organs or regions that arise embryologically from the branchial arch (e.g., chemoreceptors of the carotid body).
 - **Somatic**: neurons that transmit information to or from all nonvisceral parts of the body, including skin and muscle.
3. The third category, which is somewhat arbitrary, defines the information flow on the basis of the *embryological origin* of the structure being innervated.
 - **Special**: neurons that transmit information to or from a “special” subset of visceral or somatic structures. For example, in the case of **special**

visceral neurons, information travels to or from structures derived from the branchial arch region of the embryo (e.g., pharyngeal muscles). In the case of **special somatic** neurons, which handle only sensory information, the neurons arise from the organs of special sense (e.g., retina, taste receptors, cochlea).

- **General:** neurons that transmit information to or from visceral or somatic structures that are not in the special group.

Each axon in the body conveys information of only a single modality. In this classification scheme, a motor neuron in the spinal cord is described as a general somatic efferent neuron. A motor neuron in the brainstem that innervates branchial arch–derived chewing muscles is described as a special visceral efferent neuron. Because each of these three categories defines two options, you might expect a total of eight distinct neural modalities. In practice, however, only seven neural modalities exist. The term *special somatic efferent* neuron is not used.

Development of Neurons and Glial Cells

Neurons differentiate from the neuroectoderm

Although the embryology of the nervous system may seem like an odd place to begin studying the physiology of the brain, there are a number of reasons to start here. Knowledge of the embryology of the nervous system greatly facilitates comprehension of its complex organization. Events in the development of the nervous system highlight how different neuronal cell types evolve from a single type of precursor cell and how these neurons establish astonishingly specific connections. Finally, the characteristics of brain cell proliferation as well as the growth of neuronal processes during development provide insight into the consequences of brain injury.

At the stage of gastrulation, the vertebrate embryo consists of three primitive tissue layers: endoderm, mesoderm, and ectoderm ([Fig. 10-4](#)). The entire nervous system arises from ectoderm, which also gives rise to the skin. Underlying the ectoderm is a specialized cord of mesodermal cells called the notochord. Cells of the notochord somehow direct or “induce” the overlying ectoderm, or **neuroectoderm**, to form the neural tube in a complex process called neurulation.

FIGURE 10-4 Development of the nervous system. The left column provides a dorsal view of the developing nervous system at three different time points. The right column shows cross sections of the dorsal portion of the embryo at five different stages, three of which correspond to the dorsal views shown at the left.

The first step in neurulation is formation of the neural plate at about the beginning of the third fetal week. Initially, the neural plate is only a single layer of neuroectoderm cells. Rapid proliferation of these cells, especially at the lateral margins, creates a neural groove bordered by neural folds. Continued cell division enlarges the neural folds, and they eventually fuse dorsally to form the neural tube. The neural tube is open at both ends, the anterior and posterior neuropores. The neural tube ultimately gives rise to the brain and spinal cord. The lumen of the neural tube, the neural canal, becomes the four ventricles of the brain and the central canal of the spinal cord. Congenital malformations of the brain commonly arise from developmental defects in the neural tube ([Box 10-2](#)).

Box 10-2

Abnormalities of Neural Tube Closure

Closure of the neural tube in humans normally occurs between 26 and 28 days of gestation. A disturbance in this process results in a midline congenital abnormality called a **dysraphism** (from the Greek *dys* [abnormal] + *rhaphe* [seam or suture]). The defect can be so devastating that it is incompatible with life or, alternatively, have so little consequence that it goes unnoticed throughout life. These midline embryonic abnormalities also involve the primitive mesoderm and ectoderm associated with the neural tube. Therefore, the vertebral bodies or skull (derived from mesoderm) and the overlying skin (derived from ectoderm) may be affected along with the nervous system.

The most serious neural tube defect, occurring in 1 of 1000 deliveries, is **anencephaly**, in which the cerebral hemispheres are absent and the rest of the brain is severely malformed. Overlying malformations of the skull, brain coverings, and scalp are present (Table 10-3). Affected fetuses are often spontaneously aborted.

TABLE 10-3
Defects of Neural Tube Closure

MALFORMATION	CHARACTERISTICS
Brain Defects	
Anencephaly	Absence of the brain, with massive defects in the skull, meninges, and scalp
Cephalocele	Partial brain herniation through a skull defect (cranium bifidum)
Meningocele	Meningeal herniation through a skull or spine defect
Spina Bifida Defects	
Spina bifida occulta	Vertebral arch defect only
Spina bifida cystica	Herniation of the dura and arachnoid through a vertebral defect
Myelomeningocele	Herniation of the spinal cord and meninges through a vertebral defect

The most common dysraphisms affect formation of the spinal vertebral bodies and are called **spina bifida**. The problem may be slight and cause only a minor abnormality in closure of the vertebral arch, called spina bifida occulta (Fig. 10-7A). This malformation affects ~10% of the population, usually at the fifth lumbar or first sacral vertebra, and generally causes no significant sequelae. If the dura and arachnoid membranes herniate (i.e., protrude) through the vertebral defect, the malformation is called spina bifida cystica (see Fig. 10-7B); if the spinal cord also herniates through the defect, it is called myelomeningocele (see Fig. 10-7C). These latter problems are often more significant and may cause

severe neurological disability.

Genetic and nongenetic factors can cause dysraphism. Some severe forms of this condition appear to be inherited, although the genetic pattern suggests that multiple genes are involved. Nongenetic factors such as folic acid deficiency may also play a role. Mothers taking folic acid (see p. 1143) before and during the periconceptional period have a decreased risk of having a fetus with a neural tube closure defect. Current medical recommendations are that women *contemplating* becoming pregnant receive folic acid supplementation, and it has been suggested that bread products should be enriched with folic acid to ensure that women will have the protective advantage of this vitamin if they become pregnant. Other factors that increase the risk of these defects are maternal heat exposure (e.g., from a hot tub) and certain drugs such as the anticonvulsant valproate. Neural tube disorders can be detected during pregnancy by measuring the concentration of α -fetoprotein in maternal blood or amniotic fluid. α -fetoprotein is synthesized by the fetal liver and, for unclear reasons, increases in concentration abnormally with failure of neural tube closure.

The **neural crest** derives from lateral portions of the neural plate. Neural crest cells migrate to sites in the body where they form the vast majority of the PNS and most of the peripheral cells of the ANS, including the sympathetic ganglia and the chromaffin cells of the adrenal medulla. On the sensory side, these neural crest derivatives include unipolar neurons whose cell bodies are in the dorsal root ganglia, as well as the equivalent sensory cells of cranial nerves V, VII, IX, and X. Neural crest cells also give rise to several non-neuronal structures, including Schwann cells, satellite glial cells in spinal and cranial ganglia, and pigment cells of the skin.

The human brain begins to exhibit some regional specialization around the fourth gestational week ([Fig. 10-5A, B](#)). By then, it is possible to discern an anterior part called the **prosencephalon**, a midsection called the **mesencephalon**, and a posterior part called the **rhombencephalon**. Rapid brain growth ensues, and important new regions emerge in just another week (see [Fig. 10-5C](#)). Distinct regions called *brain vesicles*, which are destined to become separate parts of the adult brain, are set apart as swellings in the rostral-caudal plane (see [Fig. 10-5B, C](#)). The prosencephalon is now divisible into the **telencephalon**, which will give rise to the basal ganglia and cerebral cortex, and the **diencephalon**, which becomes the thalamus, subthalamus, hypothalamus, and neurohypophysis (the posterior or neural portion of the pituitary). Similarly, the rhombencephalon can now be divided into the **metencephalon**, which will give rise to the pons and cerebellum, and the **myelencephalon**, which becomes the medulla. Robust development of the cerebral cortex becomes apparent in mammals, especially humans, after the seventh week. This structure gradually expands so that it enwraps the rostral structures.

FIGURE 10-5 Embryonic development of the brain.

As the neural tube thickens with cell proliferation, a groove called the **sulcus limitans** forms on the inner, lateral wall of the neural tube (Fig. 10-6A). This anatomical landmark extends throughout the neural tube except in the farthest rostral area that will become the diencephalon and cortex. The sulcus limitans divides the neural tube into a ventral area called the basal plate and a dorsal area called the alar plate.

FIGURE 10-6 Development of the spinal cord and medulla. **A**, In this cross section through the neural tube, the sulcus limitans is the landmark that separates the ventral basal plate from the dorsal alar plate. The basal plate will form efferent (or motor-type) structures, whereas the alar plate will form afferent and associative (or sensory-type) functions. **B**, The true afferent neurons are those in the dorsal root ganglion, which derive from neural crest cells. These afferents will contact the neurons in the alar plate, which will become associative. **C**, The basal plate has developed into the ventral horn and intermediolateral column (motor), whereas the alar plate has developed into the dorsal horn (associative). **D**, The basal plate has developed into nuclei with motor functions, whereas the alar plate has developed into nuclei with sensory functions. The roof of the rostral medulla becomes the fourth ventricle. **E**, This cross section shows the same gross separation between motor and associative/sensory functions as is seen with the rostral medulla and the spinal cord. CN, cranial nerve.

Structures that derive from the **basal plate** mediate efferent functions, and structures that arise from the **alar plate** mediate afferent and associative functions. Efferent neurons are mainly motor neurons that convey information from the CNS to outside effectors (i.e., muscles or secretory cells). In a strict sense, the only true *afferent* neurons are those that derive from neural crest cells and that convey sensory information from various kinds of receptors to the CNS. In the CNS, these afferent neurons synapse on other neurons derived from the alar plate; these alar plate neurons may be referred to as afferent because they receive sensory information and pass it along to other parts of the CNS. However, it is also appropriate to call these alar plate–derived neurons associative.

The development of the spinal cord and medulla illustrates how this early anatomical division into alar and basal plates helps make sense of the final organization of these complex regions. Neurons of the alar and basal plates proliferate, migrate, and aggregate into discrete groups that have functional specificity. In the spinal cord (see [Fig. 10-6B, C](#)), the basal plate develops into the ventral horn, which contains the cell bodies of somatic motor neurons, and the intermediolateral column, which contains the cell bodies of autonomic motor neurons. Both regions contain interneurons. The alar plate in the spinal cord develops into the dorsal horn, which contains the cell bodies onto which sensory neurons synapse.

In the medulla (see [Fig. 10-6D, E](#)), as well as in the rest of the brain, aggregates of neurons are called **nuclei**. Nuclei that develop from the alar plate are generally afferent, such as the nucleus tractus solitarii, which plays an important sensory role in the ANS. Nuclei that develop from the basal plate are generally efferent, such as the dorsal motor nucleus of the vagus nerve, which plays an important *motor* role in the ANS. The choroid plexus that invaginates into the lumen of the central canal is responsible for secreting cerebrospinal fluid (see [pp. 278–279](#)).

Neurons and glial cells originate from cells in the proliferating germinal matrix near the ventricles

The trillions of neurons and glial cells that populate the brain arise from rapidly dividing stem cells called **neuroepithelial cells**  [N10-3](#) located near the ventricles (which derive from the neural canal) of the embryonic CNS. This germinal area is divided into two regions, the **ventricular zone (VZ)** and the **subventricular zone (SVZ)**. Most of the neurons in the human brain are generated during the first 120 days of embryogenesis. Growth factors such as epidermal growth factor and platelet-derived growth factor and hormones such as growth hormone influence the rate of cell division of the **neuroepithelial cells**. The signals that direct one immature neuron to become a cortical pyramidal cell and another to become a retinal ganglion cell are not understood. Neuroepithelial cells generate different classes of neural precursor cells that develop into different mature cell types. In the developing brain, **radial glial cells** (or just radial cells), so called because their processes extend from the ventricular surface to the brain's outer surface ([Fig. 10-8A](#)), appear very early in neurogenesis and generate most of the projection neurons in forebrain cortex. Inhibitory interneurons, in contrast, arise from neural precursor cells located in the SVZ. Neurons are probably not fully differentiated when first created, and their mature characteristics may depend on their interactions with the chemical environment or other cells in a specific anatomical region of the nervous system.

FIGURE 10-8 Arrangement of radial glial cells and migrating neurons. **A**, The upper portion is a coronal section of the developing occipital cerebral lobe of fetal monkey brain. The lower portion is a magnified view. The VZ contains the germinal cells that give rise to the neurons as well as to the cell bodies of the radial glial cells (or, simply, radial cells). These radial cells extend from the ventricular surface to the pial surface, which overlies the developing cortex. **B**, This more magnified view shows the cell bodies of radial cells as well as their processes that extend upward toward the cortex. Also shown are two migratory neuroblasts moving from the VZ toward the cortex along the fibers of the radial cells. The right part of the panel shows that, in the postnatal VZ, the radial cell can give rise to several major classes of cells. (Data from Rakic P: Mode of cell migration to the superficial layers of fetal monkey neocortex. *J Comp Neurol* 145:61–84, 1972; and Tramontin AD, García-Verdugo JM, Lim DA, Alvarez-Buylla A: Postnatal development of radial glia and the ventricular zone [VZ]: A continuum of the neural stem cell compartment. *Cereb Cortex* 13:580–587, 2003.)

N10-3

Stem Cells

Contributed by Bruce Ransom

The general rule that neurons are created only during embryonic development and are never replaced is valid in a practical sense for all parts of the mammalian CNS except for the olfactory bulb and the dentate gyrus of the hippocampus, which may retain a population of true stem cells. **Stem cells** are cells that have the ability to do the following:

1. Proliferate
2. Renew themselves over the life of the organism
3. Create fully differentiated cells through progenitor cells
4. Retain their multilineage potential throughout life
5. Replace cells lost to injury or disease

These stem cells create mature brain cells by engaging in **asymmetrical cell division**, which yields one stem cell and one cell that begins on the path to terminal differentiation. This latter cell is called a **progenitor cell**. It may continue to divide, but its progeny are committed to a particular line of cell differentiation (e.g., neurons or astrocytes, but not both). Stem cells can also engage in **symmetrical division** and simply create two new stem cells.

The stem cells of the nervous system are capable of generating neurons, astrocytes, and oligodendrocytes. A slowly dividing population of presumed stem cells resides in the subependymal area of the lateral ventricles (i.e., analogous to the germinal matrix of the fetal brain; see pp. 263–267). These cells are apparently the source for the olfactory neurons that are continually renewed during life. Adult stem cells from the brain proliferate in response to epidermal growth factor. It is not understood how to make these cells produce progenitor cells for neurons or glial cells. Eventually it is hoped that, by sending stem cells the right sequence of signals, it might be possible to replace neurons lost to injury or disease.

The VZ appears to produce separate **progenitor cells** that produce only neurons, oligodendrocytes, astrocytes, and ependymal cells (see [Fig. 10-8B](#)). The VZ does not contribute to the population of Schwann cells, which derive from neural crest tissue, or to microglial cells, which arise from the mesodermal cells that briefly invade the brain during early postnatal development. Recent work shows that the embryonic and perinatal VZ and SVZ may give rise to the adult SVZ, which is in part responsible for limited adult neurogenesis.

Neuronal progenitor cells appear earliest and produce nearly the entire complement of adult neurons during early embryonic life. Glial cells arise later in development. Neurons are confined to specific locations of the brain, whereas glial cells are more evenly distributed.

Many more neurons are created during fetal development than are present in the adult brain. Most neurons, having migrated to a final location in the brain and differentiated, are lost through a process called programmed cell death, or **apoptosis** (Greek for “falling off”; see [p. 1241](#)). Apoptosis is a unique form of cell death that requires protein synthesis and can be triggered by removal of specific trophic influences, such as the action of a growth factor. In contrast to necrotic cell death, which rapidly leads to loss of cell membrane integrity after some insult causes a toxic increase in $[Ca^{2+}]_i$, apoptosis evolves more slowly. For example, in the retina, ~60% of the ganglion cells and thus ~60% of the retinal axons are lost in the first 2 weeks of extrauterine life as a result of programmed retinal ganglion cell death. This process of sculpting the final form of a neuronal system by discarding neurons through programmed death is a common theme in developmental biology.

The number of glial cells in different areas of the brain appears to be determined by signals from nearby neurons or axons. For example, in the optic nerve, the final number of glial cells in the nerve is

closely determined by the number of axons. When programmed cell death is prevented by expression of the *bcl-2* gene in transgenic animals, the number of axons in the optic nerve, as well as the number of astrocytes and oligodendrocytes, is dramatically increased. Thus, glial cell–axon ratios remain relatively constant. The axon-dependent signal or signals responsible for these adjustments in glial cell number are not known, but the process appears to operate by influencing both survival and proliferation of glial cells.

Neurons migrate to their correct anatomical position in the brain with the help of adhesion molecules

During embryogenesis, the long processes of radial cells create an organized, cellular scaffolding on which neurons can migrate to their final position in the brain shortly after they appear. Migrating neurons contact radial cells (see [Fig. 10-8B](#)) and move along their processes toward their final positions in the developing cortex. Thus, the prearranged positions of these radial processes determine the direction of neuronal migration. The importance of the radial framework for assisting neuronal migration is illustrated by the failure of neurons to populate the cortex normally when the radial processes are interrupted by hemorrhage in the fetal brain.

The navigation mechanisms used by migrating cells in the nervous system and elsewhere in the body are only partially understood. Proteins that promote selective cellular aggregation are called **cell-cell adhesion molecules** (CAMs; see [p. 17](#)) and include the Ca^{2+} -dependent cadherins and Ca^{2+} -independent neural cell adhesion molecules (N-CAMs). These molecules are expressed by developing cells in an organized, sequential manner. Cells that express the appropriate adhesion molecules have a strong tendency to adhere to one another. These Velcro-like molecules can assemble cells in a highly ordered fashion; experimentally, disrupted germ cells can properly reorganize themselves into a three-layered structure that replicates the normal embryonic pattern.

Another mechanism that assists migrating cells is the presence of **extracellular matrix** molecules such as laminin and fibronectin (see [p. 17](#)). These glycoproteins are selectively secreted by both neurons and astrocytes and form a kind of extracellular roadway with which migrating cells can interact. Growing axons express at their surface **cell matrix adhesion molecules** called integrins that bind laminin and fibronectin. As a result, growing axons move together in fascicles.

Perhaps the least understood mechanism related to cell migration is **chemotaxis**, the ability of a cell to follow a chemical signal emitted from a target cell. The tips of developing or regenerating axons, called growth cones, follow such chemical cues as they grow toward their specific targets, propelled by coordinated extension of microtubules and thin filaments. Coordinated growth-cone movement also involves continuous polymerization of tubulin and actin at the leading edge of the growth cone and depolymerization at the trailing edge. This process requires that the recognition proteins on growth cones generate intracellular signals when they encounter path-finding signals. For example, a molecule called **netrin**, secreted by midline cells, attracts developing axons destined to cross the midline. On the other hand, molecules like **slit** repel axons by interacting with specific receptors on the growth cone. Such signals steer axon growth cones, perhaps by localized changes in intracellular $[\text{Ca}^{2+}]$, which leads to the strategic insertion of new patches of membrane on the surface of the growth cone.

Neurons do not regenerate

Neurons

Most human neurons arise in about the first 4 months of intrauterine life. After birth, neurons do not divide, and if a neuron is lost for any reason, it is generally not replaced, which is the main reason for the relatively limited recovery from serious brain and spinal cord injuries. It has been argued that this lack of regenerative ability is a design principle to ensure that learned behavior and memories are preserved in stable populations of neurons throughout life. A notable exception to this rule is olfactory bulb neurons, which are continually renewed throughout adult life by a population of stem cells or neuronal progenitor cells. 🟡 **N10-3** As noted above (see [pp. 263–265](#)), cells in the adult SVZ have the capacity to generate neurons and may do so to a limited extent throughout life. Learning how to induce these cells to make functional new CNS neurons after severe neural injury is the holy grail of regeneration research.

Axons

Another reason that relatively little recovery follows severe brain and spinal cord injury is that axons within the CNS do not regenerate effectively. This lack of axon regeneration in the CNS is in sharp contrast to the behavior of axons in the PNS, which can regrow and reconnect to appropriate end organs, either muscle or sensory receptors. For example, if the median nerve of the forearm is crushed by blunt trauma, the distal axon segments die off in a process called wallerian degeneration (see [Box 10-3](#)) because the sustaining relationship with their proximal cell bodies is lost. These PNS axons can slowly regenerate and connect to muscles and sensory receptors in the hand. It is believed that the inability of CNS axons to regenerate is the fault of the local environment more than it is an intrinsic property of these axons. For example, on their surface, oligodendrocytes and myelin carry molecules, such as myelin-associated glycoprotein, that inhibit axon growth. Experiments have shown that if severed CNS axons are given the opportunity to regrow in the same environment that surrounds axons in the PNS, they are capable of regrowth and can make functional connections with CNS targets. The remarkable ability of damaged peripheral nerves to regenerate, even in mammals, has encouraged hope that CNS axons might, under the right conditions, be able to perform this same feat. It would mean that victims of spinal cord injury might walk again.

Box 10-3

Axonal Degeneration and Regeneration

Axons have their own mitochondria and produce the ATP that they need to maintain the steep ion gradients necessary for excitability and survival. In this sense, they are metabolically independent of the cell body. However, they cannot make proteins and are unable to sustain themselves if separated from the cell body (see [Fig. 10-2A](#)). If an axon is cut in either the PNS or the CNS, a characteristic series of changes takes place ([Fig. 10-9](#)):

A NORMAL NEURON

B DEGENERATING NEURON

- Step 1: Degeneration of the synaptic terminals distal to the lesion.** Synaptic transmission occurring at the axon terminal fails within hours because this complex process is dependent on material provided by axonal transport. Visible changes in the degenerating terminal are seen a few days after the lesion. The terminal retracts from the postsynaptic target.
- Step 2: Wallerian degeneration.** The lesion divides the axon into proximal and distal segments. The distal segment degenerates slowly during a period of several weeks in a process named after its discoverer, Augustus Waller. Eventually, the entire distal segment is destroyed and removed.
- Step 3: Myelin degeneration.** If the affected axon is myelinated, the myelin degenerates. The myelinating cell (i.e., the Schwann cell in the PNS and the oligodendrocyte in the CNS) usually survives this process. Schwann cells are immediately induced to divide, and they begin to synthesize trophic factors that may be important for regeneration.
- Step 4: Scavenging of debris.** Microglia in the CNS and macrophages and Schwann cells in the PNS scavenge the debris created by the breakdown of the axon and its myelin. This step is more rapid in the PNS than in the CNS.
- Step 5: Chromatolysis.** After axonal injury, most neuron cell bodies swell and undergo a characteristic rearrangement of organelles called chromatolysis. The nucleus also swells and moves to an eccentric position. The endoplasmic reticulum, normally close to the nucleus, reassembles around the periphery of the cell body. Chromatolysis is reversible if the neuron survives and is able to re-establish its distal process and contact the appropriate target.
- Step 6: Retrograde transneuronal degeneration.** Neurons that are synaptically connected to injured neurons may themselves be injured, a condition called transneuronal or trans-synaptic degeneration. If the neuron that synapses on the injured cell undergoes degeneration, it is called retrograde degeneration.
- Step 7: Anterograde transneuronal degeneration.** If a neuron that received synaptic contacts from an injured cell degenerates, it is called anterograde degeneration. The magnitude of these transneuronal effects (retrograde and anterograde degeneration) is quite variable.

Glia

Unlike neurons, glial cells can be replaced if they are lost or injured in an adult. Such repopulation depends on progenitor cells committed to the glial cell lineage. Either the progenitor cells reside in a latent state (or are slowly turning over) in adult brains or true multipotential stem cells are activated by specific conditions, such as brain injury, to produce de novo glial progenitors. The most typical reaction of mammalian brains to a wide range of injuries is the formation of an **astrocytic glial scar**. This scar is produced primarily by an enlargement of individual astrocytes, a process called *hypertrophy*, and increased expression of a particular cytoskeleton protein, glial acidic fibrillary protein. Only a small degree of astrocytic *proliferation* (i.e., an increase in cell number) accompanies this reaction. **Microglial**

cells, which derive from cells related to the monocyte-macrophage lineage in blood and not from neuroepithelium, also react strongly to brain injury and are the main cells that proliferate at the injury site.

Subdivisions of the Nervous System

A rudimentary knowledge of the anatomy of the nervous system is a prerequisite to discussion of its physiology. This section provides an overview of nervous system anatomy that builds on what has already been discussed about its embryological development. We in turn consider the CNS, PNS, and ANS (see [Table 10-1](#)).

The directional terms used to describe brain structures can be somewhat confusing because the human nervous system, unlike that of lower vertebrates, bends during development. Thus, the dorsal surface of the cerebral cortex is also superior, whereas the dorsal surface of the spinal cord is also posterior ([Fig. 10-10A](#)).

A AXES OF THE CNS

B MAJOR COMPONENTS OF THE CNS

C SURFACE ANATOMY OF THE CEREBRAL CORTEX

The CNS consists of the telencephalon, cerebellum, diencephalon, midbrain, pons, medulla, and spinal cord

The CNS can be conveniently divided into five major areas: (1) telencephalon, (2) cerebellum, (3) diencephalon, (4) brainstem (consisting of the midbrain, pons, and medulla), and (5) spinal cord (see [Fig. 10-10B](#)). Each of these areas has symmetrical right and left sides.

Telencephalon

One of the crowning glories of evolution is the human **cerebral cortex**, the most conspicuous part of the paired cerebral hemispheres. The human cerebral cortex has a surface area of $\sim 2200 \text{ cm}^2$ and is estimated to contain 1.5 to 2×10^{10} neurons. The number of synaptic contacts between these cells is $\sim 3 \times 10^{14}$. The cortical surface area of mammals increases massively from mouse to monkey to humans in a ratio of $1 : 100 : 1000$. The capacity for information processing by this neural machine is staggering and includes a remarkable range of functions: thinking, learning, memory, and consciousness.

The cortex is topographically organized in two ways. First, certain areas of the cortex mediate specific functions. For example, the area that mediates motor control is a well-defined strip of cortex located in the frontal lobe (see [Fig. 10-10C](#)). Second, within a portion of cortex that manages a specific function (e.g., motor control, somatic sensation, hearing, or vision), the parts of the body spatially map onto this cortex in an orderly way. We discuss this principle of **somatotopy** on [pp. 400–401](#).

Another part of the telencephalon is the great mass of axons that stream into and out of the cerebral cortex and connect it with other regions. The **corpus callosum** and smaller white matter tracts interconnect the two cerebral hemispheres. The volume of axons needed to interconnect cortical neurons increases as a power function of cortical volume, which rises so dramatically from mice to humans. Thus, the *relative* volume of white matter to gray matter is 5-fold greater in humans than in mice. The final parts of the telencephalon are the **basal ganglia**, a functionally related group of neuron clusters consisting of the striatum (caudate nucleus and putamen), globus pallidus, amygdala, and hippocampal formation. These are all paired structures. The basal ganglia have indirect connections with motor portions of the cerebral cortex and are involved in motor control. The **amygdala** participates in the expression of emotion, and the **hippocampal formation** is crucial in the formation of new memories. Indeed, injury to both hippocampal formations can cause a severe amnesic disorder.

Cerebellum

This brain region lies immediately dorsal to the brainstem. Although the cerebellum represents only $\sim 10\%$ of the CNS by volume, it contains $\sim 50\%$ of all CNS neurons. The exceedingly large number of input connections to the cerebellum conveys information from nearly every type of receptor in the nervous system, including visual and auditory input. Combined, these afferent fibers outnumber the efferent projections by an estimated ratio of $40 : 1$.

Functionally and by virtue of its connections, the cerebellum can be divided into three parts. Phylogenetically, the vestibulocerebellum (also called the archicerebellum) is the oldest of these three parts, followed by the spinocerebellum (also called the paleocerebellum) and then by the cerebrocerebellum (also called the neocerebellum).

The **vestibulocerebellum** is closely related to the vestibular system, whose sensors are located in the inner ear and whose way stations are located in the pons and medulla. It helps maintain the body's balance. The **spinocerebellum** receives strong input from muscle stretch receptors through connections in the spinal cord and brainstem. It helps regulate muscle tone. The **cerebrocerebellum**, the largest part of the human cerebellum, receives a massive number of projections from sensorimotor portions of the cerebral cortex through neurons in the pons. It coordinates motor behavior. Much of the cerebellum's output reaches the contralateral (i.e., on the opposite side of the body) motor cortex by way of the thalamus. Other efferent projections reach neurons in all three parts of the brainstem.

Diencephalon

This brain region consists of the thalamus, the subthalamus, and the hypothalamus, each with a very different function. The **thalamus** is the main integrating station for sensory information that is bound for the cerebral cortex, where it will reach the level of conscious perception. Control of arousal and certain aspects of memory function also reside in discrete areas of the thalamus. Along with the **subthalamus**, the thalamus receives projections from the basal ganglia that are important for motor function. Input to the thalamus from the cerebellum (specifically, the cerebrocerebellum) is important for normal motor control. Patients with **Parkinson disease**, a severe movement disorder, gradually lose the ability to make voluntary movements; in some of these patients, it is possible to improve movement by stimulating certain areas of the subthalamus.

The **hypothalamus** is the CNS structure that most affects the ANS. It performs this function through strong, direct connections with autonomic nuclei in the brainstem and spinal cord. It also acts as part of the endocrine system in two major ways. First, specialized neurons located within specific nuclei in the hypothalamus synthesize certain hormones (e.g., arginine vasopressin and oxytocin) and transport them down their axons to the posterior pituitary gland, where the hormones are secreted into the blood. Second, other specialized neurons in other nuclei synthesize “releasing hormones” (e.g., gonadotropin-releasing hormone) and release them into a plexus of veins, called a portal system, that carries the releasing hormones to cells in the anterior pituitary. There, the releasing hormones stimulate certain cells (e.g., gonadotrophs) to secrete hormones (e.g., follicle-stimulating hormone or luteinizing hormone) into the bloodstream. We discuss these principles starting on [p. 1015](#) in the second edition of this text. The hypothalamus also has specialized centers that play important roles in controlling body temperature (see [p. 1200](#)), hunger (see [p. 1001](#)), thirst (see [pp. 845–846](#)), and the cardiovascular system. It is the main control center of the ANS.

Brainstem (Midbrain, Pons, and Medulla)

The brainstem lies immediately above, or rostral to, the spinal cord. Like the spinal cord, the midbrain, pons, and medulla have a segmental organization, receive sensory (afferent) information, and send out motor (efferent) signals through paired nerves that are called **cranial nerves**. The midbrain, pons, and medulla also contain important control centers for the ANS (see [Chapter 14](#)). Not only are motor neurons, autonomic neurons, and sensory neurons present at each level, but the caudal brainstem serves as a conduit for a large volume of axons traveling from higher CNS centers to the spinal cord (descending pathways) and vice versa (ascending pathways). Additionally, this portion of the brainstem contains a loosely organized interconnected collection of neurons and fibers called the **reticular formation**. This neuronal network has diffuse connections with the cortex and other brain regions and affects the level of consciousness or arousal.

The **midbrain** has somatic motor neurons that control eye movement. These neurons reside in the nuclei for cranial nerve III (CN III) and CN IV. Other midbrain neurons are part of a system, along with the cerebellum and cortex, for motor control. The midbrain also contains groups of neurons that are involved in relaying signals related to hearing and vision.

Just caudal to the midbrain is the **pons**, which contains the somatic motor neurons that control mastication (nucleus for CN V), eye movement (nucleus for CN VI), and facial muscles (nucleus for CN VII). The pons also receives somatic sensory information from the face, scalp, mouth, and nose (portion of the nucleus for CN V). It is also involved in processing information that is related to hearing and equilibrium (nucleus for CN VIII). Neurons in the ventral pons receive input from the cortex, and these neurons in turn form a massive direct connection with the cerebellum (see above) that is crucial for coordinating motor movements.

The most caudal portion of the brainstem is the **medulla**. The organization of the medulla is most similar to that of the spinal cord. The medulla contains somatic motor neurons that innervate the muscles of the neck (nucleus of CN XI) and tongue (nucleus of CN XII). Along with the pons, the medulla is involved in controlling blood pressure, heart rate, respiration, and digestion (nuclei of CN IX and X). The medulla is the first CNS way station for information traveling from the special senses of hearing and equilibrium.

Spinal Cord

Continuous with the caudal portion of the medulla is the spinal cord. The spinal cord runs from the base of the skull to the end of the body of the first lumbar vertebra (L1). Thus, it does not run the full length of the vertebral column in adults.

The spinal cord consists of 31 segments that each have a motor and sensory nerve root. (The sensory nerve root of the first cervical segment is very small and can be missing.) These nerve roots combine to form 31 bilaterally symmetrical pairs of spinal nerves. The spinal roots, nerves, and ganglia are part of the PNS (see below).

Sensory information from the skin, muscle, and visceral organs enters the spinal cord through fascicles of axons called dorsal roots ([Fig. 10-11A](#)). The point of entry is called the dorsal root entry zone. Dorsal root axons have their cell bodies of origin in the spinal ganglia (i.e., **dorsal root ganglia**) associated with that spinal segment.

A SPINAL CORD AND NERVE ROOTS

B A SPINAL REFLEX ARC

C ASCENDING AND DESCENDING TRACTS

FIGURE 10-11 Spinal cord. **A**, Each spinal segment has dorsal and ventral nerve roots that carry sensory and motor nerve fibers, respectively. **B**, The simple “flexor” reflex arc is an illustration of the four functions of the PNS: (1) a receptor transduces a painful stimulus into an action potential, (2) a primary sensory neuron conveys the information to the CNS, (3) the CNS conveys information to the target organ via a motor neuron, and (4) the electrical signals are converted to signals at the motor end plate. **C**, Ascending pathways, which carry information to more rostral areas of the CNS, are shown on the left. Descending pathways, which carry information in the opposite direction, are shown on the right.

Ventral roots contain strictly efferent fibers (see Fig. 10-11B). These fibers arise from motor neurons (i.e., general somatic efferent neurons) whose cell bodies are located in the ventral (or anterior) *gray* horns of the spinal cord (gray because they contain mainly cell bodies without myelin) and from preganglionic autonomic neurons (i.e., general visceral efferent neurons) whose cell bodies are located in the intermediolateral gray horns (i.e., between the dorsal and ventral gray horns) of the cord. Most of the

efferent fibers are somatic efferents that innervate skeletal muscle to mediate voluntary movement. The other fibers are visceral efferents that synapse with postganglionic autonomic neurons, which in turn innervate visceral smooth muscle or glandular tissue.

Each segment of the spinal cord contains groups of associative neurons in its dorsal gray horns. Some but not all incoming sensory fibers synapse on these associative neurons, which in turn contribute axons to fiber paths that both mediate synaptic interactions within the spinal cord and convey information to more rostral areas of the CNS by way of several conspicuous **ascending tracts** of axons (see [Fig. 10-11C](#)). Similarly, **descending tracts** of axons from the cerebral cortex and brainstem control the motor neurons whose cell bodies are in the ventral horn, which leads to coordinated voluntary or posture-stabilizing movements. The most important of these descending tracts is called the lateral **corticospinal tract**; ~90% of its cell bodies of origin are in the contralateral cerebral cortex. These ascending and descending tracts are located in the *white* portion of the spinal cord (white because it contains mostly myelinated axons). The spatial organization of spinal cord neurons and fiber tracts is complex but orderly and varies somewhat among the 31 segments.

If sensory fibers enter the spinal cord and synapse directly on motor neurons in that same segment, this connection underlies a simple **segmental reflex** or interaction. If the incoming fibers synapse with neurons in other spinal segments, they can participate in an **intersegmental reflex** or interaction. Finally, if the incoming signals travel rostrally to the brainstem before they synapse, they constitute a **suprasegmental interaction**.

The PNS comprises the cranial and spinal nerves, their associated sensory ganglia, and various sensory receptors

The PNS serves four main purposes: (1) it transduces physical or chemical stimuli both from the external environment and from within the body into raw sensory information through receptors; (2) it conveys sensory information to the CNS along axon pathways; (3) it conveys motor signals from the CNS along axon pathways to target organs, primarily skeletal and smooth muscle; and (4) it converts the motor signals to chemical signals at synapses on target tissues in the periphery. [Figure 10-11B](#) summarizes these four functions for a simple reflex arc in which a painful stimulus to the foot results in retraction of the foot from the source of the pain.

Like the CNS, the PNS can be divided into *somatic* and *autonomic* parts. The somatic division includes the sensory neurons and axons that innervate the skin, joints, and muscle as well as the motor axons that innervate skeletal muscle. The somatic division of the PNS primarily deals with the body's *external environment*, either to gather information about this environment or to interact with it through voluntary motor behavior. The ANS, discussed in the next section and in [Chapter 14](#), is a functionally distinct part of both the CNS and PNS (see [Table 10-1](#)). The autonomic portion of the PNS consists of the motor and sensory axons that innervate smooth muscle, the exocrine glands, and other viscera. This division mainly deals with the body's *internal environment*.

Three important aspects of the PNS are discussed in other chapters. Sensory transduction is reviewed in [Chapter 15](#), synaptic transmission in [Chapters 8](#) and [13](#), and peripheral neuronal circuits in [Chapter 16](#). Here, we focus primarily on the system of axons that is such a prominent feature of the PNS.

Axons in the PNS are organized into bundles called **peripheral nerves** ([Fig. 10-12](#)). These nerves contain, in a large nerve such as the sciatic nerve, tens of thousands of axons. Individual axons are surrounded by loose connective tissue called the **endoneurium**. Within the nerve, axons are bundled together in small groups called fascicles, each one covered by a connective tissue sheath known as the

perineurium. The perineurium contributes structural stability to the nerve. Fascicles are grouped together and surrounded by a matrix of connective tissue called the **epineurium**. Fascicles within a nerve anastomose with neighboring fascicles. Axons shift from one fascicle to another along the length of the nerve, but they tend to remain in roughly the same general area within the nerve over long distances. The interlocking meshwork of fascicles adds further mechanical strength to the nerve. Axons range in diameter from <1 to $20\text{ }\mu\text{m}$. Because axons are extremely fragile, adaptations that enhance mechanical stability are very important. Nervous tissue in the PNS is designed to be much tougher, physically, than that in the CNS. The PNS must be mechanically flexible, tolerant of minor physical trauma, and sustainable by a blood supply that is less dependable than the one providing for the CNS. A spinal cord transplanted to the lower part of the leg would not survive the running of a 100-m dash.

FIGURE 10-12 Peripheral nerve.

Axons in peripheral nerves are closely associated with Schwann cells. In the case of a myelinated axon, a Schwann cell forms a myelinated wrap around a single adjacent axon, a single internodal myelin segment between 250 and $1000\text{ }\mu\text{m}$ in length. Many such internodal myelin segments, and thus many Schwann cells, are necessary to myelinate the entire length of the axon. In an unmyelinated nerve, the Schwann cell surrounds but does not wrap multiple times around axons. Unmyelinated axons outnumber

myelinated axons by about 2 : 1 in typical human nerves. Diseases that affect the PNS can disrupt nerve function by causing either loss of myelin or axonal injury.

The functional organization of a peripheral nerve is best illustrated by a typical thoracic spinal nerve and its branches. Every spinal nerve is formed by the dorsal and ventral roots joining together and emerging from the spinal cord at that segmental level (see [Fig. 10-11](#)). The dorsal roots coalesce and display a spindle-shaped swelling called the spinal or dorsal root ganglion, which contains the cell bodies of the sensory axons in the dorsal roots. Individual neurons are called dorsal root ganglion cells or spinal ganglion cells and are typical unipolar neurons that give rise to a single process that bifurcates in a T-like manner into a peripheral and central branch (see [Fig. 10-3](#)). The central branch carries sensory information into the CNS and the peripheral branch terminates as a sensory ending. The peripheral process, which brings information toward the cell body, meets one definition of a dendrite; however, it has all the physiological and morphological features of a peripheral axon.

Spinal nerves divide into several branches that distribute motor and sensory axons to the parts of the body associated with that segment. Axons conveying autonomic motor or autonomic sensory signals also travel in these branches. These branches are said to be “mixed” because they contain both efferent and afferent axons. Further nerve division occurs as axons travel to supply their targets, such as the skin, muscle, or blood vessels. In the case of thoracic spinal nerves, the subdivision is orderly and has a similar pattern for most of the nerves. In the cervical and lumbosacral areas, however, the spinal nerves from different segments of the spinal cord intermingle to form a **nerve plexus**. The subsequent course of the nerves in the upper and lower extremities is complex. The pattern of cutaneous innervation of the body is shown in [Figure 10-13](#). The area of cutaneous innervation provided by a single dorsal root and its ganglion is called a **dermatome**. Severing a single dorsal root does not produce anesthesia in that dermatome because of overlap between the cutaneous innervation provided by adjacent dorsal roots. The sole exception to this rule is the C2 root, sectioning of which causes a patch of analgesia on the back of the head; neither C3 nor the trigeminal nerve innervates skin in this area. Also note that no dermatomes are shown for the first cervical and the coccygeal segments because the dermatomes are small or, in the case of the first cervical segment, may be missing.

FIGURE 10-13 Dermatomes. A dermatome is the area of cutaneous sensory innervation that a single spinal segment provides.

The ANS innervates effectors that are not under voluntary control

The nervous system regulates some physiological mechanisms in a way that is independent or *autonomous* of voluntary control. Control of body temperature is an example of a fundamental process that most individuals cannot consciously regulate. Other examples include blood pressure and heart rate. The absence of voluntary control means that the ANS has little cortical representation.

The ANS has three divisions: sympathetic, parasympathetic, and enteric. The sympathetic and parasympathetic divisions have both CNS and PNS parts. The enteric division lies entirely within the PNS. The **parasympathetic** and **sympathetic** efferent systems are composed of two-neuron pathways. The cell body of the first neuron is located in the CNS and that of the second in the PNS. The sympathetic and parasympathetic divisions innervate most visceral organs and have a yin-yang functional relationship. The **enteric** division regulates the rhythmic contraction of intestinal smooth muscle and also regulates the secretory functions of intestinal epithelial cells. It receives afferent input from the gut wall and is subject to modulation by the two other divisions of the ANS.

All the divisions have both efferent and afferent connections, although the efferent actions of the ANS are usually emphasized. We consider the ANS in detail in [Chapter 14](#).

Box 10-4

Peripheral Nerve Disease

The symptoms of peripheral nerve disease, or **neuropathy**, are numbness (i.e., a sensory deficit) and weakness (i.e., a motor deficit). Such symptoms may arise from disturbances in many parts of the nervous system. How, then, can one tell whether a problem is the result of disease in the PNS?

Motor axons directly innervate and have “trophic” effects on skeletal muscle. If the axon is cut or dies,

this trophic influence is lost and the muscle undergoes denervation atrophy. In addition, individual muscle fibers may twitch spontaneously (**fibrillation**). The cause of fibrillation is still debated, but it may be related to the observation that acetylcholine receptors spread beyond the neuromuscular junction and become “supersensitive” to their agonist. If true, these observations imply continuing exposure to acetylcholine, even if it is in smaller quantities. Schwann cells at denervated junctions may be the source of acetylcholine. When a motor axon is first damaged but has not yet lost continuity with the muscle fibers that it innervates, these muscle cells may twitch in unison. These small twitches can be seen under the skin and are called **fasciculations**. They are probably due to spontaneous action potentials in dying or injured motor neurons or their axons.

When the PNS is affected by a diffuse or generalized disease (e.g., the result of a metabolic problem or toxin), all peripheral nerves are involved, but symptoms arise first in the longest nerves of the body (i.e., those traveling from the spinal cord to the feet). This predilection for affecting the longest nerves often causes a “stocking pattern” defect in sensation and sometimes in strength. If both the feet and hands are affected, the process is called a “stocking and glove” defect. With progression of the disease, the level of involvement moves centripetally (i.e., up the leg, toward the trunk), and the sensory or motor dysfunction comes to involve more proximal portions of the legs and arms. One of the most common causes of this diffuse pattern of PNS involvement is the sensorimotor polyneuropathy associated with diabetes. Other causes include chronic renal failure (uremia), thiamine deficiency (often seen with alcohol abuse), and heavy-metal poisoning.

If a patient exhibits weakness or sensory loss that is associated with muscle fibrillation and atrophy and a stocking or stocking and glove pattern of sensory disturbance, a PNS problem is likely. Patients with peripheral neuropathy may also complain of tingling sensations (**paresthesias**) or pain in areas of the body supplied by the diseased nerves.

CHAPTER 11

The Neuronal Microenvironment

Bruce R. Ransom

Extracellular fluid in the brain provides a highly regulated environment for central nervous system neurons

Everything that surrounds individual neurons can be considered part of the **neuronal microenvironment**. Technically, therefore, the neuronal microenvironment includes the extracellular fluid (ECF), capillaries, glial cells, and adjacent neurons. Although the term often is restricted to just the immediate ECF, the ECF cannot be meaningfully discussed in isolation because of its extensive interaction with brain capillaries, glial cells, and cerebrospinal fluid (CSF). How the microenvironment interacts with neurons and how the brain (used here synonymously with *central nervous system*, or *CNS*) stabilizes it to provide constancy for neuronal function are the subjects of this discussion.

The concentrations of solutes in **brain extracellular fluid (BECF)** fluctuate with neural activity, and conversely, changes in ECF composition can influence nerve cell behavior. Not surprisingly, therefore, the brain carefully controls the composition of this important compartment. It does so in three major ways: First, the brain uses the **blood-brain barrier (BBB)** to protect the BECF from fluctuations in blood composition. Second, the CSF, produced by choroid plexus epithelial cells, strongly influences the composition of the BECF. Third, the surrounding glial cells “condition” the BECF.

The brain is physically and metabolically fragile

The ratio of brain weight to body weight in humans is the highest in the animal kingdom. The average adult brain weight is ~1400 g in men and ~1300 g in women—approximately the same weight as the liver (see [p. 944](#)). This large and vital structure, which has the consistency of thick pudding, is protected from mechanical injury by a surrounding layer of bone and by the CSF in which it floats.

The brain is also *metabolically* fragile. This fragility arises from its high rate of energy consumption, absence of significant stored fuel in the form of glycogen (~5% of the amount in the liver), and rapid development of cellular damage when ATP is depleted. However, the brain is not the greediest of the body's organs; both the heart and kidney cortex have higher metabolic rates. Nevertheless, although it constitutes only 2% of the body by weight, the brain receives ~15% of resting blood flow and accounts for ~20% and 50% of total resting oxygen and glucose utilization, respectively. The brain's high metabolic demands arise from the need of its neurons to maintain the steep ion gradients on which neuronal excitability depends. In addition, neurons rapidly turn over their actin cytoskeleton. Neuroglial cells, the other major cells in the brain, also maintain steep transmembrane ion gradients. More than half of the energy consumed by the brain is directed to maintain ion gradients, primarily through operation of the Na-K pump (see [pp. 115–117](#)). An interruption of the continuous supply of oxygen or glucose to the brain results in rapid depletion of energy stores and disruption of ion gradients. Because of falling ATP levels in the brain, consciousness is lost within 10 seconds of a blockade in cerebral blood flow. Irreversible nerve cell injury can occur after only 5 to 10 minutes of interrupted blood flow.

Cerebrospinal Fluid

CSF is a colorless, watery liquid. It fills the ventricles of the brain and forms a thin layer around the outside of the brain and spinal cord in the subarachnoid space. CSF is secreted within the brain by a highly vascularized epithelial structure called the **choroid plexus** and circulates to sites in the subarachnoid space, where it enters the venous blood system. The composition of CSF is highly regulated, and because it directly mixes with BECF, it helps regulate the composition of BECF. The choroid plexus can be thought of as the brain's “kidney” in that it stabilizes the composition of CSF, just as the kidney stabilizes the composition of blood plasma.

CSF fills the ventricles and subarachnoid space

The **ventricles** of the brain are four small compartments located within the brain ([Fig. 11-1A](#)). Each ventricle contains a choroid plexus and is filled with CSF. The ventricles are linked together by channels, or foramina, that allow CSF to move easily between them. The two **lateral ventricles** are the largest and are symmetrically located within the cerebral hemispheres. The choroid plexus of each lateral ventricle is located along the inner radius of this horseshoe-shaped structure (see [Fig. 11-1B](#)). The two lateral ventricles each communicate with the **third ventricle**, which is located in the midline between the thalami, through the two interventricular **foramina of Monro**. The choroid plexus of the third ventricle lies along the ventricle roof. The third ventricle communicates with the fourth ventricle by the **cerebral aqueduct of Sylvius**. The **fourth ventricle** is the most caudal ventricle and is located in the brainstem. It is bounded by the cerebellum superiorly and by the pons and medulla inferiorly. The choroid plexus of the fourth ventricle lies along only a portion of this ventricle's tent-shaped roof. The fourth ventricle is continuous with the central canal of the spinal cord. CSF escapes from the fourth ventricle and flows into the subarachnoid space through three foramina: the two laterally placed **foramina of Luschka** and the midline opening in the roof of the fourth ventricle, called the **foramen of Magendie**. We shall see below how CSF circulates throughout the subarachnoid space of the brain and spinal cord, and how it moves through brain tissue itself.

A VENTRICLES OF THE BRAIN

B CSF CIRCULATION

FIGURE 11-1 The brain ventricles and the CSF. **A**, This is a transparent view, looking from the left side of the brain. The two lateral ventricles communicate with the third ventricle, which in turn communicates with the fourth ventricle. **B**, Each ventricle contains a choroid plexus, which secretes CSF. The CSF escapes from the fourth ventricle and into the subarachnoid space through the two lateral foramina of Luschka and the single foramen of Magendie.

The brain and spinal cord are covered by two membranous tissue layers called the **leptomeninges**, which are in turn surrounded by a third, tougher layer. The innermost of these three layers is the pia mater; the middle is the arachnoid mater (or arachnoid membrane); and the outermost layer is the dura mater (Fig. 11-2). Between the arachnoid mater and pia mater (i.e., the leptomeninges) is the **subarachnoid space**, which is filled with CSF that flows from the fourth ventricle. The CSF in the subarachnoid space completely surrounds the brain and spinal cord. In adults, the subarachnoid space and the ventricles with which they are continuous contain ~150 mL of CSF, 30 mL in the ventricles and 120 mL in the subarachnoid spaces of the brain and spinal cord.

FIGURE 11-2 The meninges and ependymal cells. The figure represents a coronal section through the anterior portion of the brain. The upper inset shows the three layers of meninges: the dura mater, which here is split into two layers to accommodate the superior sagittal sinus (filled with venous blood); the arachnoid mater, which is formed by cells that are interconnected by tight junctions; and the pia mater, which closely adheres to a layer composed of astrocyte endfeet that are covered by a basement membrane (glia limitans). The lower inset shows ependymal cells lining the interior of the frontal horn of the left ventricle. Both the subarachnoid space and the cavities of the ventricles are filled with CSF.

The **pia mater** (Latin for “tender mother”) is a thin layer of connective tissue cells that is very closely applied to the surface of the brain and covers blood vessels as they plunge through the arachnoid into the brain. A nearly complete layer of astrocytic endfeet (see [p. 286](#))—the **glia limitans**—abuts the pia from the brain side and is separated from the pia by a basement membrane. The pia adheres so tightly to the associated glia limitans in some areas that the two seem to be continuous with each other; this combined structure is sometimes called the pial-glial membrane or layer. This layer does *not* restrict diffusion of substances between the BECF and the CSF.

The **arachnoid membrane** (from the Greek *arachnoeides* [cobweb-like]) is composed of layers of cells, resembling those that make up the pia, linked together by *tight junctions*. The arachnoid isolates the CSF in the subarachnoid space from blood in the overlying vessels of the dura mater. The cells that constitute the arachnoid and the pia are continuous in the trabeculae that span the subarachnoid space. These arachnoid and pial layers are relatively avascular; thus, the leptomeningeal cells that form them probably derive nutrition from the CSF that they enclose as well as from the ECF that surrounds them. The

leptomeningeal cells can phagocytose foreign material in the subarachnoid space.

The **dura mater** is a thick, inelastic membrane that forms an outer protective envelope around the brain. The dura has two layers that split to form the intracranial venous sinuses. Blood vessels in the dura mater are outside the BBB (see below), and substances could easily diffuse from dural capillaries into the nearby CSF if it were not for the blood-CSF barrier created by the arachnoid.

The brain floats in CSF, which acts as a shock absorber

An important function of CSF is to buffer the brain from mechanical injury. The CSF that surrounds the brain reduces the effective weight of the brain from ~1400 g to <50 g. This buoyancy is a consequence of the difference in the specific gravities of brain tissue (1.040) and CSF (1.007). The mechanical buffering that the CSF provides greatly diminishes the risk of acceleration-deceleration injuries in the same way that wearing a bicycle helmet reduces the risk of head injury. As you strike a tree, the foam insulation of the helmet gradually compresses and reduces the velocity of your head. Thus, the deceleration of your head is not nearly as severe as the deceleration of the outer shell of your helmet. The importance of this fluid suspension system is underscored by the consequences of reduced CSF pressure, which sometimes happens transiently after the diagnostic procedure of removal of CSF from the spinal subarachnoid space (Box 11-1). Patients with reduced CSF pressure experience severe pain when they try to sit up or stand because the brain is no longer cushioned by shock-absorbing fluid and small gravity-induced movements put strain on pain-sensitive structures. Fortunately, the CSF leak that can result from lumbar puncture is only temporary; the puncture hole easily heals itself, with prompt resolution of all symptoms.

Box 11-1

Lumbar Puncture

One of the most important diagnostic tests in neurology is the sampling of CSF by lumbar puncture. Critical information about the composition of CSF and about intracranial pressure can be obtained from this procedure. The anatomist Vesalius noted in 1543 that the ventricles are filled with a clear fluid, but the diagnostic technique of placing a needle into the lumbar subarachnoid space to obtain CSF was not introduced until 1891 by the neurologist Heinrich Quincke. **ON11-7** The method of lumbar puncture is dictated by spine anatomy. In adults, the spinal cord ends at the interspace between L1 and L2 (see p. 271). A hollow needle for sampling of CSF can be safely inserted into the subarachnoid space at the level of the L3-L4 interspace, well below the end of the spinal cord.

Once the needle is in the subarachnoid space, the physician attaches it to a manometer to measure pressure. With the patient lying on the side, normal pressure varies from 100 to 180 mm H₂O, or 7 to 13 mm Hg. With the subject in this position, and in the absence of a block to the free circulation of CSF, lumbar CSF pressure roughly corresponds to intracranial pressure. The physician can demonstrate direct communication of the pressure in the intracranial compartment to the lumbar subarachnoid space by gently compressing the external jugular veins in the neck for 10 seconds. This maneuver, called the **Queckenstedt test**, rapidly increases intracranial pressure because it increases the volume of intracranial venous blood. It quickly leads to an increase in lumbar pressure, which just as rapidly dissipates when the jugular pressure is removed.

CSF pressure can become elevated because of a pathological mass within the cranium, such as a tumor or collection of blood, or because the brain is swollen as a result of injury or infection (see Box 11-3). If a “mass lesion” (i.e., any pathological process that occupies intracranial space) is large or critically

placed, it can displace the brain and cause interference with the free circulation of CSF. For example, an expanding mass in the cerebellum can force the inferior part of the cerebellum into the foramen magnum and block flow of CSF into the spinal subarachnoid space. Under these conditions, performance of lumbar puncture can precipitate a neurological catastrophe. If a needle is placed in the lumbar subarachnoid space and fluid is removed for diagnostic examination or leaks out after the needle is removed, the ensuing decrease in pressure in the lumbar space creates a pressure gradient across the foramen magnum and potentially forces the brain down into the spinal canal. This disaster is called *herniation*. For this reason, a computed tomographic scan or magnetic resonance image of the head is usually obtained before a lumbar puncture is attempted; the imaging study can rule out the possibility of a large intracranial lesion that might raise intracranial pressure and increase the risk of herniation when the subarachnoid space is punctured and CSF withdrawn. The Queckenstedt test must also be avoided when an intracranial mass is suspected because it could enhance the pressure gradient and hasten herniation.

The choroid plexuses secrete CSF into the ventricles, and the arachnoid granulations absorb it

Total CSF production is ~500 mL/day. Because the entire volume of CSF is ~150 mL, the CSF “turns over” about three times each day. Most of the CSF is produced by the **choroid plexuses**, which are present in four locations (see Fig. 11-1): the two lateral ventricles, the third ventricle, and the fourth ventricle. The capillaries within the brain appear to form as much as 30% of the CSF.

Secretion of new CSF creates a slight pressure gradient, which drives the circulation of CSF from its ventricular sites of origin into the subarachnoid space through three openings in the fourth ventricle, as discussed above. CSF percolates throughout the subarachnoid space and is finally absorbed into venous blood in the superior sagittal sinus, which lies between the two cerebral hemispheres (see Fig. 11-2). The sites of absorption are specialized evaginations of the arachnoid membrane into the venous sinus (Fig. 11-3A). These absorptive sites are called pacchionian granulations  **N11-1** or simply **arachnoid granulations** when they are large (up to 1 cm in diameter) and **arachnoid villi** if their size is microscopic. These structures act as pressure-sensitive one-way valves for bulk CSF clearance; CSF can cross into venous blood but venous blood cannot enter CSF. The actual mechanism of CSF absorption may involve transcytosis (see pp. 477–487), or the formation of giant fluid-containing vacuoles that cross from the CSF side of the arachnoid epithelial cells to the blood side (see Fig. 11-3A). CSF may also be absorbed into spinal veins from herniations of arachnoid cells into these venous structures.

A MECHANISM OF CSF ABSORPTION

B RATE OF CSF ABSORPTION

FIGURE 11-3 Absorption of CSF. **A**, Arachnoid villi—or the larger arachnoid granulations (not shown)—are specialized evaginations of the arachnoid membrane through the dura mater and into the lumen of the venous sinus. The absorption of CSF may involve transcytosis. Note that arachnoid villi and granulations serve as one-way valves; fluid cannot move from the vein to the subarachnoid space. **B**, The rate of CSF formation is virtually insensitive to changes in the pressure of the CSF. On the other hand, the absorption of CSF increases steeply at CSF pressures above ~70 mm H₂O.

Antonio Pacchioni

Contributed by Bruce Ransom

Occasionally, arachnoid granulations are referred to by their old names: **Pacchioni's granulations**, **pacchionian bodies**, or **pacchionian granulations**—named after Italian anatomist Antonio Pacchioni.

The pressure of the CSF, which is higher than that of the venous blood, promotes net CSF movement into venous blood. When intracranial pressure (equivalent to CSF pressure) exceeds ~ 70 mm H₂O, absorption commences and increases in a graded fashion with further intracranial pressure (see [Fig. 11-3B](#)). In contrast to CSF absorption, CSF formation is not sensitive to intracranial pressure. This arrangement helps stabilize intracranial pressure. Thus, if intracranial pressure increases, CSF absorption selectively increases as well, so that absorption exceeds formation. This response lowers CSF volume and tends to counteract the increased intracranial pressure. However, if absorption of CSF is impaired even at an initially normal intracranial pressure ([Box 11-2](#)), CSF volume increases and causes an increase in intracranial pressure, which can lead to a disturbance in brain function.

Box 11-2

Normal-Pressure Hydrocephalus

Impaired CSF absorption is one mechanism proposed to explain a clinical form of ventricular enlargement called **normal-pressure hydrocephalus**. This condition is somewhat misnamed because the intracranial pressure is often intermittently elevated. Damage to the arachnoid villi can occur most commonly from infection or inflammation of the meninges or from the presence of an irritating substance, such as blood in the CSF after a subarachnoid hemorrhage. A spinal tap reveals normal pressure readings, but computed tomography or magnetic resonance imaging of the head shows enlargement of all four ventricles. Patients with normal-pressure hydrocephalus typically have progressive dementia, urinary incontinence, and gait disturbance, probably caused by stretching of axon pathways that course around the enlarged ventricles. A flexible plastic tube can be placed in one of the lateral ventricles to shunt CSF to venous blood or to the peritoneal cavity and thereby reduce CSF pressure. This procedure may reduce ventricular size and decrease neurological symptoms. The shunting procedure is also used for patients with obstructive hydrocephalus. In this condition, CSF outflow from the ventricles is blocked, typically at the aqueduct of Sylvius.

Some subarachnoid CSF flows into “sleeves” around arteries that dive from the subarachnoid space (see [Fig. 11-2](#)) deeply into the substance of the brain. This CSF appears to exit the sleeve by flowing across the pia/glia limitans and into **brain extracellular space (BECS)**, where it mixes with BECF. Moving by convection, the BECF eventually appears to cross the pia/glia limitans that surrounds veins, enter via perivenous sleeves, and return to the subarachnoid space. This parenchymal CSF circuit—termed the **glymphatic system** [N11-2](#)—may be an efficient pathway to rid the brain of extracellular debris, including glutamate and potentially dangerous peptides such as amyloid beta.

N11-2

The Glymphatic System

The parenchymal CSF flow out of the periarterial sleeves, through the parenchyma of the brain, and into the perivenous sleeves is surprisingly brisk. Fluorescent dye experimentally placed in the subarachnoid space enters the **BECS** within minutes. Evidence suggests that arterial pulsations drives this parenchymal CSF circulation. Curiously, most of this CSF exchange with BECF occurs during sleep (or, artificially, during anesthesia) when BECS volume expands, thus enhancing transit of BECF through the tortuous extracellular spaces. This recently discovered CSF circulation pattern through brain tissue has been called the **glymphatic system**.

The cellular and molecular mechanisms by which fluid would cross the pia/glia limitans to exit periarterial sleeves, or to enter perivenous sleeves, is not understood. The entire glymphatic process appears to require the water channel AQP4, which is expressed at low density in the plasma membrane over the soma of astrocytes and at extremely high density in the plasma membrane of astrocytic endfeet that abuts either CNS capillaries or the pia mater (i.e., the glia limitans). AQP4 could play a role in the shrinkage of astrocytes during sleep (thereby promoting the expansion of the BECS) or in promotion of water movement through the astrocytic endfeet.

The epithelial cells of the choroid plexus secrete the CSF

Each of the four choroid plexuses is formed during embryological development by invagination of the tela choroidea into the ventricular cavity (Fig. 11-4). The tela choroidea consists of a layer of ependymal cells covered by the pia mater and its associated blood vessels. The choroid epithelial cells (see Fig. 11-4, first inset) are specialized ependymal cells and therefore contiguous with the ependymal lining of the ventricles at the margins of the choroid plexus. Choroid epithelial cells are cuboidal and have an apical border with microvilli and cilia that project into the ventricle (i.e., into the CSF). The plexus receives its blood supply from the anterior and posterior choroidal arteries; blood flow to the plexuses—per unit mass of tissue—is ~10-fold greater than the average cerebral blood flow. Sympathetic and parasympathetic nerves innervate each plexus, and sympathetic input appears to inhibit CSF formation. A high density of relatively leaky capillaries is present within each plexus; as discussed below, these capillaries are outside the BBB. The choroid epithelial cells are bound to one another by tight junctions that completely encircle each cell, an arrangement that makes the epithelium an effective barrier to free diffusion. Thus, although the choroid capillaries are outside the BBB, the choroid epithelium insulates the ECF around these capillaries (which has a composition more similar to that of arterial blood) from the CSF. Moreover, the thin neck that connects the choroid plexus to the rest of the brain isolates the ECF near the leaky choroidal capillaries from the highly protected BECF in the rest of the brain.

FIGURE 11-4 Secretion of CSF by the choroid plexus. The top panel shows the location of the choroid plexuses in the two lateral ventricles and the third ventricle. The middle panel shows the organization of a single fold of choroidal epithelial cells, with the basolateral membranes of the epithelial cells overlying capillaries and the apical membranes facing the CSF. The bottom panel shows a single choroid epithelial cell and several of the transporters and channels that are believed to play a role in the isosmotic secretion

of CSF. Above the large leftward-pointing white arrow, the red arrows show the pathways for the secretion of Na^+ , Cl^- , HCO_3^- , and H_2O into the CSF. Below the heavy rightward-pointing black arrow, the red arrows show pathways of K^+ absorption. CA, carbonic anhydrase.

The composition of CSF differs considerably from that of plasma; thus, CSF is not just an ultrafiltrate of plasma (Table 11-1). For example, CSF has lower concentrations of K^+ and amino acids than plasma does, and it contains almost no protein. Moreover, the choroid plexuses rigidly maintain the concentration of ions in CSF in the face of large swings in ion concentration in plasma. This ion homeostasis includes K^+ , $\text{H}^+/\text{HCO}_3^-$, Mg^{2+} , Ca^{2+} , and, to a lesser extent, Na^+ and Cl^- . All these ions can affect neural function, hence the need for tight homeostatic control. The neuronal microenvironment is so well protected from the blood by the choroid plexuses and the rest of the BBB that essential **micronutrients**, such as vitamins and trace elements that are needed in very small amounts, must be selectively transported into the brain. Some of these micronutrients are transported into the brain primarily by the choroid plexus and others primarily by the endothelial cells of the blood vessels. In comparison, the brain continuously metabolizes relatively large amounts of “macronutrients,” such as glucose and some amino acids.

TABLE 11-1
Composition of CSF

SOLUTE	PLASMA (mM OF PROTEIN-FREE PLASMA)	CSF (mM)	CSF/PLASMA RATIO
Na^+	153	147	0.96
K^+	4.7	2.9	0.62
Ca^{2+}	1.3 (ionized)	1.1 (ionized)	0.85
Mg^{2+}	0.6 (ionized)	1.1 (ionized)	1.8
Cl^-	110	113	1.03
HCO_3^-	24	22	0.92
H_2PO_4^- and HPO_4^{2-}	0.75 (ionized)	0.9	1.2
pH	7.40	7.33	
Amino acids	2.6	0.7	0.27
Proteins	7 g/dL	0.03 g/dL	0.004
Osmolality	290 mOsm	290 mOsm	1.00

CSF forms in two sequential stages. First, ultrafiltration of plasma occurs across the fenestrated capillary wall (see p. 462) into the ECF beneath the basolateral membrane of the choroid epithelial cell. Second, choroid epithelial cells secrete fluid into the ventricle. CSF production occurs with a net transfer of NaCl and NaHCO_3 that drives water movement isosmotically (see Fig. 11-4, right inset, large white arrow labeled “Transepithelial fluxes”). The renal proximal tubule (see p. 761) and small intestine (see p. 903) also perform near-isosmotic transport, but in the direction of *absorption* rather than *secretion*. In addition, the choroid plexus conditions CSF by absorbing K^+ (see Fig. 11-4, right inset, thin black arrow labeled “Transepithelial fluxes”) and certain other substances (e.g., 5-hydroxyindoleacetic acid, a metabolite of serotonin).

The upper portion of the right inset of Figure 11-4 summarizes the ion transport processes that mediate CSF secretion. The net secretion of Na^+ from plasma to CSF is a two-step process. The Na-K pump in the choroid plexus, unlike that in other epithelia (see pp. 137–138), is unusual in being located on the *apical* membrane, where it moves Na^+ out of the cell into the CSF—the first step. This active movement of Na^+ out of the cell generates an inward Na^+ gradient across the *basolateral* membrane, energizing basolateral Na^+ entry—the second step—through Na-H exchange and Na^+ -coupled HCO_3^- transport. In the case of Na-H exchange, the limiting factor is the availability of intracellular H^+ , which carbonic anhydrase generates,

along with HCO_3^- , from CO_2 and H_2O . Thus, blocking of the Na-K pump with ouabain halts CSF formation, whereas blocking of carbonic anhydrase with acetazolamide slows CSF formation.

The net secretion of Cl^- , like that of Na^+ , is a two-step process. The first step is the intracellular accumulation of Cl^- by the basolateral Cl-HCO_3 exchanger. Note that the net effect of parallel Cl-HCO_3 exchange and Na-H exchange is NaCl uptake. The second step is efflux of Cl^- across the apical border into the CSF through either a Cl^- channel or a K/Cl cotransporter.

HCO_3^- secretion into CSF is important for neutralizing acid produced by CNS cells. At the basolateral membrane, the epithelial cell probably takes up HCO_3^- directly from the plasma filtrate through electroneutral Na/ HCO_3 cotransporters (see [Fig. 5-11F](#)) and the Na^+ -driven Cl-HCO_3 exchanger (see [Fig. 5-13C](#)). As noted before, HCO_3^- can also accumulate inside the cell after CO_2 entry. The apical step, movement of intracellular HCO_3^- into the CSF, probably occurs by an electrogenic Na/ HCO_3 cotransporter (see [Fig. 5-11D](#)) and Cl^- channels (which may be permeable to HCO_3^-).

The lower portion of the right inset of [Figure 11-4](#) summarizes K^+ absorption from the CSF. The epithelial cell takes up K^+ by the Na-K pump and the Na/K/Cl cotransporter at the apical membrane (see [Fig. 5-11G](#)). Most of the K^+ recycles back to the CSF, but a small amount exits across the basolateral membrane and enters the blood. The concentration of K^+ in freshly secreted CSF is ~ 3.3 mM. Even with very large changes in plasma $[\text{K}^+]$, the $[\text{K}^+]$ in CSF changes very little. The value of $[\text{K}^+]$ in CSF is significantly lower in the subarachnoid space than in choroid secretions, which suggests that brain capillary endothelial cells remove extracellular K^+ from the brain.

Water transport across the choroid epithelium is driven by a small osmotic gradient favoring CSF formation. This water movement is facilitated by the water channel aquaporin 1 (AQP1; see [p. 110](#)) on both the apical and basal membranes as in the renal proximal tubule (see [pp. 761–762](#)).

Brain Extracellular Space

Neurons, glia, and capillaries are packed tightly together in the CNS

The average width of the space between brain cells is ~20 nm, which is about three orders of magnitude smaller than the diameter of either a neuron or a glial cell body ([Fig. 11-5](#)). However, because the surface membranes of neurons and glial cells are highly folded (i.e., have a large surface-to-volume ratio), the BECF in toto has a sizable volume fraction, ~20%, of total brain volume. The fraction of the brain occupied by BECF varies somewhat in different areas of the CNS and increases during sleep. Moreover, because brain cells can increase volume rapidly during intense neural activity, the BECF fraction can reversibly decrease within seconds from ~20% to ~17% of brain volume.

FIGURE 11-5 Tight packing of neurons and astrocytes. This is an electron micrograph of a section of the spinal cord from an adult rat showing the intermingling and close apposition of neurons and glial cells, mainly astrocytes. Neurons and glial cells are separated by narrow clefts that are ~20 nm wide and not visible at this magnification. The BECF in this space creates a tortuous path for the extracellular diffusion of solutes. Astrocyte processes are colored. As, astrocytes; At, en passant synapses; Ax, unmyelinated axons; Ax₁ and Ax₂, myelinated axons; Den, dendrites; f, astrocytic fibrils; nf, neurofilaments; S, synapses; SR, smooth endoplasmic reticulum. (Modified from Peters A, Palay SL, Webster H: *The Fine Structure of the Nervous System*. Philadelphia, WB Saunders, 1976.)

Even though the space between brain cells is extremely small, diffusion of ions and other solutes within this thin BECF space is reasonably high. However, a particle that diffuses through the BECF from one side of a neuron to the other must take a circuitous route that is described by a parameter called **tortuosity**. For a normal width of the cell-to-cell spacing, this tortuosity reduces the rate of diffusion by ~60% compared with movement in free solution. Decreases in cell-to-cell spacing can further slow diffusion. For example, brain cells, especially glial cells, swell under certain pathological conditions and sometimes with intense neural activity. Cell swelling is associated with a reduction in BECF because water moves from the BECF into cells. The intense cell swelling associated with acute anoxia, for example, can reduce BECF volume from ~20% to ~5% of total brain volume. By definition, this reduced extracellular volume translates to reduced cell-to-cell spacing, which further slows the extracellular

movement of solutes between the blood and brain cells (Box 11-3).

Box 11-3

Cerebral Edema

Almost any type of insult to the brain causes cell swelling, which is frequently accompanied by a *net accumulation of water* within the brain that is referred to as **cerebral edema**. Cell swelling in the absence of net water accumulation in the brain does *not* constitute cerebral edema. For example, intense neural activity causes a rapid shift of fluid from the BECF to the intracellular space, with no net change in brain water content. In cerebral edema, the extra water comes from the blood, as shown in Figure 11-6.

FIGURE 11-6 Cerebral edema. **A**, In cerebral edema, the brain fluid that accumulates comes from the vascular compartment. Cell swelling due to the mere shift of fluid from the extracellular to the intracellular fluid is *not* cerebral edema. **B**, Although small increases in intracranial volume have little effect on pressure, additional increases in volume cause potentially life-threatening increases in pressure. Note that compliance (i.e., $\Delta V/\Delta P$) falls at increasing volumes.

The mechanisms by which glial cells and neurons swell are not completely understood. Neuron cell bodies and dendrites, but not axons, swell when exposed to high concentrations of the neurotransmitter **glutamate**. This transmitter, along with others, is released to the BECF in an uncontrolled fashion with brain injury. Activation of ionotropic glutamate receptors (see pp. 323–324) allows Na^+ to enter neurons, and water and Cl^- follow passively. Glial cells, both astrocytes and oligodendrocytes, swell vigorously under pathological conditions. One mechanism of glial swelling is an increase in $[\text{K}^+]_o$, which is a common ionic disturbance in a variety of brain pathological processes. This elevated $[\text{K}^+]_o$ causes a net uptake of K^+ , accompanied by the passive influx of Cl^- and water.

Cerebral edema can be life threatening when it is severe. The problem is a mechanical one. The skull is an inelastic container housing three relatively noncompressible substances: brain, CSF, and blood. A significant increase in the volume of CSF, blood, or brain rapidly causes increased pressure within the skull (see Fig. 11-6B). If the cerebral edema is *generalized*, it can be tolerated until intracerebral

pressure exceeds arterial blood pressure, at which point blood flow to the brain stops, with disastrous consequences. Fortunately, sensors in the medulla detect the increased intracerebral pressure and can partially compensate by increasing arterial pressure (Cushing reflex; see p. 559). *Focal* cerebral edema (i.e., edema involving an isolated portion of the brain) causes problems by displacing nearby brain tissue. This abnormality may result in distortion of normal anatomical relationships, with selective pressure on critical structures such as the brainstem.

Clinical evidence of cerebral edema results directly from the increased intracranial pressure and includes headache, vomiting, altered consciousness, and focal neurological problems. Because of its long intracranial course, the sixth cranial nerve is especially vulnerable to stretching and dysfunction.

Hyperventilation is the most effective means of combating the acute increase in intracranial pressure associated with severe cerebral edema. Hyperventilation causes a prompt respiratory alkalosis (see p. 634) that is rapidly translated to an increase in the pH surrounding vascular smooth muscle, thereby triggering vasoconstriction and reduced cerebral blood flow (see p. 559). Thus, total intracranial blood content falls, with a rapid subsequent drop in intracranial pressure. Alternatively, the brain can be partially dehydrated by adding osmoles to the blood in the form of intravenously administered mannitol (see p. 131).

The BECF is the route by which important molecules such as oxygen, glucose, and amino acids reach brain cells and by which the products of metabolism, including CO_2 and catabolized neurotransmitters, leave the brain. The BECF also permits molecules that are released by brain cells to diffuse to adjacent cells. Neurotransmitter molecules released at synaptic sites, for example, can spill over from the synaptic cleft and contact nearby glial cells and neurons, in addition to their target postsynaptic cell. Glial cells express neurotransmitter receptors, and neurons have **extrajunctional receptors**; therefore, these cells are capable of receiving “messages” sent through the BECF. Numerous trophic molecules (see p. 292) secreted by brain cells diffuse in the BECF to their targets. Intercellular communication by way of the BECF is especially well suited for the transmission of tonic signals that are ideal for longer-term modulation of the behavior of aggregates of neurons and glial cells. The chronic presence of variable amounts of neurotransmitters in the BECF supports this idea.

The CSF communicates freely with the BECF, which stabilizes the composition of the neuronal microenvironment

CSF in the ventricles and the subarachnoid space can exchange freely with BECF across two borders, the pia mater and ependymal cells. The **pial-glial membrane** (see Fig. 11-2, upper inset) has paracellular gaps through which substances can equilibrate between the subarachnoid space and BECF. **Ependymal cells** (see Fig. 11-2, lower inset) are special glial cells that line the walls of the ventricles and form the cellular boundary between the CSF and the BECF. These cells form gap junctions (see p. 45) between themselves that mediate intercellular communication, but they do not create a tight epithelium (see p. 137). Thus, macromolecules and ions can also easily pass through this cellular layer through paracellular openings (some notable exceptions to this rule are considered below) and equilibrate between the CSF in the ventricle and the BECF.

Because CSF and BECF can readily exchange with one another, it is not surprising that they have a similar chemical composition. For example, $[\text{K}^+]$ is ~ 3.3 mM in freshly secreted CSF and ~ 3 mM in both the CSF of the subarachnoid space (see Table 11-1) and BECF. The $[\text{K}^+]$ of blood is ~ 4.5 mM. However,

because of the extent and vast complexity of the extracellular space, changes in the composition of CSF are reflected slowly in the BECF and probably incompletely.

CSF is an efficient waste-management system because of its high rate of production, its circulation over the surface of the brain, and the free exchange between CSF and BECF. Products of metabolism and other substances released by cells, perhaps for signaling purposes, can diffuse into the chemically stable CSF and ultimately be removed on a continuous basis either by bulk resorption into the venous sinuses or by active transport across the choroid plexus into the blood. For example, the choroid plexus actively absorbs the breakdown products of the neurotransmitters serotonin (i.e., 5-hydroxyindoleacetic acid) and dopamine (i.e., homovanillic acid).

The ion fluxes that accompany neural activity cause large changes in extracellular ion concentration

As discussed in [Chapter 7](#), ionic currents through cell membranes underlie the synaptic and action potentials by which neurons communicate. These currents lead to changes in the ion concentrations of the BECF. It is estimated that even a single action potential can transiently lower $[\text{Na}^+]_o$ by ~ 0.75 mM and increase $[\text{K}^+]_o$ by a similar amount. Repetitive neuronal activity causes larger perturbations in these extracellular ion concentrations. Because ambient $[\text{K}^+]_o$ is much lower than $[\text{Na}^+]_o$, activity-induced changes in $[\text{K}^+]_o$ are proportionately larger and are of special interest because of the important effect that $[\text{K}^+]_o$ has on membrane potential (V_m). For example, K^+ accumulation in the vicinity of active neurons depolarizes nearby glial cells. In this way, neurons signal to glial cells the pattern and extent of their activity. Even small changes in $[\text{K}^+]_o$ can alter metabolism and ionic transport in glial cells and may be used for signaling. Changes in the extracellular concentrations of certain common amino acids, such as glutamate and glycine, can also affect neuronal V_m and synaptic function by acting at specific receptor sites. If the nervous system is to function reliably, its signaling elements must have a regulated environment. Glial cells and neurons both function to prevent excessive extracellular accumulation of K^+ and neurotransmitters.

The Blood-Brain Barrier

The blood-brain barrier prevents some blood constituents from entering the brain extracellular space

The unique protective mechanism now called the BBB was first demonstrated by Ehrlich in 1885. He injected aniline dyes intravenously and discovered that the soft tissues of the body, except for the brain, were uniformly stained. Aniline dyes, such as trypan blue, extensively bind to serum albumin, and the dye-albumin complex passes across capillaries in most areas of the body, but not the brain. This ability to exclude certain substances from crossing CNS blood vessels into the brain tissue is due to the **blood-brain barrier**. We now recognize that a BBB is present in all vertebrates and many invertebrates as well.

The need for a BBB can be understood by considering that blood is not a suitable environment for neurons. Blood is a complex medium that contains a large variety of solutes, some of which can vary greatly in concentration, depending on factors such as diet, metabolism, illness, and age. For example, the concentration of many amino acids increases significantly after a protein-rich meal. Some of these amino acids act as neurotransmitters within the brain, and if these molecules could move freely from the blood into the neuronal microenvironment, they would nonselectively activate receptors and disturb normal neurotransmission. Similarly, strenuous exercise can increase plasma concentrations of K^+ and H^+ substantially. If these ionic changes were communicated directly to the microenvironment of neurons, they could disrupt ongoing neural activity. Running a foot race might temporarily lower your IQ. Increases in $[K^+]_o$ would depolarize neurons and thus increase their likelihood of firing and releasing transmitter. H^+ can nonspecifically modulate neuronal excitability and influence the action of certain neurotransmitters. A broad range of blood constituents—including hormones, other ions, and inflammatory mediators such as cytokines—can influence the behavior of neurons or glial cells, which can express receptors for these molecules. For the brain to function efficiently, it must be spared such influences.

The choroid plexus and several restricted areas of the brain lack a BBB; that is, they are supplied by leaky capillaries. Intra-arterially injected dyes can pass into the BECS at these sites through gaps between endothelial cells. The BECF in the vicinity of these leaky capillaries is more similar to blood plasma than to normal BECF. The small brain areas that lack a BBB are called the **circumventricular organs** because they surround the ventricular system; these areas include the *area postrema*, *posterior pituitary*, *median eminence*, *organum vasculosum laminae terminalis*, *subfornical organ*, *subcommissural organ*, and *pineal gland* (Fig. 11-7). The ependymal cells that overlie the leaky capillaries in some of these regions (e.g., the choroid plexus) are linked together by tight junctions that form a barrier between the local BECF and the CSF, which must be insulated from the variability of blood composition. Whereas dyes with molecular weights up to 5000 can normally pass from CSF across the ependymal cell layer into the BECF, they do not pass across the specialized ependymal layer at the median eminence, area postrema, and infundibular recess. At these points, the localized BECF-CSF barrier is similar to the one in the choroid plexus. These specialized ependymal cells often have long processes that extend to capillaries within the portal circulation of the pituitary. Although the function of these cells is not known, it has been suggested that they may form a special route for neurohumoral signaling; molecules secreted by hypothalamic cells into the third ventricle could be taken up by these cells and transmitted to the general circulation or to cells in the pituitary.

FIGURE 11-7 Leaky regions of the BBB: the circumventricular organs. The capillaries of the brain are leaky in several areas: the area postrema, the posterior pituitary, the subfornical organ, the median eminence, the pineal gland, and the organum vasculosum laminae terminalis (OVLT). In these regions, the neurons are directly exposed to the solutes of the blood plasma. A midline sagittal section is shown.

Neurons within the circumventricular organs are directly exposed to blood solutes and macromolecules; this arrangement is believed to be part of a neuroendocrine control system for maintaining such parameters as osmolality (see [p. 844](#)) and appropriate hormone levels, among other things. Humoral signals are integrated by connections of circumventricular organ neurons to endocrine, autonomic, and behavioral centers within the CNS. In the median eminence, neurons discharge “releasing hormones,” which diffuse into leaky capillaries for carriage through the pituitary portal system to the anterior pituitary (see [p. 978](#)). The lack of a BBB in the posterior pituitary is necessary to allow hormones that are released there to enter the general circulation (see [p. 979](#)). In the organum vasculosum laminae terminalis, leakiness is important in the action of cytokines from the periphery, which act as signals to temperature control centers that are involved in fever (see [p. 1202](#)).

Continuous tight junctions link brain capillary endothelial cells

The BBB should be thought of as a physical barrier to diffusion from blood to BECF and as a selective set of regulatory transport mechanisms that determine how certain organic solutes move between the blood and brain. Thus, the BBB contributes to stabilization and protection of the neuronal microenvironment by facilitating the entry of needed substances, removing waste metabolites, and

excluding toxic or disruptive substances.

The structure of brain capillaries differs from that of capillaries in other organs ([Fig. 11-8A](#)). Capillaries in other organs generally have small, simple openings—or clefts—between their endothelial cells. In some of these other organs, windows, or fenestrae, provide a pathway that bypasses the cytoplasm of capillary endothelial cells. Thus, in most capillaries outside the CNS, solutes can easily diffuse through the clefts and fenestrae. The physical barrier to solute diffusion in *brain* capillaries (see [Fig. 11-8B](#)) is provided by the capillary endothelial cells, which are fused to each other by continuous **tight junctions** (or *zonula occludens*; see [pp. 43–44](#)). The tight junctions prevent water-soluble ions and molecules from passing from the blood into the brain through the paracellular route. Not surprisingly, the electrical resistance of the cerebral capillaries is 100 to 200 times higher than that of most other systemic capillaries.

A NONBRAIN SYSTEMIC CAPILLARY

B BRAIN CAPILLARY

C BRAIN CAPILLARY ENDOTHELIAL CELL

FIGURE 11-8 BBB function of brain capillaries. **A**, Capillaries from most other organs often have interendothelial clefts or fenestrae, which makes them relatively leaky. **B**, Brain capillaries are not leaky and have reduced transcytosis. **C**, Continuous tight junctions connect the endothelial cells in the brain, making the capillaries relatively tight. GLUT1, glucose transporter 1.

Elsewhere in the systemic circulation, molecules may traverse the endothelial cell by the process of **transcytosis** (see [p. 467](#)). In cerebral capillaries, transcytosis is uncommon, and brain endothelial cells have fewer endocytic vesicles than do systemic capillaries. However, brain endothelial cells have many more **mitochondria** than systemic endothelial cells do, which may reflect the high metabolic demands imposed on brain endothelial cells by active transport.

Other interesting features of brain capillaries are the thick **basement membrane** that underlies the endothelial cells, the presence of occasional **pericytes** within the basement membrane sheath, and the **astrocytic endfeet** (or processes) that provide a nearly continuous covering of the capillaries and other blood vessels. Astrocytes may play a crucial role in forming tight junctions between endothelial cells; experiments have shown that these glial cells can induce the formation of tight junctions between endothelial cells derived from capillaries outside the CNS. The close apposition of the astrocyte endfoot to the capillary also could facilitate transport of substances between these cells and blood.

Uncharged and lipid-soluble molecules more readily pass through the blood-brain barrier

The capacity of the brain capillaries to exclude large molecules is strongly related to the molecular mass of the molecule and its hydrated diameter ([Table 11-2](#)). With a mass of 61 kDa, prealbumin is 14 times as concentrated in blood as in CSF (essentially equivalent to BECF for purposes of this comparison), whereas fibrinogen, which has a molecular mass of 340 kDa, is ~5000 times more concentrated in blood than in CSF. Diffusion of a solute is also generally limited by ionization at physiological pH, by low lipid solubility, and by binding to plasma proteins. For example, gases such as CO₂ and O₂ and drugs such as ethanol, caffeine, nicotine, heroin, and methadone readily cross the BBB. However, ions such as K⁺ or Mg²⁺ and protein-bound metabolites such as bilirubin have restricted access to the brain. Finally, the BBB is permeable to water mainly because of the presence of AQP4 in the astrocytic endfeet (see [Fig. 11-8A](#)). Thus, water moves across the BBB in response to changes in plasma osmolality. When dehydration raises the osmolality of blood plasma (see [Box 11-3](#)), the increased osmolality of the CSF and BECF can affect the behavior of brain cells.

TABLE 11-2
Comparison of Proteins in Blood Plasma and CSF

PROTEIN	MOLECULAR WEIGHT (kDa)	HYDRODYNAMIC RADIUS (nm)	PLASMA/CSF RATIO *
Prealbumin	61	3.3	14
Albumin	69	3.6	240
Transferrin	81	3.7	140
Ceruloplasmin	152	4.7	370
IgG	150	5.3	800
IgA	150	5.7	1350
α ₂ -macroglobulin	798	9.4	1100
Fibrinogen	340	11.0	4940
IgM	800	12.1	1170
β-lipoprotein	2240	12.4	6210

*The greater the plasma/CSF ratio, the more the BBB excludes the protein from the CSF.
Ig, immunoglobulin.

Cerebral capillaries also express enzymes that can affect the movement of substances from blood to brain and vice versa. Peptidases, acid hydrolases, monoamine oxidase, and other enzymes are present in CNS endothelial cells and can degrade a range of biologically active molecules, including enkephalins,

substance P, proteins, and norepinephrine. Orally administered dopamine is not an effective treatment of Parkinson disease (see [p. 313](#)), a condition in which CNS dopamine is depleted, because dopamine is rapidly broken down by monoamine oxidase in the capillaries. Fortunately, the dopamine precursor compound L-DOPA is effective for this condition. Neutral amino-acid transporters in capillary endothelial cells move L-DOPA to the BECF, where presynaptic terminals take up the L-DOPA and convert it to dopamine in a reaction that is catalyzed by DOPA decarboxylase.

Transport by capillary endothelial cells contributes to the blood-brain barrier

Two classes of substances can pass readily between blood and brain. The first consists of the small, highly lipid-soluble molecules discussed in the preceding section. The second group consists of water-soluble compounds—either critical nutrients entering or metabolites exiting the brain—that traverse the BBB by specific transporters. Examples include glucose, several amino acids and neurotransmitters, nucleic acid precursors, and several organic acids. Two major transporter groups provide these functions: the SLC superfamily (see [pp. 111–114](#)) and ABC transporters (see [pp. 119–120](#)). **N11-3** As is the case for other epithelial cells, capillary endothelial cells selectively express these and other membrane proteins on either the luminal or basal surface.

N11-3

System L Amino-Acid Transporters in Brain Capillary Endothelial Cells

Contributed by Bruce Ransom

Large uncharged amino acids (i.e., phenylalanine, tyrosine, and leucine) are selectively transported into the brain by **system L**. As outlined in Table 36-1B, the system L protein is a heterodimer of **SLC7A8** and **SLC3A2**. It has broad substrate specificity and transports across the BBB several important drugs that act on the brain, including L-DOPA (to treat Parkinson disease), baclofen (to reduce spasticity), and gabapentin (to treat chronic pain and epilepsy).

Although the choroid plexuses secrete most of the CSF, brain endothelial cells produce some interstitial fluid with a composition similar to that of CSF. Transporters such as those shown in [Figure 11-8C](#) are responsible for this CSF-like secretion as well as for the local control of $[K^+]$ and pH in the BECF.

Glial Cells

Glial cells constitute half the volume of the brain and outnumber neurons

The three major types of glial cells in the CNS are astrocytes, oligodendrocytes, and microglial cells (Fig. 11-9, Table 11-3). As discussed in Chapter 10, the peripheral nervous system (PNS) contains other, distinctive types of glial cells, including satellite cells, Schwann cells, and enteric glia. Glial cells represent about half the volume of the brain and are more numerous than neurons. Unlike neurons, which have little capacity to replace themselves when lost, neuroglial (or simply glial) cells can proliferate throughout life. An injury to the nervous system is the usual stimulus for proliferation.

FIGURE 11-9 Astrocytes. The endfeet of both fibrous and protoplasmic astrocytes abut the pia mater (see Fig. 11-2) and the capillaries (see Fig. 11-8B).

TABLE 11-3

Glial Cell Types

GLIAL CELL TYPE	SYSTEM	LOCATION	GFAP
Astrocytes			
Fibrous astrocytes	CNS	White matter	Positive
Protoplasmic astrocytes	CNS	Gray matter	Weakly positive
Radial glial cells	CNS	Throughout brain during development	Positive
Müller cells	CNS	Retina	Positive
Bergmann glia	CNS	Cerebellum	Positive
Ependymal cells	CNS	Ventricular lining	Positive
Oligodendrocytes	CNS	Mainly white matter	Negative
Microglial cells	CNS	Throughout brain	Negative
Satellite cells	PNS	Sensory and autonomic ganglia	Weakly positive
Schwann cells	PNS	Peripheral axons	Negative
Enteric glial cells	ENS	Gut wall	Positive

ENS, enteric nervous system.

Historically, glial cells were viewed as a type of CNS connective tissue whose main function was to

provide support for the true functional cells of the brain, the neurons. This firmly entrenched concept remained virtually unquestioned for the better part of a century after the early description of these cells by Virchow in 1858. Knowledge about glial cells has accumulated slowly because these cells have proved far more difficult to study than neurons. Because glial cells do not exhibit easily recorded action potentials or synaptic potentials, these cells were sometimes referred to as silent cells. However, glial cells are now recognized as intimate partners with neurons in virtually every function of the brain.

Astrocytes supply fuel to neurons in the form of lactic acid

Astrocytes have great numbers of extremely elaborate processes that closely approach both blood vessels and neurons. This arrangement led to the idea that astrocytes transport substances between the blood and neurons. This notion may be true, but it has not been proved. Throughout the brain, astrocytes envelop neurons, and both cells bathe in a common BECF. Therefore, astrocytes are ideally positioned to modify and to control the immediate environment of neurons. Most astrocytes in the brain are traditionally subdivided into fibrous and protoplasmic types (see [Table 11-3](#)). **Fibrous astrocytes** (found mainly in white matter) have long, thin, and well-defined processes, whereas **protoplasmic astrocytes** (found mainly in gray matter) have shorter, frilly processes (see [Fig. 11-9](#)). Astrocytes are evenly spaced. In cortical regions, the dense processes of an individual astrocyte define its spatial domain, into which adjacent astrocytes do not encroach. The cytoskeleton of these and other types of astrocytes contains an identifying intermediate filament (see [p. 23](#)) that is composed of a unique protein called **glial fibrillar acidic protein (GFAP)**. The basic physiological properties of both types of astrocyte are similar, but specialized features, such as the expression of neurotransmitter receptors, vary among astrocytes from different brain regions.

During development, another type of astrocyte called the **radial glial cell** (see [pp. 263–265](#)) is also present. As discussed on [p. 267](#), these cells create an organized “scaffolding” by spanning the developing forebrain from the ventricle to the pial surface. Astrocytes in the retina and cerebellum are similar in appearance to radial glial cells. Like astrocytes elsewhere, these cells contain the intermediate filament GFAP. Retinal astrocytes, called **Müller cells**, are oriented so that they span the entire width of the retina. **Bergmann glial cells** in the cerebellum have processes that run parallel to the processes of Purkinje cells.

Astrocytes store virtually all the **glycogen** present in the adult brain. They also contain all the enzymes needed for metabolizing glycogen. The brain's high metabolic needs are primarily met by glucose transferred from blood because the brain's glucose supply in the form of glycogen is very limited. In the absence of glucose from blood, astrocytic glycogen could sustain the brain for only 5 to 10 minutes. As implied, astrocytes can share with neurons the energy stored in glycogen, but *not* by the direct release of glucose into the BECF. Instead, astrocytes break glycogen down to glucose and even further to lactate, which is transferred to nearby neurons where it can be aerobically metabolized ([Fig. 11-10](#)). The extent to which this metabolic interaction takes place under normal conditions is not known, but it may be important during periods of intense neuronal activity, when the demand for glucose exceeds the supply from blood.

FIGURE 11-10 Role of astrocytes in providing lactate as fuel for neurons. Neurons have two fuel sources. They can obtain glucose directly from the blood plasma or they can obtain lactate from astrocytes. In the direct path, the oxidation of one glucose molecule provides 30 ATP molecules to the neuron. In the transastrocyte path, conversion of two lactates to two pyruvates, and then the subsequent oxidation of the pyruvate, provides 28 molecules of ATP to the neuron. GLUT1 and GLUT3, glucose transporters 1 and 3; MCT1 and MCT2, monocarboxylate cotransporters 1 and 2.

Astrocytes can also provide fuel to neurons in the form of lactate derived directly from glucose, independent of glycogen. Glucose entering the brain from blood first encounters the astrocytic endfoot. Although it can diffuse past this point to neurons, glucose may be preferentially taken up by astrocytes and shuttled through astrocytic glycolysis to lactic acid, a significant portion of which is excreted into the BECF surrounding neurons. Several observations support the notion that astrocytes provide lactate to neurons. First, astrocytes have higher *anaerobic* metabolic rates and export much more lactate than do neurons. Second, neurons and their axons function normally when glucose is replaced by lactate, and some neurons seem to prefer lactate to glucose as fuel. Note that when they are aerobically metabolized, the two molecules of lactate derived from the breakdown of one molecule of glucose provide nearly as much ATP (28 molecules) as the complete oxidation of glucose itself (30 molecules of ATP; see [Table 58-4](#)). The advantage of this scheme for neuronal function is that it provides a form of **substrate buffering**, a second energy reservoir that is available to neurons. The availability of *glucose* in the neuronal microenvironment depends on moment-to-moment supply from the blood and varies as a result of changes in neural activity. The concentration of extracellular *lactate*, however, is buffered against such variability by the surrounding astrocytes, which continuously shuttle lactate to the BECF by metabolizing glucose or by breaking down glycogen.

Astrocytes are predominantly permeable to K^+ and also help regulate $[K^+]$.

The membrane potential of glial cells is more negative than that of neurons. For example, astrocytes have

a V_m of about -85 mV, whereas the resting neuronal V_m is about -65 mV. Because the equilibrium potential for K^+ is about -90 mV in both neurons and glia, the more negative V_m in astrocytes indicates that glial membranes have higher K^+ selectivity than neuronal membranes do (see p. 148). Although glial cells express a variety of K^+ channels, inwardly rectifying K^+ channels seem to be important in setting the resting potential. These channels are voltage gated and are open at membrane potentials that are more negative than about -80 mV, close to the observed resting potential of astrocytes. Astrocytes express many other voltage-gated ion channels that were once thought to be restricted to neurons. The significance of voltage-gated Na^+ and Ca^{2+} channels in glial cells is unknown. Because the ratio of Na^+ to K^+ channels is low in adult astrocytes, these cells are not capable of regenerative electrical responses such as the action potential.

One consequence of the higher K^+ selectivity of astrocytes is that the V_m of astrocytes is far more sensitive than that of neurons to changes in $[K^+]_o$. For example, when $[K^+]_o$ is raised from 4 to 20 mM, astrocytes depolarize by ~ 25 mV versus only ~ 5 mV for neurons. This relative insensitivity of neuronal resting potential to changes in $[K^+]_o$ in the “physiological” range may have emerged as an adaptive feature that stabilizes the resting potential of *neurons* in the face of the transient increases in $[K^+]_o$ that accompany neuronal activity. In contrast, natural stimulation, such as viewing visual targets of different shapes or orientations, can cause depolarizations of up to 10 mV in *astrocytes* of the visual cortex. The accumulation of extracellular K^+ that is secondary to neural activity may serve as a signal—to glial cells—that is proportional to the extent of the activity. For example, small increases in $[K^+]_o$ cause astrocytes to increase their glucose metabolism and to provide more lactate for active neurons. In addition, the depolarization that is triggered by the increased $[K^+]_o$ leads to the influx of HCO_3^- into astrocytes by the electrogenic Na/HCO_3 cotransporter (see p. 122); this influx of bicarbonate in turn causes a fall in extracellular pH that may diminish neuronal excitability.  **N11-4**

N11-4

Glial Modulation of Neuronal Excitability via Extracellular K^+ and pH

Contributed by Mark Bevensee, Walter Boron, Bruce Ransom

Chesler and Ransom have proposed a model (eFig. 11-1) that integrates our knowledge of acid-base transporters in neurons and astrocytes, the pH sensitivity of neuronal ion channels, and a wealth of data on changes in the composition of BECF during neuronal activity (e.g., increased $[K^+]_o$ that occurs as the result of a train of action potentials). Neural activity (step 1 in the figure) leads to a rise in $[K^+]_{BECF}$ (step 2), which would depolarize astrocytes (step 3). As first described by Siebens in renal proximal-tubule cells, this depolarization would promote electrogenic Na/HCO_3 influx (step 4), which simultaneously raises pH_i and lowers pH_{BECF} (step 5). The low pH_{BECF} would inhibit the neuronal Na^+ -driven $Cl-HCO_3$ exchanger (step 6), causing neuronal pH_i to fall (step 7). The decreases in both pH_{BECF} and neuronal pH_i complete the feedback loop by inhibiting voltage-gated channels and ligand-gated changes, thereby decreasing neuronal excitability (step 8). Indeed, low pH appears to reduce neuronal activity in experimental models of **epilepsy**.

FIGURE 11-1 Glial modulation of neuronal excitability.

Not only do astrocytes respond to changes in $[\text{K}^+]_o$, they also help regulate it (Fig. 11-11A). The need for homeostatic control of $[\text{K}^+]_o$ is clear because changes in brain $[\text{K}^+]_o$ can influence transmitter release, cerebral blood flow, cell volume, glucose metabolism, and neuronal activity. Active neurons lose K^+ into the BECF, and the resulting increased $[\text{K}^+]_o$ tends to act as a positive-feedback signal that increases excitability by further depolarizing neurons. This potentially unstable situation is opposed by efficient mechanisms that expedite K^+ removal and limit its accumulation to a maximum level of 10 to 12 mM, the so-called ceiling level. $[\text{K}^+]_o$ would rise far above this ceiling with intense neural activity if K^+ clearance depended solely on passive redistribution of K^+ in the BECF. Neurons and blood vessels can contribute to K^+ homeostasis, but glial mechanisms are probably most important. Astrocytes can take up K^+ in response to elevated $[\text{K}^+]_o$ by three major mechanisms: the Na-K pump, the Na/K/Cl cotransporter, and the uptake of K^+ and Cl^- through channels. Conversely, when neural activity decreases, K^+ and Cl^- leave the astrocytes through ion channels.

A MECHANISMS OF K^+ UPTAKE BY ASTROCYTES

B SPATIAL BUFFERING

FIGURE 11-11 K^+ handling by astrocytes.

Gap junctions couple astrocytes to one another, allowing diffusion of small solutes

The anatomical substrate for cell-cell coupling among astrocytes is the **gap junction**, which is composed of membrane proteins called connexins that form large aqueous pores connecting the cytoplasm of two adjacent cells (see pp. 158–159). Coupling between astrocytes is strong because hundreds of gap junction channels may be present between two astrocytes. Astrocytes may also be weakly coupled to oligodendrocytes. Ions and organic molecules that are up to 1 kDa in size, regardless of charge, can diffuse from one cell into another through these large channels. Thus, a broad range of biologically important molecules, including nucleotides, sugars, amino acids, small peptides, cAMP, Ca^{2+} , and inositol 1,4,5-trisphosphate (IP_3), have access to this pathway.

Gap junctions may coordinate the metabolic and electrical activities of cell populations, amplify the consequences of signal transduction, and control intrinsic proliferative capacity. The strong coupling

among astrocytes ensures that all cells in the aggregate have similar intracellular concentrations of ions and small molecules and similar membrane potentials. Thus, the network of astrocytes functionally behaves like a **syncytium**, much like the myocytes in the heart (see [p. 483](#)). In ways that are not yet clear, gap junctional communication can be important for the control of cellular proliferation. The most common brain cell-derived tumors in the CNS arise from astrocytes. Malignant astrocyte tumors, like malignant neoplasms derived from other cells that are normally coupled (e.g., liver cells), lack gap junctions. 🧠

N11-5

N11-5

Astrocytomas

Contributed by Bruce Ransom

As pointed out in the text, malignant astrocyte tumors (i.e., astrocytomas) lack gap junctions. One theory is that growth-limiting factors pass among coupled cells to regulate proliferation. Thus, if gap junctions are lost, cells with minimal intrinsic production of these factors would be more prone to escape from normal regulation and become tumor clones.

The coupling among astrocytes may also play an important role in controlling $[K^+]_o$ by a mechanism known as **spatial buffering**. The selective K^+ permeability of glia, together with their low-resistance cell-cell connections, permits them to transport K^+ from focal areas of high $[K^+]_o$, where a portion of the glial syncytium would be depolarized, to areas of normal $[K^+]_o$, where the glial syncytium would be more normally polarized (see [Fig. 11-11B](#)). Redistribution of K^+ proceeds by way of a current loop in which K^+ enters glial cells at the point of high $[K^+]_o$ and leaves them at sites of normal $[K^+]_o$, with the extracellular flow of Na^+ completing this circuit. At a site of high neuronal activity, $[K^+]_o$ might rise to 12 mM, which would produce a very large depolarization of an isolated, uncoupled astrocyte. However, because of the electrical coupling among astrocytes, the V_m of the affected astrocyte remains more negative than the equilibrium potential for K^+ (E_K) predicted for a $[K^+]_o$ of 12 mM. Thus, K^+ would tend to passively enter coupled astrocytes through channels at sites of high $[K^+]_o$. 🧠 **N11-6** As discussed in the preceding section, K^+ may also enter the astrocyte by transporters.

N11-6

K^+ Siphoning by Müller Cells

Contributed by Bruce Ransom

An additional specialization that contributes to spatial buffering is a nonuniform distribution of K^+ channels on a single cell. The density of K^+ channels on the cell membrane of retinal Müller cells (eFig. 11-2A), which are specialized astrocytes, is highest on the cell's endfoot. Thus, focal increases in $[K^+]_o$ at the endfoot cause greater depolarization than if they occur elsewhere along the cell's membrane (see eFig. 11-2B). Because the endfoot of the Müller cell, which abuts the vitreous humor of the eye, has the highest density of K^+ channels, excess extracellular K^+ is preferentially transported to the vitreous, which acts as a disposal site. It is not known whether nonuniform K^+ channel distribution is a general feature of astrocytes.

FIGURE 11-2 Role of Müller cells in spatial buffering. **A**, The Müller cells are the predominant glial cells of the retina. **B**, In an experiment on an isolated Müller cell from a salamander retina, the investigator monitored the membrane potential from the soma of the cell while ejecting K^+ from a second pipette at different points along the Müller cell. These ejections, which raise local $[K^+]_o$, produced the largest depolarizations when K^+ was ejected at the endfoot and microvilli.

Astrocytes synthesize neurotransmitters, take them up from the extracellular space, and have neurotransmitter receptors

Astrocytes synthesize at least 20 neuroactive compounds, including both glutamate and gamma-aminobutyric acid (GABA). Neurons can manufacture glutamate from glucose or from the immediate precursor molecule glutamine (Fig. 11-12). The glutamine pathway appears to be the primary one in the synthesis of synaptically released glutamate. Glutamine, however, is manufactured only in astrocytes by use of the astrocyte-specific enzyme **glutamine synthetase** to convert glutamate to glutamine. Astrocytes release this glutamine into the BECF through the SNAT3 and SNAT5 transporters (SLC38 family, see Table 5-4) for uptake by neurons through SNAT1 and SNAT2. Consistent with its role in the synthesis of glutamate for neurotransmission, glutamine synthetase is localized to astrocytic processes surrounding glutamatergic synapses. In the presynaptic terminals of neurons, glutaminase converts the glutamine to glutamate for release into the synaptic cleft by the presynaptic terminal. Finally, astrocytes take up much of the synaptically released glutamate to complete this **glutamate-glutamine cycle**. Disruption of this metabolic interaction between astrocytes and neurons can depress glutamate-dependent synaptic transmission.

FIGURE 11-12 Role of astrocytes in the glutamate-glutamine cycle. Most of the glutamate of glutamatergic neurons is generated from glutamine, which the neurons themselves cannot make. However, astrocytes take up some of the glutamate that is released at synapses (or produced by metabolism) and convert it into glutamine. The glutamine then enters the neuron, where it is converted back to glutamate. This glutamate also serves as the source for GABA in inhibitory neurons.

Glutamine derived from astrocytes is also important for synthesis of the brain's most prevalent inhibitory neurotransmitter, GABA. In the neuron, the enzyme **glutamic acid decarboxylase** converts glutamate (generated from glutamine) to GABA (see Fig. 13-8A). Because astrocytes play such an important role in the synthesis of synaptic transmitters, these glial cells are in a position to modulate synaptic efficacy.

Astrocytes have **high-affinity uptake systems** for the excitatory transmitter glutamate and the inhibitory transmitter GABA. In the case of glutamate uptake, mediated by EAAT1 and EAAT2 (SLC1 family, see Table 5-4), astrocytes appear to play the dominant role compared with neurons or other glial cells. Glutamate moves into cells accompanied by two Na^+ ions and an H^+ ion, with one K^+ ion moving in the opposite direction (see Fig. 11-12). Because a net positive charge moves into the cell, glutamate uptake causes membrane depolarization. The presynaptic cytoplasm may contain glutamate at a concentration as high as 10 mM, and vesicles may contain as much as 100 mM glutamate. Nevertheless, the glutamate uptake systems can maintain extracellular glutamate at concentrations as low as $\sim 1 \mu\text{M}$, which is crucial for normal brain function.

Neurotransmitter uptake systems are important because they help terminate the action of synaptically released neurotransmitters. Astrocyte processes frequently surround synaptic junctions and are ideally placed for this function. Under pathological conditions in which transmembrane ion gradients break down, high-affinity uptake systems may work in reverse and release transmitters, such as glutamate, into the BECF (Box 11-4).

Excitatory Amino Acids and Neurotoxicity

The dicarboxylic amino acid glutamate is the most prevalent excitatory neurotransmitter in the brain (see pp. 318–319). Although glutamate is present at millimolar levels inside neurons, the BECF has only micromolar levels of glutamate, except at sites of synaptic release (see Fig. 11-12). Excessive accumulation of glutamate in the BECF—induced by ischemia, anoxia, hypoglycemia, or trauma—can lead to neuronal injury. Astrocytes are intimately involved in the metabolism of glutamate and its safe disposition after synaptic release.

In anoxia and ischemia, the sharp drop in cellular levels of ATP inhibits the Na-K pump, which rapidly leads to large increases in $[K^+]_o$ and $[Na^+]_i$. These changes result in membrane depolarization, with an initial burst of glutamate release from vesicles in presynaptic terminals. Vesicular release, however, requires cytoplasmic ATP and probably halts rapidly. The ability of astrocytes to remove glutamate from the BECF is impeded by the elevated $[K^+]_o$, elevated $[Na^+]_i$, and membrane depolarization. In fact, the unfavorable ion gradients can cause the transporter to run in reverse and dump glutamate into the BECF. The action of rising levels of extracellular glutamate on *postsynaptic* and astrocytic receptors reinforces the developing ionic derangements by opening channels permeable to Na^+ and K^+ . This vicious cycle at the level of the astrocyte can rapidly cause extracellular glutamate to reach levels that are toxic to neurons—**excitotoxicity**.

Astrocytes express a wide variety of ionotropic and metabotropic **neurotransmitter receptors** that are similar or identical to those present on neuronal membranes. As in neurons, activation of these receptors can open ion channels or generate second messengers. In most astrocytes, glutamate produces depolarization by increasing Na^+ permeability, whereas GABA hyperpolarizes cells by opening Cl^- channels, similar to the situation in neurons (see pp. 326–327). Transmitter substances released by neurons at synapses can diffuse in the BECF to activate nearby receptors on astrocytes, thus providing, at least theoretically, a form of neuronal-glial signaling.

Astrocytes apparently can actively enhance or depress neuronal discharge and synaptic transmission by releasing neurotransmitters that they have taken up or synthesized. The release mechanisms are diverse and include stimulation by certain neurotransmitters, a fall in $[Ca^{2+}]_o$, or depolarization by elevated $[K^+]_o$. Applying glutamate to cultured astrocytes increases $[Ca^{2+}]_i$, which may oscillate. Moreover, these increases in $[Ca^{2+}]_i$ can travel in waves from astrocyte to astrocyte through gap junctions or through a propagated front of extracellular ATP release that activates astrocytic purinergic receptors, thereby increasing $[Ca^{2+}]_i$ and releasing more ATP. These $[Ca^{2+}]_i$ waves—perhaps by triggering the release of a neurotransmitter from the astrocyte—can lead to changes in the activity of nearby neurons. This interaction represents another form of glial-neuronal communication.

Astrocytes secrete trophic factors that promote neuronal survival and synaptogenesis

Astrocytes, and other glial cell types, are a source of important trophic factors and cytokines, including brain-derived neurotrophic factor (BDNF), glial-derived neurotrophic factor (GDNF), basic fibroblast growth factor (bFGF), and ciliary neurotrophic factor (CNTF). Moreover, both neurons and glial cells express receptors for these molecules, which are crucial for neuronal survival, function, and repair. The

expression of these substances and their cognate receptors can vary during development and with injury to the nervous system.

The development of fully functional excitatory synapses in the brain requires the presence of astrocytes, which act at least in part by secreting proteins called **thrombospondins**. Indeed, synapses in the developing CNS do not form in substantial numbers before the appearance of astrocytes. In the absence of astrocytes, only ~20% of the normal number of synapses form.

Astrocytic endfeet modulate cerebral blood flow

Astrocytic endfeet (see [p. 286](#)) surround not only capillaries but also small arteries. Neuronal activity can lead to astrocytic $[Ca^{2+}]_i$ waves—as previously described on [pages 291–292](#) that spread to the astrocytic endfeet, or to isolated increases in endfoot $[Ca^{2+}]_i$. In either case, the result is a rapid increase in blood vessel diameter and thus in local blood flow. A major mechanism of this vasodilation is the stimulation of phospholipase A_2 in the astrocyte, the formation of arachidonic acid, and the liberation through cyclooxygenase 1 (see [Fig. 3-11](#)) of a potent vasodilator that acts on vascular smooth muscle. This is one mechanism of neuron-vascular coupling—a local increase in neuronal activity that leads to a local increase in blood flow. Radiologists exploit this physiological principle in a form of **functional magnetic resonance imaging (fMRI)** called blood oxygen level–dependent (BOLD) MRI, which uses blood flow as an index of neuronal activity.

Astrocytic modulation of blood flow is complex, and increases in $[Ca^{2+}]_i$ in endfeet can sometimes lead to vasoconstriction.

Oligodendrocytes and Schwann cells make and sustain myelin

The primary function of oligodendrocytes as well as of their PNS equivalent, the Schwann cell, is to provide and to maintain myelin sheaths on axons of the central and peripheral nervous systems, respectively. As discussed on [p. 199](#), myelin is the insulating “electrical tape” of the nervous system (see [Fig. 7-21B](#)). **Oligodendrocytes** are present in all areas of the CNS, although their morphological appearance is highly variable and depends on their location within the brain. In regions of the brain that are dominated by myelinated nerve tracts, called white matter, the oligodendrocytes responsible for myelination have a distinctive appearance ([Fig. 11-13A](#)). Such an oligodendrocyte has 15 to 30 processes, each of which connects a myelin sheath to the oligodendrocyte's cell body. Each myelin sheath, which is up to 250 μm wide, wraps many times around the long axis of one axon. The small exposed area of axon between adjacent myelin sheaths is called the **node of Ranvier** (see [pp. 200–201](#)). In gray matter, oligodendrocytes do not produce myelin and exist as perineuronal satellite cells.

A OLIGODENDROCYTE

B SCHWANN CELL

FIGURE 11-13 Myelination of axons by oligodendrocytes and Schwann cells.

During the myelination process, the leading edge of one of the processes of the oligodendrocyte cytoplasm wraps around the axon many times (see [Fig. 11-13A](#), upper axon). The cytoplasm is then squeezed out of the many cell layers surrounding the axon in a process called **compaction**. This process creates layer upon layer of tightly compressed membranes that is called **myelin**. The myelin sheaths

remain continuous with the parent glial cells, which nourish them.

In the PNS, a single **Schwann cell** provides a single myelin segment to a single axon of a myelinated nerve (see [Fig. 11-13B](#)). This situation stands in contrast to that in the CNS, where one oligodendrocyte myelinates many axons. The process of myelination that occurs in the PNS is analogous to that outlined for oligodendrocytes. Axons of unmyelinated nerves are also associated with Schwann cells. In this case, the axons indent the surface of the Schwann cell and are completely surrounded by Schwann cell cytoplasm ([Fig. 11-14](#)).

FIGURE 11-14 Ensheathed versus myelinated axons. **A**, Ensheathed axons. This transmission electron micrograph shows a Schwann cell surrounding several *unmyelinated* peripheral axons, some of which are marked with an asterisk. The arrows point to the basal lamina. The arrowhead points to collagen fibrils. **B**, Myelinated axons. This transmission electron micrograph shows a Schwann cell (nucleus on right side of picture) surrounding a peripheral axon with several layers of myelin. The lower asterisk shows the beginning of the spiraling myelin sheath, whereas the upper asterisk indicates the termination of the spiral and a small region of noncompacted cytosol. The final magnification is ~14,000 in both panels. (Reproduced from Bunge RP, Fernandez-Valle C: In Kettemann H, Ransom RR [eds]: *Neuroglia*. New York, Oxford University Press, 1995, pp 44–57. Courtesy of Mary Bartlett Bunge.)

Myelin has a biochemical composition different from that of the oligodendrocyte or Schwann cell plasma membrane from which it arose. Although PNS myelin and CNS myelin look similar, some of the constituent proteins are different ([Table 11-4](#)). For example, proteolipid protein is the most common protein in CNS myelin (~50% of total protein) but is absent in PNS myelin. Conversely, P0 is found almost exclusively in PNS myelin.

TABLE 11-4
Proteins in Myelin

PROTEIN	CNS (% OF TOTAL MYELIN PROTEINS)	PNS (% OF TOTAL MYELIN PROTEINS)
MBP	30	<18
PLP	50	<0.01
MAG	<1	<50.1
CNP	<4	<50.4
P0	<0.01	>50
P2	<1	1–15
PMP22	<0.01	5–10
MOG	<0.05	<0.01

CNP, cyclic nucleotide phosphodiesterase; MAG, myelin-associated glycoprotein; MBP, myelin basic protein; MOG, myelin/oligodendrocyte glycoprotein; PLP, proteolipid protein; PMP22, peripheral myelin protein 22.

Myelination greatly enhances conduction of the action potential down the axon because it allows the regenerative electrical event to skip from one node to the next rather than gradually spreading down the whole extent of the axon. This process is called **saltatory conduction** (see pp. 200–201). Besides being responsible for CNS myelin, oligodendrocytes play another key role in saltatory conduction: they induce the clustering of Na⁺ channels at the nodes (see Fig. 12-5C), which is essential for saltatory conduction.

It is well known that severed axons in the PNS can regenerate with restoration of lost function. Regrowth of these damaged axons is coordinated by the Schwann cells in the distal portion of the cut nerve. Severed axons in the CNS do not show functional regrowth, in part because of the growth-retarding nature of myelin-associated glycoproteins (see pp. 267–268).

Oligodendrocytes are involved in pH regulation and iron metabolism in the brain

Oligodendrocytes and myelin contain most of the enzyme carbonic anhydrase within the brain. The appearance of this enzyme during development closely parallels the maturation of these cells and the formation of myelin. Carbonic anhydrase rapidly catalyzes the reversible hydration of CO₂ and may thus allow the CO₂/HCO₃[−] buffer system to be maximally effective in dissipating pH gradients in the brain. The pH regulation in the brain is important because it influences neuronal excitability. The classic example of the brain's sensitivity to pH is the reduced seizure threshold caused by the respiratory alkalosis secondary to hyperventilation (see p. 634).

Oligodendrocytes are the cells in the brain most involved with iron metabolism. They contain the iron storage protein ferritin and the iron transport protein transferrin. Iron is necessary as a cofactor for certain enzymes and may catalyze the formation of free radicals (see pp. 1238–1239) under pathological circumstances, such as disruption of blood flow to the brain.

Oligodendrocytes, like astrocytes, have a wide variety of neurotransmitter receptors. Unmyelinated axons can release glutamate when they conduct action potentials, and in principle, this glutamate could signal nearby oligodendrocytes. Ischemia readily injures oligodendrocytes, in part by releasing toxic levels of glutamate. Even white matter, therefore, can suffer excitotoxicity.

Microglial cells are the macrophages of the CNS

Microglial cells are of mesodermal origin and derive from cells related to the monocyte-macrophage lineage. Microglia represent ~20% of the total glial cells within the mature CNS. These cells are rapidly

activated by injury to the brain, which causes them to proliferate, to change shape, and to become phagocytic (Fig. 11-15). When activated, they are capable of releasing substances that are toxic to neurons, including free radicals and nitric oxide. It is believed that microglia are involved in most brain diseases, not as initiators but as highly reactive cells that shape the brain's response to any insult.

FIGURE 11-15 Microglial cells. Resting microglial cells become activated by injury to the brain, which causes them to proliferate and to become phagocytic.

Microglia are also the most effective antigen-presenting cells within the brain. Activated T lymphocytes are able to breach the BBB and enter the brain. To become mediators of tissue-specific disease or to destroy an invading infectious agent, T lymphocytes must recognize specific antigenic targets. Such recognition is accomplished through the process of antigen presentation, which is a function of the microglia.

CHAPTER 12

Physiology of Neurons

Barry W. Connors

Neurons receive, combine, transform, store, and send information

Neurons have arguably the most complex job of any cell in the body. Consequently, they have an elaborate morphology and physiology. Each neuron is an intricate computing device. A single neuron may receive chemical input from tens of thousands of other neurons. It then combines these myriad signals into a much simpler set of electrical changes across its cellular membrane. The neuron subsequently transforms these ionic transmembrane changes according to rules determined by its particular shape and electrical properties and transmits a *single new message* through its axon, which itself may contact and inform hundreds of other neurons. Under the right circumstances, neurons also possess the property of *memory*; some of the information coursing through a neuron's synapses may be stored for periods as long as years.

This general scheme of neuronal function applies to most neurons in the vertebrate nervous system. However, the scheme is endlessly variable. For example, each region of the brain has several major classes of neurons, and each of these classes has a physiology adapted to perform specific and unique functions. In this chapter, the general principles of neuronal function are outlined, and the almost unlimited variability contained within the general schema is discussed.

Neural information flows from dendrite to soma to axon to synapse

Numerous dendrites converge on a central soma, or cell body, from which a single axon emerges and branches multiple times (see [Fig. 10-1](#)). Each branch culminates at a presynaptic terminal that contacts another cell. In most neurons, dendrites are the principal synaptic input sites, although synapses may also be found on the soma, on the axon hillock (the region of the soma neighboring the axon), or even directly on the axons. In some primary sensory neurons, the dendrites themselves are transducers of environmental energy. Regardless of their source, signals—in the form of voltage changes across the membrane—typically flow from dendrites to soma to axon and finally to synapses on the next set of cells. Under some circumstances electrical signals may also propagate in the opposite direction, from the soma outward along dendrites to their tips.

Excitatory input to a neuron usually generates an inward flow of positive charge (i.e., an inward current) across the dendritic membrane. Because the interior of a resting neuron is polarized negatively with respect to the external environment, this inward current, which makes the membrane voltage more positive (i.e., less negative), is said to **depolarize** the cell. Conversely, inhibitory input to a neuron usually generates an outward current and, thus, hyperpolarization.

If the neuron receives its input from a neighboring cell through a chemical synapse, neurotransmitters trigger currents by activating ion channels. If the cell is a sensory neuron, environmental stimuli (e.g., chemicals, light, mechanical deformation) activate ion channels and produce a flow of current. The

change in membrane potential (V_m) caused by the flow of charge is called a **postsynaptic potential (PSP)** if it is generated at the postsynaptic membrane by a neurotransmitter and a **receptor potential** if it is generated at a sensory nerve ending by an external stimulus. In the case of synaptic transmission, the postsynaptic V_m changes may be either positive or negative. If the neurotransmitter is excitatory and produces a *depolarizing* PSP, we refer to the PSP as an **excitatory postsynaptic potential (EPSP)**; see [p. 210](#)). On the other hand, if the neurotransmitter is inhibitory and produces a *hyperpolarizing* PSP, the PSP is an **inhibitory postsynaptic potential (IPSP)**. In all cases, the stimulus produces a V_m change that may be *graded* from small to large depending on the strength or quantity of input stimuli (see [p. 174](#)). Stronger sensory stimuli generate larger receptor potentials; similarly, more synapses activated together generate larger PSPs. A graded response is one form of neural coding whereby the size and duration of the input are encoded as the size and duration of the change in the dendritic V_m .

The synaptic (or receptor) potentials generated at the ends of a dendrite are communicated to the soma, usually with substantial attenuation of the signal ([Fig. 12-1A](#)). Extended cellular processes such as dendrites behave like leaky electrical cables (see [pp. 201–203](#)). As a consequence, dendritic potentials usually decline in amplitude before reaching the soma. As an EPSP reaches the soma, it may also combine with EPSPs arriving via other dendrites on the cell; this behavior is a type of **spatial summation** and can lead to EPSPs that are substantially larger than those generated by any single synapse (see [Fig. 12-1B, C](#)). **Temporal summation** occurs when EPSPs arrive rapidly in succession; when the first EPSP has not yet dissipated, a subsequent EPSP tends to add its amplitude to the residual of the preceding EPSP (see [Fig. 12-1D](#)).

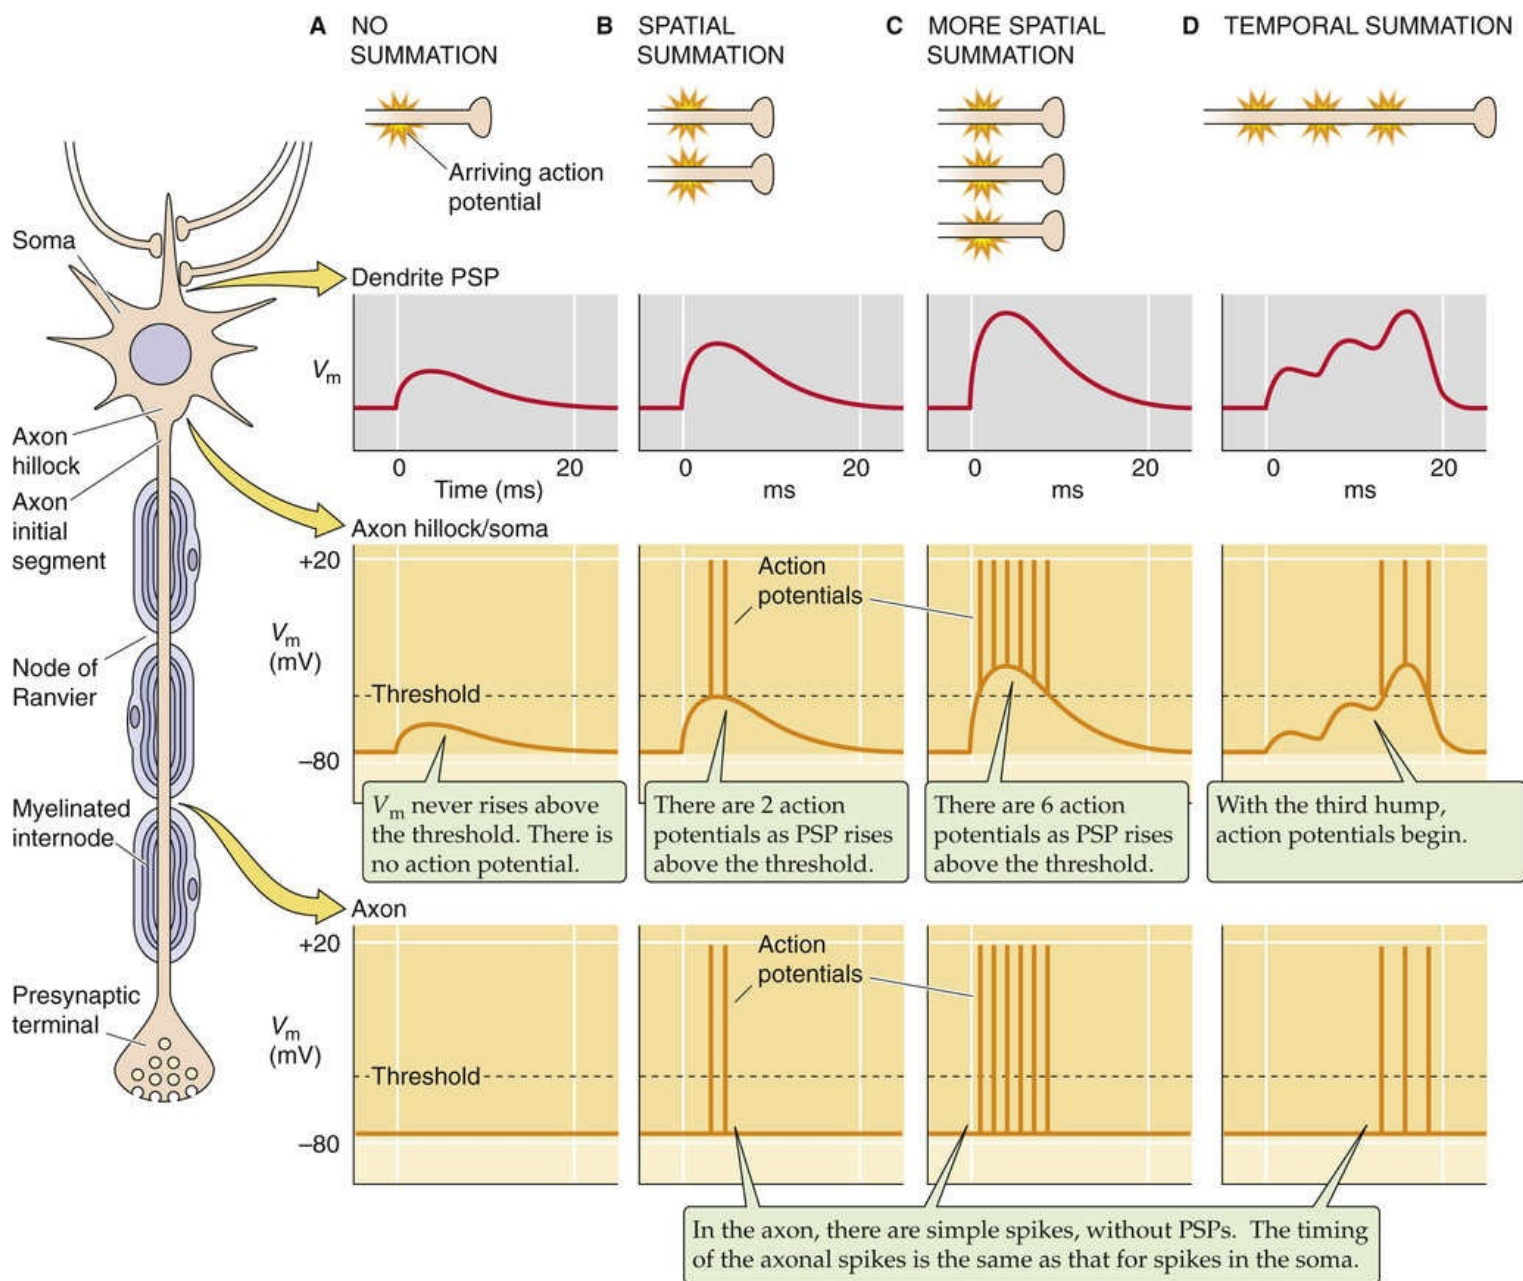

FIGURE 12-1 Spatial versus temporal summation of EPSPs.

The tendency for synaptic and receptor potentials to diminish with distance along a dendrite puts significant limitations on their signaling abilities. If nothing else happened, these depolarizing potentials would simply dwindle back to the resting membrane potential as they spread through the soma and down into the axon. At best, this passive signal might be carried a few millimeters, clearly inadequate for commanding a toe to wiggle when the axon of the motor neuron stretching from the spinal cord to the muscles moving the foot might be 1000 mm long. Some amplification is therefore necessary for certain inputs to generate effective signals to and from the central nervous system (CNS). Amplification is provided in the form of regenerating **action potentials**. If the V_m change in the soma is large enough to reach the threshold voltage (see p. 173), the depolarization may trigger one or more action potentials between the soma and axon, as shown in Figure 12-1B to D. Action potentials are large, rapid fluctuations in V_m . As described in Chapter 7, an action potential is an efficient, rapid, and reliable way to carry a signal over long distances. However, notice that generation of action potentials entails another transformation of neuronal information: the neuron converts the graded-voltage code of the dendrites (i.e., the PSPs) to a temporal code of action potentials in the axon. The initiation site for action potentials in many types of neurons is the axon initial segment, the first stretch of unmyelinated axon past the soma.

Action potentials are fixed in amplitude, not graded, and have uniform shape. So how is information encoded by action potentials? This question has no simple answer and is still hotly debated. Because one axonal spike looks like another (with slight exceptions), neurons can vary only the number of spikes and their timing. For a single axon, information may be encoded by the average rate of action potential firing, the total number of action potentials, their temporal pattern, or some combination of these mechanisms. [Figure 12-1](#) illustrates that as the synaptic potential in the soma increases in size, the resultant action potentials occur more frequently, and the burst of action potentials in the axon lasts longer. Notice also that by the time the signal has propagated well down the axon, the transformation has become complete—the graded potential has waned and vanished, whereas the action potentials have retained their size, number, and temporal pattern. The final output of the neuron is entirely encoded by these action potentials. When action potentials reach axonal terminals, they may trigger the release of a neurotransmitter at the next set of synapses, and the cycle begins again.

Signal Conduction in Dendrites

The word *dendrite* is derived from the Greek word *dendron* [tree], and indeed some dendrites resemble tree branches or roots. Inspired by trees, no doubt, the anatomist Camillo Golgi suggested in 1886 that the function of dendrites is to collect nutrients for the neuron. The truth is analogous but more interesting: dendrites arborize through a volume of brain tissue so that they can collect *information* in the form of synaptic input. The dendrites of different types of neurons exhibit a great diversity of shapes. Dendrites are often extensive, accounting for up to 99% of a neuron's membrane. The dendrites of a single neuron may receive as many as 200,000 synaptic inputs. The electrical and biochemical properties of dendrites are quite variable from cell to cell, and they have a profound influence on the transfer of information from synapse to soma.

Dendrites attenuate synaptic potentials

Dendrites tend to be long and thin. Their cytoplasm has relatively low electrical resistivity, and their membrane has relatively high resistivity. These are the properties of a *leaky electrical cable*, which is the premise for **cable theory** (see p. 201). Leaky cables are like leaky garden hoses; if ionic current (or water) enters at one end, the fraction of it that exits at the other end depends on the number of channels (or holes) in the cable (hose). A good hose has no holes and all the water makes it through, but most dendrites have a considerable number of channels that serve as leaks for ionic current (see Fig. 7-22).

Cable theory predicts how much current flows down the length of the dendrite through the cytoplasm and how much of it leaks out of the dendrite across the membrane. As summarized in Table 7-3, we can express the leakiness of the membrane by the resistance per unit area of dendritic membrane (**specific membrane resistance, R_m**), which can vary widely among neurons. The intracellular resistance per cross-sectional area of dendrite (**specific resistivity of the cytoplasm, R_i**) is also important in determining current flow inasmuch as a very resistive cytoplasm forces more current to flow out across the membrane rather than down the axis of the dendrite. Another important factor is cable diameter; thick dendrites let more current flow toward the soma than thin dendrites do. Figure 7-22C illustrates the consequences of a point source of steady current flowing into a leaky, uniform, infinitely long cable made of purely passive membrane. The transmembrane voltage generated by the current falls off exponentially with distance from the site of current injection. The steepness with which the voltage falls off is defined by the length constant (λ ; see p. 201), which is the distance over which a steady voltage decays by a factor of $1/e$ ($\sim 37\%$). Estimates of the parameter values vary widely, but for brain neurons at rest, reasonable numbers are $\sim 50,000 \Omega \cdot \text{cm}^2$ for R_m and $200 \Omega \cdot \text{cm}$ for R_i . If the radius of the dendrite (a) is $1 \mu\text{m}$ (10^{-4} cm), we can estimate the length constant of a dendrite by applying Equation 7-8.

$$\begin{aligned}\lambda &= \sqrt{\frac{a \cdot R_m}{2R_i}} = \sqrt{\frac{(10^{-4} \text{ cm}) (5 \times 10^4 \Omega \text{ cm}^2)}{2(200 \Omega \text{ cm})}} \\ &= 0.1118 \text{ cm} = 1118 \mu\text{m}\end{aligned}\tag{12-1}$$

Because dendrite diameters vary greatly, λ should also vary greatly. For example, assuming the same

cellular properties, a thin dendrite with a radius of $0.1\mu\text{m}$ would have a λ of only $354\mu\text{m}$, whereas a thick one with a radius of $5\mu\text{m}$ would have a λ of $2500\mu\text{m}$. Thus, the graded signal voltage spreads farther in a thick dendrite.

Real dendrites are certainly not infinitely long, uniform, and unbranched, nor do they have purely passive membranes. Thus, quantitative analysis of realistic dendrites is complex. The termination of a dendrite *decreases* attenuation because current cannot escape farther down the cable. Branching *increases* attenuation because current has more paths to follow. Most dendrites are tapered. Gradually expanding to an increased diameter progressively increases λ and thus progressively *decreases* attenuation. Real membranes are never completely passive because all have voltage-gated channels, and therefore their R_m values can change as a function of voltage and time. Finally, in the working brain, cable properties are not constant but may vary dynamically with ongoing brain activity. For example, as the general level of synaptic input to a neuron rises (which might happen when a brain region is actively engaged in a task), more membrane channels will open and thus R_m will drop as a function of time, with consequent shortening of dendritic length constants. However, all these caveats do not alter the fundamental *qualitative conclusion: voltage signals are attenuated as they travel down a dendrite.*

So far, we have described only how a dendrite might attenuate a *sustained* voltage change. Indeed, the usual definition of length constant applies only to a *steady-state* voltage shift. An important complication is that the signal attenuation along a cable depends on the *frequency* components of that signal—how rapidly voltage changes over time. When V_m varies over time, some current is lost to membrane capacitance (see p. 158), and less current is carried along the dendrite downstream from the source of the current. Because action potentials and EPSPs entail rapid changes in V_m , with the fastest of them rising and falling within a few milliseconds, they are attenuated much more strongly than the steady-state λ implies. If V_m varies in time, we can define a λ that depends on signal frequency (λ_{AC} , where AC stands for “alternating current”). When signal frequency is zero (i.e., V_m is steady), $\lambda = \lambda_{AC}$. However, as frequency increases, λ_{AC} may fall sharply. Thus, *dendrites attenuate high-frequency (i.e., rapidly changing) signals more than low-frequency or steady signals.* Another way to express this concept is that most dendrites tend to be **low-pass filters** in that they let slowly changing signals pass more easily than rapidly changing ones.

Figure 12-2A shows how an EPSP propagates along two different dendrites with very different length constants. If we assume the synapses trigger EPSPs of similar size in the end of each dendrite, then the dendrites with the longer λ deliver a larger signal to the axon hillock. How do leaky dendrites manage to communicate a useful synaptic signal to the soma? The problem is solved in two ways. The first solution deals with the passive properties of the dendrite membrane. The length (l) of dendrites tends to be relatively small in comparison to their λ ; thus, none extends more than one or two steady-state length constants (i.e., the l/λ ratio is <1). One way that dendrites achieve a small l/λ ratio is to have a combination of diameter and R_m that gives them a large λ . Another way is that dendrites are not infinitely long cables but “terminated” cables. Figure 12-2B shows that a signal is attenuated more in an infinitely long cable (curve *a*) than in a terminated cable whose length (l) is equal to λ (curve *b*). The attenuation of a purely passive cable would be even less if the terminated cable had a λ 10-fold greater than l (curve *c*). Recall that in our example in Figure 12-2A, such a 10-fold difference in λ underlies the difference in the amplitudes of the EPSPs arriving at the axon hillock.

FIGURE 12-2 Effect of λ on propagation of an EPSP to two different axons. **A**, The neuron at the top fires an action potential that reaches the left and right neurons below, each at a single synapse. The EPSPs are identical. However, the left neuron has a thin dendrite and therefore a small length constant ($\lambda = 0.1$ mm). As a result, the signal is almost completely attenuated by the time it reaches the axon hillock, and there is no action potential. In the right neuron, the dendrite is thicker and therefore has a larger length constant ($\lambda = 1$ mm). As a result, the signal that reaches the axon hillock is large enough to trigger an action potential. **B**, The graph shows four theoretical plots of the decay of voltage (logarithmic plot) along a dendritic cable. The voltage is expressed as a fraction of maximal voltage. The length along the cable is normalized for the length constant (λ). Thus, an l/λ of 1.0 corresponds to one length constant along the dendrite. Curve a: If the cable is infinitely long and passive, the voltage decays exponentially with increasing length, so that the semilog plot is linear. Curve b: If the cable is terminated at a length that is equal to one length constant, then voltage decays less steeply. Curve c: If the cable is terminated at a length that is equal to 10% of the length constant, the voltage decays even less steeply. Curve d: If the membrane is not passive but has a slow voltage-gated conductance, the dendritic attenuation will be much smaller. (Data from Jack JJB, Noble D, Tsien RW: *Electrical Current Flow in Excitable Cells*. Oxford, UK, Oxford University Press, 1975.)

The second solution to the attenuation problem is to endow dendrites with voltage-gated ion channels (see pp. 182–199) that enhance the signal more than would be expected in a purely “passive” system (curve d). We discuss the properties of such “active” cables in the next section.

Dendritic membranes have voltage-gated ion channels

All mammalian dendrites have voltage-gated ion channels that influence their signaling properties. Dendritic characteristics vary from cell to cell, and the principles of dendritic signaling are being studied intensively. Most dendrites have a relatively low density of voltage-gated channels (see pp. 182–199) that may amplify, or boost, synaptic signals by adding additional inward current as the signals propagate from distal dendrites toward the soma. We have already introduced the principle of an **active cable** in curve d of Figure 12-2B. If the membrane has voltage-gated channels that are able to carry more inward current (often Na^+ or Ca^{2+}) under depolarized conditions, a sufficiently strong EPSP would drive V_m into the activation range of the voltage-gated channels. These voltage-gated channels would open, and their

additional inward current would add to that generated initially by the synaptic channels. Thus, the synaptic signal would fall off much less steeply with distance than in a passive dendrite. Voltage-gated channels can be distributed all along the dendrite and thus amplify the signal along the entire dendritic length, or they can be clustered at particular sites. In either case, voltage-gated channels can boost the synaptic signal considerably, even if the densities of channels are far too low for the generation of action potentials.

An even more dramatic solution, used by a few types of dendrites, is to have such a high density of voltage-gated ion channels that they can produce *action potentials*, just as axons can. One of the best-documented examples is the Purkinje cell, which is the large output neuron of the cerebellum. As Rodolfo Llinás and colleagues have shown, when the dendrites of Purkinje cells are stimulated strongly, they can generate large, relatively broad action potentials that are mediated by voltage-gated Ca^{2+} channels (Fig. 12-3). Such Ca^{2+} spikes can sometimes propagate toward—or even into—the soma, but these Ca^{2+} action potentials do not continue down the axon. Instead, they may trigger fast Na^{+} -dependent action potentials that are generated by voltage-gated Na^{+} channels in the initial segment. The Na^{+} spikes carry the signal along the axon in the conventional way. Both types of spikes occur in the soma, where the Na^{+} spikes are considerably quicker and larger than the dendritic Ca^{2+} spikes. The faster Na^{+} spikes propagate only a short distance backward into the dendritic tree because the rapid time course of the Na^{+} spike is strongly attenuated by the inherent filtering properties of the dendrites (i.e., the λ_{AC} is smaller for the rapid frequencies of the Na^{+} action potentials than for the slower Ca^{2+} action potentials). The dendrites of certain other neurons of the CNS, including some pyramidal cells of the cerebral cortex, can also generate spikes that are dependent on Ca^{2+} , Na^{+} , or both.

FIGURE 12-3 Ca^{2+} action potentials in dendrites of Purkinje cells. Usually, dendrites do not fire action potentials; however, in these Purkinje cells of the cerebellum (*left*), the high density of voltage-gated Ca^{2+} channels in the dendrites allows the generation of *slow dendritic Ca^{2+} spikes* (records *a*, *b*, and *c* on the *right*), which propagate all the way to the axon soma. In the axon soma, these Ca^{2+} action potentials trigger fast Na^{+} action potentials (record *d* on the *right*). Moreover, the fast Na^{+} spikes back-propagate into the dendritic tree but are attenuated. Thus, these fast Na^{+} spikes appear as small spikes in the proximal dendrites (record *c*) and even smaller blips in the midlevel dendrites (record *b*). (Data from Llinás R, Sugimori M: Electrophysiological properties of in vitro Purkinje cell dendrites in mammalian cerebellar slices. *J Physiol* 305:197–213, 1980.)

Dendritic action potentials, when they exist at all, tend to be slower and weaker, and with higher thresholds, than those in axons. The reason is probably that one of the functions of dendrites is to collect and to integrate information from a large number of synapses (often thousands). If each synapse were capable of triggering an action potential, there would be little opportunity for most of the synaptic inputs to have a meaningful influence on a neuron's output. The cell's dynamic range would be truncated; that is, a very small number of active synapses would bring the neuron to its maximum firing rate. However, if dendrites are only weakly excitable, the problem of signal attenuation along dendritic cables can be solved while the cell still can generate an output (i.e., the axonal firing rate) that is indicative of the proportion of its synapses that are active.

Another advantage of voltage-gated channels in dendrites may be the selective boosting of high-frequency synaptic input. Recall that passive dendrites attenuate signals of high frequency more than those

of low frequency. However, if dendrites possess the appropriate voltage-gated channels, with fast gating kinetics, they will be better able to communicate high-frequency synaptic input.

Control of Spiking Patterns in the Soma

Electrical signals from dendrites converge and summate at the soma. Although action potentials themselves often appear first at the nearby axon hillock and initial segment of the axon, the large variety of ion channels in the soma and proximal dendritic membranes is critically important in determining and modulating the temporal patterns of action potentials that ultimately course down the axon.

Neurons can transform a simple input into a variety of output patterns

Neurophysiologists have sampled the electrical properties of many different types of neurons in the nervous system, and one general conclusion seems safe: no two types behave the same. The variability begins with the **shape and height** of individual action potentials. Most neurons within the CNS generate action potentials in the conventional way (see [Fig. 7-4](#)). Fast voltage-gated Na^+ channels (see [pp. 185–187](#)) generate a strong inward current that depolarizes the membrane from rest, usually in the range of -60 to -80 mV, to a peak that is usually between $+10$ and $+40$ mV. This depolarization represents the upstroke of the action potential. The Na^+ channels then quickly inactivate and close, and certain K^+ channels (often voltage-gated, delayed outward-rectifier channels; see [pp. 193–196](#)) open and thus cause V_m to fall and terminate the spike. However, many neurons have somewhat different spike-generating mechanisms and produce spikes with a range of shapes. 🍷 **N12-1** Although a fast Na^+ current invariably drives the fast upstroke of neuronal action potentials, an additional fast Ca^{2+} current (see [pp. 188–189](#)) can frequently occur and, if it is large enough, broaden the spike duration. Adding to the complexity, individual neurons usually have more than one type of Na^+ current and multiple types of Ca^{2+} currents. The greatest variability occurs in the repolarization phase of the spike. Many neurons are repolarized by several other voltage-gated K^+ currents in addition to the delayed outward-rectifier K^+ current, and some also have K^+ currents carried by one or more channels that are rapidly activated by the combination of membrane depolarization and a rise in $[\text{Ca}^{2+}]_i$ (see [pp. 196–197](#)).

N12-1

Shapes of Action Potentials in Various Neurons

Contributed by Barry Connors

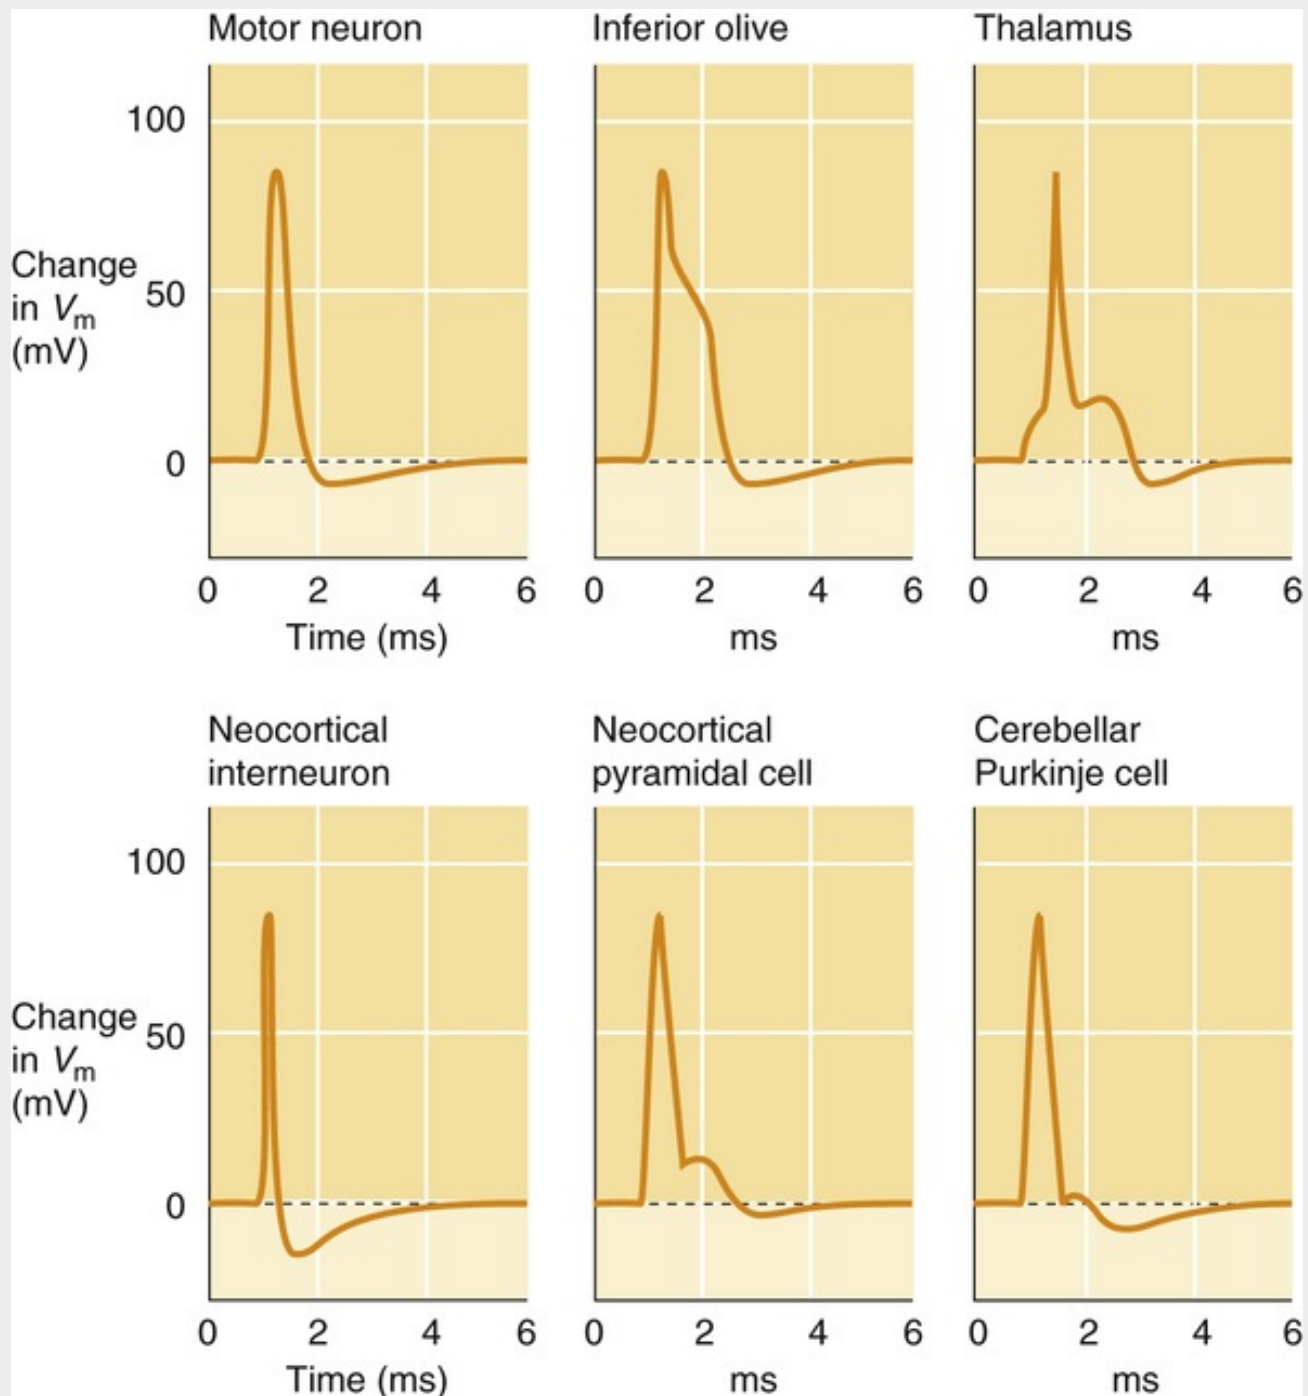

FIGURE 12-1 Range of shapes of action potentials in various neurons.

More dramatic variations occur in the **repetitive spiking patterns** of neurons, observed when the duration of a stimulus is long. One way to illustrate this principle is to apply a simple continuous stimulus (a current pulse, for example) to a neuron and to measure the neuron's output (the number and pattern of action potentials fired at its soma). The current pulse is similar to a steady, strong input of excitatory synaptic currents. The transformation from stimulus input to spiking output can take many different forms. Some examples are shown in [Figure 12-4](#), which illustrates recordings from three types of neurons in the cerebral cortex. In response to a sustained current stimulus, some cells generate a rapid train of action potentials that *do not adapt* (see [Fig. 12-4A](#)); that is, the spikes occur at a regular interval throughout the current pulse. Other cells fire rapidly at first but then *adapt strongly* (see [Fig. 12-4B](#)); that is, the spikes gradually become less frequent during the current pulse. Some cells fire a burst of action potentials and then stop firing altogether, and still others generate *rhythmic bursts* of action potentials that continue as long as the stimulus (see [Fig. 12-4C](#)). These varied behaviors are not arbitrary but are characteristic of

each neuron type, and they are as distinctive as each cell's morphology. They are also an intrinsic property of each neuron; that is, a neuron's fundamental firing pattern is determined by the membrane properties of the cell and does not require fluctuations in synaptic input. Of course, synaptic input may also impose particular firing patterns on a neuron. When a neuron is operating in situ, its firing patterns are determined by the interaction of its intrinsic membrane properties and synaptic inputs.

A INHIBITORY INTERNEURON**B SMALL PYRAMIDAL CELL****C LARGE PYRAMIDAL CELL**

FIGURE 12-4 Spiking patterns.

Rhythmically bursting cells are particularly interesting and occur in a variety of places in the brain. As described on [pages 397–398](#), they may participate in the central circuits that generate rhythmic motor output for behavior such as locomotion and respiration. Cells that secrete peptide neurohormones, such as the magnocellular neurons of the hypothalamus, are also often characterized by rhythmic bursting

behavior. These cells release either arginine vasopressin to control water retention (see pp. 844–845) or oxytocin to control lactation (see p. 1150). Rhythmic bursting is a more effective stimulus for the synaptic release of peptides than are tonic patterns of action potential. It may be that the bursting patterns and the Ca^{2+} currents that help drive them can elicit the relatively high $[\text{Ca}^{2+}]_i$ necessary to trigger the exocytosis of peptide-containing vesicles (see pp. 219–221). One additional role of rhythmically bursting neurons is to help drive the synchronous oscillations of neural activity in forebrain circuits (i.e., thalamus and cortex) during certain behavioral states, particularly sleep.

Although it has been difficult to prove, the diverse electrical properties of neurons are probably adapted to each cell's particular functions. For example, in the first stage of auditory processing in the brain, cranial nerve VIII axons from the cochlea innervate several types of neurons in the cochlear nucleus of the brainstem. The axons provide similar synaptic drive to each type of neuron, yet the output from each neuron type is distinctly different. Some are tuned to precise timing and respond only to the *onset* of the stimulus and ignore anything else; some respond, pause, and respond again; others chop the ongoing stimulus into a more rhythmic output; and still other cells transform the input very little. The mechanisms for this range of transformations include both synaptic circuitry and the diverse membrane properties of each cell type. The different properties allow some cells to be particularly well tuned to specific features of the stimulus—its onset, duration, or amplitude modulation—and they can then communicate this signal to the appropriate auditory nuclei for more complex processing.

Intrinsic firing patterns are determined by a variety of ion currents with relatively slow kinetics

What determines the variety of spiking patterns in each type of neuron, and why do neurons differ in their intrinsic patterns? The key is a large set of ion channel types that have variable and often relatively *slow* kinetics compared with the *quick* Na^+ and K^+ channels that shape the spike. For a discussion of the properties of such channels, see p. 182. Each neuron expresses a different complement of these slow channels and has a unique spatial arrangement of them on its dendrites, soma, and axon initial segment. The channels are gated primarily by membrane voltage and $[\text{Ca}^{2+}]_i$, and a neuron's ultimate spiking pattern is determined by the net effects of the slow currents that it generates. We provide three examples of systems that have been studied in detail.

1. A neuron with only fast voltage-gated Na^+ channels and delayed-rectifier K^+ channels will generate repetitive spikes when it is presented with a long stimulus. The pattern of those spikes will be quite regular over time, as for the particular type of cerebral cortical interneuron that we have already seen in Figure 12-4A.
2. If the neuron also has another set of K^+ channels that activate only very slowly, the spiking pattern becomes more time dependent: the spiking frequency may initially be very high, but it adapts to progressively lower rates as a slow K^+ current turns on to counteract the stimulus, as shown for the small pyramidal cell in Figure 12-4B. The strength and rate of adaptation depend strongly on the number and properties of the fast and slow K^+ channels.
3. A neuron, by exploiting the interplay between two or more voltage-gated currents with relatively slow kinetics, can generate spontaneous rhythmic bursting—as in the case of the large pyramidal neuron in Figure 12-4C—even without ongoing synaptic activity to drive it.

Axonal Conduction

Axons are specialized for rapid, reliable, and efficient transmission of electrical signals

At first glance, the job of the axon seems mundane compared with the complex computational functions of synapses, dendrites, and somata. After all, the axon has the relatively simple job of carrying the computed signal—a sequence of action potentials—from one place in the brain to another without changing it significantly. Some axons are thin, unmyelinated, and slow; these properties are sufficient to achieve their functions. However, the axon can be exquisitely optimized, with myelin and nodes of Ranvier, for fast and reliable saltatory conduction of action potentials over very long distances (see [p. 200](#)). Consider the sensory endings in the skin of your foot, which must send their signals to your lumbar spinal cord 1 m away (see [Fig. 10-11B](#)). The axon of such a sensory cell transmits its message in just a few tens of milliseconds! As we see in our discussion of spinal reflexes on [pages 392–395](#), axons of similar length carry signals in the opposite direction, from your spinal cord to the muscles within your feet, and they do it even faster than most of the sensory axons. Axons within the CNS can also be very long; examples include the corticospinal axons that originate in the cerebral cortex and terminate in the lumbar spinal cord. Alternatively, many central axons are quite short, only tens of micrometers in length, and they transmit their messages locally between neurons. The spinal interneuron between a sensory neuron and a motor neuron (see [Fig. 10-11B](#)) is an example. Some axons target their signal precisely, from one soma to only a few other cells, whereas others may branch profusely to target thousands of postsynaptic cells.

Different parts of the brain have different signaling needs, and their axons are adapted to the local requirements. Nevertheless, the primary function of all axons is to carry electrical signals, in the form of action potentials, from one place to other places and to do so rapidly, efficiently, and reliably. Without myelinated axons, the large, complex brains necessary to control warm, fast mammalian bodies could not exist. For *unmyelinated* axons to conduct action potentials sufficiently fast for many purposes, their diameters would have to be so large that the axons alone would take up far too much space and use impossibly large amounts of energy.

Action potentials are usually initiated at the initial segment

The soma, axon hillock, and initial segment of the axon together serve as a kind of focal point in most neurons. The many graded synaptic potentials carried by numerous dendrites converge at the soma and generate one electrical signal. During the 1950s, Sir John Eccles  [N12-2](#) and colleagues used glass microelectrodes to probe the details of this process in spinal motor neurons. Because it appeared that the threshold for action potentials in the initial segment was only ~10 mV above the resting potential, whereas the threshold in the soma was closer to 30 mV above resting potential, they concluded that the neuron's action potentials would be first triggered at the initial segment. Direct recordings from various parts of neurons now indicate that spikes begin at the initial segment, at least for many types of vertebrate neurons. EPSPs evoked in the dendrites propagate down to and through the soma and trigger an action potential in a myelin-free zone of axon ~15 to 50 μm from the soma ([Fig. 12-5A](#)). The action potential then propagates in two directions: forward—**orthodromic** conduction—into the axon, with no loss of amplitude, and backward—**antidromic** conduction—into the soma and dendrites, with strong attenuation, as we saw above in [Figure 12-3](#). Orthodromic propagation carries the signal to the next set of neurons.

The function of antidromic propagation is not completely understood. It is very likely that backwardly propagating spikes trigger biochemical changes in the neuron's dendrites and synapses and they may have a role in plasticity of synapses and intrinsic membrane properties.

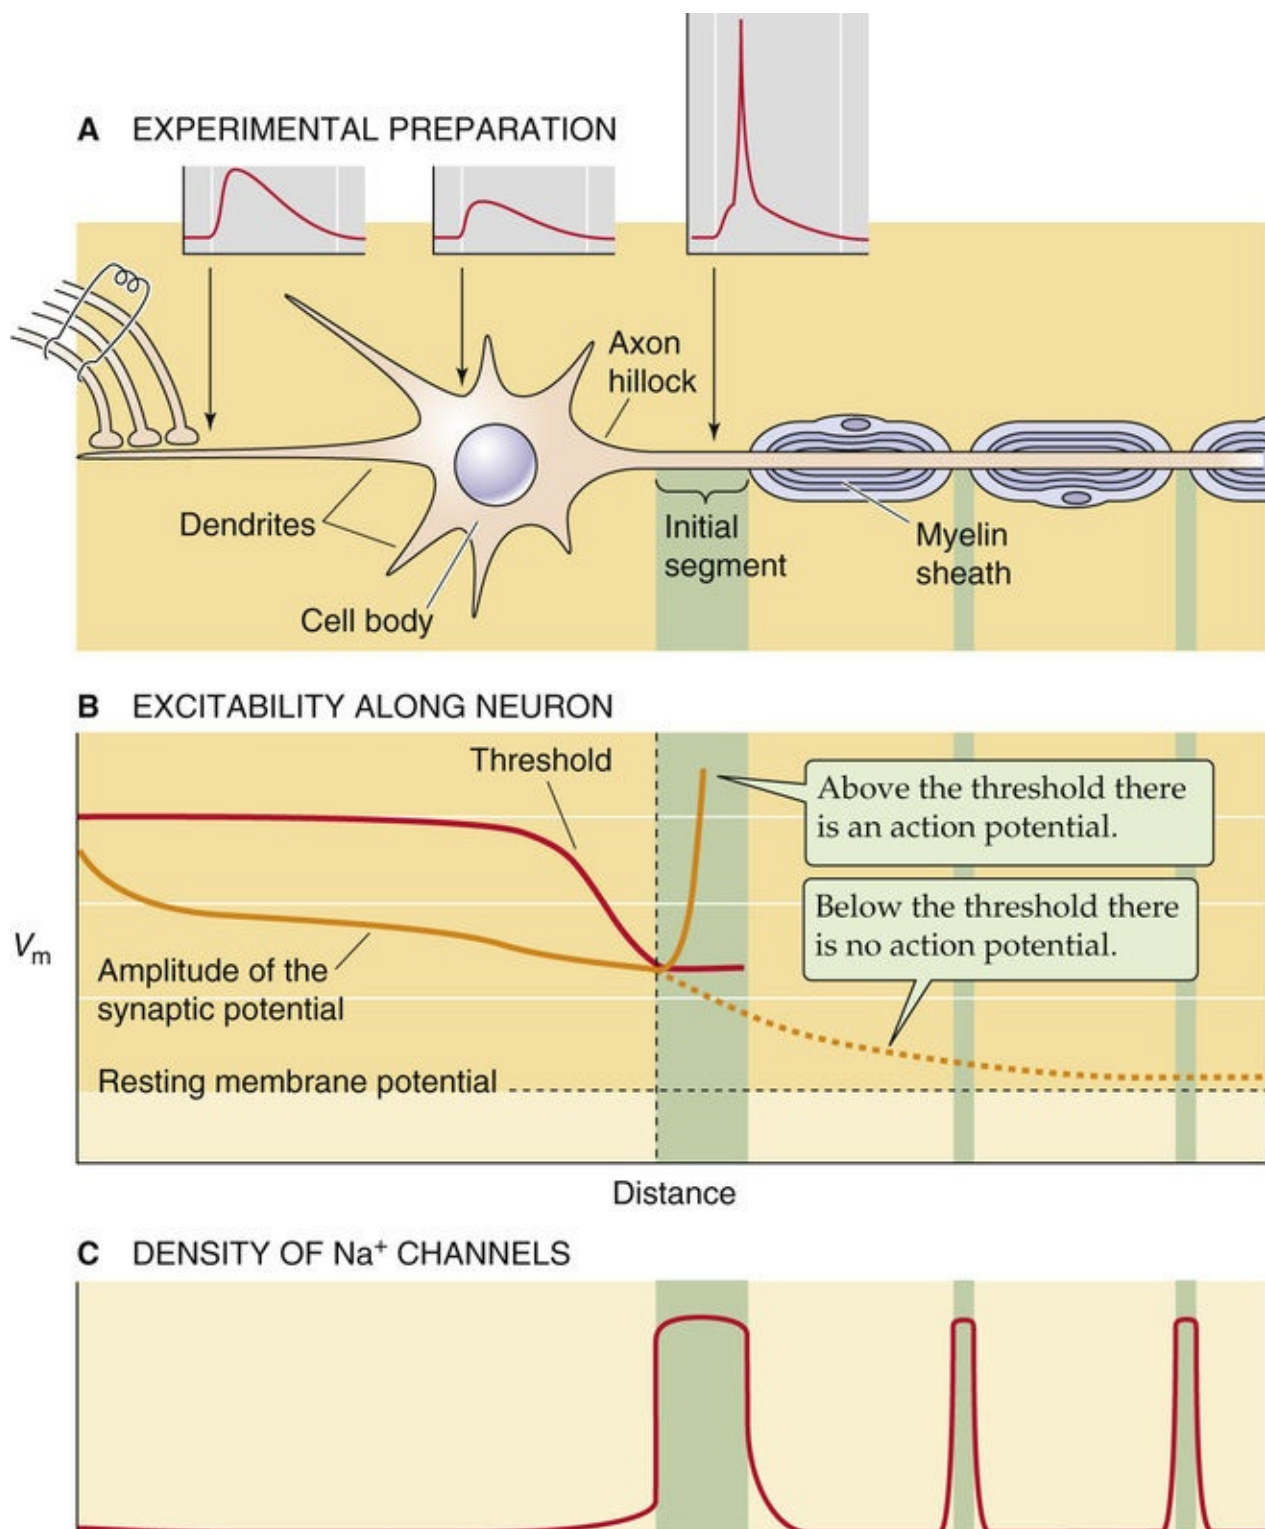

FIGURE 12-5 Simultaneous recording of action potentials from different parts of a neuron. **A**, In this hypothetical experiment, an excitatory synapse on a dendrite is stimulated and the response near that dendrite is recorded in the soma and at the initial segment. The EPSP attenuates in the soma and the initial segment, but the EPSP is large enough to trigger an action potential at the initial segment. **B**, The threshold is high (-35 mV) in regions of the neuron that have few Na^+ channels but starts to fall rather steeply in the hillock and initial segment. Typically, a stimulus of sufficient strength triggers an action potential at the initial segment. **C**, The density of Na^+ channels is high only at the initial segment and at each node of Ranvier.

The axon achieves a uniquely *low threshold* in its initial segment (see [Fig. 12-5B](#)) by two main mechanisms. First, *the initial segment has a remarkably high density of voltage-gated Na^+ channels* (see [Fig. 12-5C](#)). The Na^+ channel density in the axon initial segment is estimated to be 3-fold to 40-fold higher than in the membrane of the soma and dendrites, depending on neuron type and experimental methodology. The scaffolding protein **ankyrin-G** is a molecular marker for the initial segment and seems to be critical for organizing its unique distribution of ion channels. Second, initial segments often include Na^+ channel types (see [Table 7-1](#)) such as Nav1.6 that activate at relatively negative voltages compared to channels such as Nav1.2 that are common in the soma and dendrites. The combination of large numbers of Na^+ channels and their opening at relatively negative voltage allows the initial segment to reach action potential threshold before other sites on the dendrites and soma.

Conduction velocity of a myelinated axon increases linearly with diameter

The larger the diameter of an axon, the faster its conduction velocity, other things remaining equal. However, conduction velocity is usually much faster in myelinated axons than it is in unmyelinated axons (see [p. 200](#)). Thus, a myelinated axon 10 μm in diameter conducts impulses at about the same velocity as an unmyelinated axon $\sim 500 \mu\text{m}$ in diameter. Myelination confers not only substantial speed advantages but also advantages in efficiency. Almost 2500 of the 10- μm myelinated axons can pack into the volume occupied by one 500- μm axon!

Unmyelinated axons still have a role in vertebrates. At diameters below $\sim 1 \mu\text{m}$, unmyelinated axons in the peripheral nervous system (PNS) conduct more rapidly than myelinated ones do. In a testament to evolutionary frugality, the thinnest axons of the peripheral sensory nerves, called **C fibers**, are $\sim 1 \mu\text{m}$ wide or less, and all are unmyelinated. Axons larger than $\sim 1 \mu\text{m}$ in diameter are all myelinated ([Table 12-1](#)). Every axon has its biological price: the largest axons obviously take up the most room and are the most expensive to synthesize and to maintain metabolically. The largest, swiftest axons are therefore used sparingly. They are used only to carry sensory information about the most rapidly changing stimuli over the longest distances (e.g., stretch receptors in muscle, mechanoreceptors in tendons and skin), or they are used to control finely coordinated contractions of muscles. The thinnest, slowest C fibers in the periphery are mainly sensory axons related to chronic pain and temperature sensation, for which the speed of the message is not as critical.

TABLE 12-1

Classes of Peripheral Sensory and Motor Axons, by Size and Conduction Velocity

	ERLANGER AND GASSER'S CLASSIFICATION*					
	A α	A β	A γ	A δ	B	C
Function	Sensory afferents from proprioceptors of skeletal muscle Motor neurons to skeletal muscle	Sensory afferents from mechanoreceptors of skin	Motor fibers to intrafusal fibers of muscle spindles	Sensory afferents from pain and temperature receptors	Preganglionic neurons of the ANS	Sensory afferents from pain, temperature and itch receptors
Diameter (μ m)	13–20	6–12	3–6	1–5	<3	0.2–1.5
Conduction velocity of action potential (m/s)	80–120	35–75	12–30	5–30	3–15	0.5–2.5
Alternative classification of sensory axons from muscle and tendon†	Ia (sensory from muscle spindle fibers) Ib (sensory from Golgi tendon organs)	II		III		IV

*This A–C classification was introduced by Joseph Erlanger and Herbert Gasser, who shared the 1944 Nobel Prize in Medicine or Physiology for describing the relationship among axon diameter, conduction velocity, and function in a complex peripheral nerve.

†This I–IV classification was introduced by other investigators. It applies only to sensory axons and only to those from muscle and tendon.

ANS, autonomic nervous system.

Modified from Bear MF, Connors BW, Paradiso MP: Neuroscience: Exploring the Brain, 2nd ed. Baltimore, Lippincott Williams & Wilkins, 2001.

The relationship between form and function for axons in the CNS is less obvious than it is for those in the PNS, in part because it is more difficult to identify each axon's function. Interestingly, in the brain and spinal cord, the critical diameter for the myelination transition may be smaller than in the periphery. Many central myelinated axons are as thin as 0.2 μ m. At the other extreme, very few myelinated central axons are >4 μ m in diameter.

The myelinated axon membrane has a variety of ion channels that may contribute to its normal and pathological function. Of primary importance is the *voltage-gated Na⁺* channel, which provides the rapidly activating and inactivating inward current that yields the action potential. Nine isoforms of the α subunit of the voltage-gated Na⁺ channel exist (see Table 7-1). In normal central axons, it is specifically Nav1.6 channels that populate mature nodes of Ranvier at a density of 1000 to 2000 channels per square micrometer (see Fig. 12-5). The same axonal membrane in the internodal regions, under the myelin, has <25 channels per square micrometer (versus between 2 and 200 channels per square micrometer in unmyelinated axons). The dramatically different distribution of channels between nodal and internodal membrane has important implications for conduction along pathologically demyelinated axons (see below). K⁺ channels are relatively less important in myelinated axons than they are in most other excitable membranes. Very few of these channels are present in the nodal membrane, and fast K⁺ currents contribute little to repolarization of the action potential in mature myelinated axons. This diminished role for K⁺ channels may be a cost-cutting adaptation because the absence of K⁺ currents decreases the

metabolic expense of a single action potential by ~40%. However, some K^+ channels are located in the axonal membrane under the myelin, particularly in the paranodal region. The function of these K^+ channels is unclear; they may set the resting V_m of the internodes and help stabilize the firing properties of the axon.

Demyelinated axons conduct action potentials slowly, unreliably, or not at all

Numerous clinical disorders selectively damage or destroy myelin sheaths and leave the axonal membranes intact but bare. These **demyelinating diseases** may affect either peripheral or central axons and can lead to severely impaired conduction (Fig. 12-6). The most common demyelinating disease of the CNS is **multiple sclerosis** (Box 12-1), a progressive disorder characterized by distributed zones of demyelination in the brain and spinal cord. The specific clinical signs of these disorders vary and depend on the particular sets of axons affected.

FIGURE 12-6 Demyelination in the CNS. A cross section of a spinal root from a dystrophic mouse shows amyelinated bundles of axons (*thin borders*) surrounded by myelinated fibers (*thick borders*). Box 12-1

Demyelinating Diseases

Multiple sclerosis (MS), the most common demyelinating disease of the CNS, affects >350,000 Americans. MS is an autoimmune disease directed against the myelin or oligodendrocytes (see p. 292) and is thus a purely CNS disease. The trigger is unclear. Some have proposed a viral antigen (including canine distemper virus), but many other theories abound, none of which has been clearly proven. The viral antigen theory is based at least in part on classic studies that concluded that MS has a greater incidence in temperate regions than in the tropics and that one's risk depends on where one spent one's childhood, not adulthood. No good evidence has been presented for a viral etiology yet. MS is twice as

common in women as in men. Susceptibility to MS has also been linked to a number of genetic alleles of the human leukocyte antigen (HLA) system.

The signs and symptoms of MS are protean, but common features include the following:

1. An optic neuritis may cause decreased visual acuity.
2. Lesions of axons important for controlling eye movements may cause double vision.
3. The Lhermitte sign is an electrical sensation that shoots down the back and into the legs when the neck is flexed.

Magnetic resonance imaging can demonstrate the lesions in MS. Evoked potential studies, which measure nerve fiber conduction in various sensory pathways, yield abnormal results in almost all established cases and in about two thirds of suspected cases of MS.

MS is defined clinically as a disease that involves demyelination of the CNS with episodes separated in both time and space—at least two episodes of demyelination involving at least two separated regions of the CNS. Remissions and relapses are very common with MS. An exacerbation is due to the occurrence of active inflammation of a white matter tract in the CNS. A remission occurs when the inflammation subsides and the axons that have been demyelinated recover some of their function and are able to conduct action potentials through the area of myelin damage. However, the pathologically demyelinated fibers are not normal. Among the molecular changes that occur may be replacement of Nav1.6 channels by Nav1.2 channels in demyelinated axons. Conduction is often barely adequate under normal circumstances and may become inadequate under stressful situations, such as illness, emotional stress, and exhaustion. Under these circumstances, symptoms will reappear.

The reasons for remissions and exacerbations are not entirely clear. Conduction in the pathologically demyelinated fibers that is just barely adequate under normal circumstances may become inadequate under certain stressful situations, such as illness, emotional stress, and exhaustion; only then will symptoms become evident. A change in temperature is a classic example of circumstances changing conduction. Conduction through demyelinated axons is actually “safer” at low temperatures that slow the gating kinetics of Na^+ channels, lengthen the action potentials, and slow conduction velocity. The augmented currents of the broader spike make it more likely that the threshold for continued conduction will be reached. 🟡 **N12-3** When the body temperature of a patient with MS is elevated, for example, by fever or immersion in a hot bath, conduction is compromised and neurological deficits may appear.

N12-3

Temperature Dependence of Axonal Conduction

Contributed by Barry Connors

For a myelinated axon, decrease of just 2°C increases the duration of an action potential by $\sim 20\%$. As shown in eFigure 12-2, a temperature decrease of 7°C has an even greater effect on a myelinated axon. In the case of a demyelinated axon, a temperature decrease of 7°C can permit an action potential where one was previously not possible.

FIGURE 12-2 Temperature dependence of axonal conduction. (Data from Sears TA, Bostock H: Conduction failure in demyelination: Is it inevitable? *Adv Neurol* 31:357–375, 1981.)

Certain drugs can also prolong the duration of action potentials and facilitate conduction through demyelinated axons. Demyelination may expose the voltage-gated K^+ channels, which are normally hidden under the myelin. Activation of outwardly rectifying K^+ channels can further impair spike production in demyelinated axons. However, the K^+ channels also become accessible to pharmacological agents, such as the class of K^+ channel blockers called aminopyridines (see pp. 195–196). Blocking these K^+ channels can prolong the spike and facilitate its propagation through demyelinated regions. A slow-release formulation of 4-aminopyridine is now available for the symptomatic treatment of MS.

At present, standard treatment of MS exacerbations includes immunosuppressive agents. The most common is interferon- β , which has antiviral, antiproliferative, and immune-modulating activity. Many newer drugs are under investigation to help prevent the autoimmune attack, to reduce the damage during an attack, or to improve function in already demyelinated regions.

The most common demyelinating disease of the PNS is Landry-Guillain-Barré syndrome. After a respiratory or other viral infection, an ascending neurological syndrome develops that is characterized by the onset of weakness, leading to paralysis of the legs and subsequent involvement of the hands and arms. In severe cases, the paralysis involves the cranial nerves, and patients may lose the ability to swallow or even to breathe, which requires mechanical ventilation for a time. This initial stage of Landry-Guillain-Barré syndrome reaches a plateau in several weeks and then gradually resolves. Most patients recover completely as long as the physician recognizes the syndrome and initiates supportive treatment. Untreated, this syndrome is often fatal.

Landry-Guillain-Barré syndrome is caused by autoimmunity to the myelin sheath produced by Schwann cells in the PNS (see p. 292). These patients generally recover fully because the PNS has the ability to remyelinate itself. Axons of the CNS do not remyelinate to any significant extent, which explains why complete recovery in patients with MS is not common.

In a normal, myelinated axon, the action currents generated at a node can effectively charge the adjacent node and bring it to threshold within $\sim 20 \mu\text{sec}$ (Fig. 12-7A), because myelin serves to increase the resistance and to reduce the capacitance of the pathways between the axoplasm and the extracellular fluid (see pp. 199–201). The inward membrane current flowing across each node is actually 5-fold to 7-fold higher than necessary to initiate an action potential at the adjacent node. Removal of the insulating myelin, however, means that the same nodal action current is distributed across a much longer, leakier, higher-

capacitance stretch of axonal membrane (see [Fig. 12-7B](#)). Several consequences are possible. Compared with normal conduction, conduction in a demyelinated axon may continue, but at a *lower velocity*, if the demyelination is not too severe (see [Fig. 12-7B](#), record 1). In experimental studies, the internodal conduction time through demyelinated fibers can be as slow as 500 μ s, 25 times longer than normal. The ability of axons to transmit *high-frequency* trains of impulses may also be impaired (see [Fig. 12-7B](#), record 2). Extensive demyelination of an axon causes *total blockade* of conduction (see [Fig. 12-7B](#), record 3). Clinical studies indicate that the blockade of action potentials is more closely related to symptoms than is the simple slowing of conduction. Demyelinated axons can also become the source of spontaneous, **ectopically generated action potentials** because of changes in their intrinsic excitability (see [Fig. 12-7B](#), record 4) or mechanosensitivity (see [Fig. 12-7B](#), record 5). Moreover, the signal from one demyelinated axon can excite an adjacent demyelinated axon and induce **crosstalk** (see [Fig. 12-7C](#)), which may cause action potentials to be conducted in both directions in the adjacent axon.

Crosstalk

An adjacent axon conducts action potentials in both directions from demyelination site.

FIGURE 12-7 Demyelination. **A**, Four action potentials at the leftmost node of Ranvier are conducted—unchanged in amplitude and frequency—to the nodes that are farther to the right. **B**, Action potentials propagate from a normally myelinated region into a demyelinated area. The axial action current that was generated at the last healthy node is distributed across a long region of bare or partially myelinated axonal membrane, with its decreased resistivity and increased capacitance. Thus, the current density at the two affected nodes is greatly reduced. This panel shows five consequences of demyelination: (1) decreased velocity, which is manifested as longer delays for the arrival of the train of spikes; (2) frequency-related block, which does not pass high-frequency trains—as a result, some of the spikes are missing distally; (3) total blockade; (4) ectopic impulse generation—even though there is no input in the proximal portion of the axon, action potentials arise spontaneously beyond the lesion; and (5) increased mechanosensitivity—ectopic action potentials arise from mechanical stimulation. **C**, If the demyelination affects two adjacent axons, action potentials in one (the *top axon* in this case) cause action potentials to propagate in both directions in the adjacent axon.

CHAPTER 13

Synaptic Transmission in the Nervous System

Barry W. Connors

After meticulous study of spinal reflexes, Charles Sherrington [N10-2](#) deduced that neurons somehow communicate information, one to the next, by a mechanism that is fundamentally different from the way that they conduct signals along their axons. Sherrington had merged his physiological conclusions with the anatomical observations ([Fig. 13-1](#)) of his contemporary, the preeminent neuroanatomist Santiago Ramón y Cajal. [N10-1](#) Ramón y Cajal had proposed that neurons are distinct entities, fundamental units of the nervous system that are *discontinuous* with each other. Discontinuous neurons must nevertheless communicate, and Sherrington in 1897 proposed that the **synapse**, a specialized apposition between cells, mediates the signals. The word *synapse* implies “contiguity, not continuity” between neurons, as Ramón y Cajal himself explained it. When the fine structure of synapses was finally revealed with the electron microscope in the 1950s, the vision of Ramón y Cajal and Sherrington was amply sustained. Neurons come very close together at chemical synapses (see [p. 206](#)), but their membranes and cytoplasm remain distinct. At electrical synapses (see [p. 205](#)), which are less common than chemical synapses, the membranes remain distinct, but ions and other small solutes can diffuse through the gap junctions, a form of continuity.

B

FIGURE 13-1 Synapses of the mammalian brain. Drawings by Ramón y Cajal made from Golgi-stained cortex of the cerebellum. **A**, Basket cell (*B*) from the mouse, making synaptic contacts onto the somata of numerous postsynaptic Purkinje cells (*A*). The axon (*c*) of the basket cell branches several times to make baskets (*a* and *b*) that synapse onto the somata of Purkinje cells (axosomatic synapse). Ramón y Cajal used the osmic method to stain the Purkinje cell and the Golgi method to stain the basket cell. **B**, A single

climbing fiber (*a*) from a human, making numerous synaptic contacts onto the dendrites of a single Purkinje cell (*b*). This is an example of axodendritic synapses. Ramón y Cajal used the Golgi method to stain the climbing fiber. (From Ramón y Cajal S: Histology of the Nervous System of Man and Vertebrates. New York, Oxford University Press, 1995.)

Neuronal Synapses

The molecular mechanisms of neuronal synapses are similar but not identical to those of the neuromuscular junction

Chemical synapses use diffusible **transmitter molecules** to communicate messages between two cells. The first chemical synapse to be understood in detail was the neuromuscular junction (the nerve-muscle synapse) in vertebrate skeletal muscle, which is described in [Chapter 8](#). In this chapter, we are concerned with the properties of the synapses that occur *between neurons*. We now know that all synapses share certain basic biochemical and physiological mechanisms, and thus many basic insights gained from the neuromuscular junction are also applicable to synapses in the brain. However, neuronal synapses differ from neuromuscular junctions in many important ways; they also differ widely among themselves, and it is the diverse properties of synapses that help make each part of the brain unique.

It is useful to begin by reviewing some of the mechanisms that are common to all chemical synapses (see [Figs. 8-2](#) and [8-3](#)).  **N13-1** Synaptic transmission at chemical synapses occurs in seven steps:

N13-1

Steps in Synaptic Transmission

Contributed by Barry W. Connors

FIGURE 13-1 A chemical synapse between neurons. **A**, The resting state before the arrival of an action potential is shown. **B**, The arrival of the action potential in the presynaptic neuron triggers a series of seven events.

passively across the synaptic cleft.

Step 6: Some of the transmitter molecules bind to receptors in the postsynaptic membrane, and the activated receptors trigger some postsynaptic event, usually the opening of an ion channel or the activation of a G protein–coupled signal cascade.

Step 7: Transmitter molecules diffuse away from postsynaptic receptors and are eventually cleared away by continued diffusion, enzymatic degradation, or active uptake into cells. In addition, the presynaptic machinery retrieves the membrane of the exocytosed synaptic vesicle, perhaps by endocytosis from the cell surface.

The molecular machinery of synapses is closely related to components that are universal in eukaryotic cells (see [p. 37](#)). A large set of proteins is involved in the docking and fusion of vesicles, and the proteins present in nerve terminals are remarkably similar to the ones mediating fusion and secretion in yeast. Docking and fusion of synaptic vesicles are discussed on [page 219](#). Ligand-gated ion channels and G protein–coupled receptors (GPCRs), the receptors on the postsynaptic membrane, are also present in all eukaryotic cells and mediate processes as disparate as the recognition of nutrients and poisons, and the identification of other members of the species. Even most of the neurotransmitters themselves are simple molecules, identical or very similar to those used in general cellular metabolism. Clearly, the evolutionary roots of synaptic transmission are much older than nervous systems themselves.

Within nervous systems, however, myriad variations on the basic molecular building blocks yield synapses with wide-ranging properties. Neuronal synapses vary widely in the size of the synaptic contact, the identity of the neurotransmitter, the nature of the postsynaptic receptors, the efficiency of synaptic transmission, the mechanism used for terminating transmitter action, and the degree and modes of synaptic plasticity. Thus, the properties of neuronal synapses can be tuned to achieve the diverse functions of the brain.

A major difference between the neuromuscular junction and most neuronal synapses is the type of neurotransmitter used. All skeletal neuromuscular junctions use acetylcholine (ACh). In contrast, neuronal synapses use many transmitters. The most ubiquitous are amino acids: glutamate and aspartate excite, whereas gamma-aminobutyric acid (GABA) and glycine inhibit. Other transmitters include simple amines, such as ACh, norepinephrine, serotonin, and histamine, ubiquitous molecules such as ATP and adenosine, and a wide array of peptides.

Even more varied than the neuronal transmitters are their receptors. Whereas skeletal muscle manufactures a few modest variants of its ACh receptors, the nervous system typically has several major receptor variants for each neurotransmitter. Knowledge about the wide range of transmitters and receptors is essential to understand the chemical activity of the brain as well as the drugs that influence brain activity. For one thing, the many transmitter systems in the brain generate responses with widely varying durations that range from a few milliseconds to days ([Fig. 13-2](#)).

FIGURE 13-2 Time courses of synaptic events in the nervous system. Different transmitter systems in the brain generate responses that vary widely in how long they last in the postsynaptic cell. Note that the time axis is logarithmic. (Data from Shepherd GM: *Neurobiology*, 3rd ed. New York, Oxford University Press, 1994.)

Presynaptic terminals may contact neurons at the dendrite, soma, or axon and may contain both clear vesicles and dense-core granules

Chemical synapses between neurons are generally small, often $<1\ \mu\text{m}$ in diameter, which means that their detailed structure can be seen only with an electron microscope (Fig. 13-3); under the light microscope, brain synapses are usually visible only as swellings along or at the termination of the axons (see Fig. 13-1). These swellings are actually the silhouettes of the **bouton terminals**—the presynaptic terminals. Most presynaptic terminals arise from axons, and they can form synapses on virtually any part of a neuron. The contact site and direction of communication determine the way in which a synapse is named: **axodendritic**, **axosomatic**, and **axoaxonic** synapses (Fig. 13-4). These synapses are the most common types in the nervous system. In many cases, synapses occur on small outpockets of the dendritic membrane called **spines** and are termed **axospinous** synapses. However, not all synapses arise from axons, and **dendrodendritic**, **somatosomatic**, and even **somatodendritic** synapses may be found in the mammalian brain.

FIGURE 13-3 Electron micrograph of synapses in the cochlear nucleus. Three presynaptic terminals are filled with vesicles and make contact with the same postsynaptic dendrite. Postsynaptic densities (marking active zones) are indicated by arrows. (From Peters A, Palay SL, Webster HD: *The Fine Structure of the Nervous System: The Neurons and Supporting Cells*. Philadelphia, WB Saunders, 1976.)

FIGURE 13-4 The most common synaptic arrangements in the CNS.

Despite their differences in size, site, and shape, all synapses share one basic function: they *deliver a small amount of chemical transmitter onto a circumscribed patch of postsynaptic membrane*. To accomplish this task, they use certain common anatomical features, most of them familiar from discussions of the neuromuscular junction (see [Chapter 8](#)).

Synapses are polarized, which means that their two apposed sides have different structures. This polarity reflects the fact that most synapses transmit information primarily in one direction, although retrograde transmission also occurs in many synapses in one direction but not in the other (we will see that some rare exceptions do exist). The presynaptic side contains numerous clear **vesicles**, 40 to 50 nm in diameter, that appear empty when viewed by transmission electron microscopy. Synaptic termini may also contain large (100 to 200 nm in diameter) **dense-core secretory granules** that are morphologically quite similar to the secretory granules of endocrine cells. These granules contain neuropeptides; that is, peptides or small proteins that act as neurotransmitters and for which receptors exist in the postsynaptic membranes. Many of these neuropeptides are identical to substances secreted by “traditional” endocrine cells. Endocrine hormones such as adrenocorticotrophic hormone, vasoactive intestinal peptide, and cholecystokinin are found in dense-core secretory granules present in the terminals of certain central and peripheral neurons.

The clear synaptic vesicles (i.e., not the dense-core granules) are anchored and shifted about by a dense network of cytoskeletal proteins. Some vesicles are clustered close to the part of the presynaptic membrane that apposes the synaptic contact; these vesicle attachment sites are called **active zones**. Synaptic vesicles are lined up several deep along the active zones, which are the regions of actual exocytosis. The number of active zones per synapse varies greatly (active zones are marked with arrows

in the synapses in [Fig. 13-3](#)). Most synapses in the central nervous system (CNS) have relatively few active zones, often only 1 but occasionally as many as 10 or 20 (versus the hundreds in the neuromuscular junction). If we could view the presynaptic face of an active zone from the perspective of a synaptic vesicle, we would see filaments and particles projecting from the presynaptic membrane, often forming a regular hexagonal arrangement called a **presynaptic grid**. Specific points along the grid are thought to be the vesicle release sites.

Unlike the clear synaptic vesicles containing nonpeptide transmitters, dense-core secretory granules are distributed randomly throughout the cytoplasm of the synaptic terminus. They are not concentrated at the presynaptic density, and they do not appear to release their contents at the active zone. Although the molecular pathways that control exocytosis of the neuronal dense-core granules are still being elucidated, it appears that a rise in $[Ca^{2+}]_i$ is a primary stimulus.

The postsynaptic membrane contains transmitter receptors and numerous proteins clustered in the postsynaptic density

The postsynaptic membrane lies parallel to the presynaptic membrane, and they are separated by a narrow **synaptic cleft** (~30 nm wide) that is filled with extracellular fluid. Transmitter molecules released from the presynaptic terminal must diffuse across the cleft to reach postsynaptic receptors. The most characteristic anatomical feature of the postsynaptic side is the **postsynaptic density**, a strip of granular material visible under the electron microscope on the cytoplasmic face of the membrane (see [Fig. 13-3](#)). The most important molecular feature of the postsynaptic side is the cluster of transmitter receptors embedded within the postsynaptic membrane. Staining methods that use specific antibodies, toxins, or ligands coupled to some visible tag molecule can reveal the positions of the receptors.

In >90% of all excitatory synapses in the CNS, the postsynaptic site is a **dendritic spine**. The ubiquity of spines implies that they serve prominent functions, but their small size (usually <1 μm long) makes their function extremely difficult to study. Spines come in a variety of shapes, and their density varies from one dendrite to another ([Fig. 13-5](#)); indeed, some central neurons have no spines. The postsynaptic density of spines (as for all central synapses) contains >30 proteins in high concentration, including transmitter receptors, protein kinases, a host of structural proteins, and proteins that are involved in endocytosis and glycolysis.

FIGURE 13-5 Dendritic spines. **A**, Drawings of various dendrites in the neocortex, made from Golgi-stained material. The numerous protrusions are spines. **B**, Electron micrograph of an axospinous synapse in the neocortex. Note that the dendritic spine (S) protrudes from the dendritic shaft (D), making contact with a presynaptic terminal. (From Feldman ML: In Peters A, Jones EG [eds]: *Cerebral Cortex: Cellular Components of the Cerebral Cortex*, vol 1. New York, Plenum, 1984, pp 123–200.)

Numerous functions for spines have been proposed. It may be that spines increase the opportunity for a dendrite to form synapses with nearby axons. Many hypotheses have focused on the possibility that spines isolate individual synapses from the rest of a cell. This isolation may be electrical or chemical; the narrow spine neck may reduce current flow or the diffusion of chemicals from the spine head into the dendritic shaft. Evidence suggests that the high electrical resistance of the spine neck can amplify the size of an excitatory postsynaptic potential within the spine while reducing its amplitude along the shaft of the dendrite; this mechanism may allow neurons to integrate larger numbers of synaptic inputs. Activation of some excitatory synapses allows substantial amounts of Ca^{2+} to enter the postsynaptic cell. Spines may compartmentalize this Ca^{2+} , thus allowing it to rise to higher levels or preventing it from influencing other synapses on the cell. Because increases in postsynaptic $[\text{Ca}^{2+}]_i$ are an essential trigger for many forms of long-term synaptic plasticity, an attractive but unproven possibility is that dendritic spines play an important role in the mechanisms of learning and memory.

Some transmitters are used by diffusely distributed systems

of neurons to modulate the general excitability of the brain

The brain carries out many sensory, motor, and cognitive functions that require fast, specific, spatially organized neural connections and operations. Consider the detailed neural mapping that allows you to read this sentence or the precise timing required to play the piano. These functions require *spatially focused* networks (Fig. 13-6A).

FIGURE 13-6 Synaptic connections.

Other functions, such as falling asleep, waking up, becoming attentive, or changing mood, involve more general alterations of the brain. Several systems of neurons regulate the general excitability of the CNS. Each of these **modulatory systems** uses a different neurotransmitter, and the axons of each make widely dispersed, diffuse, almost meandering synaptic connections to carry a simple message to vast regions of the brain. This arrangement can be achieved by a *widely divergent* network (see Fig. 13-6B). The functions of the different systems are not well understood, but each appears to be essential for certain aspects of arousal, motor control, memory, mood, motivation, and metabolic state. The modulatory systems are of central importance to clinical medicine. Both the activity of psychoactive drugs and the pathological processes of most psychiatric disorders seem to involve alterations in one or more of the modulatory systems.

The brain has several modulatory systems with diffuse central connections. Although they differ in structure and function, they have certain similarities:

1. Typically, a small set of neurons (several thousand) forms the center of the system.
2. Neurons of the diffuse systems arise from the central core of the brain, most of them from the brainstem.
3. Each neuron can influence many others because each one has an axon that may contact tens of thousands of postsynaptic neurons spread widely across the brain.

4. The synapses made by some of these systems seem designed to release transmitter molecules into the extracellular fluid so that they can diffuse to many neurons rather than be confined to the vicinity of a single synaptic cleft.

The main modulatory systems of the brain are distinct anatomically and biochemically. Separate systems use norepinephrine, serotonin (5-hydroxytryptamine [5-HT]), dopamine, ACh, or histamine as their neurotransmitter. They all tend to involve numerous **metabotropic transmitter receptors** (see [p. 206](#)). Unlike ionotropic receptors, which are themselves ion channels, metabotropic receptors are coupled to enzymes such as adenylyl cyclase or phospholipase C through G proteins. For example, the brain has 10 to 100 times more metabotropic (i.e., muscarinic) ACh receptors than ionotropic (i.e., nicotinic) ACh receptors. We briefly describe the anatomy and possible functions of each major system ([Fig. 13-7](#)).

FIGURE 13-7 Four diffusely connected systems of central neurons using modulatory transmitters. **A**, Neurons containing norepinephrine are located in the locus coeruleus and innervate nearly every part of the CNS. **B**, Neurons containing serotonin are located in two groups of raphe nuclei and project to most of the brain. **C**, Neurons containing dopamine are located in the substantia nigra (and these project to the striatum) and the ventral tegmental area of the midbrain (and these project to the prefrontal cortex and parts of the limbic system). **D**, Neurons containing ACh are located in the basal forebrain complex, which includes the septal nuclei and nucleus basalis; the neurons project to the hippocampus and the neocortex. Other ACh-containing neurons originate in the pontomesencephalotegmental cholinergic complex and project to the dorsal thalamus and part of the forebrain.

Norepinephrine-containing neurons are in the tiny **locus coeruleus** (from the Latin for “blue spot” because of the pigment in its cells), located bilaterally in the brainstem (see [Fig. 13-7A](#)). Each human locus coeruleus has ~12,000 neurons. Axons from the locus coeruleus innervate just about every part of the brain: the entire cerebral cortex, the thalamus and hypothalamus, the olfactory bulb, the cerebellum, the midbrain, and the spinal cord. Just one of its neurons can make >250,000 synapses, and that cell can have one axon branch in the *cerebral* cortex and another in the *cerebellar* cortex! Locus coeruleus cells seem to be involved in the regulation of attention, arousal, and sleep-wake cycles as well as in learning

and memory, anxiety and pain, mood, and brain metabolism. Recordings from awake rats and monkeys in behavioral studies show that locus coeruleus neurons are best activated by new, unexpected, nonpainful sensory stimuli in the animal's environment. They are least active when the animals are not vigilant, just sitting around quietly digesting a meal. The locus coeruleus may participate in general arousal of the brain during interesting events in the outside world.

Serotonin-containing neurons are mostly clustered within the nine **raphé nuclei** (see [Fig. 13-7B](#)). Raphé means “ridge” or “seam” in Greek, and indeed the raphé nuclei lie to either side of the midline of the brainstem. Each nucleus projects to different regions of the brain, and together they innervate most of the CNS in the same diffuse way as the locus coeruleus neurons. Similar to neurons of the locus coeruleus, cells of the raphé nuclei fire most rapidly during wakefulness, when an animal is aroused and active. Raphé neurons are quietest during certain stages of sleep. The locus coeruleus and the raphé nuclei are part of a venerable concept called the **ascending reticular activating system**, which implicates the reticular “core” of the brainstem in processes that arouse and awaken the forebrain. Raphé neurons seem to be intimately involved in the control of sleep-wake cycles as well as the different stages of sleep. Serotonergic raphé neurons have also been implicated in the control of mood and certain types of emotional behavior. Many hallucinogenic drugs, such as lysergic acid diethylamide (LSD), apparently exert their effects through interaction with serotonin receptors. Serotonin may also be involved in clinical depression; some of the most effective drugs now used to treat depression (e.g., fluoxetine [Prozac]) are potent blockers of serotonin re-uptake and thus prolong its action in the brain.

Although **dopamine**-containing neurons are scattered throughout the CNS, two closely related groups of dopaminergic cells have characteristics of the diffuse modulatory systems (see [Fig. 13-7C](#)). One of these groups is the **substantia nigra** in the midbrain. Its cells project axons to the striatum, a part of the basal ganglia, and they somehow facilitate the initiation of voluntary movement. Degeneration of the dopamine-containing cells in the substantia nigra produces the progressively worsening motor dysfunction of Parkinson disease. Another set of dopaminergic neurons lies in the **ventral tegmental area** of the midbrain; these neurons innervate the part of the forebrain that includes the prefrontal cortex and parts of the limbic system. They have been implicated in neural systems that mediate reinforcement or reward as well as in aspects of drug addiction and psychiatric disorders, most notably schizophrenia. Members of the class of antipsychotic drugs called neuroleptics are antagonists of certain dopamine receptors.

Acetylcholine is the familiar transmitter of the neuromuscular junction and the autonomic nervous system. Within the brain are two major diffuse modulatory cholinergic systems: the **basal forebrain complex** (which innervates the hippocampus and all of the neocortex) and the **pontomesencephalotegmental cholinergic complex** (which innervates the dorsal thalamus and parts of the forebrain) (see [Fig. 13-7D](#)). The functions of these systems are poorly understood, but interest has been fueled by evidence that they are involved in the regulation of general brain excitability during arousal and sleep-wake cycles as well as perhaps in learning and memory formation.

Collectively, the diffuse modulatory systems may be viewed as providing general regulation of brain function, much like the autonomic nervous system (see [Chapter 14](#)) regulates the organ systems of the body. Because their axons spread so widely within the CNS, the few modulatory neurons can have an inordinately strong influence on behavior.

Electrical synapses serve specialized functions in the mammalian nervous system

Many cells are coupled to one another through gap junctions. The large and relatively nonselective gap

junction channels (see [p. 165](#)) allow ion currents to flow in both directions (in most types of gap junctions) or unidirectionally (in rare types). It follows from Ohm's law that if two cells are coupled by gap junctions and they have different membrane voltages, current will flow from one cell into the other (see [Fig. 6-18C](#)). If the first cell generates an action potential, current will flow through the gap junction channels and depolarize the second cell; this type of current flow, for example, is the basis for conduction of excitation across cardiac muscle. Such an arrangement has all the earmarks of a synapse, and indeed, when gap junctions interconnect neurons, we describe them as electrical synapses.

Electrical synapses would seem to have many advantages over chemical synapses: they are extremely fast and limited only by the time constants of the systems involved, they use relatively little metabolic energy or molecular machinery, they are highly reliable, and they can be bidirectional. Indeed, electrical synapses have now been observed in nearly every part of the mammalian CNS. They interconnect inhibitory neurons of the cerebral cortex and thalamus, excitatory neurons of the brainstem and retina, and a variety of other neurons in the hypothalamus, basal ganglia, and spinal cord. At nearly all of these sites, the gap junction protein connexin-36 (Cx36)—which is expressed exclusively in CNS neurons and β cells of the pancreas—is an essential component of the electrical synapse (see [Fig. 6-18C](#)). Glial cells in the brain express several other types of connexins. However, in all of the aforementioned sites, electrical synapses tend to be outnumbered by chemical synapses. Gap junctions universally interconnect the photoreceptors of the retina, astrocytes and other types of glia (see [p. 289](#)) throughout the CNS, and most types of cells early in development.

Why are chemical synapses, as complex and relatively slow as they are, more prevalent than electrical synapses in the mature brain? Comparative studies suggest several reasons for the predominance of chemical synapses among mammalian neurons. The first is **amplification**. Electrical synapses do not amplify the signal passed from one cell to the next; they can only diminish it. Therefore, if a presynaptic cell is small relative to its coupled postsynaptic cell, the current that it can generate through an electrical synapse will also be small, and thus “synaptic strength” will be low. By contrast, a small bolus of neurotransmitter from a chemical synapse can trigger an amplifying cascade of molecular events that can cause a relatively large postsynaptic change.

A second advantage of chemical synapses is their ability to either **excite** or **inhibit postsynaptic neurons selectively**. Electrical synapses are not inherently excitatory or inhibitory, although they can mediate either effect under the right circumstances. Chemical synapses can reliably inhibit by simply opening channels that are selective for ions with relatively negative equilibrium potentials; they can excite by opening channels selective for ions with equilibrium potentials positive to resting potential.

A third advantage of chemical synapses is that they can transmit information over a **broad time domain**. By using different transmitters, receptors, second messengers, and effectors, chemical synapses can produce a wide array of postsynaptic effects with time courses ranging from a few milliseconds to minutes and even hours. The effects of electrical synapses are generally limited to the time course of the presynaptic event.

A fourth advantage of chemical synapses is that they are champions of **plasticity**; their strength can be a strong function of recent neural activity, and they can therefore play a role in learning and memory, which are essential to the success of vertebrate species. Electrical synapses also display forms of long-term plasticity, although this has not been well studied in the mammalian CNS.

It might also be noted that the few perceived advantages of electrical synapses may be more apparent than real. Bidirectionality is clearly not useful in many neural circuits, and the difference in speed of transmission may be too small to matter in most cases. Electrical synapses serve important but specialized functions in the nervous system. They seem to be most prevalent in neural circuits in which

speed or a high degree of synchrony is at a premium: quick-escape systems, the fine coordination of rapid eye movements, or the synchronization of neurons generating rhythmic activity. Gap junctions are also effective in diffusely spreading current through large networks of cells, which appears to be their function in photoreceptors and glia.

Neurotransmitter Systems of the Brain

The mammalian nervous system uses dozens of different neurotransmitters that act on >100 types of receptors; these receptors stimulate numerous second-messenger systems, which in turn regulate several dozen ion channels and enzymes. We call these pathways of synaptic signaling the *transmitter systems*. It is not enough to know the identity of a transmitter to predict its effect—one must also know the nature of the components that it interacts with, and these components may vary from one part of the brain to another and even between parts of a single neuron. The components of the transmitter systems are extremely complex. This subchapter introduces the intricate and vital web of neurotransmitters. The clinical importance of the subject is difficult to overstate. It is likely that most drugs that alter mental function do so by interacting with neurotransmitter systems in the brain. Disorders of neurotransmitter systems are also implicated in many devastating brain disorders, such as schizophrenia, depression, epilepsy, Parkinson disease, the damage of stroke, and drug addiction.

Most of the brain's transmitters are common biochemicals

Most neurotransmitters are similar or identical to the standard chemicals of life, the same substances that all cells use for metabolism. Transmitter molecules can be large or small. The small ones, such as the **amino acids** glutamate, aspartate, GABA, and glycine, are also simple foods (Fig. 13-8A). Cells use amino acids as an energy source and for construction of essential proteins, but they have co-opted these common molecules for essential and widespread messenger functions in the brain. Another important class of small neurotransmitters is the amines, including the **monoamines** (e.g., ACh, serotonin, and histamine) listed in Figure 13-8B and the **catecholamines** (e.g., dopamine, norepinephrine, and epinephrine) listed in Figure 13-8C. Neurons synthesize these small transmitters by adding only a few chemical steps to the glucose and amino-acid pathways that are present in every cell. **Purine derivatives** can also be important transmitters. For example, a key molecule of cell metabolism that also serves as a neurotransmitter is ATP, which is the major chemical intermediate of energy metabolism and is present in many synaptic vesicles. It is also released from various synapses in the central and peripheral nervous systems. ATP appears to be the transmitter responsible for sympathetic vasoconstriction in small arteries and arterioles, for example. ATP acts on a variety of nucleotide receptors, both ionotropic and metabotropic. Adenosine is also a transmitter in the CNS.

A AMINO ACIDS

B MONOAMINES

C CATECHOLAMINES

FIGURE 13-8 Biosynthesis of some common small transmitter molecules. CoA, coenzyme A.

The large-molecule transmitters, which constitute a much more numerous group, are proteins or small bits of protein called **neuroactive peptides**. A few of the better-studied neuropeptides are shown in [Figure 13-9](#). Many were originally identified in non-neural tissues such as the gut or endocrine glands and were only later found in nerve terminals of the brain or peripheral nervous system. They vary in size from dipeptides (e.g., *N*-acetylasparylglutamate) to large polypeptides. Among the neuroactive peptides are the **endorphins** (*endogenous* substances with *morphine*-like actions), which include small peptides called enkephalins. The term *opioids* refers to all substances with a morphine-like pharmacology—the endorphins (endogenous) as well as morphine and heroin (exogenous).

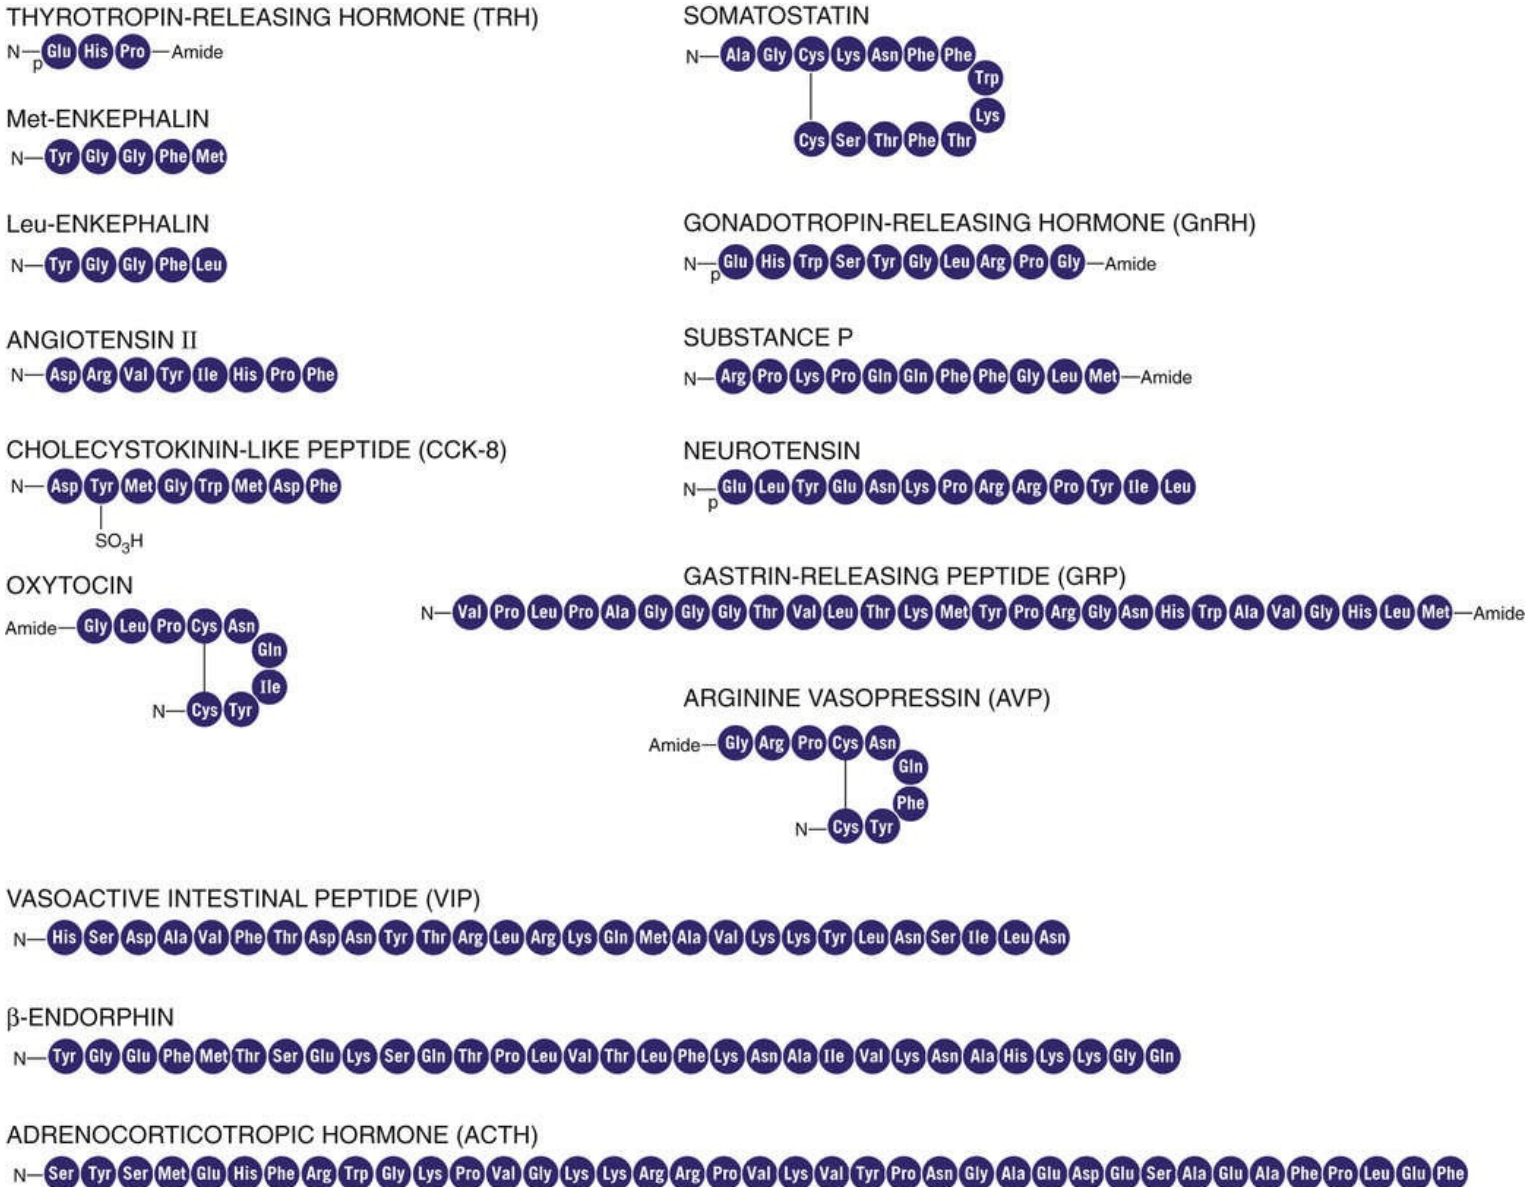

FIGURE 13-9 Structure of some neuroactive peptides. All peptides are presented with their NH₂ termini (i.e., the first to be synthesized) to the left, as is now customary for proteins in general. However, note that for many of the peptide hormones, the amino-acid residues were numbered before this convention was established. The *p* on the amino-terminal glutamate on some of these peptides stands for pyroglutamate.

 **N13-7**

Pyroglutamate and C-Terminal Amides

Contributed by Emile Boulpaep, Walter Boron, with George Farr providing the chemical structures

Figure 13-9 shows several examples of neuroactive peptides in which the N-terminal residue is pyroglutamate (indicated by a *p* in the structure shown in the figure). Similarly, the figure shows several examples in which the C-terminal residue has an amide.

Pyroglutamate

Figure 58-2 in the text shows the peptide backbone of a generic protein. Imagine that the leftmost (i.e., N-terminal) residue in this figure is the side chain for glutamate (see Table 2-1 in the text for a listing of side chains). A reaction of the carboxyl group on the glutamate side chain with the terminal amino group results in the creation of an amide derivative in the form of a five-membered ring. For example, eFigure 13-3 shows the structure of thyrotropin-releasing hormone (TRH).

EFIGURE 13-3 Structure of the tripeptide TRH.

This post-translational modification of a glutamate residue is called a pyroglutamate residue. In the figure, the peptide bonds are shown in red. The pyroglutamate is the magenta ring structure at the left.

C-Terminal Amide

Figure 58-2 shows the peptide backbone of a protein. Notice that the rightmost (i.e., C-terminal) residue in this figure has a free carboxyl group. If this carboxyl group undergoes a reaction that transfers an NH_2 , the result is an **amide group** (in the carboxyl-terminal residue of Figure 58-2, replace the O^- group with NH_2). In the above figure, this amide is the magenta NH_2 at the right.

For comparison, eFigure 13-4 shows a hypothetical tripeptide *without* the pyroglutamate at the N terminus and without the C-terminal amide.

EFigure 13-4 Structure of a hypothetical TRH-like tripeptide that, unlike TRH, lacks the N-terminal pyroglutamate and the C-terminal amide.

The synthesis of most neuropeptides begins like that of any other secretory protein (see [p. 34](#)), with the ribosome-directed assembly of a large **prehormone**. The prehormone is then cleaved to form a smaller **prohormone** in the Golgi apparatus and further reduced into small active neuropeptides that are packaged into vesicles. Thus, the synthesis of neuropeptides differs significantly from that of the small transmitters.

In summary, then, the neurotransmitters consist of a dozen or so small molecules plus 50 to 100 peptides of various sizes. The small transmitters are, as a rule, each stored and released by separate sets of neurons, although some types of neurons do use two or more small transmitters. The peptides, however, are usually stored and released from the same neurons that use one of the small transmitters ([Table 13-1](#)), an arrangement called **colocalization** of neurotransmitters. Thus, GABA may be paired with somatostatin in some synapses, serotonin and enkephalin in others, and so on. The colocalized transmitters may be released together, but of course each acts on its own receptors. In addition, both clear and dense-core vesicles contain ATP as well as their primary transmitter.

TABLE 13-1

Examples of Neuroactive Peptides That Colocalize with Small-Molecule Neurotransmitters

SMALL MOLECULE	COLOCALIZING PEPTIDE(S)
ACh	CGRP Enkephalin Galanin GnRH Neurotensin Somatostatin and enkephalin Substance P VIP
Dopamine	CCK Enkephalin Neurotensin
Epinephrine	Enkephalin Neuropeptide Y Neurotensin Substance P
GABA	CCK Enkephalin Neuropeptide Y Somatostatin Substance P VIP
Glutamate	Substance P
Glycine	Neurotensin
Norepinephrine	Enkephalin Neuropeptide Y Neurotensin Somatostatin Vasopressin
Serotonin	CCK Enkephalin Substance P and TRH TRH

CCK, cholecystokinin; CGRP, calcitonin gene-related peptide; GnRH, gonadotropin-releasing hormone; TRH, thyrotropin-releasing hormone; VIP, vasoactive intestinal peptide.

Data from Hall ZW: An Introduction to Molecular Neurobiology. Sunderland, MA, Sinauer, 1992.

One of the unique substances functioning as a transmitter is a gaseous molecule, the labile free radical **nitric oxide (NO)**. **Carbon monoxide (CO)** and hydrogen sulfide (H₂S) may also serve as transmitters, although evidence thus far is equivocal. NO is synthesized from L-arginine by many cells of the body (see p. 66). NO and CO can exert powerful biological effects by activating guanylyl cyclase, which converts GTP to cGMP. As a neurotransmitter, NO may have unique functions. It seems to be released from both presynaptic and what we normally think of as *postsynaptic* neurons. Because NO is *not* packaged into vesicles, its release does not require an increase in [Ca²⁺]_i, although its synthesis does. NO may sometimes act as a retrograde messenger, that is, from postsynaptic to presynaptic structures.  **N13-2** Because NO is small and membrane permeable, it can diffuse about much more freely than other transmitter molecules, even penetrating through one cell to affect another beyond it. On the other hand, NO is evanescent, and it breaks down rapidly. The functions of gaseous transmitters (or “gasotransmitters”) are now being vigorously studied and hotly debated.

N13-2

NO as a Neurotransmitter in the CNS

Contributed by Barry W. Connors

EFigure 13-2 NO synthesis in a central neuron. Presynaptic glutamate release triggers the entry of

Ca^{2+} through NMDA glutamate receptor channels or voltage-gated Ca^{2+} channels. Via calmodulin (CaM), Ca^{2+} stimulates nitric oxide synthase (NOS; see pp. 66–67). NO diffuses out and through cells to affect presynaptic and postsynaptic elements of the same synapse or of nearby synapses. ER, endoplasmic reticulum; NADPH, reduced nicotinamide adenine dinucleotide phosphate.

The **endocannabinoids** are another unusual group of putative neurotransmitters. They include the endogenous lipophilic molecules anandamide (from *ananda*, the Sanskrit word for “internal bliss”) and 2-arachidonoyl glycerol (2-AG), both of which are arachidonic acid metabolites. These substances are called endocannabinoids because they mimic Δ^9 -tetrahydrocannabinol (THC), the active ingredient in marijuana, by binding to and activating specific G protein–coupled “cannabinoid” receptors. Remarkably, the brain has more cannabinoid receptors than any other GPCR type. Certain activated neurons synthesize and release endocannabinoids, which move readily across membranes to presynaptic terminals and modulate the further release of conventional transmitters such as GABA and glutamate. Their normal role in the brain is currently unknown. However, activation of cannabinoid receptors with low doses of THC leads to euphoria, relaxed sensations, decreased pain, and increased hunger; it can also impair problem-solving ability, short-term memory, and motor skills. High doses can alter personality and sometimes trigger hallucinations. THC and related drugs have promise for treatment of the nausea and vomiting of cancer patients undergoing chemotherapy, suppression of chronic pain, and stimulation of appetite in some patients with acquired immunodeficiency syndrome (AIDS).

Most of the chemicals we call neurotransmitters also exist in non-neural parts of the body. Each chemical may serve dual purposes in that it can mediate communication in the nervous system but do something similar or even entirely different elsewhere. Amino acids, of course, are used to make protein everywhere. NO is a local hormone that relaxes the smooth muscle in blood vessels (see p. 480). Surprisingly, the cells with the highest ACh levels are in the cornea of the eye, although corneal cells lack specific receptors for ACh. It is not clear what ACh does for corneal cells, but it almost certainly is not acting as a transmitter. One of the most interesting nonmessenger functions of transmitter molecules is their role in the development of the brain, even before synapses have appeared. At these early stages of development, transmitters may regulate cell proliferation, migration, and differentiation, somehow helping to form the brain before they help operate it.

Synaptic transmitters can stimulate, inhibit, or modulate the postsynaptic neuron

Each neuromuscular junction has a simple and stereotyped job: when an action potential fires in the motor neuron, the junction must reliably excite its muscle cell to fire an action potential and contract. Decisions about muscle contractions (where, when, and how much) are made within the CNS, and the neuromuscular junction exists simply to communicate that decision to the muscle unambiguously and reliably. To perform this function, neuromuscular transmission has evolved to be very strong so that it is fail-safe under even the most extreme of physiological conditions.

Synapses between neurons usually have a more subtle role in communication, and they use a variety of mechanisms to accomplish their more complex tasks. Like neuromuscular junctions, some neuron-neuron synapses (**excitatory**) can rapidly excite. However, other synapses (**inhibitory**) can cause profound inhibition by decreasing postsynaptic excitability directly (postsynaptic inhibition). In a third broad class of synapse (**modulatory**), the synapse often has little or no direct effect of its own but instead regulates or

modifies the effect of other excitatory or inhibitory synapses by acting on either presynaptic or postsynaptic membranes. These three basic types of neural synapses are exemplified by their input to the *pyramidal neuron* of the cerebral cortex. In the example shown in [Figure 13-10](#), a pyramidal neuron in the visual cortex receives an excitatory synaptic input from the thalamus (with glutamate as the neurotransmitter), an inhibitory synaptic input from an interneuron (with GABA as the neurotransmitter), and a modulatory input from the locus coeruleus (with norepinephrine as the neurotransmitter).

FIGURE 13-10 Synaptic circuitry of the visual cortex. Visual pathways that originate in the retina activate neurons in the lateral geniculate nucleus of the thalamus. These glutamate-containing neurons in turn synapse on cortical pyramidal neurons and produce some *excitation*. Also within the primary visual cortex, a GABA-containing neuron mediates localized *inhibition*. Small cells in the locus coeruleus, a brainstem nucleus, make widely divergent connections onto cortical neurons and release norepinephrine and thus produce *modulation*.

Excitatory Synapses

Pyramidal cells receive excitatory inputs from many sources, including the axons of the thalamus. Most fast *excitatory synapses* in the brain use **glutamate** as their transmitter, and the thalamus-to-cerebral cortex synapses are no exception (see [Fig. 13-10](#)). **Aspartate** may also be a transmitter in some regions of the CNS. Both amino acids have similar effects on the postsynaptic excitatory amino-acid receptors. For convenience, these types of synapses are often presumptuously referred to as **glutamatergic**. These excitatory amino acids bind to a group of fast ligand-gated cation channels. When activated by synaptic glutamate, glutamate-gated channels generate an **excitatory postsynaptic potential (EPSP)** that is very similar to the one produced by ACh at the neuromuscular junction (see [p. 210](#)), except that it is usually much smaller than the EPSP in muscle. In the example shown in [Figure 13-11](#) (left side), glutamate produces the EPSP by activating a nonselective cation channel that has about the same conductance for Na^+ and K^+ . Thus, the **reversal potential** (see [p. 146](#)) of the EPSP is ~ 0 mV, about midway between the equilibrium potential for Na^+ (E_{Na}) and that for K^+ (E_{K}). An EPSP from the activation of a *single*

glutamatergic synapse in the cerebral cortex peaks at 0.01 to a few millivolts (depending on many factors, including the size of the postsynaptic cell and the size of the synapse), whereas one neuromuscular EPSP reaches a peak of ~ 40 mV—a difference of 40- to 4000-fold. Obviously, most glutamatergic synapses are not designed to be fail-safe. It takes the summation of EPSPs from many such synapses to depolarize a postsynaptic neuron to the threshold for triggering an action potential.

Action potential of presynaptic excitatory cell A

Action potential of presynaptic inhibitory cell B

If the postsynaptic cell starts at 0 mV, EPSP is absent. This voltage corresponds to the reversal potential (E_{cation}) of ligand-gated cation channels that are equally permeable to K^+ and Na^+ .

Excitatory post-synaptic potential (EPSP) of cell C

Inhibitory post-synaptic potential (IPSP) of cell C

If the postsynaptic cell starts at -71 mV, IPSP is absent. This voltage corresponds to the reversal potential (E_{Cl}) of Cl^- channels.

FIGURE 13-11 Voltage dependence of EPSPs and IPSPs in the nervous system. An excitatory

presynaptic neuron (cell A) and an inhibitory presynaptic neuron (cell B) both synapse on a third neuron (cell C). In this experiment, the investigators injected enough constant current into cell C to initially set the V_m to each of the six values shown in the figure. For each record, the experimenter first stimulated the stimulatory presynaptic neuron to produce an EPSP in the postsynaptic neuron and then stimulated the inhibitory presynaptic neuron to produce an IPSP. These EPSPs and IPSPs reflect the activities of multiple synapses onto cell C. The reversal potential for the EPSP is ~ 0 mV (i.e., stimulating the stimulatory presynaptic neuron has no effect) because Na^+ and K^+ conduct through the channel equally well. The reversal potential for the IPSP is at about -71 mV (i.e., stimulating the inhibitory presynaptic neuron has no effect). This value is E_{Cl} , which indicates that the IPSP is mediated by a Cl^- channel.

Inhibitory Synapses

Skeletal muscle cells in vertebrates have only excitatory synapses. On the other hand, virtually all central neurons have numerous excitatory *and inhibitory* synapses. Thus, the excitability of most neurons at any moment is governed by the dynamic balance of excitation and inhibition. The inhibitory transmitters **GABA** and **glycine** are the transmitters at the large majority of inhibitory synapses. Indeed, the inhibitory synapse between the interneuron and the pyramidal cell in [Figure 13-10](#) uses GABA. Both GABA and glycine bind to receptors that gate Cl^- -selective channels (see [p. 213](#)). Cl^- conductance usually has an inhibitory influence because the equilibrium potential for Cl^- (E_{Cl}) in neurons is near or slightly negative to the resting potential of the neuron. Thus, the reversal potential for the Cl^- -mediated **inhibitory postsynaptic potential (IPSP)** is the same as the E_{Cl} . If Cl^- conductance increases, the V_m has a tendency to move toward E_{Cl} (see [Fig. 13-11](#), right side). The effect is inhibitory because it tends to oppose other factors (mainly EPSPs) that might otherwise move the V_m toward or above the threshold for an action potential.

Modulatory Synapses

Many forms of *synaptic modulation* influence the nervous system (see [pp. 328–333](#)). As an example, consider the axons arising from the *locus coeruleus*, which synapse widely on pyramidal cells in the cerebral cortex (see [Figs. 13-7A](#) and [13-10](#)). These axons release the transmitter **norepinephrine**, a classic modulator with multiple effects. Norepinephrine acts on β adrenergic receptors in the pyramidal cell membrane (it may also act on α receptors at the same time). Unlike the actions of the fast amino-acid forms of synaptic transmission, this effect of norepinephrine by itself has little or no obvious influence on the activity of a resting neuron. However, a cell exposed to norepinephrine will react more powerfully when it is stimulated by a strong excitatory input (usually by glutamatergic synapses), as shown in [Figure 13-12](#). Thus, norepinephrine *modulates* the cell's response to other inputs.

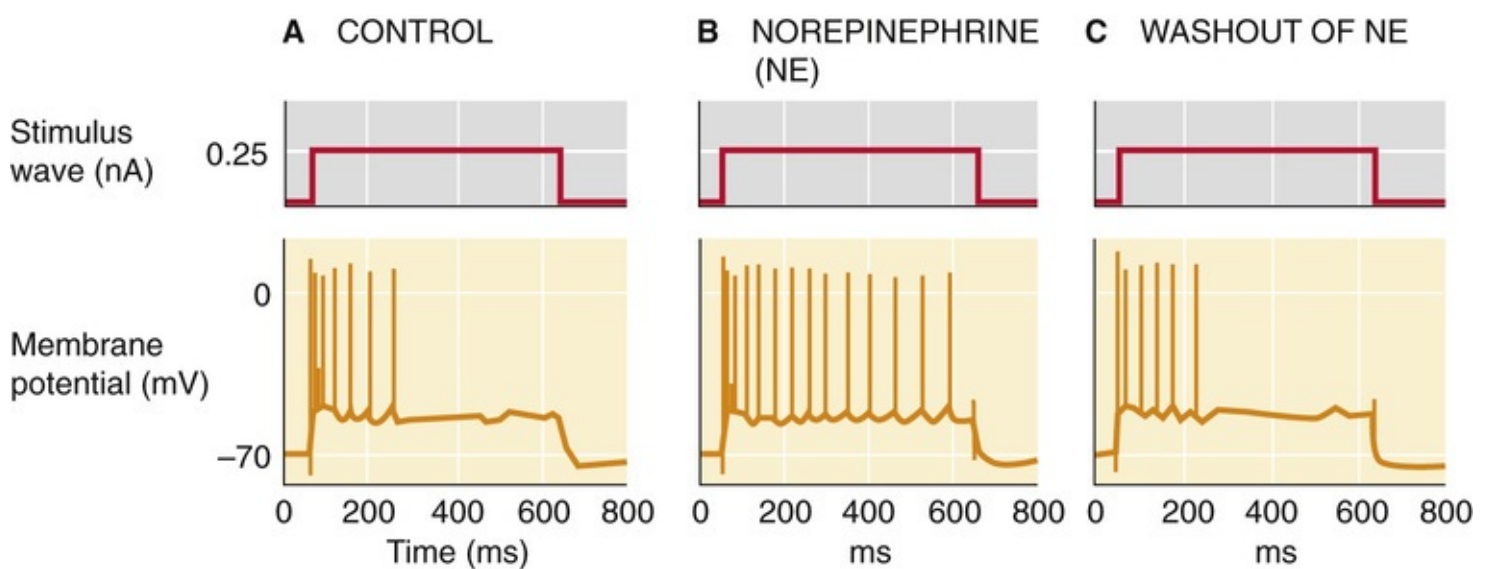

FIGURE 13-12 Modulatory effect of norepinephrine. **A**, Injecting a neuron from the hippocampus with a sustained depolarizing current pulse leads to a “phasic” action potential response: frequent spiking at the beginning but adaptation as the depolarizing current pulse is maintained. **B**, The application of norepinephrine causes the spiking that is elicited by the depolarizing current pulse to be sustained longer (“tonic”). **C**, The cell returns to its control state as in **A**. (Data from Madison DV, Nicoll RA: Actions of noradrenaline recorded intracellularly in rat hippocampal CA1 pyramidal neurones, in vitro. *J Physiol* 372:221–244, 1986.)

The molecular mechanisms of **neuromodulators** are complex and diverse, but all begin with a GPCR that activates an intracellular signal cascade (see pp. 51–66). Binding of norepinephrine to the β adrenergic receptor stimulates the intracellular enzyme adenylyl cyclase, which increases intracellular levels of cAMP (the second messenger), which in turn stimulates other enzymes to increase their rates of phosphorylation. Within the cortical neuron, phosphorylation of one or more types of K^+ channel decreases the probability of the channels' being open (see p. 163). Fewer open K^+ channels mean higher membrane resistance, greater excitability, and less adaptation of spike firing rates during prolonged stimuli. This K^+ channel pathway is but one of the many mechanisms by which norepinephrine can affect cells. Other effects are generated when norepinephrine activates other subtypes of adrenergic receptors and thus different second-messenger systems coupled to different channels or enzymes. Modulatory transmitters allow the nervous system tremendous potential and flexibility to vary its state of excitability.

G proteins may affect ion channels directly, or indirectly through second messengers

GPCRs exist in every cell (see pp. 51–66). In the preceding section we described one example, the receptor for norepinephrine and its second messenger–mediated effect on certain K^+ channels. However, norepinephrine alone has at least five major receptor types—two α receptors and three β receptors—that act on numerous effectors. In fact, each transmitter has multiple GPCRs, and their effects are complex and interactive and engage almost all aspects of cell function through several intracellular messenger systems. The various GPCRs can recognize a wide range of transmitter types, from small molecules to peptides.

Activated G proteins can trigger a wide array of responses at synapses by either of the two general pathways introduced in Chapter 3: (1) the G protein may modulate the gating of an ion channel directly or by a very short second-messenger pathway, and (2) the G protein may activate one of several enzyme systems that involve second messengers and subsequent signal cascades.

The first—and simplest—G-protein cascade involves a direct linkage from the receptor to the G protein to the channel and is sometimes called the **membrane-delimited pathway**. **N13-3** In this case

the G protein may be the only messenger between the receptor and the effector. A variety of neurotransmitters use this pathway. For example, in heart muscle, ACh binds to a certain type of muscarinic ACh receptor (M_2) that activates a G protein, the $\beta\gamma$ subunits of which in turn cause a K^+ channel to open (see Fig. 13-13B, below). Other receptors in various cells can modulate other K^+ and Ca^{2+} channels in a similar way.

FIGURE 13-13 Benefits of signal amplification. **A**, The neurotransmitter (NT) binds directly to a channel, thereby activating it. **B**, The neurotransmitter binds to a receptor that in turn activates 10 to 20 G proteins (see p. 53). In this example, each $\beta\gamma$ subunit directly activates a K^+ channel. In addition, each α subunit activates an adenylyl cyclase (AC) molecule, and each AC molecule produces many cAMP molecules that activate protein kinase A (PKA). **C**, Each activated PKA molecule can phosphorylate and thereby modulate many channels.

N13-3

The Membrane-Delimited Pathway for the Activation of Ion Channels by G Proteins

Contributed by Barry W. Connors

The first evidence for a membrane-delimited pathway came from patch-clamp experiments on inside-out patches containing a muscarinic ACh receptor (M_2), the G_s heterotrimeric G protein, and a K^+ channel capable of being activated by G proteins. These experiments showed that the G protein's $\beta\gamma$ subunits—which remain attached to the membrane—are necessary for activating the K^+ channel. Thus, everything

that is required for the signal-transduction process to work is present in the small patch of membrane. Some authors have voiced a lingering doubt that the $\beta\gamma$ subunits can directly interact with ion channels. An alternative to a direct coupling between G-protein $\beta\gamma$ subunits and the channel is that some lipid-soluble “second messenger”—which is also in the plane of the membrane—mediates the interaction between the G-protein $\beta\gamma$ subunits and the K^+ channel. However, whether the G protein–channel linkage is direct or occurs via some local membrane messenger, receptors and channels must be quite close for the membrane-delimited pathway to work.

Reference

Clapham DE. Direct G protein activation of ion channels? *Annu Rev Neurosci.* 1994;17:441–464.

One advantage of the membrane-delimited pathway is that it is relatively fast, beginning within 30 to 100 ms—not quite as fast as a ligand-gated channel, which uses no intermediary between receptor and channel, but faster than the many-messenger cascades described next. The membrane-delimited pathway is also localized in comparison to the other cascades. Because the G protein cannot diffuse very far within the membrane, only channels nearby can be affected. This type of coupling also allows flexibility because many types of receptors can be coupled to a variety of channels by use of the appropriate G-protein intermediate.

The other general type of G-protein signaling involves enzyme systems and second messengers, often diffusing through the cytoplasm, to influence an ion channel. The terminology deserves some clarification. Traditionally, the small, diffusible intracellular chemicals (e.g., cAMP, inositol 1,4,5-trisphosphate [IP_3]) that help carry the message between a transmitter receptor and a channel are called *second messengers*. The transmitter itself is counted as the first messenger, but notice that by this logic the receptor is not a messenger at all, even though it transfers a signal from the neurotransmitter to a G protein. The G protein is also not counted as a messenger, nor are the various enzymes that may come before and after the traditional second messenger in any signal cascade. Different cascades involve different numbers of messengers, but obviously, most have many more than two! Alas, the terminology is entrenched, although when we speak of second messengers, one should remember that a multiple-messenger cascade is almost always involved. As an added complication, two or more cascades, each with different types of messengers, may sometimes be activated by one type of receptor (an example of *divergence*; see below).

In [Chapter 3](#), we discussed three of these longer, and slower, G-protein signal cascades: (1) the adenylyl cyclase pathway, (2) the phospholipase C pathway, and (3) the phospholipase A_2 pathway. Each is activated by a different set of receptors, each uses a different G protein, and each generates different intracellular messengers. Some of these messengers dissolve in the watery cytoplasm, whereas others diffuse within the fatty lipid bilayer. The final link in most of the messenger cascades is a **kinase**.

In a well-known example, cAMP binds to cAMP-dependent protein kinase (protein kinase A), which then phosphorylates amino acids on K^+ or Ca^{2+} channels in the membrane. The addition of phosphate groups to the channel protein changes its conformation slightly, which may strongly influence its probability of being open (see [p. 163](#)). On [page 542](#) we discuss the stimulation of the β adrenergic receptor by norepinephrine, which ultimately results in a stronger heartbeat through phosphorylation and opening of myocardial voltage-gated Ca^{2+} channels. In the pyramidal cell of the hippocampus, stimulation of β adrenergic receptors increases $[cAMP]_i$, which can activate Ca^{2+} channels but also inhibit some K^+ channels. As a result, the cell can fire more action potentials during prolonged stimuli (see [Fig. 13-12](#)).

If transmitter-stimulated kinases were allowed to madly phosphorylate without some method of reversing the process, all proteins would quickly become saturated with phosphates and further regulation would become impossible. Protein phosphatases save the day. They act rapidly to remove phosphate groups (see pp. 57–58), and thus the degree of channel phosphorylation at any moment depends on the dynamic balance of phosphorylation and dephosphorylation.

Signaling cascades allow amplification, regulation, and a long duration of transmitter responses

At this point you may be wondering about the perversity of such complex, interconnected, indirect messenger cascades. Do these long chains of command have any benefit? Why not use simple, fast, ligand-gated channels (Fig. 13-13A) for all transmitter purposes? In fact, complex messenger cascades seem to have advantages.

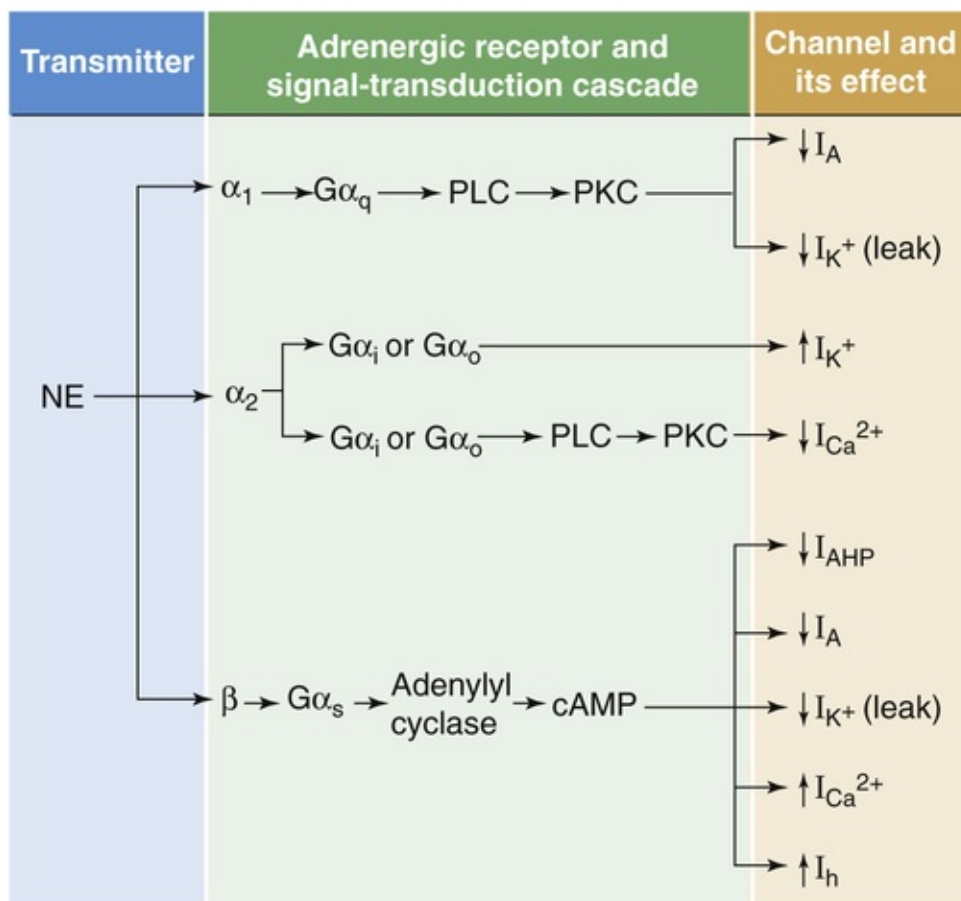

One important advantage is *amplification*. When activated, one ligand-gated channel is just that: one ion channel in one place. However, when activated, one GPCR potentially influences many channels. Signal amplification can occur at several places in the cascade (see p. 51), and a few transmitter molecules can generate a sizable cellular effect. One stimulated receptor can activate perhaps 10 to 20 G proteins, each of which can activate a channel by a membrane-delimited pathway such as the $\beta\gamma$ pathway (see Fig. 13-13B). Alternatively, the α subunit of one G protein can activate an adenylyl cyclase, which can make many cAMP molecules, and the cAMP molecules can spread to activate many kinases; each kinase can then phosphorylate many channels (see Fig. 13-13C). If all cascade components were tied together in a clump, signaling would be severely limited. The use of small messengers that can diffuse quickly also allows signaling at a distance, over a wide stretch of cell membrane. **13-4** Signaling cascades also provide many sites for further *regulation* as well as interaction between cascades. Finally, signal cascades can generate *long-lasting chemical changes* in cells, which may form the basis for, among other things, a lifetime of memories.

Neurotransmitters may have both convergent and divergent effects

Two of the most common neurotransmitters in the brain are glutamate and GABA. Either molecule can bind to any of several kinds of receptors, and each of these receptors can mediate a different effect. This ability of one transmitter to activate more than one type of receptor is sometimes called divergence.

Divergence is a rule among neurotransmitters. Nearly every well-studied transmitter can activate multiple receptor subtypes. Divergence means that one transmitter can affect different neurons (or even different parts of the same neuron) in very different ways. It also means that *if* a transmitter affects different neurons in different ways, it *could* be because each neuron has a different type of receptor. However, among transmitter systems that use second messengers, divergence may also occur at points beyond the level of the receptor. For example, norepinephrine can turn on or turn off a variety of ion channels in different cells (Fig. 13-14A). Some of these effects occur because norepinephrine activates different receptors, but some of these receptors may each activate more than one second messenger, or a single second messenger (e.g., cAMP) may activate a kinase that influences numerous different channels. Divergence may occur at any stage in the cascade of transmitter effects.

A DIVERGENT TRANSMITTER ACTIONS

B CONVERGENT TRANSMITTER ACTIONS

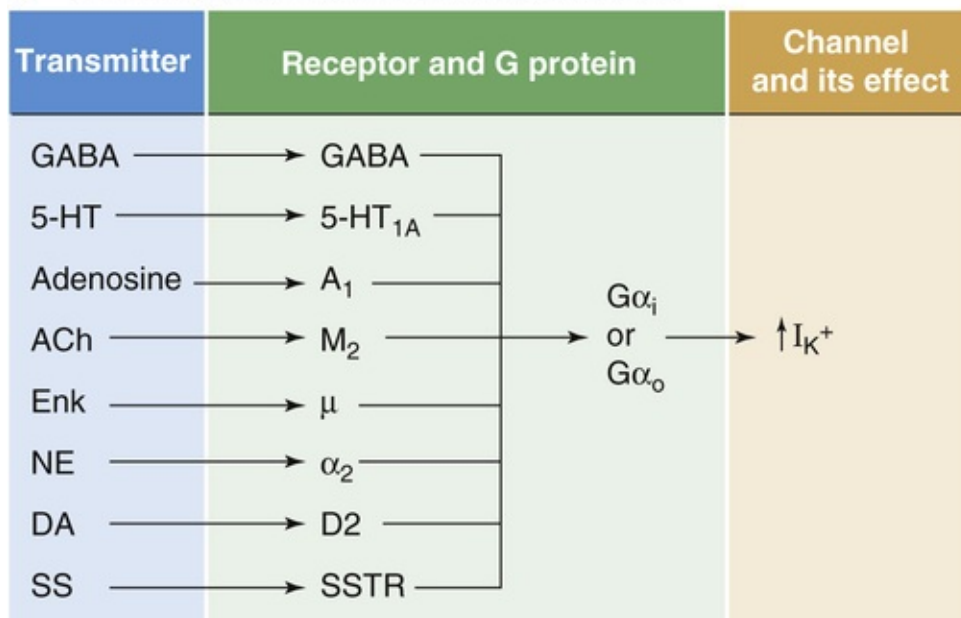

FIGURE 13-14 Divergence and convergence of transmitter effects on channels. **A**, One transmitter, norepinephrine (NE) in this case, can activate multiple receptors, which stimulate different G proteins/second messengers, which in turn either stimulate or depress the gating of many types of ion channels. I_{AHP} stands for afterhyperpolarization current, which is mediated by a Ca^{2+} -activated K^+ channel. I_h stands for hyperpolarization-activated cation current. **B**, Multiple transmitters bind to their specific receptors and, by the same or different second-messenger systems, influence the same set of ion channels. DA, dopamine; Enk, enkephalin; PKC, protein kinase C; PLC, phospholipase C; SS, somatostatin; SSTR, somatostatin receptor.

Neurotransmitters can also exhibit **convergence** of effects. This property means that multiple

transmitters, each activating its own receptor type, converge on a single type of ion channel in a single cell. For example, some pyramidal cells of the hippocampus have GABA_B, 5-HT_{1A}, A₁ (specific for adenosine), and SS (specific for somatostatin) receptors, all of which activate the same K⁺ channel (see [Fig. 13-14B](#)). Furthermore, in the same cells, norepinephrine, ACh, 5-HT, corticotropin-releasing hormone, and histamine all converge on and depress the slow Ca²⁺-activated K⁺ channels. Analogous to divergence, the molecular site of convergence may occur at a common second-messenger system, or different second messengers may converge on the same ion channel.

Divergence and convergence can occur simultaneously within neurotransmitter systems, and many of them have chemical feedback regulation built in as well.

Fast Amino Acid–Mediated Synapses in the CNS

Fast amino acid–mediated synapses account for most of the neural activity that we associate with specific information processing in the brain: events directly responsible for sensory perception, motor control, and cognition, for example. Glutamate-mediated excitation and GABA-mediated inhibition have been intensively studied. In physiological terms, these are also the best understood of the brain's synapses, and this section describes their function.

As a rule, postsynaptic events are more easily measured than presynaptic events; thus, we know more about them. Of course, by measuring postsynaptic events, we also have a window onto the functions of the presynaptic terminal, and this is often the best view we can get of presynaptic functions. For this reason, we begin our description with the downstream, postsynaptic side of the synapse and then work backward to the presynaptic side.

Most EPSPs in the brain are mediated by two types of glutamate-gated channels

Most glutamate-mediated synapses generate an EPSP with two distinct components, one much faster than the other. Both are triggered by the same presynaptic terminal releasing a single bolus of transmitter, but the two EPSP components are generated by different types of ion channels that are gated by distinct postsynaptic receptors—a case of transmitter divergence. The behavior of these channels helps in understanding the characteristics of the EPSP.

Glutamate can act on two major classes of receptors: GPCRs or *metabotropic* receptors, and ion channels or *ionotropic* receptors. As noted above, **metabotropic glutamate receptors (mGluRs)**—the *m* stands for metabotropic) have seven membrane-spanning segments and are linked to heterotrimeric G proteins (Fig. 13-15A). At least eight metabotropic receptors have been identified, and comparisons of their primary structure have been used to infer the evolutionary relationships among receptor subunits (see Fig. 13-15B). The mGluRs form three groups that differ in their sequence similarity, pharmacology, and associated signal-transduction systems.

FIGURE 13-15 Comparison of ionotropic and metabotropic glutamate receptors. In **C**, the inset shows a prototypic subunit, with a large extracellular glutamate-binding domain, a membrane-spanning segment, a short loop that partially re-enters the membrane from the cytosolic side, and two more membrane-spanning segments. Four of these subunits appear to come together to form a single channel/receptor with a central pore.

The three classes of **ionotropic glutamate receptors** are the AMPA, NMDA, and kainate receptors ([Table 13-2](#)). By definition, each is activated by binding glutamate, but their pharmacology and functions differ. The receptor names are derived from their relatively specific agonists: **AMPA** stands for α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid. **NMDA** stands for *N*-methyl-D-aspartate. The **kainate** receptor is named for one of its agonists, kainic acid, and it can also be activated by domoic acid. The three ionotropic glutamate receptors can also be distinguished by their selective antagonists. AMPA and kainate receptors, but not NMDA receptors, are blocked by drugs such as **CNQX** (6-cyano-7-nitroquinoxaline-2,3-dione). Moreover, AMPA receptors can be specifically antagonized by 2,3-benzodiazepine derivatives, such as GYKI 53655. NMDA receptors, but not AMPA and kainate receptors, are blocked by **APV** (2-amino-5-phosphonovaleric acid). Selective antagonists of kainate receptors have also been discovered.

TABLE 13-2
Ionotropic Glutamate Receptors

CLASS OF RECEPTOR	AGONIST	ANTAGONIST	KINETICS	PERMEABILITY
AMPA Genes: <i>GRIA</i> Proteins: GluA	α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid	CNQX (6-cyano-7-nitroquinoxaline-2,3-dione) GYKI 53655 (2,3-benzodiazepine derivatives)	Fast	Na ⁺ , K ⁺ (Ca ²⁺ in a few cases)

For nomenclature of ionotropic glutamate receptor genes and proteins, see [Table 6-2](#), family No. 12.

Ionotropic glutamate receptors are constructed from ~14 different subunits. Each of these has a large extracellular glutamate-binding domain, followed by a transmembrane segment, a loop that partially enters the membrane from the cytosolic side, and then two more transmembrane segments (see [Fig. 13-15C](#)). The loop appears to line the channel pore and may be important for ion selectivity. Kinetic and structural studies indicate that the receptors are heterotetramers, with four subunits arranged around a central channel. Comparisons of primary structures can be used to infer evolutionary relationships among receptor monomeric subunits. [Figure 13-15D](#) shows a hypothesized phylogenetic tree for the three classes of ionotropic glutamate receptors, with the major subtypes clustered together. Note that the various NMDA receptor subunits (e.g., GluN1, GluN2A through GluN2D) that combine to make the NMDA receptors are more closely related to each other than to the subunits (e.g., GluK1 through GluK5) that combine to make the kainate receptors or to the subunits (e.g., GluA1 through GluA4) that combine to make the AMPA receptors. The *metabotropic* and *ionotropic* glutamate receptors have separate family trees because, although both receptor types bind glutamate, they are so different in structure that they almost certainly evolved from different ancestral protein lines.

As noted above, most glutamate-mediated synapses generate an EPSP with two temporal components ([Fig. 13-16A, C](#)). The two phases of the glutamate-mediated EPSP have different pharmacological profiles, kinetics, voltage dependencies, ion dependencies, and permeabilities, and most important, they serve distinct functions in the brain. Pharmacological analysis reveals that the faster phase is mediated by an AMPA-type glutamate receptor and the slower phase by an NMDA-type glutamate receptor. These glutamate-gated channels have been extensively studied with single-channel recording methods. Both AMPA and NMDA receptors have nearly equal permeability to Na⁺ and K⁺, but they differ in several ways.

B ONLY AMPA RECEPTOR CHANNEL OPEN

D AMPA AND NMDA RECEPTOR CHANNELS OPEN

FIGURE 13-16 Glutamate-gated channels. **A**, At most glutamate-mediated synapses, the EPSP (red curve) is the sum of two components: (1) a rapid component that is mediated by an AMPA receptor (green curve) and (2) a slow component that is mediated by an NMDA receptor (orange curve). In this example, in which the postsynaptic V_m is relatively negative, the contribution of the NMDA receptor is very small. **B**, At a relatively negative initial V_m in the postsynaptic cell, as in **A**, the NMDA receptor does not open. The AMPA receptor, which is independent of postsynaptic V_m , opens. The result is a fast depolarization. **C**, In this example, in which the postsynaptic V_m is relatively positive, the contribution of the NMDA receptor is fairly large. **D**, At a relatively positive initial V_m in the postsynaptic cell, as in **C**, glutamate activates both the AMPA and the NMDA receptors. The recruitment of the NMDA receptors is important because, unlike most AMPA receptors, they allow the entry of Ca^{2+} and have slower kinetics.

AMPA-gated channels are found in most excitatory synapses in the brain, and they mediate fast excitation, with most types of AMPA channels normally letting very little Ca^{2+} into cells. Their single-channel conductance is relatively low, ~ 15 pS, and they show little voltage dependence.

NMDA-gated channels have more complex behavior. Each has a higher conductance, ~ 50 pS, and much slower kinetics. The ion selectivity of NMDA channels is the key to their functions: permeability to

Na^+ and K^+ causes depolarization and thus excitation of a cell, but their high permeability to Ca^{2+} allows them to influence $[\text{Ca}^{2+}]_i$ significantly. It is difficult to overstate the importance of intracellular $[\text{Ca}^{2+}]$. Ca^{2+} can activate many enzymes, regulate the opening of a variety of channels, and affect the expression of genes. Excess Ca^{2+} can even precipitate the death of a cell.

The gating of NMDA channels is unusual: at normal resting voltage (about -70 mV), the channel is clogged by Mg^{2+} , and few ions pass through it; the Mg^{2+} pops out only when the membrane is depolarized above about -60 mV. Thus, the NMDA channel is **voltage dependent** in addition to being ligand gated; both glutamate and a relatively positive V_m are necessary for the channel to open. How do the NMDA-gated channels open? NMDA-gated channels coexist with AMPA-gated channels in many synapses of the brain. When the postsynaptic cell is at a relatively negative resting potential (see Fig. 13-16A, B), the glutamate released from a synaptic terminal can open the AMPA-gated channel, which is voltage independent, but not the NMDA-gated channel. However, when the postsynaptic cell is more depolarized because of the action of other synapses (see Fig. 13-16C, D), the larger depolarization of the postsynaptic membrane allows the NMDA-gated channel to open by relieving its Mg^{2+} block. Indeed, under natural conditions, the slower NMDA channels open only after the membrane has been sufficiently depolarized by the action of the faster AMPA channels from many simultaneously active synapses.  **N13-4**

N13-4

Differential Ca^{2+} Permeabilities of AMPA- and NMDA-Type Glutamate Receptors

Contributed by Barry W. Connors

If the AMPA-type and NMDA-type glutamate receptor channels are so closely related phylogenetically (see Fig. 13-15D), how is it that they have such different Ca^{2+} permeabilities? Most of the AMPA-type glutamate receptor channels have a relatively low Ca^{2+} permeability because they include at least one GluA2 subunit. GluA2 (but not GluA1, GluA3, or GluA4) has a positively charged arginine residue at a particular site within the channel-forming domain. The *arginine* in GluA2 is critical for the low Ca^{2+} permeability of the native AMPA-type receptor channel. GluA1, GluA3, and GluA4 all have a neutral *glutamine* in place of the arginine. Indeed, if one constructs a complete AMPA-gated channel in which none of the four subunits has the *arginine* at the critical site, this channel will have an unnaturally high Ca^{2+} permeability. If one starts from such a channel lacking the critically placed arginines, reintroducing a single arginine into any of the four subunits restores the low Ca^{2+} permeability.

Because the NMDA-gated channel is naturally permeable to Ca^{2+} , one can guess that it follows the same structural rules as the AMPA-gated channel. Indeed, if one locates the homologous amino-acid residue where the neutral *arginine* would be in the AMPA-gated channel, one will find a neutral *asparagine* in all subunits of the NMDA-gated channel. Predictably these neutral asparagines—like glutamines at the homologous sites in the mutant subunits of the AMPA-gated channel (see previous paragraph)—allow Ca^{2+} to pass through the pore of NMDA-gated channels.

The physiological function of **kainate-gated channels** is still largely a mystery, although recent evidence suggests that they may contribute to some glutamate-mediated EPSPs in specific neuron types. The kainate receptor channels also exist on presynaptic GABAergic and glutamatergic terminals, where they regulate release of the inhibitory and excitatory transmitters (i.e., GABA and glutamate).

Most IPSPs in the brain are mediated by the GABA_A receptor, which is activated by several classes of drugs

GABA mediates the bulk of fast synaptic inhibition in the CNS, and glycine mediates most of the rest. Both the GABA_A receptor and the glycine receptor are ionotropic receptors that are, in fact, Cl⁻-selective channels. Note that GABA can also activate the relatively common GABA_B receptor, which is a GPCR or *metabotropic* receptor that is linked to either the opening of K⁺ channels or the suppression of Ca²⁺ channels. Finally, GABA can activate the ionotropic GABA_C receptor, found primarily in neurons of the retina.

Synaptic inhibition must be tightly regulated in the brain. Too much inhibition causes sedation, loss of consciousness, and coma, whereas too little leads to anxiety, hyperexcitability, and seizures. The need to control inhibition may explain why the GABA_A receptor channel has, in addition to its GABA binding site, several other sites where chemicals can bind and thus dramatically modulate the function of the GABA_A receptor channel. For example, two classes of drugs, **benzodiazepines** (one of which is the tranquilizer diazepam [Valium]) and **barbiturates** (e.g., the sedative phenobarbital), each bind to their own specific sites on the outside face of the GABA_A receptor channel. By themselves, these drugs do very little to the channel's activity. However, when GABA is around, benzodiazepines increase the *frequency* of channel opening, whereas barbiturates increase the *duration* of channel opening. In addition, the benzodiazepines can increase Cl⁻ conductance of the GABA_A receptor channel. [Figure 13-17A to D](#) shows the effects of barbiturates on both the IPSP and the single-channel currents. The result, for both the benzodiazepines and the barbiturates, is more inhibitory Cl⁻ current, stronger IPSPs, and the behavioral consequences of enhanced inhibition.

FIGURE 13-17 Physiology and structure of the GABA_A receptor channel. **A**, When a pulse of GABA is released from a synapse, it elicits a small IPSP. **B**, In the presence of a low dose of pentobarbital, the pulse of synaptic GABA elicits a much larger IPSP. Thus, the barbiturate enhances inhibition. **C**, At the single-channel level, GABA by itself elicits brief channel openings. **D**, A barbiturate (50 μ M pentobarbital, in this case) does not by itself activate the GABA_A receptor channel but increases the channel open time when GABA is present. **E**, The channel receptor is a heteropentamer. It has not only a pore for Cl^- but also separate binding sites for GABA and several classes of channel modulators. The inset shows the presumed structure of one of the five monomers. The M2 domain of each of the five subunits presumably

Surely, however, the GABA_A receptor did not evolve specialized binding sites just for the benefit of our modern drugs. This sort of logic has motivated research to find endogenous ligands, or natural chemicals that bind to the benzodiazepine and barbiturate sites and serve as regulators of inhibition. [Figure 13-17E](#) shows some of the binding sites on the GABA_A receptor. Among the potential natural modulators of the GABA_A receptor may be various metabolites of the steroid hormones progesterone, corticosterone, and testosterone. Some of these hormones increase the lifetime of GABA-activated single-channel currents or the opening frequency of these channels and may thus enhance inhibition. The steroid effect is unlike the usual genomic mechanisms of steroid hormones (see [pp. 71–72](#)). Instead, steroids modulate the GABA_A receptor in a manner similar to barbiturates—directly, through binding sites that are distinct from the other drug-binding sites on the GABA_A receptor. Thus, these steroids are not the natural agonists of the benzodiazepine and barbiturate binding sites. The GABA_A receptor is also subject to modulation by the effects of phosphorylation triggered by second-messenger signaling pathways within neurons.

The ionotropic receptors for ACh, serotonin, GABA, and glycine belong to the superfamily of ligand-gated/pentameric channels

We now know the amino-acid sequences of all major ligand-gated ion channels in the brain. Even though the receptors for ACh, serotonin, GABA, and glycine are gated by such different ligands and have such different permeabilities, they have the same overall structure: five protein subunits, with each subunit being made up of four membrane-spanning segments (as shown for the GABA_A receptor channel in [Fig. 13-17E](#) and inset). For example, inhibitory GABA_A and glycine receptors have structures very similar to those of excitatory nicotinic ACh receptors, even though the first two are selective for anions and the last is selective for cations. For both the glycine and nicotinic ACh receptors, the transmitters bind only to the α subunits, whereas for the GABA_A receptor, the transmitter GABA binds to a site at the interface of the α and β subunits.

The primary structures of the many subunit types are remarkably similar, particularly within the amino-acid sequences of the hydrophobic membrane-spanning segments. One such stretch, called the **M2 domain**, tends to have repeating sequences of the polar amino acids threonine and serine. Each of the five subunits that constitute a channel contributes one M2 domain, and the set of five combines to form the water-lined pore through which ions can flow (see [Fig. 13-17E](#)). For the channels gated by GABA and glycine, selectivity for Cl[−] may be determined by positively charged arginines and lysines near the mouth of the pore.

Not quite *all* ligand-gated channels belong to the same superfamily. We have already seen that the family of ionotropic glutamate receptors is distinct from the family of ligand-gated/pentameric channels. Extensive evidence also indicates that ATP is a synaptic transmitter between certain neurons and at neuron–smooth-muscle cell synapses, with rapid actions similar to those of glutamate and ACh. One of the **purinergic receptors** or **purinoceptors**, called **P2X**, is an ATP-gated cation channel with relatively high Ca²⁺ permeability. The sequence of this receptor bears little resemblance to those of either the ionotropic glutamate receptor family or the ligand-gated/pentameric channel superfamily. Instead, each

subunit appears to have only two membrane-spanning segments, and a full channel comprises just three subunits. Functionally, the ATP-gated channel closely resembles the nicotinic ACh receptor; structurally, it is much more akin to the channel superfamily that includes voltage-gated Na⁺ and K⁺ channels (see pp. 182–183) and to some mechanosensitive channels. This similarity appears to be a case of convergent evolution among ion channels.

Most neuronal synapses release a very small number of transmitter quanta with each action potential

A single neuromuscular junction has ~1000 active zones (see p. 210). A single presynaptic impulse releases 100 to 200 quanta of transmitter molecules (i.e., ACh), which generates an EPSP of >40 mV in the muscle cell. This is excitation with a vengeance, because the total number of quanta is far more than necessary to cause the muscle cell to fire an action potential and generate a brief contraction. Evolution has designed a neuromuscular junction that works every time, with a large margin of excess for safety. Synapses in the brain are quite different. A typical glutamatergic synapse, which has as few as one active zone, generates EPSPs of only 10 to 1000 μV. In most neurons, one EPSP is rarely enough to cause a postsynaptic cell to fire an action potential.

The basis for the small effect of central synapses has been explored by quantal analysis, with refinements of methods originally applied to the neuromuscular junction. In this approach, a single presynaptic axon is stimulated repeatedly while the postsynaptic response is recorded under voltage-clamp conditions. The frequency distribution of amplitudes of excitatory postsynaptic currents (EPSCs) is analyzed, as described for the neuromuscular junction (see Fig. 8-12B). Recall that according to standard quantal theory:

$$m = np$$

(13-1)

Here, m is the total number of quanta released, n is the maximal number of releasable quanta (perhaps equivalent to the number of active zones), and p is the average probability of release. Measurement of these parameters is very difficult. Only in rare cases in central neurons is it possible to find amplitude distributions of EPSCs with clearly separate peaks that may correspond to quantal increments of transmitter. In most cases, EPSC distributions are smooth and broad, which makes quantal analysis difficult to interpret. The analysis is hampered because EPSCs are small, it is extremely difficult to identify each small synapse, the dendrites electrically filter the recorded synaptic signals, noise arises from numerous sources (including the ion channels themselves), and synapses exhibit considerable variability. Nevertheless, what is clear is that most synaptic terminals in the CNS release only a small number of transmitter molecules per impulse, often just those contained in a single quantum (e.g., 1000 to 5000 glutamate molecules). Furthermore, the probability of release of that single quantum is often substantially less than 1; in other words, a presynaptic action potential often results in the release of no transmitter at all. When a quantum of transmitter molecules is released, only a limited number of postsynaptic receptors is available for the transmitter to bind to, usually not more than 100. In addition, because not all the receptors open their channels during each response, only 10 to 40 channels contribute current to each postsynaptic response, compared with the thousands of channels opening in concert during

each neuromuscular EPSP.

Because most glutamatergic synapses in the brain contribute such a weak excitatory effect, it may require the nearly simultaneous action of many synapses (and the summation of their EPSPs) to bring the postsynaptic membrane potential above the threshold for an action potential. *The threshold number of synapses varies greatly among neurons, but it is roughly in the range of 10 to 100.*

Some exceptions to the rule of small synaptic strengths in the CNS may be noted. One of the strongest connections in the CNS is the one between the climbing fibers and Purkinje cells of the cerebellum (see [Fig. 13-1B](#)). **Climbing fibers** are glutamatergic axons arising from cells in the inferior olivary nucleus, and they are a critical input to the cerebellum. Climbing fibers and Purkinje cells have a dedicated, one-to-one relationship. The climbing fiber branches extensively and winds intimately around each **Purkinje cell**, making numerous synaptic contacts. When the climbing fiber fires, it generates a massive EPSP (~40 mV, similar to the neuromuscular EPSP) that evokes a burst of spikes in the Purkinje cell. Like the neuromuscular junction, the climbing fiber–Purkinje cell relationship seems to be designed to deliver a suprathreshold response every time it is activated. It achieves this strength in the standard way: each climbing fiber makes ~200 synaptic contacts with each Purkinje cell.

When multiple transmitters colocalize to the same synapse, the exocytosis of large vesicles requires high-frequency stimulation

As we mentioned previously, some presynaptic terminals have two or more transmitters colocalized within them. In these cases, the small transmitters are packaged into relatively small vesicles (~40 nm in diameter), whereas neuropeptides are in larger dense-core vesicles (100 to 200 nm in diameter), as noted above. This dual-packaging scheme allows the neuron some control over the relative release rates of its two types of transmitters ([Fig. 13-18A](#)). In general, **low-frequency stimulation** of the presynaptic terminal triggers the release of only the small transmitter (see [Fig. 13-18B](#)); co-release of both transmitters requires bursts of **high-frequency stimulation** (see [Fig. 13-18C](#)). This frequency sensitivity may result from the size and spatial profile of presynaptic $[Ca^{2+}]_i$ levels achieved by the different patterns of stimulation. Presynaptic Ca^{2+} channels are located close to the vesicle fusion sites. Low frequencies of activation yield only localized elevations of $[Ca^{2+}]_i$, an amount sufficient to trigger the exocytosis of small vesicles near active zones. Larger peptide-filled vesicles are farther from active zones, and high-frequency stimulation may be necessary to achieve higher, more distributed elevations of $[Ca^{2+}]_i$. With this arrangement, it is obvious that the synaptic effect (resulting from the mixture of transmitters released) depends strongly on the way that the synapse is activated.

Plasticity of Central Synapses

Use-dependent changes in synaptic strength underlie many forms of learning

Arguably the greatest achievement of a brain is its ability to learn and to store the experience and events of the past so that it is better adapted to deal with the future. Memory is the ability to store and to recall learned changes, and nervous systems without memory are extremely handicapped. Although the biological bases for learning and memory are far from understood, certain principles have become clear. First, no single mechanism can explain all forms of memory. Even within a single organism, a variety of types of memory exist—and a variety of mechanisms underlie them. Second, evidence is strong that synapses are the physical site of many if not most forms of memory storage in the brain. As the major points of interaction between neurons, synapses are well placed to alter the processing capabilities of a neural circuit in interesting and useful ways. Third, the **synaptic strength** (i.e., the mean amplitude of the postsynaptic response) of many synapses may depend on their previous activity. The sensitivity of a synapse to its past activity can lead to a long-term change in its future effectiveness, which is all we need to build memory into a neural circuit.

Some forms of memory last just a few seconds or minutes, only to be lost or replaced by new memories. **Working memory** is an example. It is the continual series of fleeting memories that we use during the course of a day to remember facts and events, what was just spoken to us, where we put the phone down, whether we are coming or going—things that are useful for the moment but need not be stored longer. Other forms of memory may last for hours to decades and strongly resist disruption and replacement. Such **long-term memory** allows the accumulation of knowledge over a lifetime. Some memories may be formed after only a single trial (recall a particularly dramatic but unique event in your life), whereas others form only with repeated practice (examples include speaking a language or playing a guitar). Detailed descriptions of the many types of memory are beyond the scope of this chapter, but it seems obvious that no single synaptic mechanism would suffice to generate all of them. Neurophysiologists have identified many types of **synaptic plasticity**, the term for activity-dependent changes in the effectiveness of synapses, and some of their mechanisms are well understood. However, it has been very difficult to demonstrate that specific forms of memory use particular types of synaptic plasticity, and correlation of memory with synaptic plasticity remains a coveted goal of current research.

Short-term synaptic plasticity usually reflects presynaptic changes

Repetitive stimulation of neuronal synapses often yields brief periods of increased or decreased synaptic strength (Fig. 13-19). The usual nomenclature for the short-term increases in strength is **facilitation** (which lasts tens to hundreds of milliseconds), **augmentation** (which lasts several seconds), and **post-tetanic potentiation** (which lasts tens of seconds to several minutes and outlasts the period of high-frequency stimulation). Not all of them are expressed at every type of synapse. In general, the longer-lasting modifications require longer periods of conditioning stimuli. Short-term *decreases* in synaptic strength include **depression**, which can occur during high-frequency stimulation, and **habituation**, which is a slowly progressing decrease that occurs during relatively low-frequency activation.

FIGURE 13-19 Facilitation, potentiation, depression, and habituation. (Data from Levitan IB, Kaczmarek LK: The Neuron: Cell and Molecular Biology, 2nd ed. New York, Oxford University Press, 1997.)

Three potential explanations may be offered for short-term *increases* in synaptic strength. First, the presynaptic terminal may release more transmitter in response to each action potential. Second, the postsynaptic receptors may be more responsive to transmitter because of a change in their number or sensitivity. Third, both of these changes may occur simultaneously. Studies involving a variety of synapses suggest that the first explanation is most often correct. In these cases, quantal analysis usually shows that synapses become stronger because more neurotransmitter is released during each presynaptic action

potential; postsynaptic mechanisms generally do not play a role. This form of plasticity seems to depend on the influx of presynaptic Ca^{2+} during the conditioning tetanus.  **N13-5** Katz and Miledi first proposed that synaptic strength is increased because of residual Ca^{2+} left in the terminal after a conditioning train of stimuli at the neuromuscular junction. Recent work supports this hypothesis. The idea is that (1) a tetanic stimulus leads to a substantial increase in presynaptic $[\text{Ca}^{2+}]_i$ that saturates intracellular Ca^{2+} buffers; (2) the high presynaptic $[\text{Ca}^{2+}]_i$ takes a relatively long time to decline to baseline, and prolonged stimulation requires prolonged recovery times; and (3) presynaptic action potentials arriving after the conditioning tetanus generate a Ca^{2+} influx that sums with the residual $[\text{Ca}^{2+}]_i$ from the preceding tetanus to yield a larger than normal peak $[\text{Ca}^{2+}]_i$. Because the dependence of transmitter release on presynaptic $[\text{Ca}^{2+}]_i$ is highly nonlinear, the increase in release after conditioning stimuli can be large. Several types of Ca^{2+} -sensitive proteins are present in the presynaptic terminal; the Ca^{2+} binding site on synaptotagmin triggers exocytosis, whereas Ca^{2+} binding sites on other proteins—perhaps including protein kinase C (see [pp. 60–61](#)) and Ca^{2+} -calmodulin-dependent protein kinases (CaMKs; see [p. 60](#)) regulate short-term increases in transmitter release.

Short-Term Synaptic Plasticity

Contributed by Emile Boulpaep, Walter Boron

See the following:

1.  **N8-5 Quantal Nature of Transmitter Release**
2.  **N8-6 Sir Bernard Katz**
3.  **N8-7 Modulation of Quantal Release**

Several mechanisms cause short-term *decreases* in synaptic strength, including the depletion of vesicles and the inactivation of presynaptic Ca^{2+} channels. Habituation has been studied in the marine invertebrate *Aplysia*. The animal reflexively withdraws its gill in response to a stimulus to its skin. Vincent Castellucci and Eric Kandel  **N13-6** found that withdrawal becomes less vigorous—that is, the animal habituates—when the stimulus is presented repeatedly. The basis for this behavioral habituation is, at least in part, a decrease in the strength of synapses made by skin sensory neurons onto gill-withdrawal motor neurons. Using quantal analysis, Castellucci and Kandel showed that synaptic habituation is due to fewer transmitter quanta being released per action potential. Thus, as with the short-term enhancements of synaptic strength, this example of habituation is due to presynaptic modifications.

Long-term potentiation in the hippocampus may last for days or weeks

In 1973, Timothy Bliss and Terje Lømo described a form of synaptic enhancement that lasted for days or even weeks. This phenomenon, now called **long-term potentiation (LTP)**, occurred in excitatory synapses of the mammalian cerebral cortex. LTP was generated by trains of high-frequency stimulation applied to the presynaptic axons, and it was expressed as an increase in the size of EPSPs. Several properties of LTP, including its longevity and its location in cortical synapses, made it immediately attractive as a candidate for the cellular basis of certain forms of vertebrate learning. Years of intensive research have revealed many details of the molecular mechanisms of LTP. They have also provided some evidence, albeit still indirect, that LTP is involved in some forms of learning. Numerous mechanistically distinct types of LTP exist; here we discuss only the best-studied example.

LTP is easily demonstrated in several synaptic relays within the **hippocampus**, a part of the cerebral cortex that has often been considered essential for the formation of certain long-term memories. The best studied of these synapses is between the Schaffer collateral axons of CA3 pyramidal neurons (forming the presynaptic terminals) and CA1 pyramidal neurons (the postsynaptic neurons). In a typical experiment, the strength of synapses to the CA1 neuron is tested by giving a single shock about once every 10 seconds. Stimuli are applied separately to two sets of Schaffer collateral axons that form two different sets of synapses ([Fig. 13-20A](#)). If we stimulate a “control” Schaffer collateral once every 10 seconds, the amplitude of the EPSPs recorded in the postsynaptic CA1 neuron remains rather constant during many tens of minutes (see [Fig. 13-20B](#)). However, if we *pair* the presynaptic test shocks occurring once every 10 seconds to the “test” pathway with simultaneous postsynaptic depolarization of the CA1 neuron, the amplitude of the EPSP gradually increases several-fold (see [Fig. 13-20C](#)), which is indicative of LTP. In this case, the trigger for LTP was the *pairing* of a low-frequency presynaptic input and a strong postsynaptic depolarization. We already saw that Bliss and Lømo originally induced LTP by activating the presynaptic axons with brief bursts of tetanic stimulation (50 to 100 stimuli at a frequency of ~100 Hz). Both strategies—presynaptic-postsynaptic pairing protocol and tetanic presynaptic stimulation—are effective ways to induce LTP.

A EXPERIMENTAL PREPARATION

B CONTROL PATHWAY

C TEST PATHWAY

FIGURE 13-20 Causing LTP by pairing presynaptic and postsynaptic stimuli. **A**, Pyramidal CA3 neurons in the hippocampus send axons (Schaffer collaterals) to synapse on pyramidal CA1 neurons. In the case of the “control” stimulus, the stimulating electrode stimulates collaterals that activate one set of synapses on the postsynaptic CA1 neuron. In this case, the CA1 neuron receives only presynaptic stimuli. In the case of the “test” stimulus, a second electrode stimulates a different set of collaterals that activate a different set of synapses on that same CA1 neuron. However, in this case, the presynaptic stimuli will be paired with a postsynaptic depolarization that is delivered by a third microelectrode. Aside from pairing or not pairing the presynaptic stimuli with a postsynaptic stimulus, the test and control pathways are equivalent. The third microelectrode records the EPSPs from the CA1 neuron in both the test and control experiments. **B**, In this case, the control Schaffer collaterals are stimulated. Each test pulse is represented by a point on the graph. However, because the CA1 neuron is not depolarized, the amplitude of the EPSPs remains constant (i.e., there is no LTP). **C**, In this case, the test Schaffer collaterals are stimulated. When the CA1 neuron is also depolarized, the amplitude of the EPSPs greatly increases (i.e., LTP has been induced). (Data from Gustafsson B, Wigstrom H, Abraham WC, Huang YY: Long-term potentiation in the hippocampus using depolarizing current pulses as the conditioning stimulus to single-volley synaptic potentials. *J Neurosci* 7:774–780, 1987.)

The induction of LTP has several interesting features that enhance its candidacy as a memory mechanism. First, it is **input specific**, which means that only the activated set of synapses onto a particular cell will be potentiated, whereas unactivated synapses to that same neuron remain unpotentiated. Second, induction of LTP requires coincident activity of the presynaptic terminals plus significant depolarization of the postsynaptic membrane. We saw this effect in [Figure 13-20C](#), which showed that inducing LTP required coincident synaptic input and depolarization. Because single hippocampal synapses are quite weak, the requirement for substantial postsynaptic activation means that LTP is best induced in an in vivo situation by **cooperativity**—enough presynaptic axons must cooperate, or fire coincidentally, to strongly activate the postsynaptic cell. The cooperative property of LTP can be used to form associations between synaptic inputs. Imagine that two sets of weak inputs onto one cell are, by themselves, too weak to induce LTP. Perhaps each encodes some sensory feature of an object: the sight (input 1) and sound (input 2) of your pet cat. If the two firing together are strong enough to induce LTP, both sets of synaptic inputs will tend to strengthen, and the features that they encode (the sight and sound of the cat) will become associated in their enhanced ability to fire the postsynaptic cell. In contrast, for example, the sight of your cat and the sound of your alarm clock will rarely occur together, and their neural equivalents will not

become associated.

The molecular mechanisms of one form of LTP in the CA1 region of hippocampus have been partially elucidated. The synapse uses glutamate as its transmitter, and both AMPA and NMDA receptors are activated to generate an EPSP. Induction of this type of LTP depends on an increase in postsynaptic $[Ca^{2+}]_i$ levels beyond a critical level and lasting for about 1 to 2 seconds. (Recall that the *short-term* forms of enhancement required a *presynaptic* increase in $[Ca^{2+}]_i$; see the preceding section.) Under most conditions, postsynaptic $[Ca^{2+}]_i$ levels rise during a tetanic stimulus because of the activation of NMDA receptors, the only type of glutamate-activated channel that is usually permeable to Ca^{2+} (see Fig. 13-16). Recall also that the NMDA-type glutamate receptor channel is voltage dependent; to open, it requires V_m to be relatively positive. The cooperativity requirement of LTP is really a requirement for the activation of NMDA receptors so that Ca^{2+} can enter—if the postsynaptic V_m is too negative (as it is when synaptic activation is weak), NMDA channels remain mostly closed. If activation is strong (as it is when multiple inputs cooperate or when tetanus occurs), V_m becomes positive enough to allow NMDA channels to open. The stimulus-induced rise in postsynaptic $[Ca^{2+}]_i$ activates at least one essential kinase: **CaMKII** (see p. 60). Blocking this kinase with drugs prevents induction of LTP. Several other types of kinases are implicated, but the evidence that these mediate—as opposed to modulate—LTP is equivocal.

The molecular pathways leading to the expression and maintenance of LTP are more obscure after the Ca^{2+} -induced activation of CaMKII. Evidence has been presented both for and against postsynaptic and presynaptic changes as explaining the increase in synaptic strength. For the most commonly studied form of LTP described here (i.e., dependent on NMDA receptors), compelling evidence demonstrates a postsynaptic mechanism involving the recruitment of more AMPA receptors to the postsynaptic membrane. Sometimes, postsynaptic AMPA receptors appear to be functionally “silent” until LTP mechanisms activate them or insert them into the membrane. Evidence also suggests a presynaptic mechanism for enhancing transmitter release. This presynaptic hypothesis requires the presence of some unknown, rapidly diffusing retrograde messenger that can carry a signal from the postsynaptic side (where rising $[Ca^{2+}]_i$ is clearly a trigger for LTP) back to the presynaptic terminal.

Long-term depression exists in multiple forms

Memory systems may have mechanisms not only to increase synaptic strength but also to decrease it. In fact, **long-term depression (LTD)** can be induced in the same synapses within the hippocampus that generate the $[Ca^{2+}]_i$ -dependent LTP described in the preceding section. The critical feature that determines whether the synapses will strengthen or weaken is simply the frequency of stimulation that they receive. For example, several hundred stimuli delivered at 50 Hz produce LTP, the same number delivered at 10 Hz has little effect, and at 1 Hz they produce LTD. One set of synapses can be strengthened or weakened repeatedly, which suggests that each process (LTP and LTD) acts on the same molecular component of the synapses. LTD induced in this way shows the same input specificity as LTP—only the stimulated synapses onto a cell are depressed.

Multiple forms of LTD differ according to their molecular mechanisms. One type depends on activation of mGluRs; another apparently requires activation of cannabinoid receptors. We describe the type of LTD that has been studied most extensively. The induction requirements of this form of hippocampal LTD are paradoxically similar to those of LTP: LTD induced by low-frequency stimulation depends on the activation of NMDA receptors, and it requires an increase in postsynaptic $[Ca^{2+}]_i$. The key determinant of whether a tetanic stimulus induces LTP or LTD may be the level to which postsynaptic $[Ca^{2+}]_i$ rises.

Figure 13-21 illustrates a simple model of the induction mechanisms for LTD and LTP. Synaptic activation releases glutamate, which activates NMDA receptors, which in turn allow Ca^{2+} to enter the postsynaptic cell. In the case of high-frequency stimulation, postsynaptic $[\text{Ca}^{2+}]_i$ rises to very high levels; if stimulation is of low frequency, the rise in postsynaptic $[\text{Ca}^{2+}]_i$ is more modest. High levels of $[\text{Ca}^{2+}]_i$ lead to a net activation of protein *kinases*, whereas modest levels of $[\text{Ca}^{2+}]_i$ preferentially activate protein *phosphatases*, perhaps calcineurin. The kinases and phosphatases in turn act on synaptic proteins or phosphoproteins that somehow regulate synaptic strength.

FIGURE 13-21 Proposed molecular mechanism for LTP and LTD. Glutamate release from the presynaptic terminal activates NMDA receptor channels, which allow Ca^{2+} to enter the postsynaptic cell. The glutamate also activates AMPA receptor channels. Whether the ultimate effect is LTP or LTD appears to depend on the extent to which $[\text{Ca}^{2+}]_i$ rises. High levels of $[\text{Ca}^{2+}]_i$ —produced by high-frequency stimulation—lead to a net activation of protein kinases and thus phosphorylation of one or more synaptic proteins that regulate synaptic strength. One hypothetical pathway has the phosphorylated/dephosphorylated synaptic proteins modulating the AMPA receptor channel. The result is LTP. The postsynaptic neuron may also be able to influence the presynaptic terminal. A moderate increase in $[\text{Ca}^{2+}]_i$ —produced by low-frequency stimulation—preferentially activates protein phosphatases, which presumably dephosphorylate the same synaptic proteins as in the previous example. The result is LTD.

LTP-inducing stimuli phosphorylate specific residues on AMPA receptors and, conversely, dephosphorylate other residues on AMPA receptors. These post-translational changes are, however, only part of the story of long-term synaptic plasticity. LTP increases—and LTD decreases—the numbers of AMPA receptors in the postsynaptic membrane by modulating receptor trafficking into and out of the surface membrane. Longer lasting LTP- and LTD-induced changes seem to involve mechanisms that depend on protein synthesis, including structural changes in synapses and spines.

The simple scheme in [Figure 13-21](#) leaves unidentified many of the steps between the rise in postsynaptic $[\text{Ca}^{2+}]_i$ and the change in synaptic strength; most of the molecular details remain to be determined. However, if the model is correct, it means that synaptic strength (and, by implication, some memory) is under the dynamic control of cellular processes that determine postsynaptic $[\text{Ca}^{2+}]_i$. Once again in physiology, $[\text{Ca}^{2+}]_i$ has been assigned a pivotal role in a vital process.

Long-term depression in the cerebellum may be important for motor learning

A variety of other types of LTP and LTD have been described in other synapses and even within the same synapses of the CA1 region in the hippocampus. Clearly, multiple means and mechanisms may be used to strengthen and to weaken synapses in the brain over a range of time courses. We briefly describe one other well-studied type of synaptic modification in the mammalian brain, LTD in the cerebellum.

The cerebellum is a large brain structure that is important in motor control and strongly implicated in motor learning. The cortex of the cerebellum is a thin, multiply folded sheet of cells with an intricate but highly repetitious neural structure. The principal cell of the cerebellum is the **Purkinje cell**, a large neuron that uses GABA as its transmitter and whose axon forms the sole output of the cerebellar cortex. Purkinje cells receive two types of excitatory synaptic input: (1) each Purkinje cell receives powerful synaptic contact from just a single climbing fiber, which comes from a cell in the inferior olivary nucleus (see [Fig. 13-1B](#)), and (2) each Purkinje cell also receives synaptic input from ~150,000 **parallel fibers**, which originate from the tiny granule cells of the cerebellum itself. This remarkable conjunction of synaptic inputs is the basis for a theory of motor learning that was proposed by David Marr and James Albus in 1970. They predicted that the parallel-fiber synapses should change their strength only if they are active at the same time as the climbing fiber onto the same cell. This idea received important experimental support from the laboratory of Masao Ito.

Ito and colleagues monitored EPSPs in a Purkinje cell while stimulating some of its inputs from parallel fibers and its single input from the climbing fiber. They found that the EPSPs generated by the parallel fibers became smaller when both the parallel fibers *and* the cell's climbing fiber were coactivated at low frequencies. Stimulating either input alone did not cause any change. Cerebellar LTD

can last at least several hours. As with the hippocampal LTP and LTD described above, cerebellar LTD showed input specificity: only those parallel fibers coactivated with the climbing fiber were depressed, whereas others with synapses onto the cell were unchanged.

The mechanism of cerebellar LTD has some similarities to that of LTD in the hippocampus, but it is also distinctly different. Parallel-fiber synapses weaken because of reduced effectiveness—a reduction in either number or sensitivity—of *postsynaptic* AMPA-type glutamate receptors. As in the hippocampus, induction of cerebellar LTD requires an increase in postsynaptic $[Ca^{2+}]_i$. However, unlike in the hippocampus, no NMDA-type glutamate receptors are present in the mature cerebellum to mediate Ca^{2+} flux. Instead, Ca^{2+} can enter Purkinje cells through voltage-gated Ca^{2+} channels that are opened during the exceptionally powerful EPSP that the climbing fiber generates. In addition to a rise in postsynaptic $[Ca^{2+}]_i$, cerebellar LTD induction seems to require the activation of mGluRs and protein kinase C by the parallel fibers. Increases in postsynaptic $[Na^+]_i$ and NO have also been implicated in LTD induction. At present, the relationships between these putative induction factors and the molecular pathways leading to the expression of cerebellar LTD are obscure.

As we pointed out for the hippocampus, most efficient memory systems need mechanisms for both weakening and strengthening of their synapses. It turns out that parallel-fiber synapses of the cerebellum can be induced to generate LTP as well as LTD by stimulating them at relatively low frequencies (2 to 8 Hz). Cerebellar LTP, unlike hippocampal LTP, requires presynaptic but not postsynaptic increases in $[Ca^{2+}]_i$. Potentiation seems to be a result of increased transmitter release from the presynaptic terminal.

CHAPTER 14

The Autonomic Nervous System

George B. Richerson

When we are awake, we are constantly aware of sensory input from our external environment, and we consciously plan how to react to it. When we are asleep, the nervous system has a variety of mechanisms to dissociate cortical function from sensory input and somatic motor output. Among these mechanisms are closing the eyes, blocking the transmission of sensory impulses to the cortex as they pass through the thalamus, and effecting a nearly complete paralysis of skeletal muscles during rapid eye movement (REM) sleep to keep us from physically acting out our dreams.

The conscious and discontinuous nature of cortical brain function stands in sharp contrast to that of those parts of the nervous system responsible for control of our internal environment. These “autonomic” processes never stop attending to the wide range of metabolic, cardiopulmonary, and other visceral requirements of our body. Autonomic control continues whether we are awake and attentive, preoccupied with other activities, or asleep. While we are awake, we are unaware of most visceral sensory input, and we avoid any conscious effort to act on it unless it induces distress. In most cases, we have no awareness of motor commands to the viscera, and most individuals can exert voluntary control over visceral motor output in only minor ways. Consciousness and memory are frequently considered the most important functions of the human nervous system, but it is the visceral control system—including the **autonomic nervous system (ANS)**—that makes life and higher cortical function possible.

We have a greater understanding of the physiology of the ANS than of many other parts of the nervous system, largely because it is reasonably easy to isolate peripheral neurons and to study them. As a result of its accessibility, the ANS has served as a key model system for the elucidation of many principles of neuronal and synaptic function.

Organization of the Visceral Control System

The ANS has sympathetic, parasympathetic, and enteric divisions

Output from the central nervous system (CNS) travels along two anatomically and functionally distinct pathways: the **somatic motor neurons**, which innervate striated skeletal muscle; and the **autonomic motor neurons**, which innervate smooth muscle, cardiac muscle, secretory epithelia, and glands. All viscera are richly supplied by efferent axons from the ANS that constantly adjust organ function.

The autonomic nervous system (from the Greek for “self-governing,” functioning independently of the will) was first defined by Langley in 1898 as including the local nervous system of the gut and the efferent neurons innervating glands and involuntary muscle. Thus, this definition of the ANS includes only *efferent* neurons and *enteric* neurons. Since that time, it has become clear that the efferent ANS cannot easily be dissociated from visceral *afferents* as well as from those parts of the CNS that control the output to the ANS and those that receive interoceptive input. 🧠 **N14-1** This larger visceral control system monitors afferents from the viscera and the rest of the body, compares this input with current and anticipated needs, and controls output to the body's organ systems.

N14-1

Types of Afferent Input

Contributed by Emile Boulpaep, Walter Boron

Exteroceptive

Proprioceptive

Interoceptive

The ANS has three divisions: sympathetic, parasympathetic, and enteric. The **sympathetic** and **parasympathetic divisions** of the ANS are the two major efferent pathways controlling targets other than skeletal muscle ([Fig. 14-1](#)). Each innervates target tissue by a two-synapse pathway. The cell bodies of the first neurons lie within the CNS. These **preganglionic neurons** are found in columns of cells in the brainstem and spinal cord and send axons out of the CNS to make synapses with **postganglionic neurons** in peripheral ganglia interposed between the CNS and their target cells. Axons from these postganglionic neurons then project to their targets. The sympathetic and parasympathetic divisions can act independently of each other. However, in general, they work synergistically to control visceral activity and often act in opposite ways, like an accelerator and brake to regulate visceral function. An increase in output of the sympathetic division occurs under conditions such as stress, anxiety, physical activity, fear, or excitement, whereas parasympathetic output increases during sedentary activity, eating, or other “vegetative” behavior.

FIGURE 14-1 Organization of the sympathetic and parasympathetic divisions of the ANS.

The **enteric division** of the ANS is a collection of afferent neurons, interneurons, and motor neurons that form networks of neurons called **plexuses** (from the Latin “to braid”) that surround the gastrointestinal (GI) tract. It can function as a separate and independent nervous system, but it is normally controlled by the CNS through sympathetic and parasympathetic fibers.

Sympathetic preganglionic neurons originate from spinal segments T1 to L3 and synapse with postganglionic neurons in paravertebral or prevertebral ganglia

Preganglionic Neurons

The cell bodies of preganglionic sympathetic motor neurons are located in the thoracic and upper lumbar spinal cord between levels T1 and L3. At these spinal levels, autonomic neurons lie in the **intermediolateral cell column**, or lateral horn, between the dorsal and ventral horns (Fig. 14-2). Axons from preganglionic sympathetic neurons exit the spinal cord through the ventral roots along with axons from *somatic* motor neurons. After entering the spinal nerves, sympathetic efferents diverge from somatic motor axons to enter the white **rami communicantes**. These rami, or branches, are white because most preganglionic sympathetic axons are myelinated.

FIGURE 14-2 Anatomy of the sympathetic division of the ANS. The figure shows a cross section of the thoracic spinal cord and the nearby paravertebral ganglia as well as a prevertebral ganglion. Sympathetic preganglionic neurons are shown in red and postganglionic neurons in dark blue-violet. Afferent (sensory) pathways are in blue. Interneurons are shown in black.

Paravertebral Ganglia

Axons from preganglionic neurons enter the nearest sympathetic paravertebral ganglion through a white ramus. These ganglia lie adjacent to the vertebral column. Although preganglionic sympathetic fibers emerge only from levels T1 to L3, the chain of sympathetic ganglia extends all the way from the upper part of the neck to the coccyx, where the left and right sympathetic chains merge in the midline and form the coccygeal ganglion. In general, one ganglion is positioned at the level of each spinal root, but adjacent ganglia are fused in some cases. The most rostral ganglion, the **superior cervical ganglion**, arises from fusion of C1 to C4 and supplies the head and neck. The next two ganglia are the **middle cervical ganglion**, which arises from fusion of C5 and C6, and the **inferior cervical ganglion** (C7 and C8), which is usually fused with the first thoracic ganglion to form the **stellate ganglion**. Together, the middle cervical and

stellate ganglia, along with the upper thoracic ganglia, innervate the heart, lungs, and bronchi. The remaining paravertebral ganglia supply organs and portions of the body wall in a segmental fashion.

After entering a paravertebral ganglion, a preganglionic sympathetic axon has one or more of three fates. It may (1) synapse within that segmental paravertebral ganglion, (2) travel up or down the sympathetic chain to synapse within a neighboring paravertebral ganglion, or (3) enter the greater or lesser splanchnic nerve to synapse within one of the ganglia of the *prevertebral* plexus.

Prevertebral Ganglia

The **prevertebral plexus** lies in front of the aorta and along its major arterial branches and includes the prevertebral ganglia and interconnected fibers ([Fig. 14-3](#)). The major prevertebral ganglia are named according to the arteries that they are adjacent to and include the celiac, superior mesenteric, aorticorenal, and inferior mesenteric ganglia. Portions of the prevertebral plexus extend down the major arteries and contain other named and unnamed ganglia and plexuses of nerve fibers, which altogether make up a dense and extensive network of sympathetic neuron cell bodies and nerve fibers.

FIGURE 14-3 Anatomy of the sympathetic *prevertebral* plexuses. Each ganglion and its associated plexus are named after the artery with which they are associated.

Each *preganglionic* sympathetic fiber synapses on many *postganglionic* sympathetic neurons that are located within one or several nearby *paravertebral* or *prevertebral* ganglia. It has been estimated that each *preganglionic* sympathetic neuron branches and synapses on as many as 200 *postganglionic* neurons, which enables the sympathetic output to have more widespread effects. However, any impulse arriving at its target end organ has only crossed a single synapse between the *preganglionic* and *postganglionic* sympathetic neurons.

Postganglionic Neurons

The cell bodies of *postganglionic* sympathetic neurons that are located within *paravertebral* ganglia send out their axons through the nearest **gray rami communicantes**, which rejoin the spinal nerves (see [Fig. 14-2](#)). These rami are gray because most *postganglionic* axons are unmyelinated. Because *preganglionic* sympathetic neurons are located only in the thoracic and upper lumbar spinal segments (T1 to L3), *white* rami are found only at these levels ([Fig. 14-4](#), left panel). However, because *each* sympathetic ganglion sends out *postganglionic* axons, *gray* rami are present at all spinal levels from C2 or C3 to the coccyx. *Postganglionic* sympathetic axons from *paravertebral* and *prevertebral* ganglia travel to their target organs within other nerves or by traveling along blood vessels. Because the *paravertebral* and *prevertebral* sympathetic ganglia lie near the spinal cord and thus relatively far from their target organs, the *postganglionic* axons of the sympathetic division tend to be long. On their way to reach their targets, some *postganglionic* sympathetic axons travel through *parasympathetic* terminal ganglia or cranial nerve ganglia without synapsing. 🍷 [N14-2](#)

Sympathetic division

Parasympathetic division

FIGURE 14-4 Organization of the sympathetic and parasympathetic divisions of the ANS. The left panel shows the sympathetic division. The cell bodies of sympathetic preganglionic neurons (red) are in the intermediolateral column of the thoracic and lumbar spinal cord (T1–L3). Their axons project to paravertebral ganglia (the sympathetic chain) and prevertebral ganglia. Postganglionic neurons (blue) therefore have long projections to their targets. The right panel shows the parasympathetic division. The cell bodies of parasympathetic preganglionic neurons (orange) are either in the brain (midbrain, pons, medulla) or in the sacral spinal cord (S2–S4). Their axons project to ganglia very near (or even inside) the end organs. Postganglionic neurons (green) therefore have short projections to their targets.

N14-2

Tracing of Nerve Tracts Using Pseudorabies Virus

Contributed by George Richerson

The CNS neuroanatomy of autonomic control has been difficult to define experimentally. However, a technique developed by Arthur Loewy and his colleagues that traces nerve tracts with the pseudorabies virus has helped to define more clearly the central pathways for autonomic control. For example, if axons of preganglionic sympathetic neurons are exposed to pseudorabies virus, the virus is transported back into the cell bodies, where it replicates. After a delay of several days, neurons that make synapses with these preganglionic neurons (i.e., “premotor” neurons) become infected and the virus is transported to their cell bodies. After longer periods of incubation, neurons farther upstream are also infected. Histological staining can then be used at different time points to visualize neurons that contain the virus at each level upstream.

Parasympathetic preganglionic neurons originate from the brainstem and sacral spinal cord and synapse with postganglionic neurons in ganglia located near target organs

The cell bodies of preganglionic parasympathetic neurons are located in the medulla, pons, and midbrain and in the S2 through S4 levels of the spinal cord (see [Fig. 14-4](#), right panel). Thus, unlike the sympathetic—or **thoracolumbar**—division, whose preganglionic cell bodies are in the thoracic and lumbar spinal cord, the parasympathetic—or **craniosacral**—division's preganglionic cell bodies are cranial and sacral. The preganglionic parasympathetic fibers originating in the brain distribute with four cranial nerves: the oculomotor nerve (CN III), the facial nerve (CN VII), the glossopharyngeal nerve (CN IX), and the vagus nerve (CN X). The preganglionic parasympathetic fibers originating in S2 through S4 distribute with the pelvic splanchnic nerves.

Postganglionic parasympathetic neurons are located in **terminal ganglia** that are more peripherally located and more widely distributed than are the sympathetic ganglia. Terminal ganglia often lie within the walls of their target organs. Thus, in contrast to the sympathetic division, postganglionic fibers of the parasympathetic division are short. In some cases, individual postganglionic parasympathetic neurons are found in isolation or in scattered cell groups rather than in encapsulated ganglia.

Cranial Nerves III, VII, and IX

The preganglionic parasympathetic neurons that are distributed with CN III, CN VII, and CN IX originate in three groups of nuclei.

1. The **Edinger-Westphal nucleus** is a subnucleus of the oculomotor complex in the midbrain (Fig. 14-5). Parasympathetic neurons in this nucleus travel in the **oculomotor nerve** (CN III) and synapse onto postganglionic neurons in the ciliary ganglion (see Fig. 14-4, right panel). The postganglionic fibers project to two smooth muscles of the eye: the constrictor muscle of the pupil and the ciliary muscle, which controls the shape of the lens (see Fig. 15-6).

FIGURE 14-5 Supraspinal nuclei containing neurons that are part of the ANS. These nuclei contain the cell bodies of the preganglionic parasympathetic neurons (i.e., efferent). The Edinger-Westphal nucleus contains cell bodies of preganglionic fibers that travel with CN III to the ciliary ganglion. The superior salivatory nucleus contains cell bodies of preganglionic fibers that travel with CN VII to the pterygopalatine and submandibular ganglia. The inferior salivatory nucleus contains cell bodies of preganglionic fibers that travel with CN IX to the otic ganglion. The rostral portion of the nucleus ambiguus contains preganglionic cell bodies that distribute with CN IX; the rest of the nucleus ambiguus and the dorsal motor nucleus of the vagus contain cell bodies of preganglionic fibers that travel with CN X to a host of terminal ganglia in the viscera of the thorax and abdomen. The NTS, which is not part of the ANS, receives visceral afferents and is part of the larger visceral control system. The figure also illustrates other cranial nerves that are not involved in controlling the ANS (gray labels).

2. The **superior salivatory nucleus** is in the rostral medulla (see Fig. 14-5) and contains parasympathetic neurons that project, through a branch of the **facial nerve** (CN VII), to the pterygopalatine ganglion (see Fig. 14-4, right panel). The postganglionic fibers supply the lacrimal glands, which produce tears. Another branch of the facial nerve carries preganglionic fibers to the submandibular ganglion. The postganglionic fibers supply two salivary glands, the submandibular and sublingual glands.

3. The **inferior salivatory nucleus** and the rostral part of the **nucleus ambiguus** in the rostral medulla (see Fig. 14-5) contain parasympathetic neurons that project through the **glossopharyngeal nerve** (CN IX) to the otic ganglion (see Fig. 14-4, right panel). The postganglionic fibers supply a third salivary gland, the parotid gland.

Cranial Nerve X

Most parasympathetic output occurs through the **vagus nerve** (CN X). Cell bodies of vagal preganglionic parasympathetic neurons are found in the medulla within the **nucleus ambiguus** and the **dorsal motor nucleus of the vagus** (see Fig. 14-5). This nerve supplies parasympathetic innervation to all the viscera of the thorax and abdomen, including the GI tract between the pharynx and distal end of the colon (see Fig. 14-4, right panel). Among other effects, electrical stimulation of the nucleus ambiguus results in contraction of striated muscle in the pharynx, larynx, and upper esophagus due to activation of somatic motor neurons (not autonomic), as well as slowing of the heart due to activation of vagal preganglionic parasympathetic neurons. Stimulation of the dorsal motor nucleus of the vagus induces many effects in the viscera, including initiation of secretion of gastric acid, insulin, and glucagon. Preganglionic parasympathetic fibers of the vagus nerve join the esophageal, pulmonary, and cardiac plexuses and travel to terminal ganglia that are located within their target organs.

Sacral Nerves

The cell bodies of preganglionic parasympathetic neurons in the sacral spinal cord (S2 to S4) are located in a position similar to that of the preganglionic *sympathetic* neurons—although they do not form a distinct intermediolateral column. Their axons leave through ventral roots and travel with the pelvic splanchnic nerves to their terminal ganglia in the descending colon and rectum (see p. 862), as well as to the bladder (see pp. 736–737) and the reproductive organs of the male (see p. 1104) and female (see p. 1127).

The visceral control system also has an important afferent limb

All internal organs are densely innervated by visceral afferents. Some of these receptors monitor nociceptive (painful) input. Others are sensitive to a variety of mechanical and chemical (physiological) stimuli, including stretch of the heart, blood vessels, and hollow viscera, as well as P_{CO_2} , P_{O_2} , pH, blood glucose, and temperature of the skin and internal organs. Many visceral nociceptive fibers travel in sympathetic nerves (blue projections in Fig. 14-2). Most axons from physiological receptors travel with parasympathetic fibers. As is the case with somatic afferents (see p. 271), the cell bodies of visceral afferent fibers are located within the dorsal root ganglia or cranial nerve ganglia (e.g., nodose and petrosal ganglia). Ninety percent of these visceral afferents are unmyelinated.

The largest concentration of visceral afferent axons can be found in the **vagus nerve**, which carries

non-nociceptive afferent input to the CNS from all viscera of the thorax and abdomen. Most fibers in the vagus nerve are *afferents*, even though all parasympathetic preganglionic output (i.e., *efferents*) to the abdominal and thoracic viscera also travels in the vagus nerve. Vagal afferents, whose cell bodies are located in the nodose ganglion, carry information about the distention of hollow organs (e.g., blood vessels, cardiac chambers, stomach, bronchioles), blood gases (e.g., P_{O_2} , P_{CO_2} , pH from the aortic bodies), and body chemistry (e.g., glucose concentration) to the medulla.

Internal organs also have nociceptive receptors that are sensitive to excessive stretch, noxious chemical irritants, and very large decreases in pH. In the CNS, this visceral pain input is mapped (see pp. 400–401) *viscerotopically* at the level of the spinal cord because most visceral nociceptive fibers travel with the sympathetic fibers and enter the spinal cord at a specific segmental level along with a spinal nerve (see Fig. 14-2). This viscerotopic mapping is also present in the brainstem but not at the level of the cerebral cortex. Thus, awareness of visceral pain is not usually localized to a specific organ but is instead “referred” to the dermatome (see p. 273) that is innervated by the same spinal nerve. This **referred pain** results from lack of precision in the central organization of visceral pain pathways. Thus, you know that the pain is associated with a particular spinal nerve, but you do not know where the pain is coming from (i.e., from the skin or a visceral organ). For example, nociceptive input from the left ventricle of the heart is referred to the left T1 to T5 dermatomes and leads to discomfort in the left arm and left side of the chest, whereas nociceptive input from the diaphragm is referred to the C3 to C5 dermatomes and is interpreted as pain in the shoulder. This visceral pain is often felt as a vague burning or pressure sensation.

The enteric division is a self-contained nervous system of the GI tract and receives sympathetic and parasympathetic input

The enteric nervous system (ENS) is a collection of nerve plexuses that surround the GI tract, including the pancreas and biliary system. Although it is entirely peripheral, the ENS receives input from the sympathetic and parasympathetic divisions of the ANS. The ENS is estimated to contain >100 million neurons, including afferent neurons, interneurons, and efferent postganglionic parasympathetic neurons. Enteric neurons contain many different neurotransmitters and neuromodulators. Thus, not only does the total number of neurons in the enteric division exceed that of the spinal cord, but the neurochemical complexity of the ENS also approaches that of the CNS. The anatomy of the ENS as well as its role in controlling GI function is discussed in Chapter 41.

The plexuses of the ENS are a system of ganglia sandwiched between the layers of the gut and connected by a dense meshwork of nerve fibers. The **myenteric** or Auerbach's plexus (Fig. 14-6) lies between the outer longitudinal and the inner circular layers of smooth muscle, whereas the **submucosal** or Meissner's plexus lies between the inner circular layer of smooth muscle and the most internal layer of smooth muscle, the muscularis mucosae (see Fig. 41-3). In the intestinal wall, the myenteric plexus is involved primarily in the control of motility, whereas the submucosal plexus is involved in the control of ion and fluid transport. Both the myenteric and the submucosal plexuses receive *preganglionic parasympathetic* innervation from the vagus nerve (or sacral nerves in the case of the distal portion of colon and rectum). Thus, in one sense, the enteric division is homologous to a large and complex parasympathetic terminal ganglion. The other major input to the ENS is from *postganglionic sympathetic* neurons. Thus, the ENS can be thought of as “postganglionic” or as a “terminal organ” with respect to the parasympathetic division and “post-postganglionic” with respect to the sympathetic division. Input from

both the sympathetic and parasympathetic divisions modulates the activity of the ENS, but the ENS can by and large function normally without extrinsic input. The isolated ENS can respond appropriately to local stimuli and control most aspects of gut function, including initiating peristaltic activity in response to gastric distention, controlling secretory and absorptive functions, and triggering biliary contractions (Box 14-1).

FIGURE 14-6 The myenteric (Auerbach's) plexus. The image is a scanning electron micrograph of the myenteric plexus of the mouse large intestine. The external longitudinal muscle of the intestine was removed so that the view is of the plexus (the highly interconnected meshwork of neuron cell bodies, axons, and dendrites on the surface) spreading over the deeper circular layer of muscle. Box 14-1

PHOX2B

Master Gene of the Visceral Control System

During development, a complex genetic program expressed in each progenitor cell determines cell fate—ensuring that the cell migrates to the correct location and differentiates into the correct mature cell type. The genes that encode some transcription factors (see pp. 81–88) turn on at a specific time during development and trigger normal migration or differentiation of specific cell types. *phox2b* is a transcription factor required for the development of nearly all neurons within the visceral control system and almost no other class of neuron.

phox2b is expressed early in development in all neurons of the mammalian visceral control system—including preganglionic and postganglionic parasympathetic neurons, postganglionic (but not preganglionic) sympathetic enteric neurons, all visceral afferents, and neurons of the NTS, on which they synapse. No other cells express phox2b, except for neurons of the locus coeruleus in the pons (which plays an important role in cardiovascular control) and certain cranial nerve nuclei (most of which are important for respiratory output and for feeding). Knockout of the mouse *PHOX2B* gene leads to loss of development of all these neurons and is fatal. 🍌 **N14-9** In humans, heterozygous mutations in the *PHOX2B* gene cause **congenital central hypoventilation syndrome (CCHS)**, a congenital form of Ondine curse (see Box 32-5). Infants with this condition have problems with breathing while they sleep, probably because of a deficiency in detection of O₂ or CO₂ in their blood or defective integration of this information by the NTS and other nuclei of the medulla. A subset of patients with *PHOX2B* mutations also have **Hirschsprung disease** (see Box 41-2), in which the ENS does not develop normally in a portion of the colon. This combination of CCHS and Hirschsprung disease is called **Haddad syndrome**. Some CCHS patients also develop tumors of derivatives of the sympathetic nervous system called neuroblastomas.

N14-9

PHOX2B

Contributed by George Richerson

At one time, scientists searched for “master genes” responsible for directing the development of each group of neurons that share a common function (e.g., all motor neurons or all neurons that contain gamma-aminobutyric acid). This search has been largely fruitless, except for *PHOX2B*, which is the closest example of a master gene in that it is expressed almost uniquely and nearly ubiquitously in neurons of the visceral control system. The implication is that these neurons are so closely related to each other in their function that they are bound together by a common developmental program. This common bond is so primitive that a homolog of *PHOX2B* is even found in neurons of *Ciona*, a urochordate that is a marine animal made up primarily of an intestine that filters seawater.

As a rule, the neural circuits that carry out individual tasks or behaviors (e.g., locomotion, sleep, vision) are formed by several classes of neurons that follow unrelated developmental pathways before they assemble into a circuit. So far, the visceral control system is unique in that most of its constituent neuronal types differentiate under the control of the same highly specific transcription factor, phox2b. *PHOX2B* can thus be considered the “master gene” of the visceral control system.

Synaptic Physiology of the Autonomic Nervous System

The sympathetic and parasympathetic divisions have opposite effects on most visceral targets

All innervation of skeletal muscle in humans is excitatory. In contrast, many visceral targets receive both inhibitory and excitatory synaptic inputs. These antagonistic inputs arise from the two opposing divisions of the ANS, the sympathetic and the parasympathetic.

In organs that are stimulated during physical activity, the sympathetic division is excitatory and the parasympathetic division is inhibitory. For example, sympathetic input increases the heart rate, whereas parasympathetic input decreases it. In organs whose activity increases while the body is at rest, the opposite is true. For example, the parasympathetic division stimulates peristalsis of the gut, whereas the sympathetic division inhibits it.

Although antagonistic effects of the sympathetic and parasympathetic divisions of the ANS are the general rule for most end organs, exceptions exist. For example, the salivary glands are stimulated by both divisions, although stimulation by the sympathetic division has effects different from those of parasympathetic stimulation (see [p. 894](#)). In addition, some organs receive innervation from only one of these two divisions of the ANS. For example, sweat glands, piloerector muscles, and most peripheral blood vessels receive input from only the sympathetic division.

Synapses of the ANS are specialized for their function. Rather than possessing synaptic terminals that are typical of somatic motor axons, many postganglionic autonomic neurons have bulbous expansions, or **varicosities**, that are distributed along their axons within their target organ ([Fig. 14-7](#)). It was once believed that these varicosities indicated that neurotransmitter release sites of the ANS did not form close contact with end organs and that neurotransmitters needed to diffuse long distances across the extracellular space to reach their targets. However, we now recognize that many varicosities form synapses with their targets, with a synaptic cleft extending ~50 nm across. At each varicosity, autonomic axons form an “en passant” synapse with their end-organ target. This arrangement results in an increase in the number of targets that a single axonal branch can influence, with wider distribution of autonomic output.

FIGURE 14-7 Synapses of autonomic neurons with their target organs. Many axons of postganglionic neurons make multiple points of contact (varicosities) with their targets. In this scanning electron micrograph of the axon of a guinea pig postganglionic sympathetic neuron grown in tissue culture, the arrows indicate varicosities, or en passant synapses. (From Burnstock G: Autonomic neuromuscular junctions: Current developments and future directions. *J Anat* 146:1–30, 1986.)

All preganglionic neurons—both sympathetic and parasympathetic—release acetylcholine and stimulate N₂ nicotinic receptors on postganglionic neurons

At synapses between postganglionic neurons and target cells, the two major divisions of the ANS use different neurotransmitters and receptors ([Table 14-1](#)). However, in both the sympathetic and parasympathetic divisions, synaptic transmission between preganglionic and postganglionic neurons (termed ganglionic transmission because the synapse is located in a ganglion) is mediated by **acetylcholine (ACh)** acting on nicotinic receptors ([Fig. 14-8](#)). Nicotinic receptors are ligand-gated channels (i.e., ionotropic receptors) with a pentameric structure (see [pp. 212–213](#)). [Table 14-2](#) summarizes some of the properties of nicotinic receptors. The nicotinic receptors on postganglionic autonomic neurons are of a molecular subtype (N₂) different from that found at the neuromuscular junction (N₁). Both are ligand-gated ion channels activated by ACh or nicotine. However, whereas the N₁ receptors at the neuromuscular junction (see [p. 212](#)) are stimulated by decamethonium and preferentially blocked by *d*-tubocurarine, [N8-2](#) the autonomic N₂ receptors are stimulated by tetramethylammonium but resistant to *d*-tubocurarine. When activated, N₁ and N₂ receptors are both permeable to Na⁺ and K⁺. Thus, nicotinic transmission triggered by stimulation of preganglionic neurons leads to rapid depolarization of postganglionic neurons.

TABLE 14-1
Properties of the Sympathetic and Parasympathetic Divisions

	SYMPATHETIC PREGANGLIONIC	SYMPATHETIC POSTGANGLIONIC	PARASYMPATHETIC PREGANGLIONIC	PARASYMPATHETIC POSTGANGLIONIC
Location of neuron cell bodies	Intermediolateral cell column in the spinal cord (T1–L3)	Prevertebral and paravertebral ganglia	Brainstem and sacral spinal cord (S2–S4)	Terminal ganglia in or near target organ
Myelination	Yes	No	Yes	No
Primary neurotransmitter	ACh	Norepinephrine	ACh	ACh
Primary postsynaptic receptor	Nicotinic	Adrenergic	Nicotinic	Muscarinic

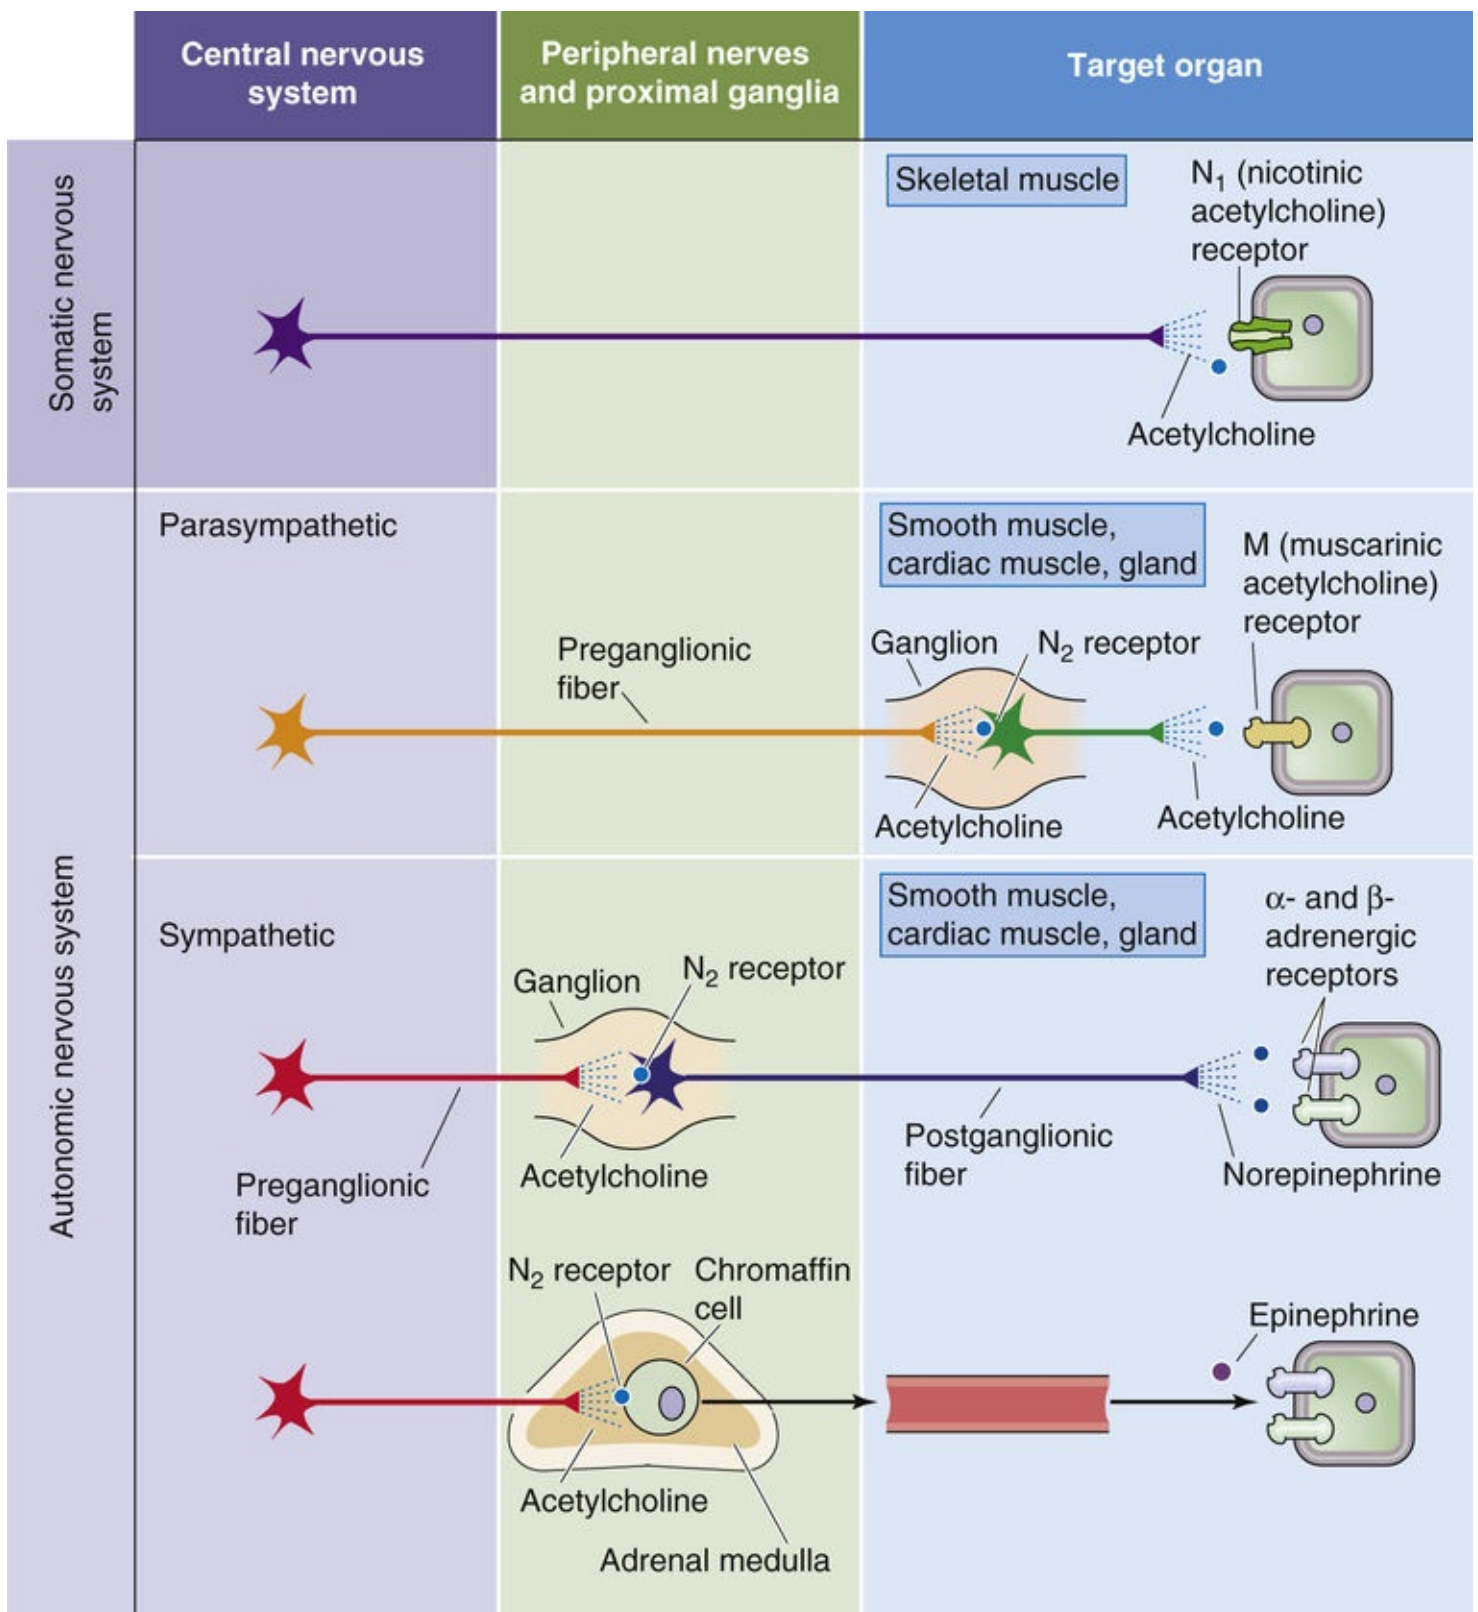

FIGURE 14-8 Major neurotransmitters of the ANS. In the case of the somatic neuron, the pathway between the CNS and effector cell is monosynaptic. The neuron releases ACh, which binds to N_1 -type nicotinic receptors on the postsynaptic membrane (i.e., skeletal muscle cell). In the case of both the parasympathetic and sympathetic divisions, the preganglionic neuron releases ACh, which acts at N_2 -type nicotinic receptors on the postsynaptic membrane of the postganglionic neuron. In the case of the postganglionic parasympathetic neuron, the neurotransmitter is ACh, but the postsynaptic receptor is a muscarinic receptor (i.e., GPCR) of one of five subtypes (M_1 to M_5). In the case of most postganglionic sympathetic neurons, the neurotransmitter is norepinephrine. The postsynaptic receptor is an adrenergic receptor (i.e., GPCR) of one of two major subtypes (α and β).

TABLE 14-2
Signaling Pathways for Nicotinic, Muscarinic, Adrenergic, and Dopaminergic Receptors

RECEPTOR TYPE	AGONISTS*	ANTAGONISTS	G PROTEIN	LINKED ENZYME	SECOND MESSENGER
N ₁ nicotinic ACh	ACh (nicotine, decamethonium)	<i>d</i> -Tubocurarine, α -bungarotoxin	—	—	—
N ₂ nicotinic ACh	ACh (nicotine, TMA)	Hexamethonium	—	—	—
M ₁ /M ₃ /M ₅ muscarinic ACh	ACh (muscarine)	Atropine, pirenzepine (M ₁)	G α_q	PLC	IP ₃ and DAG
M ₂ /M ₄ muscarinic ACh	ACh (muscarine)	Atropine, methoctramine (M ₂)	G α_i and G α_o	Adenylyl cyclase	↓ [cAMP] _i
α_1 adrenergic	NE \geq Epi (phenylephrine)	Phentolamine	G α_q	PLC	IP ₃ and DAG
α_2 adrenergic	NE \geq Epi (clonidine)	Yohimbine	G α_i	Adenylyl cyclase	↓ [cAMP] _i
β_1 adrenergic	Epi > NE (dobutamine, isoproterenol)	Metoprolol	G α_s	Adenylyl cyclase	↑ [cAMP] _i

D2	Dopamine (quinpirole)	Thioridazine	G α_i	Adenylyl cyclase	↓ [cAMP] _i

*Selective agonists are in parentheses.
DAG, diacylglycerol; Epi, epinephrine; NE, norepinephrine; PLC, phospholipase C; TMA, tetramethylammonium.

All postganglionic parasympathetic neurons release ACh and stimulate muscarinic receptors on visceral targets

All postganglionic *parasympathetic* neurons act through muscarinic ACh receptors on the postsynaptic target (see Fig. 14-8). Activation of this receptor can either stimulate or inhibit function of the target cell. Cellular responses induced by muscarinic receptor stimulation are more varied than are those induced by nicotinic receptors. **Muscarinic receptors** are G protein–coupled receptors (GPCRs; see pp. 51–66)—also known as metabotropic receptors—that (1) stimulate the hydrolysis of phosphoinositide and thus increase [Ca²⁺]_i and activate protein kinase C, (2) inhibit adenylyl cyclase and thus decrease cAMP levels, or (3) directly modulate K⁺ channels through the G-protein $\beta\gamma$ complex (see pp. 197–198 and 542). Because they are mediated by second messengers, muscarinic responses, unlike the rapid responses evoked by nicotine receptors, are slow and prolonged.

Muscarinic receptors exist in five different pharmacological subtypes (M₁ to M₅) that are encoded by five different genes. All five subtypes are highly homologous to each other but very different from the nicotinic receptors, which are ligand-gated ion channels. Subtypes M₁ through M₅ are each stimulated by ACh and muscarine and are blocked by atropine. These muscarinic subtypes have a heterogeneous distribution among tissues, and in many cases a given cell may express more than one subtype. 🟡N14-3 Although a wide variety of *antagonists* inhibit the muscarinic receptors, none is completely selective for a specific subtype. However, it is possible to classify a receptor on the basis of its affinity profile for a battery of antagonists. Selective *agonists* for the different isoforms have not been available.

N14-3

Muscarinic Receptors

Contributed by George Richerson

Muscarinic receptors are found both presynaptically and postsynaptically throughout the ANS. Many smooth muscles coexpress multiple muscarinic subtypes, each of which may play a different role in neurotransmission. Thus, it is sometimes difficult to predict the effects of applying ACh to a particular

A molecular characteristic of the muscarinic receptors is that the third cytoplasmic loop (i.e., between the fifth and sixth membrane-spanning segments) is different in M_1 , M_3 , and M_5 on the one hand and M_2 and M_4 on the other. This loop appears to play a role in coupling of the receptor to the G protein downstream in the signal-transduction cascade. In general M_1 , M_3 , and M_5 preferentially couple to $G\alpha_q$ and then to phospholipase C, with release of inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (see p. 58). On the other hand M_2 and M_4 preferentially couple to $G\alpha_i$ or $G\alpha_o$ to inhibit adenylyl cyclase and thus decrease $[cAMP]_i$ (see p. 53).

Most postganglionic sympathetic neurons release norepinephrine onto visceral targets

Most postganglionic sympathetic neurons release **norepinephrine** (see Fig. 14-8), which acts on target cells through adrenergic receptors. The sympathetic innervation of sweat glands is an exception to this rule. **N14-4** Sweat glands are innervated by sympathetic neurons that release ACh and act via muscarinic receptors (see p. 571). The adrenergic receptors are all GPCRs and are highly homologous to the muscarinic receptors (see p. 341). Two major types of adrenergic receptors are recognized, α and β , each of which exists in multiple subtypes (e.g., α_1 , α_2 , β_1 , β_2 , and β_3). In addition, there are heterogeneous α_1 and α_2 receptors, with three cloned subtypes of each. Table 14-2 lists the signaling pathways that are generally linked to these receptors. For example, β_1 receptors in the heart activate the G_s heterotrimeric G protein and stimulate adenylyl cyclase, which antagonizes the effects of muscarinic receptors.

N14-4

Cholinergic Sympathetic Neurons

Contributed by Emile Boulpaep, Walter Boron

From a macroscopic anatomical point of view, there is no doubt that the cholinergic sympathetic nerve endings of **sudomotor nerves** (i.e., the nerves that cause sweat secretion) and some vasomotor nerves are distal to the sympathetic ganglia. In this sense, these fibers are clearly “*postganglionic*.” Indeed, these rare cholinergic sympathetic fibers run together from the sympathetic ganglion to the target organ together with the majority of adrenergic fibers.

From a physiological point of view, all of the sympathetic neurons that reach the adrenal medulla (see p. 343) are “*preganglionic*.” That is, these fibers derive from neuron cell bodies that lie in the intermediolateral cell column of the spinal cord. Their axons then transit through the paravertebral ganglia of the sympathetic trunk (see the left side of Fig. 14-4) without synapsing, and then follow along the splanchnic nerves. Most of these axons then go directly to the adrenal medulla, where they synapse on their targets, the *chromaffin cells*. However, some axons transit through the **celiac ganglion**—again without synapsing—before reaching their target chromaffin cells in the adrenal medulla. Thus, all sympathetic fibers that synapse on chromaffin cells are physiologically “*preganglionic*”: a single neuron carries information from the spinal cord to the target cell. However, the sympathetic neurons that traverse the celiac ganglion before reaching the adrenal medulla could—from a macroscopic anatomical point of

view—be regarded as *postganglionic*.

Authors in the 1960s and 1970s suggested that cholinergic sympathetic fibers that innervate the sweat glands (see pp. 342 and 571) and some of the vascular smooth muscle in skeletal muscle (see p. 539) derive from neuronal cell bodies in the spinal cord. This situation would be analogous to that of the cholinergic sympathetic innervation of the adrenal medulla. If this were true, then one could regard these cholinergic sympathetic sudomotor/vasomotor fibers—physiologically—as being “preganglionic.” However, more recent experiments suggest that these cholinergic sympathetic fibers can arise from neuron cell bodies located in sympathetic ganglia and that these neurons develop from neural crest cells (see p. 261). Using antibodies directed against **choline acetyltransferase** (i.e., the enzyme that catalyzes the conversion of acetyl coenzyme A and choline into ACh; see Fig. 13-8B and p. 210) and the **vesicular ACh transporter** (VAChT, which transports ACh from the cytoplasm of the nerve terminal into the synaptic vesicles; see Fig. 8-15), Schäfer and colleagues demonstrated that VAChT-positive “principal ganglionic cells” (i.e., postganglionic neurons) are present in *paravertebral sympathetic ganglia* at all levels of the thoracolumbar paravertebral chain. These observations are consistent with the idea that sudomotor nerve fibers and some vasomotor nerve fibers (e.g., skeletal microvasculature) are **cholinergic postganglionic sympathetic neurons**. These authors also demonstrated VAChT-positive principal ganglionic cells in two other sympathetic ganglia: the stellate and superior cervical ganglia.

Schäfer and colleagues also studied the developmental biology of postganglionic sympathetic neurons. They found that a small minority of sympathetic neurons have a cholinergic phenotype even during early embryonic development—before the neurons innervate sweat glands.

Thus, a true postganglionic sympathetic neuron—postganglionic in both the gross anatomical and the physiological sense of the word—can be cholinergic. In other words, a preganglionic sympathetic “first” neuron, with its cell body in the intermediolateral column, may synapse in a sympathetic ganglion with a postganglionic sympathetic “second” neuron that releases ACh at its nerve terminals. Thus, it is no longer necessary to assume that cholinergic sympathetic sudomotor/vasomotor neurons are, in fact, preganglionic fibers that traversed the sympathetic ganglion without synapsing.

Adrenergic receptor subtypes have a tissue-specific distribution. α_1 receptors predominate on blood vessels, α_2 on presynaptic terminals, β_1 in the heart, β_2 in high concentration in the bronchial muscle of the lungs, and β_3 in fat cells. This distribution has permitted the development of many clinically useful agents that are selective for different subtypes and tissues. For example, α_1 agonists are effective as nasal decongestants, and α_2 antagonists have been used to treat impotence. β_1 agonists increase cardiac output in congestive heart failure, whereas β_1 antagonists are useful antihypertensive agents. β_2 agonists are used as bronchodilators in patients with asthma and chronic lung disease.

The adrenal medulla (see pp. 1030–1034) is a special adaptation of the sympathetic division, homologous to a postganglionic sympathetic neuron (see Fig. 14-8). It is innervated by preganglionic

sympathetic neurons, and the postsynaptic target cells, which are called **chromaffin cells**, have nicotinic ACh receptors. However, rather than possessing axons that release norepinephrine onto a specific target organ, the chromaffin cells reside near blood vessels and release **epinephrine** into the bloodstream. This neuroendocrine component of sympathetic output enhances the ability of the sympathetic division to broadcast its output throughout the body. Norepinephrine and epinephrine both activate all five subtypes of adrenergic receptor, but with different affinities (see [Table 14-2](#)). In general, the α receptors have a greater affinity for norepinephrine, whereas the β receptors have a greater affinity for epinephrine.

Postganglionic sympathetic and parasympathetic neurons often have muscarinic as well as nicotinic receptors

The simplified scheme described in the preceding discussion is very useful for understanding the function of the ANS. However, two additional layers of complexity are superimposed on this scheme. First, some postganglionic neurons, both sympathetic and parasympathetic, have *muscarinic* in addition to nicotinic receptors. Second, at all levels of the ANS, certain neurotransmitters and postsynaptic receptors are neither cholinergic nor adrenergic. We discuss the first exception in this section and the second in the following section.

If we stimulate the release of ACh from preganglionic neurons or apply ACh to an autonomic ganglion, many postganglionic neurons exhibit both nicotinic and muscarinic responses. Because *nicotinic receptors* (N_2) are ligand-gated ion channels, nicotinic neurotransmission causes a fast, monophasic excitatory postsynaptic potential (EPSP). In contrast, because *muscarinic receptors* are GPCRs, neurotransmission by this route leads to a slower electrical response that can be either inhibitory or excitatory. Thus, depending on the ganglion, the result is a multiphasic postsynaptic response that can be a combination of a fast EPSP through a nicotinic receptor plus either a slow EPSP or a slow inhibitory postsynaptic potential (IPSP) through a muscarinic receptor. [Figure 14-9A](#) shows a fast EPSP followed by a slow EPSP.

A FAST AND SLOW EPSPs

B M CURRENT PRESENT

C M CURRENT INHIBITED BY MUSCARINE

FIGURE 14-9 An example of dual nicotinic and muscarinic neurotransmission between sympathetic preganglionic and postganglionic neurons. **A**, Stimulation of a frog preganglionic sympathetic neuron releases ACh, which triggers a fast EPSP (due to activation of *nicotinic* receptors on the postganglionic sympathetic neuron), followed by a slow EPSP (due to activation of *muscarinic* receptors on the postganglionic neuron). **B**, In a rat sympathetic postganglionic neuron, the M current (mediated by a K^+ channel) is normally active, hyperpolarizing the neuron. Thus, injecting current elicits only a single action potential. **C**, In the same experiment as in **B**, adding muscarine stimulates a muscarinic receptor (i.e., GPCR) and triggers a signal-transduction cascade that blocks the M current. One result is a steady-state depolarization of the cell. Injecting current now elicits a train of action potentials. (A, Data from Adams PR, Brown DA: Synaptic inhibition of the M-current: Slow excitatory post-synaptic potential mechanism in bullfrog sympathetic neurones. *J Physiol* 332:263–272, 1982; B and C, data from Brown DA, Constanti A: Intracellular observations on the effects of muscarinic agonists on rat sympathetic neurones. *Br J Pharmacol* 70:593–608, 1980.)

A well-characterized effect of muscarinic neurotransmission in autonomic ganglia is inhibition of a specific K^+ current called the **M current**. The M current is widely distributed in visceral end organs,

autonomic ganglia, and the CNS. In the baseline state, the K^+ channel that underlies the M current is active and thereby produces slight hyperpolarization. In the example shown in [Figure 14-9B](#), with the stabilizing M current present, electrical stimulation of the neuron causes only a single spike. If we now add muscarine to the neuron, activation of the muscarinic receptor turns off the hyperpolarizing M current and thus leads to a small depolarization. If we repeat the electrical stimulation in the continued presence of muscarine (see [Fig. 14-9C](#)), repetitive spikes appear because loss of the stabilizing influence of the M current increases the excitability of the neuron. The slow, modulatory effects of muscarinic responses greatly enhance the ability of the ANS to control visceral activity beyond what could be accomplished with only fast nicotinic EPSPs.

Nonclassic transmitters can be released at each level of the ANS

In the 1930s, Sir Henry Dale [N14-5](#) first proposed that sympathetic nerves release a transmitter similar to epinephrine (now known to be norepinephrine) and parasympathetic nerves release ACh. For many years, attention was focused on these two neurotransmitters, primarily because they mediate large and fast postsynaptic responses that can be easily studied. In addition, a variety of antagonists are available to block cholinergic and adrenergic receptors and thereby permit clear characterization of the roles of these receptors in the control of visceral function. More recently, it has become evident that some neurotransmission in the ANS involves neither adrenergic nor cholinergic pathways. Moreover, many neuronal synapses use more than a single neurotransmitter. Such **cotransmission** is now known to be common in the ANS. As many as eight different neurotransmitters may be found within some neurons, a phenomenon known as **colocalization** (see [Table 13-1](#)). Thus, ACh and norepinephrine play important but not exclusive roles in autonomic control.

N14-5

Sir Henry H. Dale

For more information about Sir Henry H. Dale and the work that led to his Nobel Prize, visit <http://www.nobel.se/medicine/laureates/1936/index.html> (accessed October 2014).

The distribution and function of **nonadrenergic, noncholinergic (NANC) transmitters** are only partially understood. However, these transmitters are found at every level of autonomic control ([Table 14-3](#)), where they can cause a wide range of postsynaptic responses. These nonclassic transmitters may cause slow synaptic potentials or may modulate the response to other inputs (as in the case of the M current) without having obvious direct effects. In other cases, nonclassic transmitters have no known effects and may be acting in ways that have not yet been determined.

ATP			X			X

Although colocalization of neurotransmitters is recognized as a common property of neurons, it is not clear what controls the release of each of the many neurotransmitters. In some cases, the proportion of neurotransmitters released depends on the level of neuronal activity (see pp. 327–328). For example, medullary raphe neurons project to the intermediolateral cell column in the spinal cord, where they co-release serotonin, thyrotropin-releasing hormone, and substance P onto sympathetic preganglionic neurons. The proportions of released neurotransmitters are controlled by neuronal firing frequency: at low firing rates, serotonin is released alone; at intermediate firing rates, thyrotropin-releasing hormone is also released; and at high firing rates, all three neurotransmitters are released. This frequency-dependent modulation of synaptic transmission provides a mechanism for enhancing the versatility of the ANS.

Two of the most unusual nonclassic neurotransmitters, ATP and nitric oxide, were first identified in the ANS

It was not until the 1970s that a nonadrenergic, noncholinergic class of *sympathetic* or *parasympathetic* neurons was first proposed by Geoffrey Burnstock and colleagues, who suggested that ATP might act as the neurotransmitter. This idea, that a molecule used as an intracellular energy substrate could also be a synaptic transmitter, was initially difficult to prove. However, it is now clear that neurons use a variety of classes of molecules for intercellular communication (see pp. 314–322). Two of the most surprising examples of nonclassic transmitters, nitric oxide (NO) and ATP, were first identified and studied as neurotransmitters in the ANS, but they are now known to be more widely used throughout the nervous system.

ATP

ATP is colocalized with norepinephrine in postganglionic sympathetic vasoconstrictor neurons. It is contained in synaptic vesicles, is released on electrical stimulation, and induces vascular constriction when it is applied directly to vascular smooth muscle. The effect of ATP results from activation of P₂ **purinoceptors** on smooth muscle, which include ligand-gated ion channels (P2X) and GPCRs (P2Y and P2U). P2X receptors are present on autonomic neurons and smooth-muscle cells of blood vessels, the urinary bladder, and other visceral targets. P2X receptor channels have a relatively high Ca²⁺ permeability (see [p. 327](#)). In smooth muscle, ATP-induced depolarization can also activate voltage-gated Ca²⁺ channels (see [pp. 189–190](#)) and thus lead to an elevation in [Ca²⁺]_i and a rapid phase of contraction ([Fig. 14-10](#)). Norepinephrine, by binding to α₁ adrenergic receptors, acts through a heterotrimeric G protein (see [pp. 51–66](#)) to facilitate the release of Ca²⁺ from intracellular stores and thereby produce a slower phase of contraction. Finally, the release of neuropeptide Y may, after prolonged and intense stimulation, elicit a third component of contraction.

FIGURE 14-10 Cotransmission with ATP, norepinephrine, and neuropeptide Y in the ANS. In this example, stimulation of a postganglionic sympathetic neuron causes three phases of contraction of a vascular smooth-muscle cell. Each phase corresponds to the response of the postsynaptic cell to a different neurotransmitter or group of transmitters. In phase 1, ATP binds to a P2X purinoceptor (a ligand-gated cation channel) on the smooth-muscle cell, which leads to depolarization, activation of voltage-gated Ca^{2+} channels, increased $[\text{Ca}^{2+}]_i$, and the rapid phase of contraction. In phase 2, norepinephrine, acting through an α_1 adrenergic receptor and a G_q /PLC/ IP_3 cascade, leads to Ca^{2+} release from internal stores and the second phase of contraction. In phase 3, when neuropeptide Y is present, it acts through a Y1 receptor to somehow cause an increase in $[\text{Ca}^{2+}]_i$ and thus produces the slowest phase of contraction. ER, endoplasmic reticulum; PLC, phospholipase C.

Nitric Oxide

In the 1970s, it was also discovered that the vascular endothelium produces a substance that induces relaxation of vascular smooth muscle. First called endothelium-derived relaxation factor, it was identified as the free radical NO in 1987. NO is an unusual molecule for intercellular communication because it is a short-lived gas. It is produced locally from L-arginine by the enzyme nitric oxide synthase (NOS; see pp. 66–67). The NO then diffuses a short distance to a neighboring cell, where its effects are primarily mediated by the activation of guanylyl cyclase.

NOS is found in the preganglionic and postganglionic neurons of both the sympathetic and parasympathetic divisions as well as in vascular endothelial cells. It is not specific for any type of neuron inasmuch as it is found in both norepinephrine- and ACh-containing cells as well as neurons containing a variety of neuropeptides. Figure 14-11 shows how a parasympathetic neuron may simultaneously release NO, ACh, and vasoactive intestinal peptide, each acting in concert to lower $[\text{Ca}^{2+}]_i$ and relax vascular

smooth muscle.

FIGURE 14-11 Action of NO in the ANS. Stimulation of a postganglionic parasympathetic neuron can cause more than one phase of relaxation of a vascular smooth-muscle cell, corresponding to the release of a different neurotransmitter or group of transmitters. The first phase in this example is mediated by both NO and ACh. The neuron releases NO, which diffuses to the smooth-muscle cell. In addition, ACh binds to M₃ muscarinic receptors (i.e., GPCRs) on endothelial cells; this leads to production of NO, which also diffuses to the smooth-muscle cell. Both sources of NO activate guanylyl cyclase (GC) and raise [cGMP]_i in the smooth muscle cell and contribute to the first phase of relaxation. In the second phase, which tends to occur more with prolonged or intense stimulation, the neuropeptide VIP (or a related peptide) binds to receptors on the smooth-muscle cell and causes delayed relaxation through an increase in [cAMP]_i or a decrease in [Ca²⁺]_i.

Central Nervous System Control of the Viscera

Sympathetic output can be massive and nonspecific, as in the fight-or-flight response, or selective for specific target organs

In 1915, Walter Cannon  **N14-6** proposed that the entire sympathetic division is activated together and has a uniform effect on all target organs. In response to fear, exercise, and other types of stress, the sympathetic division produces a massive and coordinated output to all end organs simultaneously, and parasympathetic output ceases. This type of sympathetic output is used to ready the body for life-threatening situations—the so-called **fight-or-flight** response. Thus, when a person is presented with a fearful or menacing stimulus, the sympathetic division coordinates all body functions to respond appropriately to the stressful situation. This response includes increases in heart rate, cardiac contractility, blood pressure, and ventilation of the lungs; bronchial dilatation; sweating; piloerection; liberation of glucose into the blood; inhibition of insulin secretion; reduction in blood clotting time; mobilization of blood cells by contraction of the spleen; and decreased GI activity. This mass response is a primitive mechanism for survival. In some people, such a response can be triggered spontaneously or with minimal provocation; each individual episode is then called a panic attack.

N14-6

Walter B. Cannon

For more information about Walter B. Cannon, visit <http://www.the-aps.org/fm/presidents/introwbc.html> (accessed August 2015).

The fight-or-flight response is an important mechanism for survival, but under normal nonstressful conditions, output of the sympathetic division can also be more discrete and organ specific. In contrast to Cannon's original proposal, the sympathetic division does not actually produce uniform effects on all visceral targets. Different postganglionic sympathetic neurons have different electrophysiological properties and release other neurotransmitters in addition to norepinephrine. This specific distribution of neuroactive chemicals among neurons is called chemical coding. For example, depolarization of guinea pig postganglionic sympathetic neurons in the *lumbar* sympathetic chain ganglia causes a *brief* burst of action potentials in 95% of the neurons and release of norepinephrine together with ATP and neuropeptide Y. These neurons are thought to innervate arteries and to induce vasoconstriction (see [Fig. 14-10](#)). In contrast, depolarization of postganglionic sympathetic neurons in the *inferior mesenteric ganglion* causes sustained firing in 80% of the neurons and release of norepinephrine together with somatostatin. These neurons appear to control gut motility and secretion. Thus, sympathetic neurons have cellular properties that are substantially variable. This variability permits the sympathetic division to produce different effects on targets with different functions.

Parasympathetic neurons participate in many simple involuntary reflexes

As opposed to neurons in the sympathetic division, neurons in the parasympathetic division function only in a discrete, organ-specific, and reflexive manner. Together with specific visceral afferents and a small number of interneurons, parasympathetic neurons mediate simple reflexes involving target organs. For example, the output of the baroreceptor reflex (see pp. 537–539) is mediated by preganglionic parasympathetic neurons in the dorsal motor nucleus of the vagus. Other examples include urination in response to bladder distention (see pp. 736–737); salivation in response to the sight or smell of food (see p. 895); vagovagal reflexes (see p. 857) in the GI tract, such as contraction of the colon in response to food in the stomach; and bronchoconstriction in response to activation of receptors in the lungs (see pp. 717–718). The pupillary light reflex is an example of an involuntary parasympathetic reflex that can be tested at the bedside (see p. 362).

A variety of brainstem nuclei provide basic control of the ANS

In addition to nuclei that contain parasympathetic preganglionic neurons (see Fig. 14-5), a variety of other brainstem structures are also involved in visceral control. These structures include the nucleus tractus solitarius, area postrema, ventrolateral medulla, medullary raphe, reticular formation, locus coeruleus, and parabrachial nucleus. These nuclei within the lower part of the brainstem mediate autonomic reflexes, control specific autonomic functions, or modulate the general level of autonomic tone. In some cases, these nuclei play a well-defined role in one specific autonomic function. For example, stimulation of a group of neurons in the rostral portion of the ventrolateral medulla increases sympathetic output to the cardiovascular system—without affecting respiration or sympathetic output to other targets. In other cases, these nuclei are linked to more than one autonomic function. For example, the medullary raphe contains serotonergic neurons that project to cardiovascular, respiratory, and GI neurons, the reticular activating system, and pain pathways. Therefore, these neurons can affect the background level of autonomic tone. The specific functions of some nuclei are not known, and their involvement in autonomic control is inferred from their anatomical connections, a correlation between neuron activity and activity in autonomic nerves, or the effect of lesions.

One of the most important lower brainstem structures is the **nucleus tractus solitarius (NTS)** in the medulla. The NTS contains second-order sensory neurons that receive all input from peripheral chemoreceptors (see pp. 710–713) and baroreceptors input (see p. 537), as well as non-nociceptive afferent input from every organ of the thorax and abdomen. Visceral afferents from the vagus nerve make their first synapse within the NTS, where they combine with other visceral (largely unconscious) afferent impulses derived from the glossopharyngeal (CN IX), facial (CN VII), and trigeminal (CN V) nerves. These visceral afferents form a large bundle of nerve fibers—the **tractus solitarius**—that the NTS surrounds. Afferent input is distributed to the NTS in a viscerotopic manner, with major subnuclei devoted to respiratory, cardiovascular, gustatory, and GI input. The NTS also receives input and sends output to many other CNS regions (Table 14-4), including the brainstem nuclei described above as well as the hypothalamus and the forebrain. These widespread interconnections allow the NTS to influence and to be influenced by a wide variety of CNS functions. Thus, the NTS is the major lower brainstem command center for visceral control. It integrates multiple inputs from visceral afferents and exerts control over autonomic output, thereby participating in autonomic reflexes that maintain the homeostasis of many basic visceral functions.

TABLE 14-4**Connections to and from the Nucleus Tractus Solitarii****Receives Input from**

Vagus nerve (peripheral chemoreceptor/aortic bodies and aortic baroreceptor, as well as non-nociceptive afferent input from every organ of the thorax and abdomen)

Glossopharyngeal nerve (taste and peripheral chemoreceptors/carotid bodies, carotid baroreceptor)

Facial nerve (taste)

Ventrolateral medulla

Medullary raphé

Area postrema

Periaqueductal gray substance

Parabrachial nucleus

Hypothalamus

Cerebral cortex

Sends Output to

Intermediolateral cell column (preganglionic sympathetic neurons) and sacral parasympathetic neurons

Phrenic motor nucleus and other respiratory output pathways

Dorsal motor nucleus of the vagus (preganglionic parasympathetic neurons from the vagus nerve)

Nucleus ambiguus (preganglionic parasympathetic neurons from the vagus nerve)

Ventrolateral medulla

Medullary raphé

Area postrema

Parabrachial nuclei

Reticular formation

Forebrain nuclei

Hypothalamus

The forebrain can modulate autonomic output, and reciprocally, visceral sensory input integrated in the brainstem can influence or even overwhelm the forebrain

Only a subset of the nervous system is necessary to maintain autonomic body homeostasis under most conditions. The necessary structures include (1) the brainstem nuclei discussed in the preceding section, (2) the brainstem nuclei that contain the parasympathetic preganglionic neurons, (3) the spinal cord, and (4) the peripheral ANS. These components are capable of acting autonomously, even without input from higher (i.e., rostral) forebrain regions. However, forebrain regions do play a role in coordinating and

modulating activity in the lower centers. Many rostral CNS centers influence autonomic output; these centers include the hypothalamus, amygdala, prefrontal cortex, entorhinal cortex, insula, and other forebrain nuclei.

The **hypothalamus**, especially the paraventricular nucleus, is the most important brain region for coordination of autonomic output. The hypothalamus projects to the parabrachial nucleus, medullary raphé, NTS, central gray matter, locus coeruleus, dorsal motor nucleus of the vagus, nucleus ambiguus, and intermediolateral cell column of the spinal cord. Thus, the hypothalamus can initiate and coordinate an integrated response to the body's needs, including modulation of autonomic output as well as control of neuroendocrine function by the pituitary gland (see [p. 978](#)). The hypothalamus coordinates autonomic function with feeding, thermoregulation, circadian rhythms, water balance, emotions, sexual drive, reproduction, motivation, and other brain functions and thus plays a dominant role in the integration of higher cortical and limbic systems with autonomic control. The hypothalamus can also initiate the fight-or-flight response. 🧠 [N14-7](#)

N14-7

Fight-or-Flight Response

Contributed by Emile Boulpaep, Walter Boron

Walter B. Cannon 🧠 [N14-6](#) described the fight-or-flight response for the first time in 1929.

Reference

Cannon W. *Bodily Changes in Pain, Hunger, Fear, and Rage*. Appleton: New York; 1929.

The hypothalamus often mediates interactions between the forebrain and the brainstem. However, a number of forebrain regions also have direct connections to brainstem nuclei involved in autonomic control. Most of these forebrain regions are part of the **limbic system** rather than the neocortex. The paucity of direct neocortical connections probably explains why individuals trained to control autonomic output by biofeedback can generally produce only relatively minor effects on overall autonomic activity rather than regulate output to specific organs. Most individuals are incapable of even limited cortical control over the ANS. However, even though we may have only minimal *conscious* control of autonomic output, cortical processes can strongly modulate the ANS. Emotions, mood, anxiety, stress, and fear can all alter autonomic output ([Table 14-5, top](#) section). The pathways for these effects are unknown, but they could be mediated by direct connections or through the hypothalamus.

TABLE 14-5

Interactions Between Cortical and Autonomic Function

Examples of Descending Cortical Control of Autonomic Output

Fear—initiates fight-or-flight response

Panic attacks—initiate activation of sympathetic division, increased breathing, and feeling of suffocation

Emotional stress (e.g., first day in gross anatomy lab) or painful stimuli—lead to massive vasodilation and hypotension, i.e., vasovagal syncope (fainting)

Seizures—can induce sudden cardiac death from massive sympathetic output and arrhythmias or sudden respiratory death from apnea

Chronic stress—can lead to peptic ulcers from increased gastric acid secretion

Sleep deprivation—in rats leads to death from loss of thermoregulation and cardiovascular control

Cognitive activity—can initiate sexual arousal

Nervousness (e.g., before an exam) can lead to diarrhea

Examples in Which Visceral Afferents Overwhelm Cortical Function (i.e., Nothing Else Seems to Matter)

Hunger

Nausea

Dyspnea

Visceral pain

Bladder and bowel distention

Hypothermia/hyperthermia

Not only does forebrain function influence the ANS, visceral activity also influences forebrain function. Visceral afferents reach the neocortex. However, because these afferents are not represented viscerotopically, they cannot be well localized. Nevertheless, visceral afferents can have profound effects on cortical function. Visceral input can modulate the excitability of cortical neurons ([Box 14-2](#)) and, in some cases, can result in such overpowering sensory stimuli that it is not possible to focus cortical activity on anything else (see [Table 14-5](#), bottom section).

Box 14-2

Vagus Nerve Stimulation in the Treatment of Epilepsy

It is often not appreciated just how much effect the ANS can have on cortical function. Table 14-5 (bottom section) lists several examples in which strong input from visceral afferents can overwhelm cortical function to the point that concentrating on anything else is nearly impossible. As we have already noted, not only does the vagus nerve contain parasympathetic preganglionic *motor* fibers, it also contains a wide variety of *sensory* fibers from viscera in the thorax and abdomen. Discovery of the influence of vagal afferent input on seizures has led to development of the vagus nerve stimulator, which is used clinically. The surgically implanted device electrically stimulates the vagus nerve for 30 seconds every 5 minutes, 24 hours per day. In addition, when patients feel a seizure coming on (an aura), they can activate the device with a hand-held magnet to deliver extra pulses. Clinical studies have shown that this treatment reduces the number of seizures by about half in about one in four patients. It remains to be determined whether a subgroup of patients may be particularly responsive to this treatment. Side effects include hoarseness, coughing, and breathlessness. That this approach works at all indicates how important visceral input is to cortical function. Vagal input can influence many rostral brain structures, but it is not yet clear whether stimulation of peripheral chemoreceptor afferents, pulmonary afferents, or

other visceral afferent pathways is important for the anticonvulsant effect. If the specific pathways could be identified, it might be possible to selectively stimulate these pathways or to activate them pharmacologically to produce an anticonvulsant effect with fewer side effects.

CNS control centers oversee visceral feedback loops and orchestrate a feed-forward response to meet anticipated needs

The ANS maintains physiological parameters within an optimal range by means of **feedback loops** made up of sensors, afferent fibers, central autonomic control centers (discussed in the preceding section), and effector systems. These feedback loops achieve homeostasis by monitoring input from visceral receptors and adjusting the output of both the sympathetic and parasympathetic divisions to specific organs so that they maintain activity at a set-point determined by involuntary CNS control centers. As we have already noted, the sympathetic and parasympathetic divisions usually act in opposite ways to make these adjustments. Blood pressure control is an example of a visceral feedback loop in which the CNS monitors current blood pressure through afferents from baroreceptors, compares it with an internally determined set-point, and appropriately adjusts output to the heart, blood vessels, adrenal gland, and other targets. An increase in blood pressure (see [pp. 537–539](#)) causes a reflex decrease in sympathetic output to the heart and an increase in parasympathetic output.

Instead of merely responding through feedback loops, the ANS also anticipates the future needs of the individual. For example, when a person begins to exercise, sympathetic output increases before the increase in metabolic need to prevent an exercise debt from occurring (see [p. 1214](#)). Because of this anticipatory response, alveolar ventilation rises to such an extent that blood levels of CO₂ (a byproduct of exercise) actually drop at the onset of exercise. This response is the opposite of what would be expected if the ANS worked purely through feedback loops, in which case an obligatory increase in CO₂ levels would have preceded the increase in respiratory output (see [pp. 716–717](#)). Similarly, a trained athlete's heart rate begins to increase several seconds before the starting gun fires to signal the beginning of a 100-m dash. This anticipation of future activity, or **feed-forward** stimulation prior to (and during) exercise, is a key component of the regulation of homeostasis during stress because it prevents large changes in physiological parameters that could be detrimental to optimal function. This type of response probably resulted in an evolutionary advantage that permitted the body to respond rapidly and more efficiently to a threat of danger. A system relying solely on feedback could produce a response that is delayed or out of phase with respect to the stimulus. The central neuronal pathways responsible for this anticipatory or feed-forward response are not known.

The ANS has multiple levels of reflex loops

The human nervous system is built in a hierarchy that mirrors phylogenetic evolution (see [pp. 269–274](#)). Each of the successively more primitive components is capable of independent, organized, and adaptive behavior. In turn, the activity of each of the more primitive levels is modulated by rostral, more phylogenetically advanced components. 🍷 [N14-8](#)

Hierarchical Reflex Loops in the ANS

Contributed by George Richerson

EFigure 14-1 At the lowest level, the ENS is an independent system consisting of afferent neurons, interneurons, and motor neurons. One level up, the autonomic ganglia control the autonomic end organs, including the ENS. One further level up, the spinal cord controls certain autonomic ganglia and integrates response among different spinal cord levels. The brainstem receives inputs from visceral afferents and coordinates the control of all viscera. Finally, forebrain CNS centers receive input from the brainstem and coordinate the activity of the ANS via input to the brainstem.

The **enteric nervous system** of humans is homologous to the most primitive nervous system, the neural net of jellyfish. In both cases, the component neurons control motility and nutrient absorption and respond appropriately to external stimuli.

The **autonomic ganglia** are homologous to ganglionic nervous systems, such as those of annelid worms. Autonomic ganglia were previously considered a simple relay station for signals from the CNS to the periphery, but it is now clear that they integrate afferent input from the viscera and have substantial independent control mechanisms. The largest of the sympathetic ganglia, the superior cervical ganglion, contains about 1 million neurons. In addition to postganglionic cell bodies, autonomic ganglia also contain interneurons. Axons from interneurons, sensory receptors located in the end organs, and preganglionic neurons converge with postganglionic neuron dendrites to form a dense network of nerve fibers, or a **neuropil**, within the ganglion. This neuropil confers considerable computational capability on the ganglia. Whereas feedback from skeletal muscle occurs only in the CNS, the peripheral synapses of visceral afferents result in substantial integration of autonomic activity at peripheral sites. This integration is enhanced by the variety of neurotransmitters released, for example, by interneurons in autonomic ganglia (see [Table 14-3](#)). Thus, although fast neurotransmission from preganglionic neurons to postganglionic neurons is an important role of the autonomic ganglia, the ganglia are not simply relays.

The **spinal cord**, which coordinates activity among different root levels, first appeared with the evolution of chordates. The CNS of amphioxus, a primitive chordate, is essentially just a spinal cord. In humans who experience transection of the low cervical spinal cord—and in whom the outflow of the respiratory system is spared (see [Chapter 32](#))—the caudal spinal cord and lower autonomic ganglia can still continue to maintain homeostasis. However, these individuals are incapable of more complex responses that require reflexes mediated by the cranial nerve afferents and cranial parasympathetic outflow. In many patients, this situation can lead to maladaptive reflexes such as autonomic hyperreflexia, in which a full bladder results in hypertension and sweating ([Boxes 14-3 and 14-4](#)).

Box 14-3

Crosstalk between Autonomic Functions Can be Pathological

Visceral control of each of the body's organs occurs relatively independently of control of the others. However, some overlap in control systems can be noted for different components of the ANS. For example, stimulation of the baroreceptors causes inhibition of respiration. Conversely, the decrease in thoracic pressure that occurs during inspiration normally triggers a reflex decrease in heart rate. Many neurons in the brainstem and spinal cord have a firing pattern that is modulated in time with both the heartbeat and respiratory activity. This spillover may be responsible for the frequent observation of **sinus arrhythmia** on electrocardiograms of normal patients, in whom the heart rate is irregular because of an exaggeration of the normal influence of respiration on heart rate. These phenomena have no clear

evolutionary advantage. Instead, they may simply be due to an error in separating closely related physiological control mechanisms.

In some cases, overlap between physiological control mechanisms can have serious consequences. For example, control of micturition overlaps with cardiorespiratory control. An increase in bladder pressure can lead to apnea and hypertension. Conversely, each breath is accompanied by an increase in neural outflow to the bladder. In patients with obstruction of urinary outflow, as can be seen in men with enlarged prostates, the bladder can become severely distended. If this obstruction is relieved suddenly by insertion of a catheter and the bladder is drained too rapidly, blood pressure can drop precipitously. In extreme cases, the hypotension causes syncope (fainting) or a stroke. A similar phenomenon can occur in some people with less provocation. During emptying of a relatively full bladder, blood pressure can drop precipitously and lead to **postmicturition syncope**, with the patient suddenly falling unconscious on the bathroom floor.

Box 14-4

Horner Syndrome

One of the keys to neurological diagnosis has always been neuroanatomical localization (Fig. 14-12). A classic condition in which it is important to define neuroanatomy is **Horner syndrome**: the combination of unilateral **ptosis** (drooping eyelid), **miosis** (small pupil), and **anhidrosis** (lack of sweating). Sympathetic neurons innervate the *smooth muscle* that elevates the eyelid (superior tarsal muscle), the pupillary dilator muscle, and the sweat glands of the face. Horner syndrome results from loss of the normal sympathetic innervation on one side of the face. The differential diagnosis for this syndrome is large, but it can be narrowed if the site of involvement of the sympathetic pathways can be identified. Involvement of *first-order sympathetic neurons* can occur at their cell bodies in the hypothalamus or along their axons traveling down to the ipsilateral intermediolateral column of the spinal cord. Thus, a first-order Horner syndrome can be due to ischemia of the lateral medulla (e.g., occlusion of the posterior inferior cerebellar artery, so-called Wallenberg syndrome). In this case, other brainstem abnormalities will also be present. The *second-order sympathetic neurons*, or *preganglionic neurons*, can be affected at their origin in the intermediolateral column or along their axons. Those that supply the eye synapse in the superior cervical ganglion. A second-order Horner syndrome can be the first sign that a Pancoast tumor exists in the apex of the lung and is encroaching on the sympathetic nerves as they travel to the superior cervical ganglion. Finally, *third-order sympathetic neurons*, or *postganglionic neurons*, can be involved at the ganglion or along their course to the eye. Because they travel within the wall of the carotid artery, these sympathetic nerves can be damaged during a carotid artery “dissection.” Dissection is separation of the layers of the wall of the artery, often caused by a neck injury. In time, the damage to the vessel can lead to a blood clot that will obstruct blood flow. Thus, a Horner syndrome can be a warning that, without treatment, a stroke may be imminent. The key to proper diagnosis is to determine what nearby structures may be involved (the company that it keeps). Two pharmacological tests can also be administered. A dilute 2% to 10% cocaine solution blocks norepinephrine re-uptake into synaptic terminals so that the buildup of norepinephrine near the pupillary dilator muscle will dilate the pupil in a healthy person. Cocaine treatment will have less effect on the pupil of a patient with Horner syndrome regardless of where the lesion is because less norepinephrine is in the synaptic cleft. To determine if the Horner syndrome is postganglionic, a solution containing hydroxyamphetamine (Paredrine) can then be given. This drug will cause release of norepinephrine from synaptic terminals if they are present, so it will not cause pupillary dilation in a patient with a third-order Horner syndrome. A combination of a

Careful neurological examination with these tests will usually allow one to determine where in the sympathetic pathways damage has occurred, thus narrowing the differential diagnosis.

FIGURE 14-12 Anatomy of the sympathetic innervation to the eyelid, pupil, and facial sweat glands relevant in Horner syndrome. The diagram shows the three segments of this pathway: (1) A neuron with its cell body in the hypothalamus sends its axon down the intermediolateral column in the spinal cord (first-order neuron). (2) A preganglionic sympathetic neuron with its cell body in the intermediolateral column gets synaptic input from (1) and sends an axon to the superior cervical ganglion (second-order neuron). (3) A postganglionic sympathetic neuron with its cell body in the superior cervical ganglion sends axons to the superior tarsal (smooth) muscle that elevates the eyelid (along with the levator palpebrae skeletal muscle innervated by somatic motor neurons of CN III), pupillary dilator (smooth) muscles, and sweat glands of the face (third-order neuron). A lesion at any point in this pathway causes Horner syndrome.

All vertebrates have a brain that is segmented into three parts (see [p. 261](#)): the prosencephalon, mesencephalon, and rhombencephalon. With evolution, the more rostral parts took on a more dominant role. The brain of the ammocoete larva of the lamprey is dominated by the **medulla**, which is also the most vital part of the human brain; in contrast to destruction of more rostral structures, destruction of the medulla leads to instant death in the absence of life support. The medulla coordinates all visceral control and optimizes it for survival. In humans, normal body homeostasis can continue indefinitely with only a medulla, spinal cord, and peripheral ANS.

In fish, the **midbrain** became the dominant CNS structure in response to the increasing importance of vision. The brain of primitive reptiles is only a brainstem and paleocortex, without a neocortex; the corpus striatum is the dominant structure. Thus, the brainstem is sometimes referred to as the reptilian brain. Finally, the **neocortex** appeared in mammals and became dominant. The phylogenetically advanced portions of the CNS rostral to the medulla—including the hypothalamus, limbic system, and cortex—coordinate activity of the ANS with complex behaviors, motivations, and desires, but they are not required for normal homeostasis.

As a result of this hierarchy, impulses from most visceral afferents never reach the cortex, and we are not usually conscious of them. Instead, they make synapses within the enteric plexuses, autonomic ganglia, spinal cord, and brainstem, and they close reflex loops that regulate visceral output at each of these levels.

CHAPTER 15

Sensory Transduction

Barry W. Connors

Sensory receptors convert environmental energy into neural signals

Sensation is a cognitive process that requires the full powers of the central nervous system (CNS). Sensation begins with the sensory receptors that actually interface with the world, and these receptors use energy from the environment to trigger electrochemical signals that can be transmitted to the brain—a process called **sensory transduction**. An understanding of transduction processes is crucial for several reasons. Without these processes, sensation fails. Moreover, a variety of diseases that specifically affect sensory receptors can impair or abolish sensation without damaging the brain. Transduction also sets the basic limits of perception. It determines the sensitivity, range, speed, versatility, and vigor of a sensory system.

We have a variety of senses, each tuned to particular types of environmental energy. These **sensory modalities** include the familiar ones of seeing, hearing, touching, smelling, and tasting, as well as our senses of pain, balance, body position, and movement. In addition, other intricate sensory systems of which we are not conscious monitor the internal milieu and report on the body's chemical and metabolic state. Early in the 19th century, the physiologist Johannes Müller recognized that neurons that are specialized to evaluate a particular type of stimulus energy will produce the appropriate sensation regardless of how they are activated. For example, banging your eye can produce perceptions of light even in the dark, and seizure activity in a region of the cortex devoted to olfaction can evoke repulsive smells even in a rose garden. This property has been called **univariance**; in other words, the sensory receptor and its subsequent neural circuits do not know what stimulated them—they give the same type of response regardless. Specificity for each modality is ensured by the structure and position of the sensory receptor.

Sensory transduction uses adaptations of common molecular signaling mechanisms

Evolution is a conservative enterprise. Good ideas are retained, and with slight modification they are adapted to new purposes. Sensory transduction is a prime example of this principle. The sensory processes that are now understood at the molecular level use systems that are closely related to the ubiquitous signaling molecules in eukaryotic cells. Some modalities (vision, olfaction, some types of taste, and other chemoreception) begin with integral membrane proteins that belong to the superfamily of G protein–coupled receptors (GPCRs; see [pp. 51–52](#)). The second-messenger pathways use the same substances that are used for so many nonsensory tasks in cells, such as cyclic nucleotides, inositol phosphates, and kinases. Other sensory systems (mechanoreceptors, including the hair cells of audition and the vestibular organs, as well as some taste cells) use modified membrane ion channels in the primary transduction process. Although the structures of most of these channels have not yet been determined, their

biophysical properties are generally unremarkable, and they are likely to be related to other, nonsensory ion channels. Indeed, the gating of many ion channels from “nonsensory” cells is sensitive to the physical distortion of the membrane that they lie in, which implies that mechanosensitivity is a widespread (although perhaps epiphenomenal) feature of integral membrane proteins.

To achieve a specificity for certain stimulus energies, many sensory receptors must use specialized cellular structures. These, too, are usually adapted from familiar components. Various receptors are slightly modified epithelial cells. Some situate their transduction sites on modified cilia, whereas others use muscle cells or collagen fibers to channel the appropriate forces to the sensory axon. Many are neurons alone, often just bare axons with no specialization visible by microscopy. Most sensory transduction cells (e.g., oxygen and taste sensors, but not olfactory receptors) lack their own axon to communicate with the CNS. For these cells, the communication system of choice is a relatively standard, Ca^{2+} -dependent system of synaptic transmission onto a primary sensory neuron.

Sensory transduction requires detection and amplification, usually followed by a local receptor potential

Functionally, sensory transducers follow certain general steps. Obviously, they must detect stimulus energy, but they must do so with enough selectivity and speed that stimuli of different types, from different locations, or with different timing are not confused. In most cases, transduction also involves one or more steps of signal amplification so that the sensory cell can reliably communicate the detection of small stimuli (e.g., a few stray photons or a smattering of drifting molecules) to a large brain in an environment with much sensory noise. The sensory cell must then convert the amplified signal into an electrical change by altering the gating of some ion channel. This channel gating leads to alterations of the membrane potential (V_m) in the receptor cell—otherwise known as a **receptor potential**. The receptor potential is not an action potential but a graded electrotonic event that can either modulate the activity of other channels (e.g., voltage-gated Na^+ or Ca^{2+} channels) or trigger action potentials in a different portion of the same cell. Very often, the receptor potential regulates the flux of Ca^{2+} into the cell and thus controls the release of some synaptic transmitter molecule onto the sensory afferent neuron.

Ultimately, receptor potentials determine the rate and pattern of action potential firing in a sensory neuron. This firing pattern is the signal that is actually communicated to the CNS. Useful information may be encoded in many features of the firing, including its rate, its temporal patterns, its periodicity, its consistency, and its patterns when compared with the signals of other sensory neurons of the same or even different modalities.

Chemoreception

Chemoreceptors are ubiquitous, diverse, and evolutionarily ancient

Every cell is bathed in chemicals. Molecules can be food or poison, or they may serve as signals of communication between cells, organs, or individuals. The ability to recognize and respond to environmental chemicals can allow cells to find nutrients, avoid harm, attract a mate, navigate, or regulate a physiological process. Chemoreception has basic and universal advantages. It is the oldest form of sensory transduction, and it exists in many forms. Chemoreception does not even require a nervous system. Single-celled organisms such as bacteria can recognize and respond to substances in their environment. In the broadest sense, every cell in the human body is chemosensitive, and chemical signaling between cells is the basis for internal communication through endocrine systems and neurotransmission. In this chapter, we restrict ourselves to chemoreception as a sensory system, the interface between the nervous system and the external and internal chemical milieu.

Chemicals reach the human body by oral or nasal ingestion, contact with the skin, or inhalation, and once there, they diffuse or are carried to the surface membranes of receptor cells through the various aqueous fluids of the body (e.g., mucus, saliva, tears, cerebrospinal fluid [CSF], blood plasma). The nervous system constantly monitors these chemical comings and goings with a diverse array of chemosensory receptors. The most familiar of these receptors are the sensory organs of taste (**gustation**) and smell (**olfaction**). However, chemoreception is widespread throughout the body. Chemoreceptors in the skin, mucous membranes, respiratory tract, and gut warn against irritating substances, and chemoreceptors in the carotid bodies (see [pp. 710–712](#)) measure blood levels of O_2 , CO_2 , and $[H^+]$.

Taste receptors are modified epithelial cells, whereas olfactory receptors are neurons

The tasks of gustatory and olfactory receptors appear similar at first glance. Both recognize the concentration and identity of dissolved molecules, and they communicate this information to the CNS. In fact, the two systems operate in parallel during eating, and the flavors of most foods are strongly dependent on both taste *and* smell. The anatomy of the human olfactory system is well adapted to detect odors orthonasally, from the environment, and retronasally, from volatile chemicals released as we chew food. However, the receptor cells of gustation and olfaction are quite different. Olfactory receptors are neurons. Each olfactory cell has small dendrites at one end that are specialized to identify chemical stimuli, and at the other end an axon projects directly into the brain. Taste receptor cells are not neurons but rather modified epithelial cells that synapse onto the axons of sensory neurons that communicate with the CNS.

Taste Receptor Cells

Taste receptors are located mainly on the dorsal surface of the tongue ([Fig. 15-1A](#)), concentrated within small but visible projections called **papillae** (see [Fig. 15-1B](#)). Papillae are shaped like ridges, pimples, or mushrooms, and each is a few millimeters in diameter. Each papilla in turn has numerous **taste buds** (see [Fig. 15-1C](#)). One taste bud contains 50 to 150 taste receptor cells, numerous basal and supporting

cells that surround the taste cells, plus a set of sensory afferent axons. Most people have 2000 to 5000 taste buds, although exceptional cases range from 500 to 20,000.

FIGURE 15-1 Taste receptors.

The chemically sensitive part of a taste receptor cell is a small apical membrane region near the surface of the tongue. The apical ends have thin extensions called **microvilli** that project into the **taste pore**, a small opening on the surface of the tongue where the taste cells are exposed to the contents of the mouth. Taste cells form synapses with the primary sensory axons near the bottom of the taste bud. However, processing may be more complicated than a simple receptor-to-axon relay. Receptor cells also make both electrical and chemical synapses onto some of the basal cells, some basal cells synapse onto the sensory axons, and some type of information-processing circuit may be present within each taste bud itself.

Cells of the taste bud undergo a constant cycle of growth, death, and regeneration. Each taste cell lives about 2 weeks. The turnover of taste cells depends on the influence of the sensory nerve because if the nerve is cut, taste buds degenerate.

Olfactory Receptor Cells

We smell with receptor cells in the thin **main olfactory epithelium**, which is placed high in the nasal cavity (Fig. 15-2A). We will not discuss several other accessory olfactory systems, including the vomeronasal organ, which primarily detect pheromones. The main olfactory epithelium has three primary cell types: **olfactory receptor cells** are the site of transduction; **support cells** are similar to glia and, among other things, help produce mucus; and stem cells, called **basal cells**, are the source of new receptor cells (see Fig. 15-2B). Olfactory receptors (similar to taste receptors) continually die, regenerate, and

grow in a cycle that lasts ~4 to 8 weeks. Olfactory receptor cells are one of the very few types of neurons in the mammalian nervous system that are regularly replaced throughout life.

A NASAL CAVITY AND OLFACTORY BULB

B OLFACTORY EPITHELIUM

FIGURE 15-2 Olfactory reception.

As we breathe or sniff, chemical odorants waft through the many folds of the nasal passages. However, to contact the receptor cells, odorants must first dissolve in and diffuse through a thin mucous layer, which has both a viscous and a watery portion. The normal olfactory epithelium exudes a mucous layer 20 to 50 μm thick. Mucus flows constantly and is normally replaced about every 10 minutes. Mucus is a complex, water-based substance containing dissolved glycosaminoglycans (see [p. 39](#)); a variety of proteins, including antibodies, odorant-binding proteins, and enzymes; and various salts. The antibodies are critical because olfactory cells offer a direct route for viruses (e.g., rabies) or bacteria to enter the brain. **Odorant-binding proteins** in the mucus probably facilitate the diffusion of odorants toward and away from the receptors. Enzymes may help clear the mucus of odorants and thus speed recovery of the receptors from transient odors.

Both the absolute size and the receptor density of the olfactory epithelium vary greatly among species, and they help determine olfactory acuity. The surface area of the human olfactory epithelium is only $\sim 10\text{ cm}^2$, but this limited area is enough to detect some odorants at concentrations as low as a few parts per trillion. The olfactory epithelia of some dogs may be over 170 cm^2 , and dogs have >100 times as many receptors in each square centimeter as humans do. The olfactory acuity of some breeds of dog is legendary and far surpasses that of humans. Dogs can often detect the scent of someone who walked by hours before.

Complex flavors are derived from a few basic types of taste

receptors, with contributions from sensory receptors of smell, temperature, texture, and pain

Studies of taste discrimination in humans imply that we can distinguish among 4000 to 10,000 different chemicals with our taste buds. However, behavioral evidence suggests that these discriminations represent only five primary taste qualities: **bitter**, **salty**, **sweet**, and **sour** plus a primary quality called **umami** (“delicious” in Japanese). Umami is the taste of certain L-amino acids, epitomized by L-glutamate (monosodium glutamate [MSG], the familiar culinary form). Growing evidence suggests that mammals have a taste system for free fatty acids. Unlike an olfactory receptor cell, which apparently expresses only one receptor type (see [p. 358](#)), a taste receptor cell may express several.

In many cases, there is an obvious correlation between the chemistry of **tastants** (i.e., chemicals being tasted) and the quality of their taste. Most acids taste sour and most salts taste salty. However, for many other tastants, the linkage between taste and chemical structure is not clear. The familiar sugars (e.g., sucrose and fructose) are satisfyingly sweet, but certain proteins (e.g., monellin) and artificial sweeteners (e.g., saccharin and aspartame, the latter of which is made from two amino acids: L-aspartyl-L-phenylalanine methyl ester) are 10,000 to 100,000 times sweeter by weight than these sugars. Bitter substances are also chemically diverse. They include simple ions such as K^+ (KCl actually simultaneously evokes both bitter and salty tastes), larger metal ions such as Mg^{2+} , and complex organic molecules such as quinine.

If the tongue has only four or five primary taste qualities available to it, how does it discriminate among the myriad complex flavors that embellish our lives? First, the tongue's response to each tastant reflects distinct proportions of each of the primary taste qualities. In this sense, the taste cells are similar to the photoreceptors of our eyes; with only three different types of color-selective photoreceptive cone cells, we can distinguish a huge palette of colors. Second, the flavor of a tastant is determined not only by its taste but also by its smell. Taste and smell operate in parallel, with information converging in the CNS to aid the important discrimination of foods and poisons. For example, without the aid of olfaction, an onion tastes much like an apple—and both are quite bland. Third, the mouth is filled with other types of sensory receptors that are sensitive to texture, temperature, and pain, and these modalities enhance both the identification and enjoyment of foods. A striking example is the experience of spicy food, which is enjoyable to some but painful to others. The spiciness of hot peppers is generated by the chemical **capsaicin**, not because of its activation of taste receptor cells but because of its stimulation of heat-sensitive pain receptors in the mouth.

Taste transduction involves many types of molecular signaling systems

The chemicals that we taste have diverse structures, and taste receptors have evolved a variety of mechanisms for transduction. The taste system has adapted many types of membrane-signaling systems to its purposes. Tastants may pass directly through ion channels (salty and sour), bind to and block ion channels (sour) or bind to membrane receptors that activate second-messenger systems, which in turn open or close ion channels (sweet, bitter, and umami). Taste cells use specialized variations of these processes to initiate meaningful signals to the brain.

The receptor potentials of taste cells are usually depolarizing. At least some taste receptor cells can fire action potentials similar to those of neurons, but if the membrane is sufficiently depolarized by whatever means, voltage-gated Ca^{2+} channels open, and Ca^{2+} enters the cytoplasm and triggers the release

of transmitter molecules. Both the type of neurotransmitter and its mechanism of its release differ by cell type. Sour and salty taste cells use a conventional Ca^{2+} -triggered vesicular mechanism to release serotonin onto gustatory axons, whereas sweet-, bitter-, and umami-selective taste cells use a Ca^{2+} -triggered nonvesicular mechanism to release ATP as their transmitter.

Evidence from mice suggests that each taste receptor cell responds to only one of the five basic taste modalities. Each of the taste receptor cells is, in turn, hard-wired to the CNS to convey a particular taste quality. For example, if we genetically alter a mouse to express a bitter receptor in sweet taste receptor cells, the mouse—naturally attracted to sweet tastants—will be attracted to bitter tastants, which now will taste sweet.

The complex diversities of taste transduction are not yet fully understood. The following is a summary of the best-understood transduction processes for the five primary taste qualities in mammals (Fig. 15-3).

FIGURE 15-3 Cellular basis of taste transduction. Although, for convenience, we show two taste modalities in **A** and three in **B**, individual taste cells do not express more than one of the taste mechanisms. ER, endoplasmic reticulum; PIP_2 , phosphatidylinositol 4,5-bisphosphate; PLC, phospholipase C.

Salty

The most common salty-tasting chemical is NaCl, or table salt. The taste of salt is mainly the taste of the cation Na⁺. At relatively low concentrations (10 to 150 mM), NaCl is usually attractive to animals; at higher concentrations it is increasingly aversive. Completely different mechanisms transduce low and high [NaCl]. Salt-sensitive taste cells detect low [NaCl] using the epithelial Na⁺ channel ENaC (see Fig.

15-3A), which is blocked by the drug amiloride (see pp. 758–759). These cells also have an amiloride-insensitive cation channel that contributes to salt transduction. Unlike the Na^+ channel that generates action potentials in excitable cells, the taste channels are relatively insensitive to voltage and stay open at rest. However, transduction of the $[\text{Na}^+]$ in a mouthful of food is somewhat analogous to the behavior of a neuron during the upstroke of an action potential. When $[\text{Na}^+]$ rises outside the receptor cell, the gradient for Na^+ across the membrane becomes steeper, Na^+ diffuses down its electrochemical gradient (i.e., it flows into the cell), and the resultant inward current causes the membrane to depolarize to a new voltage. Neurons depolarize during their action potential by increasing Na^+ conductance at a fixed Na^+ gradient (see Fig. 7-4). In contrast, Na^+ -sensitive taste cells depolarize by increasing the Na^+ gradient at a fixed Na^+ permeability. The resultant graded depolarization of the taste cell is defined as its receptor potential.

High concentrations of NaCl and other salts taste bad to humans, and animals normally avoid ingesting them. In mice, high $[\text{NaCl}]$ activates bitter and sour taste cells, although the mechanism is not clear. Bitter and sour tastants normally trigger avoidance, and the offensive qualities of high $[\text{NaCl}]$ seem to stimulate the same avoidance pathways.

Anions may affect the taste of salts by modulating the saltiness of the cation or by adding a taste of their own. NaCl tastes saltier than Na acetate, perhaps because the larger an anion is, the more it *inhibits* the salty taste of the cation. Na saccharin is sweet because the anion saccharin activates sweetness receptors; it is not salty because Na^+ is present at a very low concentration.

Sour

Sourness is evoked by protons (H^+ ions). Acidity may affect taste receptors in several ways (see Fig. 15-3A). Sour taste cells express a type of acid-sensitive channel complex comprising the nonselective cation channel TRPP3 (see Table 6-2, family No. 5; also known as PKD2L1) and PKD1L3; both are related to proteins implicated in polycystic kidney disease. Selective elimination of taste cells expressing TRPP3 abolishes the gustatory response to acidic stimuli. Protons may also affect the gating of other cation-selective channels such as the hyperpolarization-activated channels (HCNs; see Table 6-2, family No. 3) and the acid-sensitive channels (ASICs; see Table 6-2, family No. 14) that would lead to depolarization of taste cells.

Carbonated liquids evoke interesting sensations. Carbonation—high levels of dissolved CO_2 —can activate the gustatory, olfactory, and somatosensory neurons. Sour taste cells seem to be critical for the gustatory features of CO_2 . These cells express an extracellular form of carbonic anhydrase, CA IV, an enzyme that rapidly catalyzes the conversion of CO_2 into HCO_3^- and H^+ . Thus, in the presence of CA IV, increased $[\text{CO}_2]$ leads to the production of H^+ that may act on effectors in the receptor cells to mediate the taste of carbonation. Consistent with this, mountain climbers taking acetazolamide, the carbonic anhydrase inhibitor, to treat acute mountain sickness (see p. 1232) have reported that beer and soda taste disappointingly flat.

Sweet

Sweetness is sensed when molecules bind to specific receptor sites on the taste cell membrane and activate a cascade of second messengers (see Fig. 15-3B). Two families of taste receptor genes—the T1R family and T2R family—seem to account for sweet, bitter, and umami transduction. These taste receptors are GPCRs (see pp. 51–66), and all use the same basic second-messenger pathway. In the case of sweetness transduction, the tastant (e.g., a sugar molecule) binds to a taste receptor that consists of a

dimer of T1R2 and T1R3 GPCRs. The activated receptor then activates a G protein that stimulates phospholipase C (PLC), which in turn increases its production of the messenger inositol 1,4,5-trisphosphate (IP₃; see p. 58). IP₃ triggers the release of Ca²⁺ from internal stores, and the rise in [Ca²⁺]_i then activates a relatively nonselective cation channel called TRPM5 (see Table 6-2, family No. 5), which is specific for taste cells. Opening TRPM5 depolarizes the taste cell, triggering the release of neurotransmitter onto the primary gustatory axon (see Fig. 15-3B). The sweet receptor complex—the T1R2/T1R3 dimer—is broadly sensitive to sweet-tasting substances. It appears that sweet-sensing taste cells do not express receptors for either bitter or umami.  **N15-1**

N15-1

Diversity of Sweet and Umami Taste Reception

Contributed by Barry Connors

Taste receptors are quite diverse among species, and this leads to considerably different taste preferences that may be adaptations to each animal's ecological niche. Preferences for sweet substances are strongly determined by the T1R subunits. Some species, notably cats and some other carnivores, lack a functional T1R2 gene and are indifferent to compounds that humans consider sweet. Mice are usually uninterested in aspartame, the artificial sweetener favored by people, but introducing the human T1R2 gene into the taste cells of a mouse makes them responsive to aspartame. Some mammalian species (including all types of bats) lack a functional T1R1 receptor and presumably cannot taste amino acids.

Bitter

Bitterness often warns of poison. Perhaps because poisons are so chemically diverse, we have about 25 different types of bitter receptors to sense them. These are dimers of GPCRs in the T2R family. Animals are not very good at distinguishing between different bitter substances, probably because each bitter taste cell expresses most or all of the 25 T2Rs. It may be more important to recognize that something is bitter, and potentially poisonous, than it is to recognize precisely what type of poison it may be. Bitter compounds trigger responses at much lower concentrations (i.e., they have much higher affinities) than sweet and umami substances. Stimulation of the T2Rs activates a second-messenger pathway that is apparently identical to the one that sweet receptors activate: G proteins, PLC, IP₃, [Ca²⁺]_i increase, and TRPM5 channel opening. We do not confuse the tastes of sweet and bitter substances because even though they trigger similar signaling systems, each transduction cascade occurs within a specific sweet or bitter taste cell. Moreover, each taste cell makes synaptic contact with a different primary gustatory axon that leads into the CNS.

Amino Acids

Amino acids are critical nutrients that are vital as an energy source and for construction of proteins. Probably as a consequence, many amino acids taste good, although some taste bitter. The **umami** taste, which we know well from some Asian restaurants, is triggered by a mechanism very similar to that for sweet taste. The umami receptor is a heterodimer comprising two members of the T1R family, T1R1 and T1R3. Note that the umami and sweet receptors share T1R3. The taste for some L-amino acids seems to depend on T1R1 because mice that lack it are unable to discriminate glutamate and other amino acids, although they retain their ability to detect sweet substances.  **N15-1** The umami receptor activates the

same signaling mechanisms that sweet and bitter receptors do: G proteins, PLC, IP_3 , $[Ca^{2+}]_i$ increase, and TRPM5 channel opening. Again, by isolating the umami receptors in taste cells that do not also express sweet and bitter receptors, the CNS can distinguish the various tastes from one another by somehow knowing which taste cell connects to a particular gustatory axon.

Olfactory transduction involves specific receptors, G protein–coupled signaling, and a cyclic nucleotide–gated ion channel

Our ability to smell chemicals is better developed than our ability to taste them. By one estimate, we can smell >400,000 different substances. Interestingly, ~80% of them smell unpleasant. As with taste, it seems likely that smell evolved to serve important protective functions, such as warning us away from harmful substances. The *main* and *accessory* olfactory systems can also detect pheromones, volatile chemicals used by individuals of a species to trigger stereotyped behavioral or hormonal changes. In some species, olfaction even allows one individual to detect whether others are dangerous or ill. With the ability to discriminate so many different smells, you might also expect many different types of transduction mechanisms, as in the taste system. In fact, the *main* olfactory receptors probably use only one second-messenger mechanism. [Figure 15-4](#) summarizes the chain of events in the main olfactory receptor cells that leads to action potentials in the olfactory nerve (i.e., cranial nerve I [CN I]).

Step 1: The odorant binds to a specific **olfactory receptor protein** in the cell membrane of a cilium of an olfactory receptor cell.

Step 2: Receptor activation stimulates a heterotrimeric G protein called **G_{olf}** (see [Table 3-2](#)).

Step 3: The α subunit of G_{olf} in turn activates an **adenylyl cyclase** (specifically, ACIII), which produces cAMP.

Step 4: The cAMP binds to a **CNG** cyclic nucleotide–gated cation channel (see [Table 6-2](#), family No. 4).

Step 5: Opening of this channel increases permeability to Na^+ , K^+ , and Ca^{2+} .

Step 6: The net inward current leads to membrane depolarization and increased $[Ca^{2+}]_i$.

Step 7: The increased $[Ca^{2+}]_i$ opens Ca^{2+} -activated Cl^- channels called **anoctamin2** (ANO2; see [Table 6-2](#), family No. 17). Opening of these channels produces more depolarization because of the relatively high $[Cl^-]_i$ of olfactory receptor neurons.

Step 8: If the receptor potential exceeds the threshold, it triggers action potentials in the soma that travel down the axon and into the brain.

FIGURE 15-4 Cellular mechanism of odor sensation.

All this molecular machinery, with the exception of the action potential mechanism, is squeezed into the thin cilia of olfactory receptor cells. Moreover, additional modulatory schemes also branch from this basic pathway.

Olfactory receptor cells express a huge family of receptor proteins; in fact, olfactory receptor genes are the largest family of mammalian genes known! Their discovery in the early 1990s earned Linda Buck and Richard Axel the 2004 Nobel Prize in Physiology or Medicine. **N15-2** Rodents have >1000 different olfactory receptor genes. Humans have ~350 genes that encode functional receptor proteins. This family of olfactory receptor proteins belongs to the superfamily of GPCRs (see pp. 51–52) that also includes the phototransduction protein rhodopsin and the taste receptors for sweet, bitter, and umami described above as well as the receptors for a wide variety of neurotransmitters.

N15-2

Richard Axel and Linda Buck

For more information about Richard Axel and Linda Buck and the work that led to their Nobel Prize, visit http://nobelprize.org/nobel_prizes/medicine/laureates/2004/ (accessed December 2014).

The extracellular surfaces of olfactory receptor proteins have odorant binding sites, each slightly different from the others. Presumably, each receptor protein can bind only certain types of odorants; therefore, some degree of selectivity is conferred to different olfactory receptor cells. Remarkably, each receptor cell seems to express only a single gene of the 1000 different odorant receptor genes in rodents.

Thus, 1000 different types of olfactory receptor cells are present, each identified by the one receptor gene that it expresses. Because each odorant may activate a large proportion of the different receptor types, the central olfactory system's task is to decode the patterns of receptor cell activity that signals the identity of each smell.

The structure of the olfactory cAMP-gated channel is closely related to that of the light-activated channel in photoreceptors of the retina, which is normally gated by an increase in $[cGMP]_i$. The olfactory channel and the photoreceptor channel almost certainly evolved from one ancestral CNG channel, just as the olfactory receptor and photoreceptor proteins probably evolved from an ancestral receptor with seven membrane-spanning segments.

Termination of the olfactory response occurs when odorants diffuse away, scavenger enzymes in the mucous layer break them down, or cAMP in the receptor cell activates other signaling pathways that end the transduction process.

Visual Transduction

The environment of most species is enveloped by light (Fig. 15-5). Animals have evolved a variety of mechanisms to transduce and detect light. Their brains analyze visual information to help them locate food, avoid becoming food, find a mate, navigate, and generally recognize distant objects. Light is an exceptionally useful source of information about the world because it is nearly ubiquitous and can travel far and fast and in straight lines with relatively little dispersion of its energy. The vertebrate eye, which we describe here, has two major components: an **optical** part to gather light and to focus it to form an image and a **neural** part (the retina) to convert the optical image into a neural code.

FIGURE 15-5 Electromagnetic spectrum. AC, alternating current.

The optical components of the eye collect light and focus it onto the retina

The optical structures of the eye are among the most sophisticated of the specialized non-neural sensory endings, and they are often compared with a camera. As cameras have become more technologically sophisticated, the analogy has improved because the eye has systems to focus automatically, adjust its sensitivity for widely different light levels, move to track and stabilize a target, and even keep its surface washed and clear (obviously, cameras still have room for improvement). The similarity to a camera breaks down when we consider the retina, which is decidedly not like standard photographic film or electronic light detectors.

Figure 15-6A shows a cross section through the human eye. A ray of light entering the eye passes through several relatively transparent elements to reach the retina; these elements include a thin film of tears and then the cornea, the aqueous humor, the lens, and finally the vitreous humor. **Tears** are a surprisingly complex liquid, based on a plasma ultrafiltrate. They bathe the cornea in a layer that is

<10 μm thick, keep it wet, and allow O_2 to diffuse from the air to the corneal cells. Tears also contain lysozymes and antibodies to counter infection, a superficial oily layer that greatly slows evaporation and prevents spillage at the lid margins, and a thin mucoid layer to wet the surface of the cornea and to allow the tears to spread smoothly. Tears also help flush away foreign substances. The **cornea** is a thin, transporting epithelium that is devoid of blood vessels and has a cell structure specialized to maintain its high transparency. **N15-2A** The **ciliary epithelium**, a part of the ciliary body, constantly secretes **aqueous humor**, a protein-free ultrafiltrate of blood plasma, into the posterior chamber of the eye. The aqueous humor then flows between the iris and the anterior surface of the lens and reaches the **anterior chamber** through the pupil. This aqueous humor keeps the anterior portion of the eye slightly pressurized (~20 mm Hg), which helps maintain the eye's shape. The canals of Schlemm drain the aqueous humor. Excess pressure in the anterior chamber produces a disease called **glaucoma**. In the most common form of glaucoma, blockage of the canals of Schlemm leads to increased intraocular pressure. Pressure damages and kills ganglion cell axons at the optic disc, where they leave the eye and enter the optic nerve. The **lens** is an onion-like structure with closely packed columnar cells that are arranged in concentric shells and encased by a thin, tough, transparent capsule that is composed of epithelial cells. The cells of the lens have a high concentration of proteins called α -crystallins, which help increase the density of the lens and enhance its focusing power. The **posterior chamber**, which is filled with a gelatinous substance called **vitreous humor**, is also kept pressurized by the production of aqueous humor.

FIGURE 15-6 The eye. **A**, Cross section of the right human eye, viewed from the top. **B**, Bending of light by a structure depends not only on the radius of curvature but also on the difference in the indices of refraction of the two adjoining media.

The Cornea

Contributed by Mark Parker

The **cornea** is a transparent structure that consists of a collagen matrix called the **stroma** sandwiched between two layers of epithelia. The anterior **corneal epithelium** is a stratified squamous layer that faces the tear-film on the surface of the eye. The posterior corneal epithelium, or **corneal endothelium**, is a simple cuboidal cell layer that faces the aqueous humor in the anterior chamber of the eye. The stroma accounts for approximately 90% of the total thickness of the cornea. The transparency of the stroma depends on the maintenance of the appropriate hydration state or **deturgescence** of the collagen matrix. Disturbance of the structural array of collagen fibers within the matrix by dehydration or overhydration of the stroma results in increased scattering of light rays, a phenomenon called **corneal opacification**, and a consequent loss of vision. Both epithelial layers contribute toward maintaining stromal deturgescence. The anterior corneal epithelium protects the hydrated stroma from physical damage and prevents evaporation of fluid from the stroma. The corneal endothelium forms a leaky barrier between the stroma and the anterior chamber, allowing the paracellular leak of nutrient-rich fluid from the aqueous humor into the stroma. The endothelial cells pump ions from the stromal fluid into the aqueous humor via a transcellular route, thereby promoting the return of fluid from the stroma back into the anterior chamber, preventing **corneal edema**. Disruption of stromal collagen-structure or endothelial pump-function produces a group of diseases called **corneal dystrophies**.

The light must be focused to generate a clear optical image on the retina. This is accomplished by the cornea and, to a lesser extent, the lens. Focusing requires the path of the light to be bent, or refracted. Refraction can occur when light passes from a medium in which it travels relatively fast into a medium in which it travels relatively slowly, or vice versa. The **index of refraction** for a substance is essentially a measure of the speed of light within it; for example, light travels faster through air (index of refraction, 1.0003) than through the denser substance of the cornea (index of refraction, 1.376). Two things determine how much a light ray is refracted: the difference in the refractive indices of the two media and the angle between the incident light and the interface between the two media. Simple convex lenses use curved surfaces to control the refraction of light rays so that they converge (or focus) on a distant surface. The focal power (D) of one surface of a spherical lens is

$$\text{Focal power} = \frac{n_2 - n_1}{r} \quad (15-1)$$

Here, n_1 and n_2 are the refractive indices of the first and second medium and r is the radius of curvature of the lens in meters. The unit of focal power is a *diopter* ($1 \text{ D} = 1 \text{ m}^{-1}$). Focal power is the reciprocal of

focal length. Thus, parallel light rays entering a 1-D lens are focused at 1 m and those entering a 2-D lens are focused at 0.5 m.

In the case of the eye, most of the focusing takes place at the interface between the air and the tear-covered anterior surface of the cornea because this region is where light encounters the greatest disparity in refractive indices on its path to the retina (see [Fig. 15-6B](#)). With a change of 0.376 in refractive index and a radius of outer curvature of 7.8 mm in a typical human cornea, the focal power is 48.2 D. The curvature on the inner surface of the cornea is reversed, so some focal power is lost as light passes into the aqueous humor. However, the change in refractive index at this surface is only 0.040, so the change is only -5.9 D. The lens of the eye, with convex curvature on both sides, has a potentially greater focal power than the cornea. However, because of the small difference in refractive index between the substance of the lens and the aqueous and vitreous humors surrounding it, the effective focal power of the lens is lower. The summed focal power of the optics of the relaxed eye is ~60 D, which allows it to focus light from distant objects onto the retina, the center of which is ~24 mm behind the surface of the cornea ([Fig. 15-7A](#)). The position of the retinal image is, of course, upside down relative to the object that produced it.

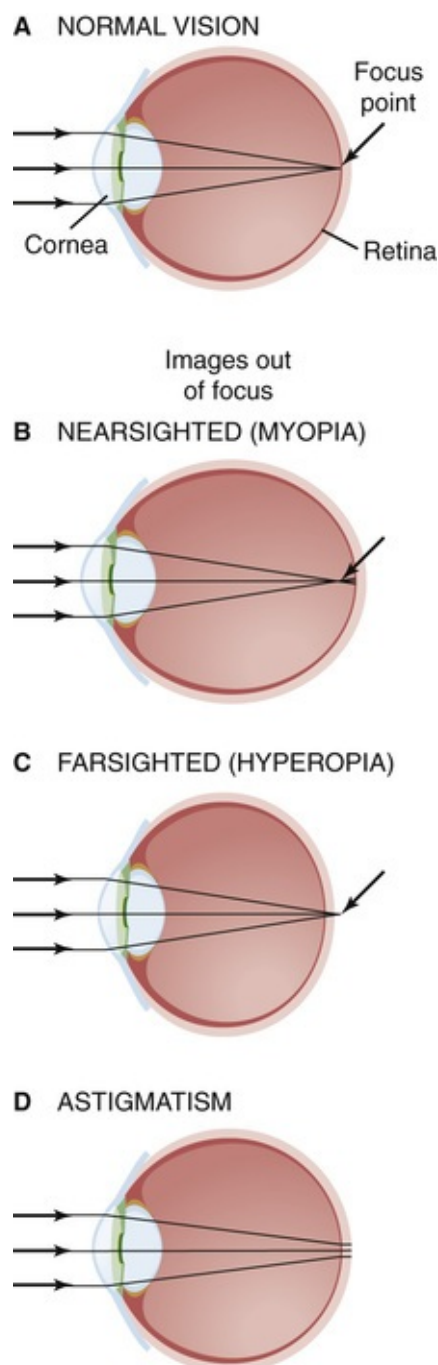

FIGURE 15-7 How the eye focuses light. A distant point source of light generates parallel light rays at the surface of the cornea. **A**, In the normal eye the cornea and lens refract light to focus at a small spot on the retina. **B**, The myopic eye is abnormally long and focuses distant objects in front of the retina. **C**, The hyperopic eye is abnormally short and focuses distant objects behind the retina when the lens is relaxed. **D**, The eye with astigmatism (caused by abnormal curvature of the cornea or lens) cannot focus a point of light onto a small spot.

A normal *resting* eye is focused on distant objects, beyond ~ 7 m. If it were fixed in this position, it would be impossible to see objects that are close up. To focus objects that are closer than 7 m away, the eye needs to increase its focal power, a process called **accommodation**. The eye achieves this goal by changing the shape of the lens (see Fig. 15-6A). At rest, the lens is suspended around its edge by elastic **zonal fibers** that keep its capsule stretched and relatively flattened. To accommodate, the ciliary muscle fibers contract and release some of the tension in the zonal fibers. Relieved of the radial pull of its fibers, the lens becomes rounder. This increased curvature means increased focal power and a shift of the focal point closer to the eye (see Equation 15-1). There are limits to accommodation, of course, and they are strongly age dependent. Young children have the most pliable lenses and can increase their focal power up to 12 to 14 D. Their **near point**, the closest distance that they are able to focus, is about at the end of

their nose.

With age, the lens becomes stiffer and less able to round up and accommodate. By age 30, the near point is ~10 cm, and by the mid-40s, it stretches beyond arm's length. The loss of accommodation with age is called **presbyopia** (from the Greek *presbus* [old] + *ops* [eye]); it is the reason that glasses for reading are unavoidable for almost everyone past middle age. Additional refractive flaws may be caused by an eye that is too long or short for its focusing power or by aberrations in the refracting surfaces of the eye. **Myopia**, or nearsightedness, occurs when the eye is too long; distant objects focus in front of the retina and appear blurred (see [Fig. 15-7B](#)). **Hyperopia** (or hypermetropia), or farsightedness, is a feature of eyes that are too short; even with the lens fully accommodated, a near object focuses behind the retina and appears blurry (see [Fig. 15-7C](#)). People with myopia can wear concave lenses that move the focal plane of all images back toward the retina. Those with hyperopia can wear convex lenses that move the focal plane forward. **Astigmatism** is caused by uneven curvature of the refractive surfaces of the eye (see [Fig. 15-7D](#)). As a result, a point source of light cannot be brought to a precise focus on the retina. The resultant diffuse focusing leads to blurring of the image. Most people with astigmatic vision can also wear lenses that compensate for the aberrant focusing properties of their eyes.

The **iris** is the colored structure that is visible through the window of the cornea. The iris's hue comes from pigments in its cells, but its function is to create and to adjust the round opening that it encircles—the **pupil**. The pupil is like the aperture of the camera, and the iris is the diaphragm that regulates the amount of light allowed to enter the eye. The iris has sphincter muscles, innervated by postganglionic *parasympathetic* fibers from the ciliary ganglion (see [Fig. 14-4](#) and [Fig. 15-8](#)), that allow it to constrict (**miosis**).  **N15-3** The iris also has radially oriented muscles, innervated by postganglionic *sympathetic* fibers from the superior cervical ganglion (see [Fig. 14-4](#)), that allow it to dilate (**mydriasis**). Pupil size depends on the balance of the two autonomic inputs. The regulation of pupillary size by ambient light levels is called the **pupillary light reflex** (see [Fig. 15-8](#)). Light striking the retina stimulates fibers in the optic nerve that synapse in the brainstem in the nuclei of the posterior commissure. The next neuron projects to the Edinger-Westphal nuclei on both sides of the brain (see [Fig. 14-5](#)), stimulating preganglionic parasympathetic neurons that travel to both ciliary ganglia. These neurons activate postganglionic parasympathetic neurons that constrict both pupils. Thus, control of the pupils in the two eyes is “yoked”: an increase in light to only one eye causes its pupil to constrict (the **direct light response**), but it also causes an identical constriction in the other eye, even if that eye saw only constant light levels (the **consensual light response**). Pupillary responses serve two functions: (1) they regulate the total amount of light that enters the eye (over a range of ~16-fold), and (2) they affect the quality of the retinal image in the same way that the aperture affects the depth of focus of a camera (a smaller pupil diameter gives a greater depth of focus).

FIGURE 15-8 Pupillary light reflex. The figure shows the parasympathetic pathways that lead to constriction of the pupils. Pupil diameter depends on the balance between these parasympathetic pathways as well as the sympathetic pathways shown in [Figure 14-4](#). Note that most of the axons from the retinal ganglion cells synapse in the lateral geniculate nucleus (LGN; see [Fig. 16-8](#)).

N15-3

Importance of Pupil Size for Depth of Focus

Contributed by Barry Connors

Imagine that a photographer focuses a camera on an object by adjusting the focal power of the camera lens (see Equation 15-1). In principle, only objects at a particular distance from the camera will be in sharp focus. However, if the photographer stops down the diaphragm behind the lens of a camera (to high F values), only fairly parallel rays of light can enter the camera, so that the depth of focus is very broad. In other words, because the camera is receiving very little information concerning the distance to an

object, objects at rather different distances from the camera may all appear to be more or less in focus.

Just the opposite happens when the photographer opens up the diaphragm (to very low F values). In this case, the depth of focus is very shallow, so that the only objects that are in sharp focus are those at a particular distance from the camera. Other objects that are closer or further from the camera will appear blurred to varying extents, depending on their distance from the point of optimal focus.

In the eye, **miosis** (pupillary constriction) is the equivalent of a stopped-down diaphragm (high F value), whereas **mydriasis** (pupillary dilation) is the equivalent of a fully open diaphragm (low F value). Thus, under conditions of mydriasis (e.g., with sympathetic stimulation or in response to low light levels), the depth of focus can be very shallow, which can cause close objects to appear blurred if the lens is unable to sufficiently accommodate (i.e., to increase its focal power). Blurring is especially problematic with increasing age (e.g., >40 years), when accommodation becomes progressively limited—a condition known as presbyopia.

Other peripheral structures are also essential to proper visual function. The most important are the extraocular muscles that control eye movements. [Figure 15-6A](#) shows two such muscles, the lateral and medial rectus muscles. The extraocular muscles determine the direction of gaze, the tracking of objects, and the coordination of the two eyes to keep their retinal images aligned as the eye, head, and visual world move about. Nuclei in the brainstem also control these tracking functions.

The retina is a small, displaced part of the CNS

The retina is a very thin (~200 μm thick in humans) sheet of tissue that lines the back of the eye and contains the light-sensitive cells, the **photoreceptors**. Photoreceptors capture photons, convert their light energy into chemical free energy, and ultimately generate a synaptic signal for relay to other visual neurons in the retina.

The retina is, histologically and embryologically, a part of the CNS. Not only does it transduce light into neural signals, but it also does some remarkably complex processing of visual information before passing it on to other regions of the brain. In addition to the photoreceptor cells, the retina has four additional types of neurons that form an orderly but intricate neural circuit ([Fig. 15-9](#)). One type, the **ganglion cell**, generates the sole output of the retina by sending its axons to the thalamus through the optic nerve (CN II).

FIGURE 15-9 Neural circuits in the primate retina. Notice that the incoming light reaches intrinsically photosensitive retinal ganglion cells (ipRGCs) immediately, but hits rod and cone photoreceptor cells only after passing through several thin, transparent layers of other neurons. The pigment epithelium absorbs

the light not absorbed by the photoreceptor cells and thus minimizes reflections of stray light. The ganglion cells communicate to the thalamus by sending action potentials down their axons. However, the photoreceptor cells and other neurons communicate by graded synaptic potentials that are conducted electrotonically.

The retina is a highly laminated structure. Through a quirk of evolution, the photoreceptors of the vertebrate eye—rods and cones—are on the *outer* surface of the retina, that is, the side facing *away* from the vitreous humor and incoming light. Thus, to reach the transducing cells, light has to first pass through all the retinal neurons. This path causes only minor distortion of image quality because of the thinness and transparency of the neural layers. This seemingly inverted arrangement may actually be an advantage for housekeeping of the eye. Rods and cones undergo a continuous process of renewal, sloughing off membrane from their outer segments and rebuilding them. They also demand a relatively high energy supply. Because they face the back of the eye, these photoreceptors are close to the **pigment epithelium**, which aids the renewal process, and to the blood vessels that supply the retina. These poorly transparent structures (i.e., pigment epithelium and blood vessels) are thus isolated from the light path. In fact, the pigment epithelium also *absorbs* photons that are not first captured by photoreceptors, before they can be reflected and degrade the visual image.

Each human eye has $>100 \times 10^6$ photoreceptors but only 1×10^6 ganglion cells, which implies a high degree of convergence of information as it flows from the transducing cells to the output cells. Some of this convergence is mediated by a set of interneurons (i.e., cells that make synaptic connections only within the retina) called **bipolar** cells, which directly connect photoreceptors and ganglion cells in a mainly radial direction (see Fig. 15-9). The two remaining types of retinal neurons, horizontal cells and amacrine cells, are interneurons that mainly spread horizontally. **Horizontal cells** synapse within the outer layer of the retina and interconnect photoreceptors and bipolar cells to themselves and to each other. Horizontal cells often mediate interactions over a wide area of retina. **Amacrine cells** synapse within the inner layer of the retina and interconnect both bipolar cells and ganglion cells. The circuitry of the retina is much more complex than this picture implies. One hint of this complexity is that its four primary types of neurons are in turn divided into at least 10 to 20 distinct subtypes, each with different physiological and morphological features.

The thinness of the mammalian retina has an interesting biophysical consequence. Because signaling distances are so short, synaptic potentials can usually spread effectively within its neurons without the help of conventional action potentials. Electrotonic spread of potentials along the dendrites is generally enough. The main exceptions are the ganglion cells, which use action potentials to speed visual information along their axons to the thalamus, which is deep within the brain.

There are three primary types of photoreceptors: rods, cones, and intrinsically photosensitive ganglion cells

The two main types of photoreceptors, **rods** and **cones**, are named for their characteristic shapes (see Fig. 15-9). The human retina has only one type of rod, which is responsible for our monochromatic dark-adapted vision, and three subtypes of cones, which are responsible for the color-sensitive vision that we experience in brighter environments. Rods outnumber cones by at least 16 : 1, and each type of photoreceptor is spread in a distinct pattern across the retina.

The mammalian retina has a third type of light-sensitive cell, the **intrinsically photosensitive retinal ganglion cell (ipRGC)**. This cell is a rare subtype of ganglion cell that expresses its own photopigment. Unlike the vast majority of ganglion cells, ipRGCs can respond to bright light even in the absence of input

from rods and cones. The ipRGCs are involved in several nonimaging functions of the visual system.

In the central area of the primate retina is a small pit 300 to 700 μm in diameter (which accounts for 1 to 2.3 degrees of visual angle) called the **fovea**, which collects light from the center of our gaze (see [Fig. 15-6](#)). Several adaptations of the fovea allow it to mediate the highest visual acuity in the retina. Neurons of the inner layer of retina are actually displaced laterally to the side of the fovea to minimize light scattering on the way to the receptors. In addition, within the fovea, the ratio of photoreceptors to ganglion cells falls dramatically. Most foveal receptors synapse on only one bipolar cell, which synapses on only one ganglion cell ([Fig. 15-10A](#)). Because each ganglion cell is devoted to a very small portion of the visual field, central vision has high resolution. In other words, the **receptive field** of a foveal ganglion cell (i.e., the region of stimulus space that can activate it) is small. At the periphery, the ratio of receptors to ganglion cells is high (see [Fig. 15-10B](#)); thus, each ganglion cell has a large receptive field. The large receptive field reduces the spatial resolution of the peripheral portion of the retina but increases its sensitivity because more photoreceptors collect light for a ganglion cell. Foveal vision is purely cone mediated, and the sheet of foveal photoreceptors consists of only the smallest cones packed at the highest density ($\sim 0.3 \mu\text{m}$ from the center of one cone to another). Cone density falls to very low levels outside the fovea, and rod density rises. Both rods and cones mediate peripheral vision (i.e., nonfoveal vision, or vision at visual angles >10 degrees away from the center of the fovea and thus the center of gaze).

FIGURE 15-10 Comparison of the synaptic connections and receptive fields in the fovea and periphery of the retina.

Rods and cones are elongated cells with synaptic terminals, an inner segment, and an outer segment (see [Fig. 15-9](#)). The **synaptic terminals** connect to the inner segment by a short axon. The **inner segment** contains the nucleus and metabolic machinery; it synthesizes the photopigments and has a high density of mitochondria. The inner segment also serves an optical function—its high density funnels photons into the outer segment. A thin ciliary stalk connects the inner segment to the outer segment. The **outer segment** is the transduction site, although it is the last part of the cell to see the light. Structurally, the outer segment is a highly modified cilium. Each rod outer segment has ~1000 tightly packed stacks of *disk membranes*, which are flattened, membrane-bound intracellular organelles that have pinched off from the outer membrane. Cone outer segments have similarly stacked membranes, except that they are infolded and remain continuous with the outer membrane. The disk membranes contain the photopigments—**rhodopsin** in rods and molecules related to rhodopsin in cones. Rhodopsin moves from its synthesis site in the inner segment through the stalk and into the outer segment through small vesicles whose membranes are packed with rhodopsin to be incorporated into the disks.

Rods and cones hyperpolarize in response to light

The remarkable psychophysical experiments of [Hecht and colleagues in 1942](#) demonstrated that five to seven photons, each acting on only a single rod, are sufficient to evoke a sensation of light in humans. Thus, the rod is performing at the edge of its physical limits because there is no light level smaller than 1 photon. To detect a single photon requires a prodigious feat of signal amplification. As Denis Baylor has pointed out, “the sensitivity of rod vision is so great that the energy needed to lift a sugar cube one centimeter, if converted to a blue-green light, would suffice to give an intense sensation of a flash to every human who ever existed.”

Phototransduction involves a cascade of chemical and electrical events to detect, to amplify, and to signal a response to light. As do many other sensory receptors, photoreceptors use electrical events (receptor potentials) to carry the visual signal from the outer segment to their synapses. Chemical messengers diffusing over such a distance would simply be too slow. A surprising fact about the receptor potential of rods and cones is that it is *hyperpolarizing*. Light causes the cell's V_m to become *more negative* than the resting potential that it maintains in the dark ([Fig. 15-11A](#)). At low light intensities, the size of the receptor potential rises linearly with light intensity; but at higher intensities, the response saturates.

A LIGHT-EVOKED HYPERPOLARIZATIONS

B LIGHT STIMULATING A SINGLE ROD

C DARK

D LIGHT

FIGURE 15-11 Phototransduction. **A**, The experiment for which results are summarized here was performed on a red-sensitive cone from a turtle. A brief flash of light causes a hyperpolarization of the photoreceptor cell. The size of the peak and the duration of the receptor potential increase with the increasing intensity of the flash. At low light intensities, the magnitude of the peak increases linearly with light intensity. At high intensities, the peak response saturates, but the plateau becomes longer. **B**, A single rod has been sucked into a pipette, which allows the investigators to monitor the current. The horizontal white band is the light used to stimulate the rod. **C**, In the absence of light, Na^+ enters the outer segment of the rod through cGMP-gated channels and depolarizes the cell. The electrical circuit for this dark current is completed by K^+ leaving the inner segment. The dark current, which depolarizes the cell, leads

to constant transmitter release. **D**, In the presence of light, Na^+ can no longer enter the cell because cGMP levels are low, and the cGMP-gated channel closes. The photoreceptor cell thus hyperpolarizes, and transmitter release decreases. (**A**, Data from Baylor DA, Hodgkin AL, Lamb TD: The electrical response of turtle cones to flashes and steps of light. *J Physiol* 242:685–727, 1974; **B**, from Baylor DA, Lamb TD, Yau K-W: Responses of retinal rods to single photons. *J Physiol* 288:613–634, 1979.)

Hyperpolarization is an essential step in relaying the visual signal because it directly modulates the rate of transmitter release from the photoreceptor onto its postsynaptic neurons. This synapse is conventional in that it releases more transmitter—in this case glutamate—when its presynaptic terminal is depolarized and less when it is hyperpolarized. Thus, a flash of light causes a *decrease* in transmitter secretion. The upshot is that the vertebrate photoreceptor is most active in the dark.

How is the light-induced hyperpolarization generated? **Figure 15-11B** shows a method to measure the current flowing across the membrane of the outer segment of a single rod. In the dark, each photoreceptor produces an ionic current that flows steadily into the outer segment and out of the inner segment. This **dark current** is carried mainly by inwardly directed Na^+ ions in the outer segment and by outwardly directed K^+ ions from the inner segment (see **Fig. 15-11C**). Na^+ flows through a nonselective cation channel of the outer segment, which light indirectly regulates, and K^+ flows through a K^+ channel in the inner segment, which light does not regulate. Na^+ carries ~90% of the dark current in the outer segment, and Ca^{2+} , ~10%. In the dark, V_m is about -40 mV. Na-K pumps, primarily located within the inner segments, remove the Na^+ and import K^+ . An Na-Ca exchanger removes Ca^{2+} from the outer segment.

Absorption of photons leads to closure of the nonselective cation channels in the outer segment. The total conductance of the cell membrane decreases. Because the K^+ channels of the inner segment remain open, K^+ continues to flow out of the cell, and this outward current causes the cell to hyperpolarize (see **Fig. 15-11D**). The number of cation channels that close depends on the number of photons that are absorbed. The range of one rod's sensitivity is 1 to ~1000 photons.

Baylor and colleagues measured the minimum amount of light required to produce a change in receptor current (see **Fig. 15-11B**). They found that absorption of 1 photon suppresses a surprisingly large current, equivalent to the entry of $>10^6$ Na^+ ions, and thus represents an enormous amplification of energy. The single-photon response is also much larger than the background electrical noise in the rod, as it must be to produce the rod's high sensitivity to dim light. Cones respond similarly to single photons, but they are inherently noisier and their response is only $\sim 1/50$ the size of that in the rod. Cone responses do not saturate, even at the brightest levels of natural light. Cones also respond faster than rods.

Rhodopsin is a G protein–coupled “receptor” for light

How can a single photon stop the flow of 1 million Na^+ ions across the membrane of a rod cell? The process begins when the photon is absorbed by rhodopsin, the light receptor molecule. **Rhodopsin** is one of the most tightly packed proteins in the body, with a density of ~30,000 molecules per square micrometer in the disk membranes. Thus, the packing ratio is 1 protein molecule for every 60 lipid molecules! One rod contains $\sim 10^9$ rhodopsin molecules. This staggering density ensures an optimized capture rate for photons passing through a photoreceptor. Even so, only ~10% of the light entering the eye is used by the receptors. The rest is either absorbed by the optical components of the eye or passes between or through the receptors. Rhodopsin has two key components: retinal and the protein opsin. Retinal is the aldehyde of **vitamin A**, or retinol (~500 Da). **Opsin** is a single polypeptide (~41 kDa) with seven membrane-spanning segments (**Fig. 15-12A**). It is a member of the superfamily of GPCRs (see **pp. 51–52**) that includes many neurotransmitter receptors as well as the olfactory receptor molecules.

A RHODOPSIN

B RETINAL

C VISUAL TRANSDUCTION

FIGURE 15-12 Rhodopsin, transducin, and signal transduction at the molecular level. **A**, The opsin molecule is a classic seven-transmembrane receptor that couples to transducin, a G protein. When the opsin is attached to retinal (magenta structure) via amino-acid residue 296 in the seventh (i.e., most C-terminal) membrane-spanning segment of opsin, the assembly is called rhodopsin. **B**, The absorption of a photon by 11-*cis* retinal causes the molecule to isomerize to all-*trans* retinal. **C**, After rhodopsin absorbs a photon of light, it activates many transducins. The activated α subunit of transducin ($G\alpha_i$) in turn activates phosphodiesterase, which hydrolyzes cGMP. The resultant decrease in $[cGMP]_i$ closes cGMP-gated channels and produces a hyperpolarization (receptor potential). GMP, 5'-guanylate monophosphate; NCKX1, the $Na^+/(Ca^{2+}-K^+)$ exchanger (SLC24A1). (A, Data from Palczewski K, Kumasaka T, Miyano, M et al: Crystal structure of rhodopsin: A G protein-coupled receptor. *Science* 289(5480):739–745, 2000. Reconstructed figure is courtesy of S. Filipek and K. Palczewski.)

To be transduced, photons are actually absorbed by **retinal**, which is responsible for rhodopsin's color. The tail of retinal can twist into a variety of geometric configurations, one of which is a kinked and unstable version called **11-*cis* retinal** (see Fig. 15-12B). The *cis* form sits within a pocket of the opsin (comparable to the ligand-binding site of other GPCRs) and is covalently bound to it. However, because of its instability, the *cis* form can exist only in the dark. If 11-*cis* retinal absorbs a photon, it isomerizes within 1 ps to a straighter and more stable version called **all-*trans* retinal**. This isomerization in turn triggers a series of conformational changes in the opsin that lead to a form called **metarhodopsin II**, which can activate an attached molecule called transducin. Transducin carries the signal forward in the cascade and causes a reduction in Na^+ conductance. Soon after isomerization, all-*trans* retinal and opsin separate in a process called **bleaching**; this separation causes the color to change from the rosy red of rhodopsin (*rhodon* is Greek for the color “rose”) to the pale yellow of opsin. The photoreceptor cell converts all-*trans* retinal to retinol (vitamin A), which then translocates to the pigment epithelium and becomes 11-*cis* retinal. This compound makes its way back to the outer segment, where it recombines with opsin. This cycle of rhodopsin regeneration takes a few minutes.

Transducin is so named because it transduces the light-activated signal from rhodopsin into the photoreceptor membrane's response (see Fig. 15-12C). Transducin was the first of the large family of GTP-binding proteins (G proteins; see p. 52) to be identified, and its amino-acid sequence is very similar to that of other G proteins (see Table 3-2). When it is activated by metarhodopsin, the α subunit of transducin exchanges a bound GDP for a GTP and then diffuses within the plane of the membrane to stimulate a **phosphodiesterase** that hydrolyzes cGMP to 5'-guanylate monophosphate.

cGMP is the diffusible second messenger that links the light-activated events of the disk membranes to the electrical events of the outer membrane. A key discovery by Fesenko and colleagues in 1985 showed that the “light-sensitive” cation channel of rods is actually a cGMP-gated cation channel (see pp. 169–172). This CNG channel was the first of its kind to be discovered (we have already discussed a similar channel in olfactory receptors). In the dark, a **constitutively active guanylyl cyclase** that synthesizes cGMP from GTP keeps cGMP levels high within the photoreceptor cytoplasm. This high $[cGMP]_i$ causes the cGMP-gated cation channels to spend much of their time open and accounts for the dark current (see Fig. 15-11C). Because light stimulates the phosphodiesterase and thus decreases $[cGMP]_i$, light reduces the number of open cGMP-gated cation channels and thus reduces the dark current. The photoreceptor then hyperpolarizes, transmitter release falls, and a visual signal is passed to retinal neurons.

Strong amplification occurs along the phototransduction pathway. The absorption of 1 photon activates 1 metarhodopsin molecule, which can activate ~ 700 transducin molecules within ~ 100 ms. These transducin molecules activate phosphodiesterase, which increases the rate of cGMP hydrolysis by ~ 100 -fold. One photon leads to the hydrolysis of ~ 1400 cGMP molecules by the peak of the response, thus reducing $[cGMP]_i$ by $\sim 8\%$ in the cytoplasm around the activated disk. This decrease in $[cGMP]_i$ closes

~230 of the 11,000 cGMP-gated channels that are open in the dark. As a result, the dark current falls by ~2%.

The cGMP-gated channel has additional interesting properties. It responds within milliseconds when $[cGMP]_i$ rises, and it does not desensitize in response to cGMP. The concentration-response curve is very steep at low $[cGMP]_i$ because opening requires the simultaneous binding of three cGMP molecules. Thus, the channel has switch-like behavior at physiological levels of cGMP. Ion conductance through the channel also has steep voltage dependence because Ca^{2+} and Mg^{2+} strongly block the channel (as well as permeate it) within its physiological voltage range. This open-channel block (see Fig. 7-20D) makes the normal single-channel conductance very small, among the smallest of any ion channel; the open channel normally carries a current of only 3×10^{-15} A (3 fA)! The currents of ion channels are inherently “noisy” as they flicker open and closed. However, the 11,000 channels—each with currents of 3 fA—summate to a rather noise-free dark current of 11,000 channels \times 3 fA per channel = 33 pA. In contrast, if 11 channels—each with currents of 3 pA—carried the dark current of 33 pA, the 2% change in this signal (0.66 pA) would be smaller than the noise produced by the opening and closing of a single channel (3 pA). Thus, the small channels give the photoreceptor a high signal-to-noise ratio.

The $[cGMP]_i$ in the photoreceptor cell represents a dynamic balance between the synthesis of cGMP by guanylyl cyclase and the breakdown of cGMP by phosphodiesterase. Ca^{2+} , which enters through the relatively nonselective cGMP-gated channel, synergistically inhibits the guanylyl cyclase and stimulates the phosphodiesterase. These Ca^{2+} sensitivities set up a negative-feedback system. In the dark, the incoming Ca^{2+} prevents runaway increases in $[cGMP]_i$. In the light, the ensuing decrease in $[Ca^{2+}]_i$ relieves the inhibition on guanylyl cyclase, inhibits the phosphodiesterase, increases $[cGMP]_i$, and thus poises the system for channel reopening.

When a light stimulus terminates, the activated forms of each component of the transduction cascade must be inactivated. One mechanism of this termination process appears to involve the channels themselves. As described in the preceding paragraph, closure of the cGMP-gated channels in the light leads to a fall in $[Ca^{2+}]_i$, which helps replenish cGMP and facilitates channel reopening. Two additional mechanisms involve the proteins rhodopsin kinase and arrestin. **Rhodopsin kinase** phosphorylates light-activated rhodopsin and allows it to be recognized by arrestin. **Arrestin**, an abundant cytosolic protein, binds to the phosphorylated light-activated rhodopsin and completely terminates its ability to activate transducin.

The eye uses a variety of mechanisms to adapt to a wide range of light levels

The human eye can operate effectively over a 10^{10} -fold range of light intensities, which is the equivalent of going from almost total darkness to bright sunlight on snow. However, moving from a bright to a dark environment, or vice versa, requires time for adaptation before the eye can respond optimally. Adaptation is mediated by several mechanisms. One mechanism mentioned above is regulation of the size of the pupil by the iris, which can change light sensitivity by ~16-fold. That still leaves the vast majority of the range to account for. During **dark adaptation**, two additional mechanisms with very different time courses are evident, as we can see from a test of the detection threshold for the human eye (Fig. 15-13). The first phase of adaptation is finished within ~10 minutes and is a property of the cones; the second takes at least 30 minutes and is attributed to the rods. A fully dark-adapted retina, relying on rods, can have a light threshold that is as much as 15,000 times lower than a retina relying on cones. In essence, then, the human

eye has two retinas in one, a rod retina for low light levels and a cone retina for high light levels. These two systems can operate at the same time; when dark adapted, the rods can respond to the lowest light levels, but cones are available to respond when brighter stimuli appear.

FIGURE 15-13 Effect of dark adaptation on the visual threshold. The subject was exposed to light at a level of 1600 millilumens and then switched to the dark. The graph is a plot of the time course of the subject's relative threshold (on a log scale) for detecting a light stimulus. (Data from Hecht S, Shlaer S, Smith EL, et al: The visual functions of the complete color blind. *J Gen Physiol* 31:459–472, 1948.)

The rapid and slow phases of adaptation that are discussed in the preceding paragraph have both neural and photoreceptor mechanisms. The *neural* mechanisms are relatively fast, operate at relatively low ambient light levels, and involve multiple mechanisms within the neuronal network of the retina. The *photoreceptor* mechanisms involve some of the processes that are described in the previous section. Thus, in bright sunlight, rods become ineffective because most of their rhodopsin remains inactivated, or bleached. cGMP-gated channels are closed and thus Ca^{2+} entry is blocked, so $[\text{Ca}^{2+}]_i$ falls to a few nanomolar as Ca^{2+} is removed by the $\text{Na}^+/(\text{Ca}^{2+}-\text{K}^+)$ exchanger NCKX1 (SLC24A1; see [Table 5-4](#)). After returning to darkness, the rods slowly regenerate rhodopsin and become sensitive once again. However, a component of the cGMP system also regulates photoreceptor sensitivity. In the dark, when baseline $[\text{cGMP}]_i$ is relatively high, substantial amounts of Ca^{2+} enter through cGMP-gated channels. The resultant high $[\text{Ca}^{2+}]_i$ (several hundred nanomolars) inhibits guanylyl cyclase and stimulates phosphodiesterase, thereby preventing $[\text{cGMP}]_i$ from rising too high. Conversely, when background light levels are high, this same feedback system causes baseline $[\text{cGMP}]_i$ to remain high so that $[\text{cGMP}]_i$ can fall in response to further increases in light levels. Otherwise, the signal-transduction system would become saturated. In

other words, the photoreceptor adapts to the increased background light intensity and remains responsive to small changes. Additional adaptation mechanisms regulate the sensitivity of rhodopsin, guanylyl cyclase, and the cGMP-gated channel. Clearly, adaptation involves an intricate network of molecular interactions.

Color vision depends on the different spectral sensitivities of the three types of cones

The human eye responds only to a small region of the electromagnetic spectrum (see [Fig. 15-5](#)), but within it, we are exquisitely sensitive to the light's wavelength. We see assorted colors in a daytime panorama because objects absorb some wavelengths while reflecting, refracting, or transmitting others. Different sources of light may also affect the colors of a scene; the light from tungsten bulbs is reddish, whereas that of fluorescent bulbs is bluish.

Research on color vision has a long history. In 1801, Thomas Young first outlined the trichromatic theory of color vision, which was championed later in the 19th century by Hermann von Helmholtz. These investigators found that they could reproduce a particular sample hue by mixing the correct intensities of three lights with the primary hues blue, green, and red. They proposed that color vision, with its wide range of distinct, perceived hues, is based on only three different pigments in the eye, each absorbing a different range of wavelengths. Microspectrophotometry of single cones in 1964 amply confirmed this scheme. Thus, although analysis of color by the human brain is sophisticated and complex, it all derives from the responses of only three types of photopigments in cones.

Our sensitivity to the wavelength of light depends on the retina's state of adaptation. When it is dark adapted (also called **scotopic** conditions), the spectral sensitivity curve for human vision is shifted toward shorter wavelengths compared with the curve obtained after light adaptation (**photopic** conditions; [Fig. 15-14A](#)). The absolute sensitivity to light can also be several orders of magnitude higher under scotopic conditions (see [Fig. 15-13](#)). The primary reason for the difference in these curves is that rods are doing the transduction of dim light under dark-adapted conditions, whereas cones transduce in the light-adapted eye. As we would predict, the spectral sensitivity curve for scotopic vision is quite similar to the absorption spectrum of the rods' rhodopsin, with a peak at 500 nm.

A SPECTRAL SENSITIVITY UNDER DARK- AND LIGHT-ADAPTED CONDITIONS

B ABSORBANCE SPECTRA OF THE HUMAN PHOTOPIGMENTS

FIGURE 15-14 Sensitivity of vision and photoreceptors at different wavelengths of light. **A**, The graph shows the results of a psychophysical experiment. Under dark-adapted (scotopic) conditions, the human eye is maximally sensitive at ~500 nm. Under light-adapted (photopic) conditions, the eye is maximally sensitive at ~560 nm. **B**, The spectral sensitivity of rods (obtained with a spectrophotometer) peaks at ~500 nm; that of the three types of cones peaks at ~420 nm for the S (blue) cone, ~530 nm for the M (green) cone, and ~560 nm for the L (red) cone; and that of melanopsin peaks at ~475 nm. Each

absorbance spectrum has been normalized to its peak sensitivity. (A, Data from Knowles A: The biochemical aspects of vision. In Barlow HB, Mollon JD [eds]: The Senses. Cambridge, UK, Cambridge University Press, 1982, pp 82–101; B, rhodopsin data from Dartnall HJ, Bowmaker JK, Mollon JD: Microspectrophotometry of human photoreceptors. In Mollon JD, Sharpe LT [eds]: Colour Vision. London, Academic Press, 1983, pp 69–80; melanopsin data from Matsuyama T, Yamashita T, Imamoto Y, Shichida Y: Photochemical properties of mammalian melanopsin. Biochemistry 51:5454–5462, 2012.)

The spectral sensitivity of the light-adapted eye depends on the photopigments in the cones. Humans have three different kinds of cones, and each expresses a photopigment with a different absorbance spectrum. The peaks of their absorbance curves fall at ~420, 530, and 560 nm, which correspond to the violet, yellow-green, and yellow-red regions of the spectrum (see [Fig. 15-14B](#)). The three cones and their pigments were historically called blue, green, and red, respectively. They are now more commonly called S, M, and L (for short, medium, and long wavelengths); we use this terminology here. Because the absolute sensitivity of the short-wavelength cone is only one tenth that of the other two, the spectral sensitivity of photopic human vision is dominated by the two longer-wavelength cones (compare the spectral sensitivity functions in [Fig. 15-14A](#) with the absorbance spectra of the cones in [Fig. 15-14B](#)).

Single cones do not encode the wavelength of a light stimulus. If a cone responds to a photon, it generates the same response regardless of the wavelength of that photon. A glance at [Figure 15-14B](#) shows that each type of cone pigment can absorb a wide range of wavelengths. The pigment in a cone is more likely to absorb photons when their wavelength is at its peak absorbance, but light hitting the cone on the fringe of its absorbance range can still generate a large response if the light's intensity is sufficiently high. This property of response **univariance** is the reason that vision in an eye with only one functioning pigment (e.g., scotopic vision using only rods) can only be monochromatic. With a single pigment system, the distinction between different colors and between differences in intensity is confounded. Two different cones (as in most New World monkeys), each with a different but overlapping range of wavelength sensitivities, remove much of the ambiguity in encoding the wavelength of light stimuli. With three overlapping pigments (as in Old World monkeys and humans), light of a single wavelength stimulates each of the three cones to different degrees, and light of any other wavelength stimulates these cones with a distinctly different pattern. Because the nervous system can compare the *relative* stimulation of the three cone types to decode the wavelength, it can also distinguish changes in the intensity (luminance) of the light from changes in its wavelength.

Color capabilities are not constant across the retina. The use of multiple cones is not compatible with fine spatial discrimination because of wavelength-dependent differences in the eye's ability to focus light, known as **chromatic aberration**, and because very small objects may stimulate only single cones. The fovea has only M and L cones, which limits its color discrimination in comparison to the peripheral portions of the retina but leaves it best adapted to discriminate fine spatial detail ([Box 15-1](#)).

Box 15-1

Inherited Defects in Color Vision

Inherited defects in color vision are relatively common, and many are caused by mutations in visual pigment genes. For example, 8% of white males and 1% of white females have some defect in their L or M pigments caused by X-linked recessive mutations. A single abnormal pigment can lead to either **dichromacy** (the absence of one functional pigment) or **anomalous trichromacy** (a shift in the absorption spectrum of one pigment relative to normal), often with a consequent inability to distinguish certain colors. Jeremy Nathans and colleagues found that men have only one copy of the L pigment gene; but located right next to it on the X chromosome, they may have one to three copies of the M pigment gene.

He proposed that homologous recombination could account for the gene duplication, loss of a gene, or production of the hybrid L-M genes that occur in red-green color blindness. Hybrid L-M pigments have spectral properties intermediate between those of the two normal pigments, probably because their opsins possess a combination of the traits of the two normal pigments.

Lack of two of the three functional cone pigments leads to **monochromacy**. The number of people who have such true color blindness is very small, <0.001% of the population. For example, S-cone monochromacy is a rare X-linked disorder in which both L and M photopigments are missing because of mutations on the X chromosome. The S pigment gene is on chromosome 7.

The four different human visual pigments have a similar structure. The presence of retinal and the mechanisms of its photoisomerization are essentially identical in each. The main difference is the primary structure of the attached protein, the opsin. M and L opsins share 96% of their amino acids. Pairwise comparisons among the other opsins show only 44% or lower sequence similarity, however. Apparently, the different amino-acid structures of the opsins affect their charge distributions in the region of the 11-*cis* retinal and shift its absorption spectrum to give the different pigments their specific spectral sensitivities.

The ipRGCs have unique properties and functions

The ipRGC, the third retinal photoreceptor, differs from rods and cones in fundamental ways. First, instead of expressing rhodopsin or cone opsins, ipRGCs use a related but unique light-sensitive protein called **melanopsin** that is most sensitive in the blue part of the spectrum (~475 nm; see [Fig. 15-14B](#)). Second, ipRGCs depolarize in response to light, and if the stimulus is strong enough, they generate action potentials. Rods and cones hyperpolarize when illuminated and never generate action potentials. Third, to reach threshold, the ipRGCs require very bright light—several orders of magnitude stronger than the threshold for cone responses. Fourth, ipRGCs take seconds to respond, and they quite faithfully maintain their responses even when light levels are sustained for hours.

Most of the molecular components of melanopsin-mediated phototransduction in ipRGCs are unknown. However, ipRGCs resemble invertebrate photoreceptors much more than they resemble rods and cones. Melanopsin seems to activate a G protein of the G_q family (see [Table 3-2](#)), which stimulates PLC to produce IP_3 and diacylglycerol (DAG); this causes TRP channels to open and depolarizes the neuron. When light hits rods and cones it reduces $[cGMP]_i$, causing CNG channels to close and hyperpolarizing the photoreceptor (see [p. 368](#)). Ironically, although ipRGCs are by definition intrinsically photosensitive they also receive some input from rods and cones via synapses of bipolar cells and amacrine cells.

What are the functions of ipRGCs? With their slow, maintained responses to relatively bright light, they seem well equipped for reporting the levels of ambient daytime illumination. With their very large receptive fields, sparse numbers, and sluggishness, ipRGCs are not well adapted to the image-forming functions we usually think of as “vision”—processes that cones and rods perform so well. In fact, ipRGCs help to mediate a variety of non-image-forming processes that are reflexive and subconscious. The body maintains circadian rhythms for most physiological processes; some ipRGCs send axons to the suprachiasmatic nuclei in the hypothalamus to ensure that its circadian clock is synchronized with the light-dark cycles of day and night. The ipRGCs mediate the pupillary light reflex by sending axons to the pretectal nuclei (see [Fig. 15-8](#)). Activity of ipRGCs inhibits the production of melatonin by the pineal gland. They also provide photic information to some of the brain's sleep-wake regulatory systems.

Vestibular and Auditory Transduction: Hair Cells

Balancing on one foot and listening to music both involve sensory systems that have similar transduction mechanisms. Sensation in both the vestibular and auditory systems begins with the inner ear, and both use a highly specialized kind of receptor called the **hair cell**. Common structure and function often suggest a common origin, and indeed, the organs of mammalian hearing and balance both evolved from the **lateral line organs** present in all aquatic vertebrates. The lateral line consists of a series of pits or tubes along the flanks of an animal. Within each indentation are clusters of sensory cells that are similar to hair cells. These cells have microvilli-like structures that project into a gelatinous material that in turn is in contact with the water in which the animal swims. The lateral line is exquisitely sensitive to vibrations or pressure changes in the water in many animals, although it is also sensitive to temperature or electrical fields in some species. Reptiles abandoned the lateral line during their evolution, but they retained the hair cell-centered sensory structures of the inner ear that evolved from the lateral line.

The vestibular system generates our sense of balance and the auditory system provides our sense of hearing. **Vestibular sensation** operates constantly while we are awake and communicates to the brain the head's orientation and changes in the head's motion. Such information is essential for generating muscle contractions that will put our body where we want it to be, reorienting the body when something pushes us aside (vestibulospinal reflexes), and moving our eyes continually so that the visual world stays fixed on our retinas even though our head may be nodding about (vestibulo-ocular reflexes).  **N15-4** Vestibular dysfunction can make it impossible to stabilize an image on our moving retinas, and it causes the disconcerting feeling that the world is uncontrollably moving around—**vertigo**. Walking and standing can be difficult or impossible. With time, compensatory adjustments are made as the brain learns to substitute more visual and proprioceptive cues to help guide smooth and accurate movements.

N15-4

Vestibulo-ocular Reflexes

Contributed by Philine Wangemann

Through **vestibulospinal reflexes**, the vestibular system influences body posture, which is essential for balancing our body, preventing it from falling, and—when falling—lifting our head to prevent it from impact injury. Further, through **vestibulo-ocular reflexes**, the vestibular system influences movements of the eyes, which stabilize images on our retinas during head movements.

Since visual processing in the retina is relatively slow, it is necessary to stabilize the images of the world on the retina. Stabilizing reflexes, collectively called vestibulo-ocular reflexes, enable you to read this text while shaking your head. Note that it is much more difficult to read while shaking the book! The vestibular system measures head movements and elicits compensatory movements of the eyes (eFig. 15-1). The position of each eye is controlled by three pairs of muscles that control horizontal, vertical and rotational eye movements. Vestibulo-ocular reflexes are linked to all five vestibular organs to enable compensatory eye movements in every direction. Muscles that control **horizontal eye movements** are linked to the horizontal semicircular canals and the utricle. Muscles that control **vertical eye movements** are linked to the anterior and posterior semicircular canals and the saccule. Finally, muscles that control **rotational eye movements** are linked to the anterior and posterior semicircular canals and the utricle. Vestibulo-ocular reflexes can be suppressed during the observation of moving targets—for example,

watching a bird or a ball flying by.

During large rotations, for example during spinning, the eye movements required for stabilizing an image on the retina exceed the limits of the orbit. Under these conditions, vestibulo-ocular reflexes elicit fast reset movements of the eyes. Alternations between slow movements of the eyes intended to stabilize images on the retina and fast reset motions are called **nystagmus** (from the Greek *nystagmos* [tired or sleepy, like the nodding movement of the head just before falling asleep]). Nystagmus can occur in all directions and is named by the direction of the *fast reset phase* (e.g., rightward nystagmus). Lesions of the vestibular system, for example in head trauma or stroke, can lead to a **spontaneous nystagmus** when altered neuronal activity is falsely interpreted as head movements. Nystagmus induced by body rotations or by a caloric test is used clinically to evaluate vestibular function because lesions alter or eliminate nystagmus. The **caloric test** consists of introducing cold (30°C) or warm (40°C) water into the external ear canal. Temperature changes induce convective movements of endolymph that are interpreted as head rotations. Comparisons of the caloric responses of the left and right ear can be used to localize lesions.

EFIGURE 15-1 Example of a vestibulo-ocular reflex. **A**, Head rotation to the left causes endolymph to push and pull on the cupulae of the left and right horizontal canals, respectively. **B**, Movement of the cupula tilts hair bundles in the ampulla of the left horizontal canal in the stimulatory direction, leading to excitation of afferent dendrites and an increase in the frequency of action potentials. Conversely, movement of the cupula tilts hair bundles in the ampulla of the right horizontal canal in the inhibitory direction, which leads to a cessation of afferent stimulation and a decrease in the frequency of action potentials. **C**, Head rotations have a linear component that results from centrifugal forces against gravity. Centrifugal forces move the otolith membranes of the left and right macula utricles to the left.

Displacements of the otolith membranes causes stimulation and inhibition of afferent activity depending on the orientation of the hair bundles. Note that the simple left head movement is coded by an intricate pattern of increased and decreased neuronal activity. The pattern is analyzed by the vestibular nuclei and used to elicit compensatory movements of the eyes to ensure that images remain stable on the retina during head movements. (Courtesy Philine Wangemann.)

Auditory sensation is often at the forefront of our conscious experience, unlike vestibular information, which we rarely notice unless something goes wrong. Hearing is an exceptionally versatile process that allows us to detect things in our environment, to precisely identify their nature, to localize them well at a distance, and, through language, to communicate with speed, complexity, nuance, and emotion.

Bending the stereovilli of hair cells along one axis causes cation channels to open or to close

Hair cells are mechanoreceptors that are specialized to detect minuscule movement along one particular axis. The hair cell is an epithelial cell (see pp. 43–45); the hair bundles project from the apical end, whereas synaptic contacts occur at the basal end. Hair cells are somewhat different in the vestibular and auditory systems. In this section, we illustrate concepts mainly with the vestibular hair cell (Fig. 15-15A), which comes in two subtypes. Vestibular **type I** cells have a bulbous basal area, surrounded by a calyx-shaped afferent nerve terminal (see Fig. 15-15B, left). Vestibular **type II** hair cells are more cylindrical and have several simple, bouton-shaped afferent nerve terminals (see Fig. 15-15B, right). Auditory hair cells also come in two varieties, **inner hair cells** and **outer hair cells** (see pp. 378–380). However, all hair cells sense movement in basically the same way.

A VESTIBULAR HAIR BUNDLES

B VESTIBULAR HAIR CELLS

FIGURE 15-15 Vestibular hair cells. **A**, Scanning electron micrograph of a bullfrog hair cell from the sensory epithelium of the saccule. **B**, Type I and type II cells. (**A**, From Corey DP, Assad JA: In Corey DP, Roper SD [eds]: Sensory Transduction. New York, Rockefeller University Press, 1992; **B**, data from Philine Wagemann, Kansas State University.)

As part of their hair bundles, *vestibular* hair cells (see Fig. 15-15B) have one large **kinocilium**, which is a true cilium with the characteristic 9 + 2 pattern of microtubules (see Fig. 2-11C). The role of the kinocilium is unknown. In mammals, *auditory* hair cells lose their kinocilium with maturity.

Both vestibular and auditory hair cells have 50 to 150 **stereovilli**, which are filled with actin and are more akin to microvilli. The stereovilli—often called stereocilia, although they lack the typical 9 + 2 pattern of true cilia—are 0.2 to 0.8 μm in diameter and are generally 4 to 10 μm in height. These “hairs” are arranged in a neat array. In the *vestibular* system, the kinocilium stands tallest along one side of the bundle and the stereovilli fall away in height to the opposite side (see Fig. 15-15B). Stereovilli are narrower at their base and insert into the apical membrane of the hair cell, where they make a sort of hinge before connecting to a cuticular plate. Within the bundle, stereovilli are connected one to the next, but they can slide with respect to each other as the bundle is deflected side to side. The ends of the stereovilli are interconnected with very fine strands called **tip links**, which are visible by electron microscopy.

The epithelium of which the hair cells are a part separates perilymph from endolymph. The **perilymph** bathes the basolateral side of the hair cells. In composition (i.e., relatively low $[\text{K}^+]$, high $[\text{Na}^+]$), perilymph is similar to CSF. Its voltage is zero—close to that of most other extracellular fluids in the body. The basolateral resting potential of vestibular hair cells and auditory inner hair cells is about -40 mV (see Fig. 15-15B). The **endolymph** bathing the stereovilli is singular in composition. It has a very

high $[K^+]$ (150 mM) and a very low $[Na^+]$ (1 mM), more like cytoplasm than extracellular fluid. It also has a relatively high $[HCO_3^-]$ (30 mM). The voltage of the vestibular endolymph is ~ 0 mV relative to perilymph. Across the apical membrane of vestibular hair cells, the *chemical* gradient for K^+ is small. However, the *electrical* gradient is fairly large, ~ 40 mV. Thus, a substantial force tends to drive K^+ into the vestibular hair cell across the apical membrane. We will see that the driving force for K^+ influx is even higher in the auditory system (see [p. 378](#)).

The appropriate stimulus for a hair cell is the bending of its hairs, but not just any deflection will do. Bending of the hair bundle *toward* the longer stereovilli ([Fig. 15-16A](#)) excites the cell and causes a depolarizing **receptor potential** (see [pp. 353–354](#)). Bending of the hair bundle *away from* the longer stereovilli (see [Fig. 15-16B](#)) hyperpolarizes the cell. Only tiny movements are needed. In auditory hair cells, as little as 0.5 nm (which is the diameter of a large atom) gives a detectable response, and the response is saturated at ~ 150 nm, about the diameter of one stereovillus or 1 degree of angular deflection! In fact, the sensitivity of hair cells is limited only by noise from the brownian motion of surrounding molecules. The cell is also exquisitely selective to direction. If the hairs are bent along the axis 90 degrees to their preferred direction, they are less than one tenth as responsive.

A POSITIVE MECHANICAL DEFORMATION

Mechanical deformation toward the kinocilium opens K^+ channels in the stereocilia.

B NEGATIVE MECHANICAL DEFORMATION

Mechanical deformation away from the kinocilium causes the K^+ channels to close.

Ca^{2+} enters the cell, allowing vesicle fusion and the release of transmitter.

FIGURE 15-16 Mechanotransduction in the hair cell. Both panels portray a vestibular hair cell, with an endolymph voltage of 0 mV. **A**, At rest, a small amount of K^+ leaks into the cells, driven by the negative membrane potential and high apical $[K^+]$. Mechanical deformation of the hair bundle *toward* the longer stereovilli increases the opening of nonselective cation channels at the tips of the stereovilli, which allows K^+ influx and depolarizes the cell. In all hair cells except the auditory outer hair cells, the depolarization activates voltage-sensitive Ca^{2+} channels on the basal membrane, causing release of synaptic vesicles and stimulating the postsynaptic membrane of the accompanying sensory neuron. **B**, Mechanical deformation of the hair bundle *away* from the longer stereovilli causes the nonselective cation channels to close, which leads to hyperpolarization.

Mechanotransduction in hair cells seems to be accomplished by directly linking the movement of the stereovilli to the gating of apical mechanosensitive cation channels. Electrical measurements, as well as the imaging of intracellular Ca^{2+} , imply that the transduction channels are located near the tips of the stereovilli. How is channel gating connected to movement of the hairs? The latency of channel opening is extremely short, $<40\ \mu\text{s}$. If one deflects the hairs more rapidly, the channels are activated more quickly. This observation suggests a direct, physical coupling inasmuch as diffusion of a second messenger would take much longer. Corey and Hudspeth have suggested a spring-like molecular linkage between the movement of stereovilli and channel gating. The tip links may be the tethers between stereovilli and the channels, with the channels located at the lower ends of the tip links. Tip links themselves are formed from two types of cadherins, cadherin 23 and protocadherin 15, which form strands of high stiffness. Brief exposure to low- Ca^{2+} solutions destroys the tip links, without otherwise causing obvious harm to the cells, and thereby abolishes transduction.

The mechanosensitive channels at the tips of the stereovilli are nonselective cation channels with relatively large unitary conductances (150 to 300 picosiemens, depending on hair cell type), allowing monovalent and some divalent cations, including Ca^{2+} , to pass easily. Each stereovillus has no more than two channels, which makes their identification elusive. Under physiological conditions, K^+ carries most of the current through the transduction channels. When the cell is at rest—hairs straight up—a small but steady leak of depolarizing K^+ current flows through the cell. This leak allows the hair cell to respond to both positive and negative deflections of its stereovilli. A positive deflection—toward the tallest stereovilli—further opens the apical channels, leading to *influx* of K^+ and thus *depolarization*. K^+ leaves the cell through mechanoinsensitive K^+ channels on the basolateral side (see Fig. 15-16A), along a favorable electrochemical gradient. A negative deflection closes the apical channels and thus leads to *hyperpolarization* (see Fig. 15-16B).

A hair cell is not a neuron. Hair cells do not project axons of their own, and most do not generate action potentials. Instead—in the case of vestibular hair cells and auditory inner hair cells—the membrane near the presynaptic (i.e., basolateral) face of the cell has voltage-gated Ca^{2+} channels that are somewhat active at rest but more active during mechanically induced depolarization (i.e., the receptor potential) of the hair cell. The Ca^{2+} that enters the hair cell through these channels triggers the graded release of glutamate as well as aspartate in the case of vestibular hair cells. These excitatory transmitters stimulate the postsynaptic terminal of sensory neurons that transmit information to the brain. The greater the transmitter release, the greater the rate of action potential firing in the postsynaptic axon.

In mammals, all hair cells—whether part of the vestibular or auditory system—are contained within bilateral sets of interconnected tubes and chambers called, appropriately enough, the **membranous labyrinth** (Fig. 15-17). The **vestibular** portion has five sensory structures: two **otolithic organs**, which detect gravity (i.e., head position) and linear head movements, and three **semicircular canals**, which detect head rotation. Also contributing to our sense of spatial orientation and motion are proprioceptors (see pp. 383–389) and the visual system (see pp. 359–371).  **N15-5** The **auditory** portion of the labyrinth is the spiraling **cochlea**, which detects rapid vibrations (sound) transmitted to it from the surrounding air.

N15-5

Spatial Orientation

Contributed by Philine Wangemann

Proprioceptors in the skin, in tendons and muscles, and in joints provide information about posture, and the visual system provides clues from our surrounding. Although the vestibular system contributes to our conscious perception of motion and body position, vestibular information is mostly processed subconsciously. Through **vestibulospinal reflexes**, the vestibular system influences body posture, which is essential for balancing our body, preventing it from falling, and, when it falls, lifting our head to prevent it from impact injury. Further, through **vestibulo-ocular reflexes**, **N15-4** the vestibular system influences movements of the eyes, which stabilize images on our retinas during head movements.

The ultimate function of each of these sensory structures is to transmit mechanical energy to their hair cells. In each case, transduction occurs in the manner described above. The specificity of the transduction process depends much less on the hair cells than on the structure of the labyrinth organs around them.

The otolithic organs (saccule and utricle) detect the orientation and linear acceleration of the head

The **otolithic organs** are a pair of relatively large chambers—the **saccule** and the **utricle**—near the center of the labyrinth (see Fig. 15-17B). These otolithic organs as well as the semicircular canals are (1) lined

by epithelial cells, (2) filled with endolymph, (3) surrounded by perilymph, and (4) encased in the temporal bone. Within the epithelium, specialized **vestibular dark cells** secrete K^+ and are responsible for the high $[K^+]$ of the endolymph. The mechanism of K^+ secretion is similar to that by the stria vascularis in the auditory system (see [p. 378](#)).

The saccule and utricle each have a sensory epithelium called the **macula**, which contains the hair cells that lie among a bed of supporting cells. The stereovilli project into the gelatinous **otolithic membrane**, a mass of mucopolysaccharides that is studded with otoliths or otoconia ([Fig. 15-18A, B](#)). **Otoconia** are crystals of calcium carbonate, 1 to 5 μm in diameter, that give the otolithic membrane a higher density than the surrounding endolymph. With either a change in the angle of the head or a linear acceleration, the inertia of the otoconia causes the otolithic membrane to move slightly, deflecting the stereovilli.

C AMPULLA OF A SEMICIRCULAR CANAL

D DIRECTION OF HAIR BUNDLES

FIGURE 15-18 Vestibular sensory organs. **A**, In the saccule, the longer stereocilia point *toward* the reversal line. **B**, In the utricle, the longer stereocilia point *away from* the reversal line. **C**, In the ampulla, all stereocilia point in the same direction. **D**, The arrows point toward the longer stereocilia (and kinocilia) and thereby indicate the directions of greatest sensitivity for opening the transduction channels. (Data from Philine Wangemann, Kansas State University.)

The macula is vertically oriented (in the sagittal plane) within the **saccule** and horizontally oriented within the **utricle** when the head is tilted down by ~25 degrees, as during walking. Recall that hair cells are depolarized or hyperpolarized when stereocilia bend toward or away from the kinocilium, respectively (see Fig. 15-16). In the saccule, the kinocilia point *away from* a curving **reversal line** that divides the macula into two regions (see Fig. 15-18D). In the utricle, the kinocilia point *toward* the reversal line. The hair cells of the saccule and utricle respond well to changes in head angle and to acceleration of the sort that is experienced as a car or an elevator starts or stops. Of course, the head can tilt or experience acceleration in many directions. Indeed, the orientations of hair cells of the saccule and utricle covers a full range of directions. Any tilt or linear acceleration of the head will enhance the stimulation of some hair cells, reduce the stimulation of others, and have no effect on the rest.

Each hair cell synapses on the ending of a primary sensory axon that is part of the **vestibular nerve**,

which in turn is a branch of the vestibulocochlear nerve (CN VIII). The cell bodies of these sensory neurons are located in Scarpa's ganglion within the temporal bone. The dendrites project to multiple hair cells, which increases the signal-to-noise ratio. The axons project to the ipsilateral vestibular nucleus in the brainstem. 🟡N15-6 Because the saccule and utricle are paired structures (one on each side of the head), the CNS can simultaneously use information encoded by the full population of otolithic hair cells and unambiguously interpret any angle of tilt or linear acceleration. The push-pull arrangement of increased/decreased activity within each macula (for hair cells of opposite orientation) and between maculae on either side of the head enhances the fidelity of the signal.

N15-6

Vestibular Innervation

Contributed by Philine Wangemann

The vestibular system is innervated by the **vestibular nerve**, which is a branch of CN VIII. The vestibular nerve is comprised of afferent and efferent fibers.

Afferent fibers consist of dendrites of nerve cells from Scarpa's ganglion housed within the temporal bone. Afferent dendrites contact multiple hair cells within small regions of a macula or crista. Integration over several sensory cells increases the signal-to-noise ratio of the sensory information. Axons of Scarpa's ganglion cells contact the ipsilateral vestibular nuclei in the brainstem. Vestibular nuclei analyze information from the labyrinths on both sides of the head and control oculomotor and postural reflexes.

Efferent innervation of the vestibular labyrinth originates from cell bodies that are located lateral to the facial genu in the brainstem. Bilateral axons to the left and right vestibular system synapse onto afferent calyces of type I hair cells and onto type II vestibular hair cells. Vestibular efferent innervation has been hypothesized to maintain long-term calibration of afferent activity between the two vestibular labyrinths.

The semicircular canals detect the angular acceleration of the head

Semicircular canals (see Fig. 15-17B) also sense acceleration, but not the linear acceleration that the otolithic organs prefer. *Angular acceleration* generated by sudden head rotations is the primary stimulus for the semicircular canals. Shake your head side to side or nod it up and down. Each rotation of your head will excite some of your canals and inhibit others.

The semicircular canals stimulate their hair cells differently than the otolithic organs. In each canal, the hair cells are clustered within a sensory epithelium (the **crista ampullaris**) that is located in a bulge along the canal called the **ampulla** (see Fig. 15-18C). The hair bundles—all of which have the same orientation—project into a gelatinous, dome-shaped structure called the **cupula**, which spans the lumen of the ampulla. The cupula contains no otoconia, and its mucopolysaccharides have the same density as the surrounding endolymph. Thus, the cupula is not sensitive to *linear* acceleration. However, with a sudden rotation of the canal, the endolymph tends to stay behind because of its inertia. 🟡N15-4 The endolymph exerts a force on the movable cupula, much like wind on a sail. This force bows the cupula, which bends the hairs and (depending on the direction of rotation) either excites or suppresses the release of transmitter from the hair cells onto the sensory axons of the vestibular nerve. This arrangement makes the semicircular canals very sensitive to angular acceleration of the head. 🟡N15-7

Sensitivity of Semicircular Canals to Head Rotation

Contributed by Barry Connors

If head rotation is maintained at a constant velocity, the friction between the endolymph and the canal walls eventually makes the two move together, so that the bending of the cupula gradually extinguishes during ~15 seconds. When rotation is then stopped, the inertia of the endolymph causes bending of the cupula in the other direction and thus gives a temporary sensation of counter-rotation.

Each side of the head has three semicircular canals that lie in approximately orthogonal planes. The **anterior** canal is tilted ~41 degrees anterolaterally from the sagittal plane, the **posterior** canal is tilted ~56 degrees posterolaterally from the sagittal plane, and the **lateral** canal is tipped ~25 degrees back from the horizontal plane. Because each canal best senses rotation about a particular axis, the three together give a good representation of all possible angles of head rotation. This complete representation is further ensured because each canal is paired with another on the opposite side of the head. Each member of a pair sits within the same plane and responds to rotation about the same axis. However, whereas rotation excites the hair cells of one canal, it inhibits the canals of its contralateral axis mate. This push-pull arrangement presumably increases the sensitivity of detection.

The outer and middle ears collect and condition air pressure waves for transduction within the inner ear

Sound is a perceptual phenomenon that is produced by periodic longitudinal waves of low pressure (rarefactions) and high pressure (compressions) that propagate through air at a speed of 330 to 340 m/s. Absolute sound depends on the amplitude of the longitudinal wave, measured in pascals (Pa). Intensities of audible sounds are commonly expressed in **decibel sound pressure level** (dB SPL), which relates the absolute sound intensity (P_T) to a reference pressure (P_{ref}) of 20 μPa , close to the average human threshold at 2000 Hz.

$$\text{dB SPL} = 10 \times \log_{10} \frac{(P_T)^2}{(P_{\text{ref}})^2} = 20 \times \log_{10} \frac{P_T}{P_{\text{ref}}} \quad (15-2)$$

The logarithmic scale compresses the wide extent of sound pressures into a convenient range. An increase of 6 dB SPL corresponds to a doubling of the absolute sound pressure level; an increase of 20 dB SPL corresponds to a 10-fold increase.

Sound can be a **pure tone** of a single frequency, measured in hertz (Hz). Sounds produced by musical instruments or the human voice consist of a perceived fundamental frequency (pitch) and overtones. Sound that is **noise** contains no recognizable periodic elements. 🟡**N15-8** Pure tones are used clinically for the determination of hearing thresholds (**pure-tone audiogram**). Humans do not perceive sounds that have the same sound pressure level but different frequencies as equally loud. The psychoacoustic **phon scale** accounts for these differences in perception. 🟡**N15-9**

Sound Waveforms

Contributed by Philine Wangemann

FIGURE 15-2 Waveforms of a pure tone, a sound, and noise. A pure tone (*left panel*) consists of a sine wave of only one single frequency. Noise (*right panel*) does not contain any recognizable periodic elements. Other sounds (*middle panel*) have a notable periodic pattern and consist of multiple superimposed waves. (Courtesy Philine Wangemann.)

N15-9

Phon Scale

Contributed by Philine Wangemann

Sounds that have identical **decibel sound pressure levels (dB SPL)** are not perceived as equally loud at all frequencies. The **phon scale**, which accounts for these differences in perception, has been developed by asking a number of human subjects to adjust the intensities of test tones to be equal in loudness to reference tones of 1000 Hz (eFig. 15-3). The normal hearing threshold is ~4 phon, discomfort is perceived at 110 phon, and the pain threshold is at 130 phon. Industrial noise levels are often given in units of A-weighted decibels, or dB(A). The dB(A) scale is weighted to approximate human loudness perception.

FIGURE 15-3 Relationship between sound pressure level (dB SPL) and frequency (Hz) of continuous pure tones of equal loudness. Combinations of sound pressure levels and frequencies that are perceived as equally loud are graphed as equal-loudness-level contours. The human ear is most sensitive between 1000 and 5000 Hz. Equal-loudness-level contours for 4 to 80 phon are based on ISO 226:2003 and equal-loudness-level contours for 110 and 130 phon are based on ISO 226:1987. (Courtesy Philine Wangemann.)

Sound waves vary in frequency, amplitude, and direction; our auditory systems are specialized to discriminate all three. We can also interpret the rapid and intricate temporal patterns of sound frequency and amplitude that constitute words and music. Encoding of sound frequency and amplitude begins with mechanisms in the cochlea, followed by further analysis in the CNS. To distinguish the direction of a sound along the horizontal plane, the brain compares signals from the two ears.

All mammalian ears are strikingly similar in structure. The ear is traditionally divided into outer, middle, and inner components (see [Fig. 15-17A](#)). We discuss the outer and middle ear here. The inner ear consists of the membranous labyrinth, with both its vestibular and auditory components.

Outer Ear

Proceeding from outside to inside, the most visible part of the ear is the **pinna**, a skin-covered flap of cartilage, and its small extension, the **tragus**. Together, they funnel sound waves into the **external auditory canal**. These structures, which compose the outer ear, focus sound waves on the tympanic membrane. Many animals (e.g., cats) can turn each pinna independently to facilitate hearing without changing head position. The shapes of the pinna and tragus tend to emphasize certain sound frequencies over others, depending on their angle of incidence. The external ear parts in humans are essential for localization of sounds in the vertical plane. Sound enters the auditory canal both directly and after being reflected; the sound that we hear is a combination of the two. Depending on a sound's angle of elevation, it is reflected differently off the pinna and tragus. Thus, we hear a sound coming from above our head slightly differently than a sound coming from straight in front of us.

The external auditory canal is lined with skin and penetrates ~2.5 cm into the temporal bone, where it ends blindly at the eardrum (or **tympanic membrane**). Sound causes the tympanic membrane to vibrate, much like the head of a drum.

Middle Ear

The air-filled chamber between the tympanic membrane on one side and the **oval window** on the other is

the middle ear (see Fig. 15-17A). The **eustachian tube** connects the middle ear to the nasopharynx and makes it possible to equalize the air pressure on opposite sides of the tympanic membrane. The eustachian tube can also provide a path for throat infections and epithelial inflammation to invade the middle ear and lead to otitis media. The primary function of the middle ear is to transfer vibrations of the tympanic membrane to the oval window (Fig. 15-19). The key to accomplishing this task is a chain of three delicate bones called **ossicles**: the **malleus** (or hammer), **incus** (anvil), and **stapes** (stirrup). The ossicles are the smallest bones in the body.

FIGURE 15-19 The middle ear. Displacement of the stapes and the oval window moves fluid in the scala vestibuli, causing opposite fluid movement in the scala tympani and thus an opposite displacement of the round window. (Data from Philine Wangemann, Kansas State University.)
