Cortical and suprapontine centers in the brain normally inhibit the micturition reflex, which the **pontine micturition center (PMC)** coordinates. The PMC controls both the bladder detrusor muscle and the urinary sphincters. During the **storage phase**, stretch receptors in the bladder send afferent signals to the brain via the pelvic splanchnic nerves. One first senses the urge for voluntary bladder emptying at a volume of ~150 mL and senses fullness at 400 to 500 mL. Nevertheless, until a socially acceptable opportunity to void presents itself, efferent impulses from the brain, in a learned reflex, inhibit presynaptic parasympathetic neurons in the sacral spinal cord that would otherwise stimulate the detrusor muscle. Voluntary contraction of the external urinary sphincter probably also contributes to storage.

The **voiding phase** begins with a voluntary relaxation of the external urinary sphincter, followed by relaxation of the internal sphincter. When a small amount of urine reaches the proximal (posterior)

urethra, afferents signal the cortex that voiding is imminent. The micturition reflex now continues as pontine centers no longer inhibit the parasympathetic preganglionic neurons that innervate the detrusor muscle. As a result, the bladder contracts, expelling urine. Once this micturition reflex has started, the initial bladder contractions lead to further trains of sensory impulses from stretch receptors, thus establishing a self-regenerating process (see [Fig. 33-13](#), red spikes moving to the left). At the same time, the cortical centers inhibit the external sphincter muscles. Voluntary urination also involves the voluntary contraction of abdominal muscles, which further raises bladder pressure and thus contributes to voiding and complete bladder emptying.

The basic bladder reflex that we have just discussed, although inherently an autonomic spinal cord reflex, may be either facilitated or inhibited by higher centers in the central nervous system that set the level at which the threshold for voiding occurs.

Because of the continuous flow of urine from the kidneys to the bladder, the function of the various sphincters, and the nearly complete emptying of the bladder during micturition, the entire urinary system is normally sterile ([Box 33-1](#)).

Box 33-1

Pathophysiology of Micturition

Lesions in the nervous system can lead to bladder dysfunction, the characteristics of which will depend on the site of the neural lesion. Three major classes of lesions can be distinguished:

- 1. Combined afferent and efferent lesions.** Severing both afferent and efferent nerves initially causes the bladder to become distended and flaccid. In the chronic state of the so-called decentralized bladder, many small contractions of the progressively hypertrophied bladder muscles replace the coordinated micturition events. Although small amounts of urine can be expelled, a residual volume of urine remains in the bladder after urination.
- 2. Afferent lesions.** When only the sacral dorsal roots (sensory fibers) are interrupted, reflex contractions of the bladder in response to stimulation of the stretch receptors are totally abolished. The bladder frequently becomes distended, the wall thins, and bladder tone decreases. However, some residual contractions remain because of the intrinsic contractile response of smooth muscle to stretch. As a rule, a residual urine volume is present after urination.
- 3. Spinal cord lesions.** The effects of spinal cord transection (e.g., in paraplegic patients) include the initial state of **spinal shock** in which the bladder becomes overfilled and exhibits sporadic voiding (“overflow incontinence”). With time, the voiding reflex is re-established, but with no voluntary control. Bladder capacity is often reduced and reflex hyperactivity may lead to a state called *spastic neurogenic bladder*. Again, the bladder cannot empty completely, so that significant residual urine is present. Urinary tract infections are frequent because the residual urine volume in the bladder serves as an incubator for bacteria. In addition, during the period of “overflow incontinence,” before the voiding reflex is re-established, these patients have to be catheterized frequently, which further predisposes to urinary tract infections.

CHAPTER 34

Glomerular Filtration and Renal Blood Flow

Gerhard Giebisch, Erich E. Windhager, Peter S. Aronson

Glomerular Filtration

A high glomerular filtration rate is essential for maintaining stable and optimal extracellular levels of solutes and water

Qualitatively, the filtration of blood plasma by the renal glomeruli is the same as the filtration of blood plasma across capillaries in other vascular beds (see pp. 467–468). Glomerular ultrafiltration results in the formation of a fluid—the **glomerular filtrate**—with solute concentrations that are similar to those in plasma water. However, proteins, other high-molecular-weight compounds, and protein-bound solutes are present at reduced concentration. The glomerular filtrate, like filtrates formed across other body capillaries, is free of formed blood elements, such as red and white blood cells.

Quantitatively, the rate of filtration that occurs in the glomeruli greatly exceeds that in all the other capillaries of the circulation combined because of greater Starling forces (see pp. 467–468) and higher capillary permeability. Compared with other organs, the kidneys receive an extraordinarily large amount of blood flow—normalized to the mass of the organ—and filter an unusually high fraction of this blood flow. Under normal conditions, the **glomerular filtration rate (GFR)** (see p. 732) of the two kidneys is 125 mL/min or 180 L/day. Such a large rate of filtrate formation is required to expose the entire extracellular fluid (ECF) frequently (>10 times a day) to the scrutiny of the renal-tubule epithelium. If it were not for such a high turnover of the ECF, only small volumes of blood would be “cleared” per unit time (see p. 731) of certain solutes and water. Such a low clearance would have two harmful consequences for the renal excretion of solutes that renal tubules *cannot adequately secrete*.

First, in the face of a sudden increase in the plasma level of a toxic material—originating either from metabolism or from food or fluid intake—the excretion of the material would be delayed. A high blood flow and a high GFR allow the kidneys to eliminate harmful materials rapidly by filtration.

A second consequence of low clearance would be that steady-state plasma levels would be very high for waste materials that depend on filtration for excretion. The following example by Robert Pitts, a major contributor to renal physiology, illustrates the importance of this concept. Consider two individuals consuming a diet that contains 70 g/day of protein, one with normal renal function (e.g., GFR of 180 L/day) and the other a renal patient with sharply reduced glomerular filtration (e.g., GFR of 18 L/day). Each individual produces 12 g/day of nitrogen in the form of urea (urea nitrogen) derived from dietary protein and must excrete this into the urine. However, these two individuals achieve urea balance at very different blood urea levels. We make the simplifying assumption that the tubules neither absorb nor secrete urea, so that *only* filtered urea can be excreted, and *all* filtered urea is excreted. The normal individual can excrete 12 g/day of urea nitrogen from 180 L of blood plasma having a [blood urea nitrogen] of 12 g/180 L, or 6.7 mg/dL. In the patient with end-stage renal disease (ESRD), whose GFR may be only 10% of normal, excreting 12 g/day of urea nitrogen requires that each of the 18 L of filtered blood plasma have a blood urea nitrogen level that is 10 times higher, or 67 mg/dL. Thus, excreting the same amount of urea nitrogen—to maintain a steady state—requires a much higher plasma blood urea nitrogen concentration in the ESRD patient than in the normal individual.

The clearance of inulin is a measure of GFR

The ideal **glomerular marker** for measuring GFR would be a substance X that has the same concentration in the glomerular filtrate as in plasma and that also is not reabsorbed, secreted, synthesized, broken down, or accumulated by the tubules (Table 34-1). In Equation 33-4, we saw that

$$\begin{array}{ccc} \text{Input into} & & \text{Output into} \\ \text{Bowman's space} & & \text{urine} \\ \hline \underbrace{P_X \cdot GFR} & = & \underbrace{U_X \cdot \dot{V}} \\ \hline \frac{\text{mg}}{\text{mL}} \cdot \frac{\text{mL}}{\text{min}} & = & \frac{\text{mg}}{\text{mL}} \cdot \frac{\text{mL}}{\text{min}} \end{array}$$

(34-1)

P_X is the concentration of the solute in plasma, GFR is the sum of volume flow of filtrate from the plasma into all Bowman's spaces, U_X is the urine concentration of the solute, and \dot{V} is the urine flow. Rearranging this equation, we have

$$\begin{array}{l} GFR = \frac{U_X \times \dot{V}}{P_X} \\ \frac{\text{mL}}{\text{min}} = \frac{(\text{mg/mL}) \times (\text{mL/min})}{(\text{mg/mL})} \end{array}$$

(34-2)

Note that Equation 34-2 has the same form as the clearance equation (see Equation 33-3) and is identical to Equation 33-5. Thus, the plasma clearance of a glomerular marker is the GFR. ●**N34-1**

TABLE 34-1
Criteria for Use of a Substance to Measure GFR

- | |

N34-1

Units of Clearance

Contributed by Erich Windhager, Gerhard Giebisch

Clearance values are conventionally given in milliliters of **total** plasma per minute, even though plasma consists of 93% “water” and 7% protein, with only the “plasma water”—that is, the protein-free plasma solution, including all solutes small enough to undergo filtration—undergoing glomerular filtration. As pointed out in Chapter 5 (see Table 5-2) the concentrations of plasma solutes can be expressed in millimoles per liter of total plasma, or millimoles per liter of protein-free plasma (i.e., plasma water). Customarily, clinical laboratories report values in millimoles (or milligrams) per deciliter of **plasma**, not plasma **water**. When we say that the GFR is 125 mL/min, we mean that each minute the kidney filters

all ions and small solutes contained in 125 mL of *plasma*. However, because the glomerular capillary blood retains the proteins, only $0.93 \times 125 \text{ mL} = 116 \text{ mL}$ of plasma **water** appear in Bowman's capsule. Nevertheless, GFR is defined in terms of **volume of blood plasma** filtered per minute rather than in terms of the **volume of protein-free plasma solution** that actually arrives in Bowman's space (i.e., the filtrate).

Inulin is an exogenous starch-like fructose polymer that is extracted from the Jerusalem artichoke and has a molecular weight of 5000 Da. Inulin is freely filtered at the glomerulus, but neither reabsorbed nor secreted by the renal tubules (Fig. 34-1A). Inulin also fulfills the additional requirements listed in Table 34-1 for an ideal glomerular marker.

FIGURE 34-1 Clearance of inulin.

Assuming that GFR does not change, three tests demonstrate that inulin clearance is an accurate marker of GFR. First, as shown in Figure 34-1B, the rate of inulin excretion ($U_{\text{In}} \cdot \dot{V}$) is directly proportional to the plasma inulin concentration (P_{In}), as implied by Equation 34-2. The slope in Figure 34-1B is the inulin clearance. Second, inulin clearance is independent of the plasma inulin concentration (see Fig. 34-1C). This conclusion was already implicit in Figure 34-1B, in which the slope (i.e., inulin clearance) does not

vary with P_{In} . Third, inulin clearance is independent of urine flow (see Fig. 34-1D). Given a particular P_{In} , after the renal corpuscles filter the inulin, the total amount of inulin in the urine does not change. Thus, diluting this glomerular marker in a large amount of urine, or concentrating it in a small volume, does not affect the total amount of inulin excreted ($U_{\text{In}} \cdot \dot{V}$). If the urine flow is high, the urine inulin concentration will be proportionally low, and vice versa. Because ($U_{\text{In}} \cdot \dot{V}$) is fixed, $(U_{\text{In}} \cdot \dot{V})/P_{\text{In}}$ is also fixed.

Two lines of evidence provide direct proof that inulin clearance represents GFR. First, by collecting filtrate from single glomeruli, Richards and coworkers showed in 1941 that the concentration of inulin in Bowman's space of the mammalian kidney is the same as that in plasma. Thus, inulin is freely filtered. Second, by perfusing single tubules with known amounts of labeled inulin, Marsh and Frasier showed that the renal tubules neither secrete nor reabsorb inulin.

Although the inulin clearance is the most reliable method for measuring GFR, it is not practical for clinical use. One must administer inulin intravenously to achieve reasonably constant plasma inulin levels. Another deterrent is that the chemical analysis for determining inulin levels in plasma and urine is sufficiently demanding to render inulin unsuitable for routine use in a clinical laboratory.

The normal value for GFR in a 70-kg man is ~125 mL/min. Population studies show that GFR is proportional to body surface area. Because the surface area of an average 70-kg man is 1.73 m², the normal GFR in men is often reported as 125 mL/min per 1.73 m² of body surface area. In women, this figure is 110 mL/min per 1.73 m². Age is a second variable. GFR is very low in the newborn, owing to incomplete development of functioning glomerular units. Beginning at ~2 years of age, GFR normalizes for body surface area and gradually falls off with age as a consequence of progressive loss of functioning nephrons.

The clearance of creatinine is a useful clinical index of GFR

Because inulin is not a convenient marker for routine clinical testing, nephrologists use other compounds that have clearances similar to those of inulin. The most commonly used compound in human studies is ¹²⁵I-iothalamate. However, even ¹²⁵I-iothalamate must be infused intravenously and is generally used only in clinical research studies rather than in routine patient care.

The problems of intravenous infusion of a GFR marker can be completely avoided by using an *endogenous* substance with inulin-like properties. **Creatinine** is such a substance, and **creatinine clearance (C_{Cr})** is commonly used to estimate GFR in humans. Tubules, to a variable degree, secrete creatinine, which, by itself, would lead to a ~20% overestimation of GFR in humans. Moreover, when GFR falls to low levels with chronic kidney disease, the overestimation of GFR by C_{Cr} becomes more appreciable. In clinical practice, determining C_{Cr} is an easy and reliable means of assessing the GFR, and such determination avoids the need to inject anything into the patient. One merely obtains samples of venous blood and urine, analyzes them for creatinine concentration, and makes a simple calculation (see Equation 34-3 below). Although C_{Cr} may overestimate the absolute level of GFR, assessing changes in C_{Cr} is extremely useful for monitoring relative changes in GFR in patients.

The source of plasma creatinine is the normal metabolism of **creatine phosphate** in muscle. In men, this metabolism generates creatinine at the rate of 20 to 25 mg/kg body weight per day (i.e., ~1.5 g/day in a 70-kg man). In women, the value is 15 to 20 mg/kg body weight per day (i.e., ~1.2 g/day in a 70-kg woman), owing to a lower muscle mass. In the steady state, the rate of urinary creatinine excretion equals this rate of metabolic production. Because metabolic production of creatinine largely depends on muscle mass, the daily excretion of creatinine depends strongly not only on gender but also on age, because

elderly patients tend to have lower muscle mass. For a C_{Cr} measurement, the patient generally collects urine over an entire 24-hour period, and the plasma sample is obtained by venipuncture at one time during the day based on the assumption that creatinine production and excretion are in a steady state.

Frequently, clinicians make a further simplification, using the **endogenous plasma concentration of creatinine (P_{Cr})**, normally 1 mg/dL, as an instant index of GFR. This use rests on the inverse relationship between P_{Cr} and C_{Cr} :

$$C_{Cr} = \frac{U_{Cr} \cdot \dot{V}}{P_{Cr}} \approx \text{GFR}$$

(34-3)

In the steady state, when metabolic production in muscle equals the urinary excretion rate ($U_{Cr} \cdot \dot{V}$) of creatinine, and both remain fairly constant, this equation predicts that a plot of P_{Cr} versus C_{Cr} (i.e., P_{Cr} versus GFR) is a rectangular hyperbola ([Fig. 34-2](#)). For example, in a healthy person whose GFR is 100 mL/min, plasma creatinine concentration is ~1 mg/dL. The product of GFR (100 mL/min) and P_{Cr} (1 mg/dL) is thus 1 mg/min, which is the rate both of creatinine production and of creatinine excretion. If GFR suddenly drops to 50 mL/min ([Fig. 34-3](#), top), the kidneys will initially filter and excrete less creatinine (see [Fig. 34-3](#), middle), although the production rate is unchanged. As a result, the plasma creatinine level will rise to a new steady state, which is reached at a P_{Cr} of 2 mg/dL (see [Fig. 34-3](#), bottom). At this point, the product of the reduced GFR (50 mL/min) and the elevated P_{Cr} (2 mg/dL) will again equal 1 mg/min, the rate of endogenous production of creatinine. Similarly, if GFR were to fall to one fourth of normal, P_{Cr} would rise to 4 mg/dL. This concept is reflected in the right-rectangular hyperbola of [Figure 34-2](#). **N34-2**

FIGURE 34-2 Dependence of plasma creatinine and blood urea nitrogen on the GFR. In the steady state, the amount of creatinine appearing in the urine per day ($U_{Cr} \cdot \dot{V}$) equals the production rate. Because all filtered creatinine ($P_{Cr} \cdot C_{Cr}$) appears in the urine, ($P_{Cr} \cdot C_{Cr}$) equals ($U_{Cr} \cdot \dot{V}$), which is constant. Thus, P_{Cr} must increase as C_{Cr} (i.e., GFR) decreases, and vice versa. If we assume that the kidney handles urea in the same way that it handles inulin, then a plot of blood urea nitrogen versus GFR will have the same shape as that of creatinine concentration versus GFR.

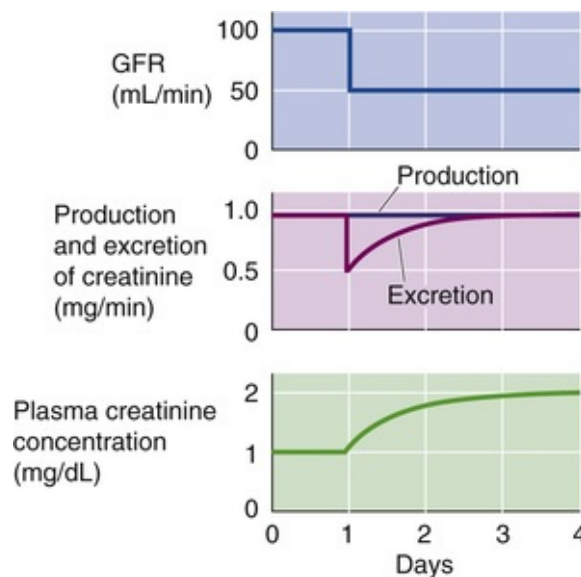

FIGURE 34-3 Effect of suddenly decreasing the GFR on plasma creatinine concentration.

N34-2

Calculating Estimated Glomerular Filtration Rate

Contributed by Gerhard Giebisch, Peter Aronson, Walter Boron, Emile Boulpaep

Clinicians can use the **plasma creatinine concentration (P_{Cr})** to calculate C_{Cr} —that is, the **estimated GFR (eGFR)**—without the necessity of collecting urine. Researches have derived empirical equations for calculating eGFR based on patient data, including not only P_{Cr} , but also parameters that include patient age, weight, gender, and race. In using these equations, we recognize that daily creatinine

excretion depends on muscle mass, which in turn depends on age, weight, sex, and race. An example is the **Modification of Diet in Renal Disease (MDRD) Study** equation:

$$\frac{\text{eGFR}}{\text{mL}/(\text{min} \cdot 1.73 \text{m}^2)} = 175 \underbrace{(\text{P}_{\text{Cr}})^{-1.154}}_{\text{mg/dL}} \cdot \underbrace{(\text{Age})^{-0.203}}_{\text{Years}} \cdot (0.742[\text{if female}]) \cdot (1.212[\text{if African American}])$$

(NE 34-1)

Thus, the **MDRD** calculation takes into account P_{Cr} , age, sex, and—in the United States—whether or not the person is African American. Because MDRD is normalized to body surface area, it does not include body weight.

Improving upon the MDRD equation was the **Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI)** calculator for eGFR (<http://www.qxmd.com/calculate-online/nephrology/ckd-epi-egfr>):

$$\frac{\text{eGFR}}{\text{mL}/(\text{min} \cdot 1.73 \text{m}^2)} = 141 \cdot \left[\text{smaller of } \left(\frac{\text{P}_{\text{Cr}}}{k} \right) \text{ or } 1 \right]^a \cdot \left[\text{larger of } \left(\frac{\text{P}_{\text{Cr}}}{k} \right) \text{ or } 1 \right]^{-1.209} \cdot (0.993)^{\text{Age}} \cdot (1.018[\text{if female}]) \cdot (1.159[\text{if African American}])$$

(NE 34-2)

Here, k is 0.7 for females and 0.9 for males, and a is -0.329 for females and -0.411 for males. In the first bracketed term, we take the *larger* of (P_{Cr}/k) or 1, whereas in the second bracketed term, we take the *smaller* of (P_{Cr}/k) or 1. Like the MDRD calculation, the CKD-EPI eGFR is normalized to body surface area (i.e., it does not include body weight).

The Cockcroft-Gault calculator for eGFR,

$$\frac{\text{eGFR}}{\text{mL/min}} = \frac{140(\text{Age}) \cdot \overbrace{(\text{Weight})}^{\text{kg}} \cdot (0.85[\text{if female}])}{72 \underbrace{(\text{P}_{\text{Cr}})}_{\text{mg/dL}}}$$

(NE 34-3)

takes into account P_{Cr} , weight (ideally, lean body mass), sex, and age. For example, for a male aged 22 and weighing 60 kg, the Cockcroft-Gault calculator

$$\frac{\text{eGFR}}{\text{mL/min}} = \frac{140(22) \cdot \overbrace{(60 \text{ kg})}^{\text{kg}} \cdot (1[\text{for a male}])}{72 \underbrace{(1.0)}_{\text{mg/dL}}} = 122 \text{mL/min} = 175 \text{L/day}$$

(NE 34-4)

yields an eGFR of 122 mL/min.

The National Kidney Foundation (NKF) recommends that one calculate eGFR with each determination of P_{Cr} .

Molecular size and electrical charge determine the filterability of solutes across the glomerular filtration barrier

The glomerular filtration barrier consists of four elements (see p. 726): (1) the glycocalyx overlying the endothelial cells, (2) endothelial cells, (3) the glomerular basement membrane, and (4) epithelial podocytes. Layers 1, 3, and 4 are covered with negative charges from anionic proteoglycans. The gene mutations that cause excessive urinary excretion of albumin (nephrotic syndrome; see p. 727) generally affect slit diaphragm proteins, which suggests that the junctions between adjacent podocytes are the predominant barrier to filtration of macromolecules.

Table 34-2 summarizes the permselectivity of the glomerular barrier for different solutes, as estimated by the ratio of solute concentration in the ultrafiltrate versus the plasma (UF_x/P_x). The ratio UF_x/P_x , also known as the **sieving coefficient** for the solute X, depends on molecular weight and effective molecular radius. Investigators have used two approaches to estimate UF_x/P_x . The first, which is valid for all solutes, is the **micropuncture** technique (see Fig. 33-9A). Sampling fluid from Bowman's space yields a direct measurement of UF_x , from which we can compute UF_x/P_x . The second approach, which is valid only for solutes that the kidney neither absorbs nor secretes, is to compute the **clearance ratio** (see p. 733),  N34-3 the ratio of the clearances of X (C_x) and inulin (C_{In}).

TABLE 34-2
Permselectivity of the Glomerular Barrier

SUBSTANCE	MOLECULAR WEIGHT (Da)	EFFECTIVE MOLECULAR RADIUS* (nm)	RELATIVE CONCENTRATION IN FILTRATE (UF _X /P _X)
Na ⁺	23	0.10	1.0
K ⁺	39	0.14	1.0
Cl ⁻	35	0.18	1.0
H ₂ O	18	0.15	1.0
Urea	60	0.16	1.0
Glucose	180	0.33	1.0
Sucrose	342	0.44	1.0
Polyethylene glycol	1,000	0.70	1.0
Inulin	5,200	1.48	0.98
Lysozyme	14,600	1.90	0.8
Myoglobin	16,900	1.88	0.75
Lactoglobulin	36,000	2.16	0.4
Egg albumin	43,500	2.80	0.22
Bence Jones protein	44,000	2.77	0.09
Hemoglobin	68,000	3.25	0.03
Serum albumin	69,000	3.55	<0.01

*The effective molecular radius is the Einstein-Stokes radius, which is the radius of a sphere that diffuses at the same rate as the substance under study.

N34-3

Clearance Ratio

Contributed by Erich Windhager, Gerhard Giebisch

The clearance ratio is the ratio of the clearances of X (C_X) and inulin (C_{In}):

$$\frac{C_X}{C_{In}} = \frac{(U_X \times \dot{V})/P_X}{(U_{In} \times \dot{V})/P_{In}} = \frac{U_X/P_X}{U_{In}/P_{In}}$$

(NE 34-5)

The symbols U, \dot{V} , and P have the same meanings as in Chapter 33: namely, U is urine concentration, \dot{V} is urine flow, P_X is the plasma concentration of the solute X, and P_{In} is the plasma concentration of inulin. We can now regroup the terms in the rightmost quotient to create the following expression:

$$\frac{C_X}{C_{In}} = \frac{U_X/(U_{In}/P_{In})}{P_X}$$

(NE 34-6)

We will now show that—if the tubules transport neither X nor inulin—the numerator, U_X/(U_{In}/P_{In}), is in fact the concentration of X in Bowman's capsule, UF_X, where the symbol UF means ultrafiltrate. Between Bowman's capsule and the final urine, the reabsorption of water by the tubules should have concentrated both inulin and X to the same extent, provided neither inulin nor X is secreted or absorbed. The extent to which inulin has been concentrated is merely U_{In}/P_{In}. Therefore, if we know the concentration of X in the

urine, we merely divide U_X by U_{In}/P_{In} to obtain the concentration of X in Bowman's capsule:

$$U_X/(U_{In}/P_{In}) = UF_X$$

(NE 34-7)

Therefore, in Equation NE 34-6 we can replace the term $U_X/(U_{In}/P_{In})$ by UF_X :

$$\frac{C_X}{C_{In}} = \frac{UF_X}{P_X}$$

(NE 34-8)

Thus, the ratio UF_X/P_X is the same as the **clearance ratio**, which is the value shown in the rightmost column of Table 34-2. The clearance ratio is an index of the sieving coefficient (UF_X/P_X) of the glomerular filtration barrier for solute X.

Inspection of Table 34-2 shows that substances of low **molecular weight** (<5500 Da) and small **effective molecular radius** (e.g., water, urea, glucose, and inulin) appear in the filtrate in the same concentration as in plasma ($UF_X/P_X \approx 1$). In these instances, no sieving of the contents of the fluid moving through the glomerular “pores” occurs, so that the water moving through the filtration slits by convection carries the solutes with it.  **N34-4** As a result, the concentration of the solute in the filtrate is the same as that in bulk plasma. The situation is different for substances with a molecular weight that is greater than ~14 kDa, such as lysozyme. Larger and larger macromolecules are increasingly restricted from passage.

N34-4

Filtration of Solutes Through Water-Filled Pores

Contributed by Erich Windhager, Gerhard Giebisch

Filtration of solutes across the glomerular capillary barrier can be modeled as the movement of molecules through water-filled pores. The flux of a solute X (J_X) through such glomerular pores—the rate at which X crosses a unit area of the barrier—is the sum of the convective and the diffusional flux:

Total flux	=	Convective flux	+	Diffusional flux
J_X	=	$J_V [X]_p (1 - \sigma_X)$	+	(Permeability of X) \times ($P_X - UF_X$)

(NE 34-9)

In this equation, J_V is the flux of *fluid volume* through the barrier, which is proportional to GFR. P_X and UF_X are the solute concentrations in plasma and filtrate, respectively.* σ_X is the reflection coefficient

for X (see p. 468). The **reflection coefficient** is a measure of how well the barrier restricts or “reflects” the movement of the solute X as water moves across the barrier by convective flow. σ_X varies between zero (when convective movement of X is unrestricted) and unity (when the solute cannot pass at all through the pore together with water). We use “permeability” here in the same sense as “permeability coefficient” on page 108 and in [N5-6](#).

As we saw on page 742 and in Table 34-2, the filtrate/filtrand ratio (UF_X/P_X)—also known as the sieving coefficient—is unity for small solutes, such as urea, glucose, sucrose, and inulin. For these solutes, filtration does not lead to the development of a concentration gradient across the glomerular barrier. In other words, $(P_X - UF_X)$ is zero. Thus, the diffusional flux in Equation NE 34-9 disappears, and all the movement of these small molecules must occur by convection.

For larger molecules, *both* the convective and diffusional terms in Equation NE 34-9 contribute to the flux of the solute X. At a normal GFR, any restriction to the movement of X (i.e., $\sigma_X > 0$) will cause the concentration of X to be less in the filtrate than in the plasma ($UF_X < P_X$). As a result, there is a concentration gradient favoring the diffusion of X from plasma into Bowman's space, as described by Equation NE 34-9. Two factors will enhance the relative contribution of the diffusional component. First, the more restricted the solute by the barrier, the lower the concentration of X in the filtrate, and thus the greater the driving force for diffusion. Second, the greater and greater the GFR, the greater the flow of water into Bowman's space, the greater the dilution of X in Bowman's space, the lower the UF_X , and thus the greater the driving force for diffusion of X.

For partially restricted molecules, the greater the GFR, the lower the UF_X —as we just saw—and thus the lower the filtrate/filtrand ratio. In the extreme case in which GFR falls to zero, the filtrate/filtrand ratio approaches unity as even relatively large molecules ultimately reach diffusion equilibrium. On the other hand, if GFR increases to very high values, the convective flow of water carrying low concentrations of the partially restricted solute dominates, and the filtrate/filtrand concentration ratio drops. Because hemodynamic factors such as blood pressure affect GFR (see pp. 745–750), one must carefully control these factors—and thus GFR—in order to use clearance ratios of macromolecules to characterize glomerular permeability.

*Caution! Do not confuse P_X , the permeability of X, with the concentration of X in the blood plasma, which is denoted by a nonitalicized P_X —an issue discussed in [N33-6](#).

In addition to molecular weight and radius, **electrical charge** also makes a major contribution to the permselectivity of the glomerular barrier. [Figure 34-4A](#) is a plot of the clearance ratio for uncharged, positively charged, and negatively charged dextran molecules of varying molecular size. Two conclusions can be drawn from these data. First, *neutral* dextrans with an effective molecular radius of <2 nm pass readily across the glomerular barrier. For dextrans with a larger radius, the clearance ratio decreases with an increase in molecular size, so that passage ceases when the radius exceeds 4.2 nm. Second, *anionic* dextrans (e.g., dextran sulfates) are restricted from filtration, whereas *cationic* dextrans (e.g., diethylaminoethyl dextrans) pass more readily into the filtrate. For negatively charged dextrans, the relationship between charge and filterability is characterized by a left shift of the curve relating molecular size to clearance ratio, whereas the opposite is true for positively charged dextrans.

A DEPENDENCE OF FILTERABILITY ON CHARGE AND SIZE

B DEPENDENCE OF FILTERABILITY OF ANIONIC DEXTRANS ON CHARGE OF GLOMERULAR BARRIER

FIGURE 34-4 Clearance ratios of dextrans. (Data from Bohrer MP, Baylis C, Humes HD, et al: Permeability of the glomerular capillary wall: Facilitated filtration of circulating polycations. *J Clin Invest* 61:72–78, 1978.)

The previously discussed results suggest that the glomerular filtration barrier carries a net negative charge that restricts the movement of anions but enhances the movement of cations. In some experimental models of glomerulonephritis, in which the glomerular barrier loses its negative charge, the permeability of the barrier to negatively charged macromolecules is enhanced. [Figure 34-4B](#) compares clearance ratios of dextran sulfate in normal rats and in rats with nephrotoxic serum nephritis. Clearance ratios of dextran sulfate are uniformly greater in the animals with nephritis. Thus, the disease process destroys negative charges in the filtration barrier and accelerates the passage of negatively charged dextrans. The red curve in [Figure 34-4A](#) shows that a neutral dextran with the same effective radius as albumin (i.e., 3.5 nm) would have a clearance ratio of ~0.1, which would allow substantial filtration and excretion. However, because albumin is highly negatively charged, its clearance ratio is nearly zero, similar to that of anionic

dextrans (see Fig. 34-4A, green curve), and it is restricted from filtration. Glomerular diseases causing loss of negative charge in the glomerular barrier lead to the development of albuminuria. Glomerular diseases causing high rates of albumin filtration can lead to a low plasma [albumin] and the development of edema (see Box 20-1), a clinical condition known as **nephrotic syndrome**. 🍷N34-5

N34-5

Effect of Molecular Shape on Permselectivity

Contributed by Gerhard Giebisch, Erich Windhager

In addition to molecular size (i.e., effective molecular radius) and electrical charge, the shape of macromolecules may also affect the permselectivity of the glomerular barrier. Thus, two molecules can diffuse at the same rate—and thus have the same **effective molecular radius**—but have different shapes. Rigid or globular molecules have lower clearance ratios (i.e., sieving coefficients) than molecules of a similar size (e.g., dextrans), which are highly deformable.

Hydrostatic pressure in glomerular capillaries favors glomerular ultrafiltration, whereas oncotic pressure in capillaries and hydrostatic pressure in Bowman's space oppose it

As is the case for filtration in other capillary beds (see pp. 467–468), glomerular ultrafiltration depends on the product of the ultrafiltration coefficient (K_f) and net Starling forces.

$$\text{GFR} = K_f \cdot \underbrace{[(P_{GC} - P_{BS}) - (\pi_{GC} - \pi_{BS})]}_{P_{UF}}$$

(34-4)

Figure 34-5A provides a schematic overview of the driving forces affecting ultrafiltration. **Hydrostatic pressure in the glomerular capillary (P_{GC})** favors ultrafiltration. **Hydrostatic pressure in Bowman's space (P_{BS})** opposes ultrafiltration. **Oncotic pressure in the glomerular capillary (π_{GC})** opposes ultrafiltration. **Oncotic pressure of the filtrate in Bowman's space (π_{BS})** favors ultrafiltration. Thus, two forces favor filtration (P_{GC} and π_{BS}), and two oppose it (P_{BS} and π_{GC}).

A FORCES AFFECTING ULTRAFILTRATION

P_{GC} = Glomerular capillary hydrostatic pressure
 π_{BS} = Bowman's space oncotic pressure
 P_{BS} = Bowman's space hydrostatic pressure
 π_{GC} = Glomerular capillary oncotic pressure

B STARLING FORCES ALONG THE GLOMERULAR CAPILLARIES

C P_{UF} ALONG THE GLOMERULAR CAPILLARIES

FIGURE 34-5 Glomerular ultrafiltration. In **B**, the oncotic pressure of the glomerular capillary (π_{GC}), which starts off at the value of normal arterial blood, rises as ultrafiltration removes fluid from the capillary. In **C**, P_{UF} is the net driving force favoring ultrafiltration. **N34-9**

N34-9

Starling Forces Along the Glomerular Capillary

Contributed by Walter Boron

The π_{GC} curve in Figure 34-5B is the result of a computer simulation that is based on Equation 34-4 (shown here as Equation NE 34-10):

$$GFR = K_f \cdot \underbrace{[(P_{GC} - P_{BS}) - (\pi_{GC} - \pi_{BS})]}_{P_{UF}} \quad (\text{NE 34-10})$$

We recall from the text that, by definition, FF is related to **GFR** and **RPF** by Equation 34-6 (shown here as Equation NE 34-11):

$$FF = \frac{GFR}{RPF}$$

(NE 34-11)

Thus,

$$FF \cdot RPF = GFR = K_f \cdot \underbrace{[(P_{GC} - P_{BS}) - (\pi_{GC} - \pi_{BS})]}_{P_{UF}}$$

$$FF = \frac{K_f}{RPF} \cdot \underbrace{[(P_{GC} - P_{BS}) - (\pi_{GC} - \pi_{BS})]}_{P_{UF}}$$

$$FF = K_f^* \cdot \underbrace{[(P_{GC} - P_{BS}) - (\pi_{GC} - \pi_{BS})]}_{P_{UF}}$$

(NE 34-12)

Note that K_f^* is merely K_f/RPF .

Equation NE 34-10 is presented in textbooks—including ours—as if it applies to the **macroscopic GFR** (e.g., 125 mL/min) that the two kidneys together produce via the actions of all ~2,000,000 of their glomeruli. In reality, Equation NE 34-10 really applies only to a **microscopic GFR**, that is, a rate of filtration at a particular point along the glomerular capillary of a particular glomerulus.* The reasons are that (1) π_{GC} —and thus P_{UF} —change continuously along the glomerular capillary, and (2) K_f as well as this π_{GC} profile are not identical for all glomeruli. Thus, Equation NE 34-10 really is valid only at a particular point along a particular glomerular capillary, where π_{GC} has a particular value.† The same is true for Equation NE 34-12. To make this point more clear, we will define the **microscopic filtration fraction (ff)** and its counterpart k_f^* —relevant for a small stretch of a particular glomerular capillary—as we march down this capillary:

$$ff = k_f^* \cdot \underbrace{[(P_{GC} - P_{BS}) - (\pi_{GC} - \pi_{BS})]}_{P_{UF}}$$

(NE 34-13)

We will now apply Equation NE 34-13 at multiple points along a theoretical monolithic capillary, arbitrarily dividing the capillary into 100 identical segments. For the first of these 100 segments, we assume that all the terms that determine P_{UF} have the values shown in Figure 34-5A at distance (x) = 0:

$$P_{GC} = 50 \text{ mm Hg}$$

$$\pi_{GC} = 25 \text{ mm Hg}$$

$$P_{BS} = 10 \text{ mm Hg}$$

$$\pi_{BS} = 0 \text{ mm Hg}$$

Thus, at $x = 0$, the forces favoring filtration are $(P_{GC} + \pi_{BS}) = 50$ mm Hg (green curve in Fig. 34-5C), whereas the forces opposing filtration are $(P_{BS} + \pi_{GC}) = 35$ mm Hg (red curve in Fig. 34-5C). The **net ultrafiltration pressure (P_{UF})** at time = 0 is therefore $50 - 35 = 15$ mm Hg (vertical distance between the green and red curves, colored gold in Fig. 34-5C).

We then apply Equation NE 34-13, multiplying this $(P_{UF})_{\text{Distance}=0}$ by a preassigned value for k_i^* . Recall that this value of k_i^* has built into it not only the microscopic filtration coefficient per se, but also microscopic RPF, and it has the units $(\text{mm Hg})^{-1}$. Thus, the product of k_i^* and P_{UF} in our model is the fraction of the initial ECF volume (inside the glomerular capillary) lost in the first of the 100 segments of the capillary—the ff. Below, we will see that, for a normal RPF, k_i^* has the value $0.0001765 (\text{mm Hg})^{-1}$. Thus, the fraction of ECF lost from the capillary in the first 1% of the capillary is

$$\text{ff in first of 100 segments} = \frac{0.0001765}{\text{mm Hg}} \cdot \underbrace{15 \text{ mm Hg}}_{P_{UF}} = 0.265\%$$

(NE 34-14)

That is, about 0.265% of the ECF originally in the capillary is lost (i.e., filtered) in the first 1% of the glomerular capillary. Stated differently, after the blood has passed the 1% mark, the ECF volume remaining in the glomerular capillary would be only $100\% - 0.265\% = 99.735\%$ as large as it was at the outset.

Because the mass of proteins in the blood ECF is fixed (we assume no filtration of proteins), π_{GC} must rise by the fraction by which ECF falls. In our example, at the end of the first 1% of distance, π_{GC} would be $(25 \text{ mm Hg})/0.99735 \cong 25.0664$ mm Hg. We will then use this new value of π_{GC} in the computation for the second iteration (i.e., for the second increment of 1%), and so on, for a total of 100 iterations; that is, for the entire 100% of the distance. At the end of 100 iterations, we can sum up the 100 microscopic ff values to arrive at the macroscopic FF.

What is a bit tricky is assigning the value for k_i^* . We do it in the following way. First, we define a **standard GFR** value (which we take to be 125 mL/min) and a **standard RPF** value (600 mL/min). Next, we guess at a provisional value for the standard k_i^* , insert it into the above equation, go through the 100 iterations, and then add up the 100 ff values to arrive at the macroscopic FF. From this FF value—as well as RPF—we compute GFR using Equation NE 34-11. If this provisional standard k_i^* does not produce the desired GFR of 125 mL/min, we make another guess and repeat the process until we eventually arrive at the **standard k_i^*** . In our case, this standard k_i^* is $0.0001765 (\text{mm Hg})^{-1}$. Note that this value includes the standard RPF of 600 mL/min.

The π_{GC} curve in Figure 34-5B actually represents a “low” RPF of 70.6 mL/min versus the standard RPF of 600 mL/min. The ratio of these two values is $600/70.6 \cong 8.5 \dots$ and in our model we achieve this low RPF by multiplying our standard k_i^* by a factor of ~ 8.5 , from $0.0001765 (\text{mm Hg})^{-1}$ to $0.0015 (\text{mm Hg})^{-1}$.

Note that because π_{GC} exponentially rises from its initial value of 25 mm Hg to an asymptotic value of 40 mm Hg, P_{UF} exponentially decays from a maximal value of 15 mm Hg to zero, as shown by the vertical

distance between the green and red curves (the gold area) in Figure 34-5C.

See also  N34-11.

*This principle also applies to the version of Fick's law that we use to describe the diffusion of gases from the alveolar air to the blood, or vice versa. See Equation 30-4, which is the simplified version of the equation (analogous to Equation NE 34-10 above) as well as the more precise Equation 30-9.

†As in the text, we are assuming that the values of all the other parameters are fixed.

The **net driving force favoring ultrafiltration** (P_{UF}) at any point along the glomerular capillaries is the difference between the hydrostatic pressure difference and the oncotic pressure difference between the capillary and Bowman's space. Thus, GFR is proportional to the **net hydrostatic force** ($P_{GC} - P_{BS}$) minus the **net oncotic force** ($\pi_{GC} - \pi_{BS}$).

As far as the hydrostatic pressure difference is concerned, the unique arrangement in which afferent and efferent arterioles flank the glomerular capillary keeps the first term, P_{GC} , at ~ 50 mm Hg (see Fig. 34-5B), a value that is twice as high as that in most other capillaries (see pp. 467–468). Moreover, direct measurements of pressure in rodents show that P_{GC} decays little between the afferent and efferent ends of glomerular capillaries. The second term of the hydrostatic pressure difference, P_{BS} , is ~ 10 mm Hg and does not vary along the capillary.

As far as the oncotic driving forces are concerned, the first term, π_{BS} , is very small (see Fig. 34-5B). The second term, π_{GC} starts off at 25 mm Hg at the beginning of the capillary. As a consequence of the continuous production of a protein-free glomerular filtrate—and the resulting concentration of plasma proteins—the oncotic pressure of the fluid left behind in the glomerular capillary progressively rises along the capillary.

Figure 34-5C compares the two forces *favoring* ultrafiltration ($P_{GC} + \pi_{BS}$) with the two forces *opposing* ultrafiltration ($P_{BS} + \pi_{GC}$) and shows how they vary along the glomerular capillary. The rapid increase in the oncotic pressure of capillary blood (π_{GC}) is the major reason why the forces favoring and opposing filtration may balance each other at a point some distance before the end of the glomerular capillary. Beyond this point, P_{UF} is zero and the system is said to be in **filtration equilibrium** (i.e., no further filtration).

Note that K_f in Equation 34-4 is the product of the hydraulic conductivity of the capillary (L_p) and the effective surface area available for filtration (S_f), as defined in Table 20-4. We use K_f because it is experimentally difficult to assign values to either L_p or S_f . The value of K_f of the glomerular filtration barrier exceeds—by more than an order of magnitude—the K_f of all other systemic capillary beds combined. This difference in K_f values underlies the tremendous difference in filtration, ~ 180 L/day in the kidneys (which receive $\sim 20\%$ of the cardiac output) compared with ~ 20 L/day (see pp. 475–476) in the combined *arteriolar* ends of capillary beds in the rest of the body (which receive the other $\sim 80\%$).

Alterations in the glomerular capillary surface area—owing to changes in mesangial-cell contractility (see p. 727)—can produce substantial changes in the S_f component of K_f . These cells respond to extrarenal hormones such as systemically circulating angiotensin II (ANG II), arginine vasopressin (AVP), and parathyroid hormone. Mesangial cells also produce several vasoactive agents, such as prostaglandins and ANG II.

Renal Blood Flow

Renal blood flow (RBF) is ~1 L/min out of the total cardiac output of 5 L/min. Normalized for weight, this blood flow amounts to ~350 mL/min for each 100 g of tissue, which is 7-fold higher than the normalized blood flow to the brain (see [p. 558](#)). **Renal plasma flow (RPF)** is

$$\text{RPF} = (1 - \text{Hct}) \cdot \text{RBF}$$

(34-5)

Given a hematocrit (Hct) of 0.40 (see [p. 102](#)), the “normal” RPF is ~600 mL/min.

Increased glomerular plasma flow leads to an increase in GFR

At low glomerular plasma flow ([Fig. 34-6A](#)), **filtration equilibrium** occurs halfway down the capillary. At higher plasma flow (i.e., normal for humans), the profile of net ultrafiltration forces (P_{UF}) along the glomerular capillary stretches out considerably to the right (see [Fig. 34-6B](#)) so that the point of equilibrium would be reached at a site actually beyond the end of the capillary. Failure to reach equilibrium (**filtration disequilibrium**) occurs because the increased delivery of plasma to the capillary outstrips the ability of the filtration apparatus to remove fluid and simultaneously increase capillary oncotic pressure. As a result, π_{GC} rises more slowly along the length of the capillary.

A LOW GLOMERULAR PLASMA FLOW

FIGURE 34-6 Dependence of the GFR on plasma flow. N34-10

N34-10

Dependence of Glomerular Filtration Rate and Filtration Fraction on Renal Plasma Flow

Contributed by Walter Boron

N34-9 described our computer model for generating plots of π_{GC} versus distance along the glomerular capillary. The curves in Figure 34-6A are the same as in Figure 34-5C, and represent a *low* **RPF** of 70.6 mL/min. For this condition of low RPF, we computed the π_{GC} curve using a k_i^* of $0.0015 \text{ (mm Hg)}^{-1}$. (Remember from N34-9 that k_i^* is the embodiment of both the microscopic K_f and RPF.) As described

in **N34-9**, summing the individual filtration events along the capillary yields the **FF**, which is 37.5% in this case. This is one of the points along the left end of the curve in Figure 34-6E. Multiplying RPF and FF yields the macroscopic **GFR**, which is the rather low value of 26.47 mL/min. This is one of the points along the left end of the curve in Figure 34-6D.

The curves in Figure 34-6B represent a *normal* RPF of 600 mL/min. For this condition of normal RPF, we computed the π_{GC} curve using a k_i^* of $0.0001765 \text{ (mm Hg)}^{-1}$. Summing the individual filtration events along the capillary yields the FF, which is 20.8% in this case. This is the identified point along the curve in Figure 34-6E. Multiplying RPF and FF yields the macroscopic GFR, which is the normal value of 125 mL/min. This is identified point along the curve in Figure 34-6D.

The curves in Figure 34-6C represent a *high* RPF of 1200 mL/min. For this high RPF, we computed the π_{GC} curve using a k_i^* of $0.00008825 \text{ (mm Hg)}^{-1}$, that is, half the value in the “normal” example. Summing the individual filtration events along the capillary yields the FF, which is 11.9% in this case. This is one of the points along the right end of the curve in Figure 34-6E. Multiplying RPF and FF yields the macroscopic GFR, which is the elevated value of 142.6 mL/min. This is one of the points along the right end of the curve in Figure 34-6D.

Using the approach outlined in **N34-9** we generated π_{GC} curves—and thus FF and GFR values—for a wide range of RPF values. The plots in Figure 34-6D and E are the results of these simulations.

As glomerular blood flow increases from low (see Fig. 34-6A) to normal (see Fig. 34-6B), the site of filtration equilibrium shifts distally (i.e., toward the efferent arteriole). This shift has two important consequences: First, as one progresses along the capillary, P_{UF} (and hence filtration) remains greater when blood flow is higher. Second, more of the glomerular capillary is exposed to a net driving force for filtration, which increases the useful surface area for filtration. Thus, the end of the capillary that is “wasted” at low plasma flow rates really is “in reserve” to contribute when blood flow is higher.

A further increase in plasma flow stretches out the π_{GC} profile even more, so that P_{UF} is even higher at each point along the capillary (see Fig. 34-6C). Single-nephron GFR (SNGFR) is the sum of individual filtration events along the capillary. Thus, SNGFR is proportional to the yellow area that represents the product of P_{UF} and effective (i.e., nonwasted) length along the capillary. Because the yellow areas progressively increase from Figure 34-6A to Figure 34-6C, SNGFR increases with glomerular plasma flow. However, this increase is not linear. Compared with the normal situation, the GFR summed for both kidneys increases only moderately with *increasing* RPF, but decreases greatly with *decreasing* RPF (see Fig. 34-6D). Indeed, clinical conditions causing an acute fall in renal perfusion result in an abrupt decline in GFR.

The relationship between GFR and RPF also defines a parameter known as the **filtration fraction (FF)**, which is the volume of filtrate that forms from a given volume of plasma entering the glomeruli:

$$FF = \frac{GFR}{RPF}$$

(34-6)

Because the normal GFR is ~125 mL/min and the normal RPF is ~600 mL/min, the normal FF is ~0.2. Because GFR saturates at high values of RPF, FF is greater at low plasma flows than it is at high plasma flows.

The dependence of GFR on RPF is analogous to the dependence of alveolar O₂ and CO₂ transport on pulmonary blood flow (see pp. 671–673).

Afferent and efferent arteriolar resistances control both glomerular plasma flow and GFR

The renal microvasculature has two unique features. First, this vascular bed has two major sites of resistance control, the afferent and the efferent arterioles. Second, it has two capillary beds in series, the glomerular and the peritubular capillaries. As a consequence of this unique architecture, significant pressure drops occur along both arterioles (Fig. 34-7), glomerular capillary pressure is relatively high throughout, and peritubular capillary pressure is relatively low. Selective constriction or relaxation of the afferent and efferent arterioles allows for highly sensitive control of the hydrostatic pressure in the intervening glomerular capillary, and thus of glomerular filtration.

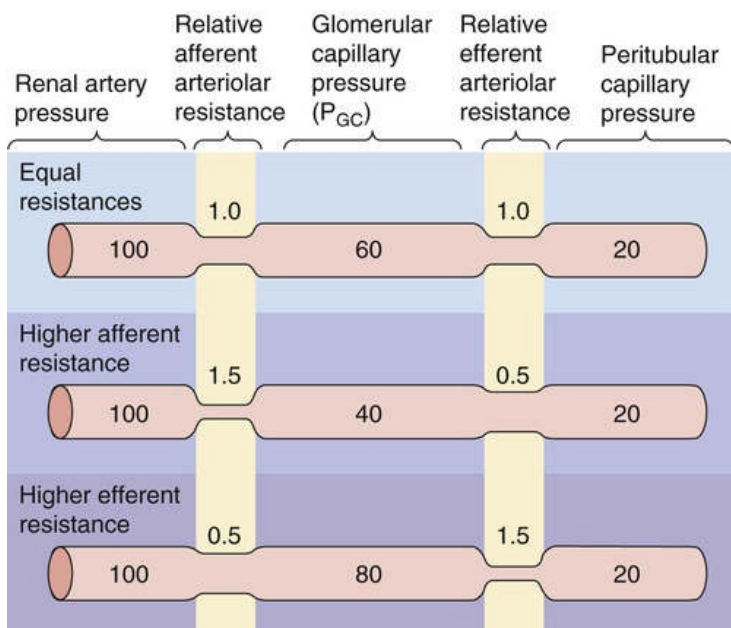

FIGURE 34-7 Pressure profile along the renal vasculature.

Figure 34-8A provides an idealized example in which we reciprocally change afferent and efferent arteriolar resistance while keeping total arteriolar resistance—and thus glomerular plasma flow—constant. Compared with an initial condition in which the afferent and efferent arteriolar resistances are the same (see Fig. 34-8A, top panel), constricting the *afferent* arteriole while relaxing the efferent arteriole lowers P_{GC} (see Fig. 34-8A, middle panel). Conversely, constricting the *efferent* arteriole while relaxing the afferent arteriole raises P_{GC} (see Fig. 34-8A, lower panel). From these idealized P_{GC} responses, one might predict that an increase in afferent arteriolar resistance would decrease the GFR and

that an increase in efferent arteriolar resistance should have the opposite effect. However, physiological changes in the afferent and efferent arteriolar resistance usually do not keep overall arteriolar resistance constant. Thus, changes in arteriolar resistance generally lead to changes in glomerular plasma flow, which, as discussed above, can influence GFR independent of glomerular capillary pressure.

A RECIPROCAL CHANGES IN AFFERENT AND EFFERENT ARTERIOLAR RESISTANCE

B CONSTRICTION OF ONLY AFFERENT ARTERIOLE

C CONSTRICTION OF ONLY EFFERENT ARTERIOLE

FIGURE 34-8 Role of afferent and efferent arteriolar resistance on pressure and flows. In **A**, the sum of afferent and efferent arteriolar resistances is always 2, whereas in **B** and **C**, the total resistance changes.

Figure 34-8B and C show somewhat more realistic effects on RPF and GFR as we change the resistance of a *single* arteriole. With a selective increase of *afferent* arteriolar resistance (see Fig. 34-8B), both capillary pressure and RPF decrease, which leads to a monotonic decline in the GFR. In contrast, a selective increase of *efferent* arteriolar resistance (see Fig. 34-8C) causes a steep increase in glomerular capillary pressure but a decrease in RPF. As a result, over the lower range of resistances, GFR increases with efferent resistance as an increasing P_{GC} dominates. On the other hand, at higher resistances, GFR begins to fall as the effect of a declining RPF dominates. These opposing effects on glomerular capillary pressure and RPF account for the biphasic dependence of GFR on efferent resistance.

The examples in Figure 34-8B and C, in which only afferent or efferent resistance is increased, are still somewhat artificial. During sympathetic stimulation, or in response to ANG II, both afferent *and* efferent resistances increase. Thus, RPF decreases. The generally opposing effects on GFR of increasing both afferent resistance (see Fig. 34-8B) and efferent resistance (see Fig. 34-8C) explain why the combination of both keeps GFR fairly constant despite a decline in RPF.

In certain clinical situations, changes in either the afferent or the efferent arteriolar resistance dominate. A striking example is the decrease in *afferent arteriolar* resistance—and large increase in RPF—that occurs with the loss of renal tissue, as after a nephrectomy in a kidney donor. As a result, GFR in the **remnant kidney** nearly doubles (see Fig. 34-8B). Another example is a situation that occurs in patients with congestive heart failure, who thus have a tendency toward decreased renal perfusion and—for reasons not well understood—greatly increased levels of vasodilatory prostaglandins (PGE_2 and PGI_2). In these patients, GFR depends greatly on prostaglandin-mediated afferent arteriolar dilatation. Indeed, blocking prostaglandin synthesis with nonsteroidal anti-inflammatory drugs (NSAIDs; see p. 64) often leads to an acute fall in GFR in such patients.

An example of an *efferent arteriolar* effect occurs in patients with congestive heart failure associated with decreased renal perfusion. GFR in such patients depends greatly on efferent arteriolar constriction due to increased endogenous angiotensin levels. Administering angiotensin-converting enzyme inhibitors (ACE-Is) to such patients often leads to an abrupt fall in GFR. If we imagine that the peak of the GFR curve in Figure 34-8C represents the patient before treatment, then reducing the resistance of the efferent arteriole would indeed cause GFR to decrease.

Peritubular capillaries provide tubules with nutrients and retrieve reabsorbed fluid

Peritubular capillaries originate from the efferent arterioles of the superficial and juxtamedullary glomeruli (see Fig. 33-1C). The capillaries from the superficial glomeruli form a dense network in the cortex, and those from the juxtamedullary glomeruli follow the tubules down into the medulla, where the capillaries are known as the vasa recta (see pp. 722–723). The peritubular capillaries have two main functions. First, these vessels deliver oxygen and nutrients to the epithelial cells. Second, they are responsible for taking up from the interstitial space the fluid and solutes that the renal tubules reabsorb.

The Starling forces that govern filtration in other capillary beds apply here as well (Fig. 34-9A). However, in peritubular capillaries, the pattern is unique. In “standard” systemic capillaries, Starling forces favor filtration at the arteriolar end and absorption at the venular end (see pp. 471–472).

Glomerular capillaries resemble the early part of these standard capillaries: the Starling forces always favor filtration (see Fig. 34-9B, yellow area). The peritubular capillaries are like the late part of standard capillaries: the Starling forces always favor absorption (see Fig. 34-9C, brown area).

Comparison of Starling Forces along the Glomerular versus Peritubular Capillaries

Contributed by Walter Boron

Figure 34-9B shows the same pair of curves as Figure 34-6B. These represent a *normal* **RPF** of 600 mL/min. **N34-10**

What makes peritubular capillaries unique is that glomerular capillaries and the efferent arteriole precede them. Glomerular filtration concentrates the plasma proteins and thereby elevates the oncotic

pressure of blood entering the peritubular capillary network (π_{PC}) to ~ 35 mm Hg. In addition, the resistance of the efferent arteriole decreases the intravascular hydrostatic pressure (P_{PC}) to ~ 20 mm Hg (see Fig. 34-9A). Interstitial oncotic pressure (π_o) is 4 to 8 mm Hg, and interstitial hydrostatic pressure (P_o) is probably 6 to 10 mm Hg. The net effect is a large net absorptive pressure at the beginning of the peritubular capillary. Along the peritubular capillary, π_{PC} falls modestly because of the reabsorption of protein-poor fluid from the interstitium into the capillary, and hydrostatic pressure probably falls modestly as well. Even so, the Starling forces remain solidly in favor of absorption along the entire length of the peritubular capillary, falling from ~ 17 mm Hg at the arteriolar end to ~ 12 mm Hg at the venular end (see Fig. 34-9C).

The net absorptive force at the beginning of the peritubular capillaries is subject to alterations in upstream arteriolar resistances and FF. For instance, expansion of the ECF volume (Fig. 34-10) inhibits the renin-angiotensin system (see pp. 841–842), leading to a relatively larger decrease in efferent than in afferent arteriolar resistance, and therefore to a rise in P_{PC} . The fall in total arteriolar resistance causes a rise in RPF that is larger than the increase in GFR, thereby causing a fall in FF. Thus, more fluid remains inside the glomerular capillary, and the blood entering the peritubular capillaries has an oncotic pressure that is not as high as it otherwise would be (e.g., $\pi_{PC} < 35$ mm Hg). The fall in efferent arteriolar resistance also raises the P_{PC} (e.g., $P_{PC} > 20$ mm Hg). As a consequence of the low π_{PC} and high P_{PC} , the peritubular capillaries take up less interstitial fluid (see pp. 763–765). **N34-6** The reverse sequence of events takes place during volume contraction and in chronic heart failure.

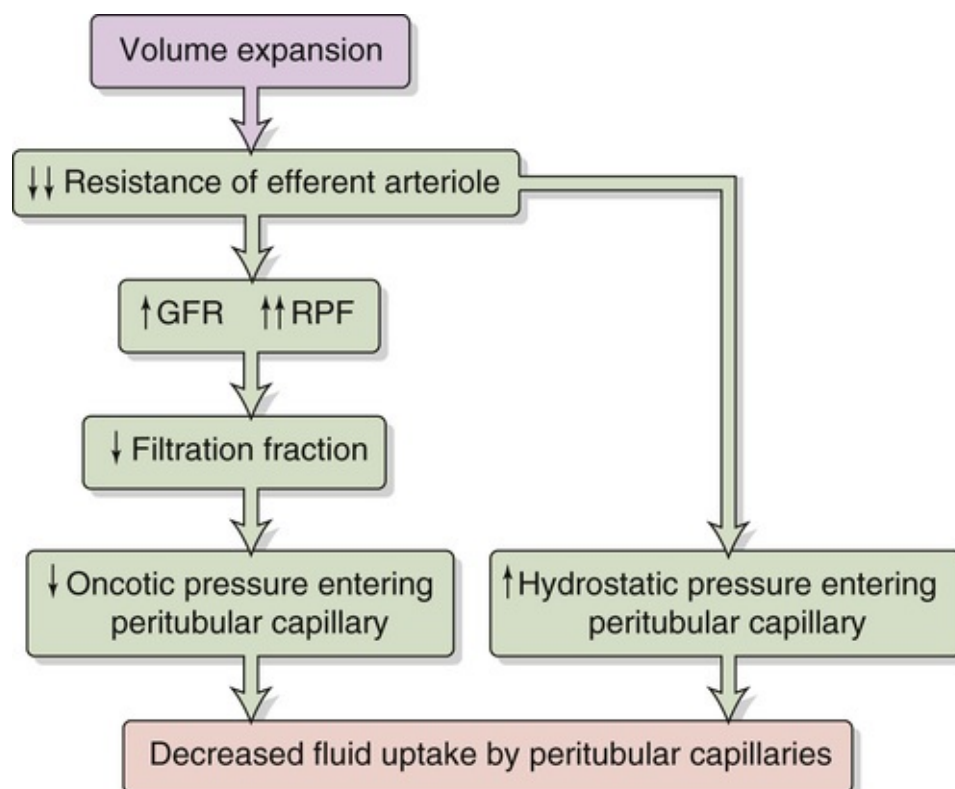

FIGURE 34-10 Effect of volume expansion on fluid uptake by the peritubular capillaries.

Effects of Hemodynamic Changes on Fluid Reabsorption by the Peritubular Capillaries

Contributed by Emile Boulpaep, Walter Boron

The paragraph in the text analyzes an example in which expansion of the ECF volume inhibits the renin-angiotensin system, producing hemodynamic changes—that is, decreases in both *afferent* and *efferent* arteriolar resistance, but more so the latter. Thus, the fractional rise in GFR is less than the fractional rise in RPF, so that the FF falls. The analysis in the text focuses on forces *inside* the peritubular capillaries: P_{PC} and π_{PC} . In addition, the hemodynamic changes in our example also lead to altered forces *outside* the peritubular capillaries. These changes in interstitial forces reduce fluid absorption—from the tubule lumen to the interstitium—by the proximal tubule. Thus, in this example, an increase in ECF volume leads to changes in renal hemodynamics, resulting in a parallel rise in GFR and a fall in fluid reabsorption from the proximal tubule to its peritubular capillaries. The result is an appropriate increase in fluid excretion into the urine.

We discuss the effect of hemodynamic changes on Na^+ and fluid transport in more depth beginning on page 763.

Lymphatic capillaries are mainly found in the cortex, in association with blood vessels. They provide an important route for removing protein from the interstitial fluid. Proteins leak continuously from the peritubular capillaries into the interstitial fluid. Total renal lymph flow is small and amounts to <1% of RPF.

Blood flow in the renal cortex exceeds that in the renal medulla

Measurements of regional blood flow in the kidney show that ~90% of the blood leaving the glomeruli in efferent arterioles perfuses cortical tissue. The remaining 10% perfuses the renal medulla, with only 1% to 2% reaching the papilla. The relatively low blood flow through the medulla, a consequence of the high resistance of the long vasa recta, is important for minimizing washout of the hypertonic medullary interstitium and thus for producing a concentrated urine (see [pp. 813–815](#)).

The clearance of para-aminohippurate is a measure of RPF

As discussed in [Chapter 33](#), for any solute (X) that the kidney neither metabolizes nor produces, the only route of entry to the kidney is the renal artery, and the only two routes of exit are the renal vein and the ureter (see [Fig. 33-7](#)):

$$\overbrace{\frac{P_{X,a}}{\text{mmol}} \cdot \frac{RPF_a}{\text{mL}}}_{\text{Arterial input of X}} = \overbrace{\left(\frac{P_{X,v}}{\text{mmol}} \cdot \frac{RPF_v}{\text{mL}} \right)}_{\text{Venous output of X}} + \overbrace{\left(\frac{U_X}{\text{mmol}} \cdot \frac{\dot{V}}{\text{mL}} \right)}_{\text{Urine output of X}}$$

(34-7)

The foregoing equation (a restatement of [Equation 33-1](#)) is an application of the Fick principle used for measurements of regional blood flow (see [p. 423](#)). To estimate arterial RPF (RPF_a)—or, more simply, RPF—we could in principle use the clearance of *any substance* that the kidney measurably excretes into the urine, as long as it is practical to obtain samples of systemic arterial plasma, renal venous plasma, and urine. The problem, of course, is sampling blood from the renal vein.

However, we can avoid the need for sampling the renal vein if we choose a substance that the kidneys clear so efficiently that they leave almost *none* in the renal vein. **Para-aminohippurate (PAH)** is such a substance (see [pp. 731–732](#)). Because PAH is an organic acid that is not normally present in the human body, PAH must be administered by continuous intravenous infusion. Some PAH binds to plasma proteins, but a significant amount remains freely dissolved in the plasma and therefore filters into Bowman's space. However, the kidney filters only ~20% of the RPF (i.e., $\text{FF} = \sim 0.2$), and a major portion of the PAH remains in the plasma that flows out of the efferent arterioles. PAH diffuses out of the peritubular capillary network and reaches the basolateral surface of the proximal-tubule cells. These cells have a high capacity to secrete PAH from blood into the tubule lumen against large concentration gradients. This PAH-secretory system (see [pp. 779–781](#)) is so efficient that—as long as we do not overwhelm it by infusing too much PAH—almost no PAH (~10%) remains in the renal venous blood. We can therefore assume that all the PAH presented to the kidney appears in the urine:

$$\text{PAH excreted} = \text{PAH filtered in glomerulus} + \text{PAH secreted in urine by tubules}$$

(34-8)

In the example of [Figure 34-11](#), the concentration of filterable PAH in the arterial blood plasma (P_{PAH}) is 10 mg/dL or 0.1 mg/mL. If RPF is 600 mL/min, then the arterial load of PAH to the kidney is 60 mg/min. Of this amount, 12 mg/min appears in the glomerular filtrate. If the tubules secrete the remaining 48 mg/min, then the entire 60 mg/min of PAH presented to the kidney appears in the urine. That is, in the idealized example of [Figure 34-11](#), during a single passage of blood the kidneys clear 100% of PAH presented to them. In practice, the kidneys excrete only ~90% of the arterial load of PAH, provided P_{PAH} does not exceed 12 mg/dL. The excretion of 90% rather than 100% of the arterial load of PAH reflects the 10% of the RBF that perfuses the medulla, where the tubules do not secrete PAH.

FIGURE 34-11 Renal handling of PAH.

As long as we do not infuse too much PAH—that is, as long as virtually no PAH remains in the renal venous blood—Equation 34-7 reduces to the equation for the clearance of PAH, as introduced in Table 33-2B:

$$C_{PAH} = RPF = \frac{U_{PAH} \cdot \dot{V}}{P_{PAH}} \quad (34-9)$$

If we apply this equation to the example in Figure 34-11,

$$C_{PAH} = RPF = \frac{60 \text{ mg/min}}{10 \text{ mg/dL}} = \frac{60 \text{ mg/min}}{0.1 \text{ mg/mL}} = 600 \text{ mL/min}$$

(34-10)

To compute RPF, we need to collect a urine sample to obtain ($U_{PAH} \cdot \dot{V}$) and a blood sample to obtain P_{PAH} . However, the blood sample need not be arterial. For example, one can obtain venous blood from the arm, inasmuch as skeletal muscle extracts negligible amounts of PAH.

Control of Renal Blood Flow and Glomerular Filtration

Autoregulation keeps RBF and GFR relatively constant

An important feature of the renal circulation is its remarkable ability to maintain RBF and GFR within narrow limits, although mean arterial pressure may vary between ~80 and 170 mm Hg (Fig. 34-12, middle and bottom panels). Stability of blood flow—known as **autoregulation** (see p. 481)—is also a property of the vascular beds serving two other vital organs, the brain and the heart. Perfusion to all three of these organs must be preserved in emergency situations, such as hypotensive shock. Autoregulation of the renal blood supply is independent of the influence of renal nerves and circulating hormones, and persists even when one perfuses isolated kidneys with erythrocyte-free solutions. Autoregulation of RBF—and, consequently, autoregulation of GFR, which depends on RBF (see Fig. 34-6D)—stabilizes the filtered load of solutes that reaches the tubules over a wide range of arterial pressures. Autoregulation of RBF also protects the fragile glomerular capillaries against increases in perfusion pressure that could lead to structural damage.

FIGURE 34-12 Autoregulation of RBF and GFR. (Data on RBF from Arendshorst WJ, Finn WF, Gottschalk CW: Autoregulation of renal blood flow in the rat kidney. *Am J Physiol* 228:127–133, 1975.)

The kidney autoregulates RBF by responding to a rise in renal arterial pressure with a proportional increase in the resistance of the afferent arterioles. Autoregulation comes into play during alterations in arterial pressure that occur, for example, during changes in posture, light to moderate exercise, and sleep. It is the *afferent arteriole* where the autoregulatory response occurs, and where the resistance to flow rises with increasing perfusion pressure (see Fig. 34-12, top panel). In contrast, *efferent* arteriolar

resistance, glomerular and peritubular capillary resistances, as well as venous resistance all change very little over the range of normal to high renal arterial pressures. However, in the range of *low* renal perfusion pressures—as in congestive heart failure—efferent arteriolar resistance increases, and thereby minimizes decreases in GFR.

Two basic mechanisms—equally important—underlie renal autoregulation: a myogenic response of the smooth muscle of the afferent arterioles and a tubuloglomerular feedback mechanism.

Myogenic Response

The afferent arterioles have the inherent ability to respond to changes in vessel circumference by contracting or relaxing—a myogenic response (see [p. 481](#)). The mechanism of contraction is the opening of stretch-activated nonselective cation channels in vascular smooth muscle. The resultant depolarizing leads to an influx of Ca^{2+} that stimulates contraction (see [p. 477](#)).

Tubuloglomerular Feedback

The juxtaglomerular apparatus (JGA; see [p. 727](#)) mediates tubuloglomerular feedback (TGF).  **N40-3** The macula densa cells in the thick ascending limb sense an increase in GFR and, in classic feedback fashion, translate this to a contraction of the afferent arteriole, a fall in P_{GC} and RPF, and hence a decrease in GFR.

Experimental evidence for the existence of a TGF mechanism rests on measurements of SNGFR. One introduces a wax block into the lumen of the proximal tubule to block luminal flow ([Fig. 34-13A](#)). Upstream from the wax block, a pipette collects the fluid needed to compute SNGFR (see [Equation 33-13](#)). Downstream of this wax block, another pipette perfuses the loop of Henle with known solutions and at selected flows. The key observation is that an inverse relationship exists between the late proximal perfusion rate (i.e., fluid delivery to the macula densa) and SNGFR (see [Fig. 34-13B](#)).

A EXPERIMENTAL PREPARATION**B DEPENDENCE OF SNGFR ON DISTAL TUBULE FLOW**

FIGURE 34-13 Tubuloglomerular feedback. (B, Modified from Navar LG: Regulation of renal hemodynamics. Adv Physiol Educ 20:S221–S235, 1998.)

The mechanism of TGF is thought to be the following:

1. An increase in arterial pressure leads to increases in glomerular capillary pressure, RPF, and GFR.
2. Increased GFR leads to an increased delivery of Na^+ , Cl^- , and fluid into the proximal tubule and, ultimately, to the macula densa cells of the JGA.
3. Macula densa cells do not sense flow per se, but the higher luminal $[\text{Na}^+]$ or $[\text{Cl}^-]$ resulting from high flow. Increases in luminal $[\text{Na}^+]$ and $[\text{Cl}^-]$ —via the apical Na/K/Cl cotransporter (see p. 122) of the macula densa cell—translate to parallel increases in *intracellular* $[\text{Na}^+]$ and $[\text{Cl}^-]$. Indeed, blocking the Na/K/Cl cotransporter with furosemide (see p. 757) not only blocks the uptake of Na^+ and Cl^- into the macula densa cells, but also interrupts TGF.
4. The rise in $[\text{Cl}^-]_i$, in conjunction with a basolateral Cl^- channel, leads to a depolarization.
5. The depolarization activates a basolateral nonselective cation channel, which allows Ca^{2+} to enter the macula densa cell.
6. Increased $[\text{Ca}^{2+}]_i$ causes the macula densa cell to release paracrine agents, particularly adenosine and ATP, which breaks down to adenosine.

7. Adenosine, binding to A₁ adenosine receptors on the smooth-muscle cells, triggers contraction of nearby vascular smooth-muscle cells (see [Table 20-8](#)).
8. Increased afferent arteriolar resistance decreases GFR, counteracting the initial increase in GFR.

Several factors modulate the sensitivity of the TGF mechanism (see [Fig. 34-13B](#)). Indeed, investigators have suggested that several of these factors may be physiological signals from the macula densa cells or modulators of these signals ([Table 34-3](#)).

High-protein diet

Volume expansion and a high-protein diet increase GFR by reducing TGF

The **sensitivity** of TGF is defined as the change in SNGFR for a given change in the perfusion rate of the loop of Henle. Thus, sensitivity is the absolute value of the slope of the curves in [Figure 34-13B](#). The **set-point** of the feedback system is defined as the loop-perfusion rate at which SNGFR falls by 50%.

Both the intrinsic sensitivity of the macula densa mechanism and the initial set-point for changes in flow are sensitive to changes in the ECF volume. Expansion of the ECF decreases the sensitivity (i.e., steepness) of the overall feedback loop. Conversely, volume contraction increases the sensitivity of TGF, thus helping preserve fluid by reducing GFR. Many of these effects may be mediated by ANG II, which is a required cofactor for TGF responses.

Of clinical importance is the observation that a **high-protein diet** increases GFR and RPF by indirectly lowering the sensitivity of the TGF mechanism. A high-protein diet somehow enhances NaCl reabsorption proximal to the macula densa, so that luminal [NaCl] at the macula densa falls. As a consequence, the flow in the loop of Henle (and thus GFR) must be higher to raise [NaCl] to a given level at the macula densa. A high-protein diet may thereby decrease TGF, increasing glomerular capillary pressure. This sequence of events may lead, particularly in the presence of intrinsic renal disease, to progressive glomerular damage.

Four factors that modulate RBF and GFR play key roles in regulating effective circulating volume

Changes in effective circulating volume (see [pp. 554–555](#)) trigger responses in four parallel effector

pathways that ultimately modulate either renal hemodynamics or renal Na⁺ reabsorption. The four effector pathways are (1) the renin-angiotensin-aldosterone axis, (2) the sympathetic nervous system, (3) AVP, and (4) atrial natriuretic peptide (ANP). Beginning on [page 836](#), we discuss the integrated control of effective circulating volume. Here, we focus on the direct actions of the four effector pathways on renal hemodynamics.

Renin-Angiotensin-Aldosterone Axis

In terms of renal hemodynamic effects, the most important part of the renin-angiotensin-aldosterone axis is its middle member, the peptide hormone ANG II (see [pp. 841–842](#)). ANG II has multiple actions on renal hemodynamics ([Table 34-4](#)). The net effect of ANG II on blood flow and GFR depends on multiple factors. Under normal conditions, the effect of ANG II is primarily to mediate *efferent* arteriolar constriction, an effect that tends to maintain GFR when renal perfusion is reduced. The reason is that prostaglandins counteract any tendency of ANG II to constrict the *afferent* arteriole. Indeed, inhibition of prostaglandin production by NSAIDs unmasks the constriction of the afferent arteriole, resulting in a decline in GFR.

TABLE 34-4
Hemodynamic Actions of ANG II on the Kidney

SITE	ACTION	PROPERTIES
Renal artery and afferent arteriole	Constriction	Ca ²⁺ influx through voltage-gated channels Prostaglandins may counteract the constriction during volume contraction or low effective circulating volume
Efferent arteriole	Constriction	May depend on Ca ²⁺ mobilization from internal stores Insensitive to Ca ²⁺ channel blockers
Mesangial cells	Contraction with reduction in K _f	Ca ²⁺ influx Ca ²⁺ mobilization from internal stores
TGF mechanism	Increased sensitivity	Increased responsiveness of afferent arteriole to signal from macula densa
Medullary blood flow	Reduction	May be independent of changes in cortical blood flow

Modified from Arendshorst WJ, Navar LG: In Schrier RW, Gottschalk CW (eds): Diseases of the Kidney, vol 1, 5th ed. Boston, Little, Brown, 1993, pp 65–117.

Sympathetic Nerves

Sympathetic tone to the kidney may increase either as part of a general response—as occurs with pain, stress, trauma, hemorrhage or exercise—or as part of a more selective renal response to a decrease in effective circulating volume (see [pp. 842–843](#)). In either case, sympathetic nerve terminals release **norepinephrine** into the interstitial space. At relatively high levels of nerve stimulation, both afferent and efferent arteriolar resistances rise, thus generally decreasing RBF and GFR. The observation that the RBF may fall more than the GFR is consistent with a preferential *efferent* arteriolar constriction. With maximal nerve stimulation, however, afferent vasoconstriction predominates and leads to drastic reductions in both RBF and GFR.

In addition, sympathetic stimulation triggers granular cells to increase their release of renin (see [p. 841](#)), raising levels of ANG II, which acts as described above. Finally, sympathetic activation—even at levels too low to reduce RBF and GFR—causes increased reabsorption of Na⁺ by proximal tubules (see [pp. 766–768](#)).

Arginine Vasopressin

In response to increases in the osmotic pressure of the ECF, the posterior pituitary releases AVP—also

known as antidiuretic hormone (see [p. 843](#)). Although the principal effect of this small polypeptide is to increase water absorption in the collecting duct, AVP also increases vascular resistance. Despite physiological fluctuations of circulating AVP levels, total RBF and GFR remain nearly constant. Nevertheless, AVP may decrease blood flow to the renal *medulla*, thereby minimizing the washout of the hypertonic medulla; this hypertonicity is essential for forming a concentrated urine.

In amphibians, reptiles, and birds, the generalized vascular effects of AVP are more pronounced than they are in mammals. In humans, severe decreases in effective circulating volume (e.g., shock) cause a massive release of AVP via nonosmotic stimuli (see [p. 586](#)). Only under these conditions does AVP produce a systemic vasoconstriction and thus contribute to maintaining systemic blood pressure (see [p. 553](#)).

Atrial Natriuretic Peptide

Atrial myocytes release ANP in response to increased atrial pressure and thus effective circulating volume (see [p. 843](#)). ANP markedly vasodilates afferent and efferent arterioles, thereby increasing cortical and medullary blood flow, and lowers the sensitivity of the TGF mechanism (see [Table 34-3](#)). The net effect is an increase in RPF and GFR. ANP also affects renal hemodynamics indirectly by inhibiting secretion of renin (thus lowering ANG II levels).

Even without affecting GFR, low levels of ANP can be natriuretic by inhibiting Na⁺ reabsorption by tubules. First, ANP inhibits aldosterone secretion by the adrenal gland (and thereby reduces Na⁺ reabsorption; see [pp. 765–766](#)). Second, ANP acts *directly* to inhibit Na⁺ reabsorption by the inner medullary collecting duct (see [p. 768](#)). At higher levels, ANP decreases systemic arterial pressure and increases capillary permeability. ANP plays a role in the diuretic response to the redistribution of ECF and plasma volume into the thorax that occurs during space flight and water immersion (see [p. 1233](#)).

Other vasoactive agents modulate RBF and GFR

Many other vasoactive agents, when infused systemically or applied locally to the renal vasculature, modulate RBF and GFR. Despite considerable research on such hemodynamic actions, the precise role of individual vasoactive agents in the response to physiological and pathophysiological stimuli remains uncertain because of the following three observations: (1) several agents with opposing actions are often released simultaneously; (2) blocking a specific vasoactive messenger may have relatively little effect on renal hemodynamics; and (3) a single vasoactive agent may have different, or even opposing, actions at low and high concentrations. Nevertheless, renal and extrarenal agents may cooperate to provide a full and physiologically adequate response to a wide spectrum of challenges.  [N34-7](#)

Epinephrine

Released by the chromaffin cells of the adrenal medulla (see [p. 1030](#)), epinephrine exerts dose-dependent effects on the kidney that are similar to those of norepinephrine (see [p. 752](#)).  **N34-8**

N34-8

Effects of Epinephrine on Renal Hemodynamics

Contributed by Gerhard Giebisch, Erich Windhager

Epinephrine increases renal vascular resistance. At lower epinephrine levels, GFR may be maintained despite a significant reduction of RBF, similar to the effects of moderate sympathetic nerve stimulation (see [p. 752](#)). This effect implies preferential *efferent* vasoconstriction. At higher doses, epinephrine decreases both GFR and RBF, similar to the effects of intense sympathetic nerve stimulation.

Dopamine

Dopaminergic nerve fibers terminate in the kidney, and dopamine receptors are present in renal blood vessels. In addition, proximal-tubule cells both produce dopamine and express dopamine receptors. The renal effects of dopamine—vasodilation and inhibition of Na⁺ reabsorption by tubules—are opposite to the effects of epinephrine and norepinephrine.

Endothelins

The endothelins are peptides with a strong vasoconstrictor action (see [p. 480](#)) but a very short half-life. The hemodynamic actions of endothelins are limited to local effects, because little of these hormones

escapes into the general circulation. In the kidney, several agents—ANG II, epinephrine, higher doses of AVP, thrombins, and shear stress—trigger release of endothelins from the endothelium of renal cortical vessels and mesangial cells. The endothelins act locally to constrict smooth muscles of renal vessels and thus most likely are a link in the complex network of local messengers between endothelium and smooth muscle. When administered systemically, endothelins constrict the afferent and efferent arterioles and reduce the ultrafiltration coefficient (K_f). The result is a sharp reduction in both RBF and GFR.

Prostaglandins

In the kidney, vascular smooth-muscle cells, endothelial cells, mesangial cells, and tubule and interstitial cells of the renal medulla are particularly important for synthesizing locally acting prostaglandins from arachidonic acid via the cyclooxygenase pathway (see pp. 62–64). The effects of prostaglandins are complex and depend on the baseline vasoconstriction exerted by ANG II. Indeed, prostaglandins appear mainly to be protective and are important under conditions in which the integrity of the renal circulation is threatened. In particular, local intrarenal effects of prostaglandins prevent excessive vasoconstriction, especially during increased sympathetic stimulation or activation of the renin-angiotensin system. Accelerated prostaglandin synthesis and release are responsible for maintaining fairly constant blood flow and GFR in conditions of high ANG II levels (e.g., during surgery, following blood loss, or in the course of salt depletion).

Leukotrienes

Probably in response to inflammation, the renal vascular smooth-muscle cells and glomeruli—as well as leukocytes and blood platelets—synthesize several leukotrienes from arachidonic acid via the lipoxygenase pathway (see pp. 64–65). These locally acting vasoactive agents are strong vasoconstrictors; their infusion reduces RBF and GFR.

Nitric Oxide

The endothelial cells of the kidney use nitric oxide synthase (NOS) to generate nitric oxide (NO; see p. 66) from L-arginine. NO has a strong smooth muscle-relaxing effect and—under physiological, unstressed conditions—produces significant renal vasodilation. NO probably defends against excess vasoconstrictor effects of agents such as ANG II and epinephrine. Injecting NOS inhibitors into the systemic circulation constricts afferent and efferent arterioles, increasing renal vascular resistance and producing a sustained fall of RBF and GFR. Moreover, NOS inhibitors blunt the vasodilatation that is triggered by low rates of fluid delivery to the macula densa as part of the TGF mechanism.

Transport of Sodium and Chloride

Gerhard Giebisch, Erich E. Windhager, Peter S. Aronson

The kidneys help to maintain the body's **extracellular fluid (ECF)** volume by regulating the amount of Na^+ in the urine. Sodium salts (predominantly NaCl) are the most important contributor to the osmolality of the ECF; hence, where Na^+ goes, water follows. This chapter focuses on how the kidneys maintain the ECF volume by regulating excretion of Na^+ and its most prevalent anion, Cl^- .

The normal daily urinary excretion of Na^+ is only a tiny fraction of the total Na^+ filtered by the kidneys ([Fig. 35-1](#)). The filtered load of Na^+ is the product of the glomerular filtration rate (GFR, ~ 180 L/day) and the plasma Na^+ concentration of ~ 142 mM (neglecting the small difference from $[\text{Na}^+]$ in protein-free plasma water; see [Table 5-2](#)), or $\sim 25,500$ mmol/day. This amount is equivalent to the Na^+ in ~ 1.5 kg of table salt, more than nine times the total quantity of Na^+ present in the body fluids. For subjects on a typical Western diet containing ~ 120 mmol of Na^+ , the kidneys reabsorb $\sim 99.6\%$ of the filtered Na^+ by the time the tubule fluid reaches the renal pelvis. Therefore, even minute variations in the fractional reabsorptive rate can lead to changes in total-body Na^+ that markedly alter ECF volume and, hence, body weight and blood pressure. Thus, it is not surprising that each nephron segment makes its own unique contribution to Na^+ homeostasis.

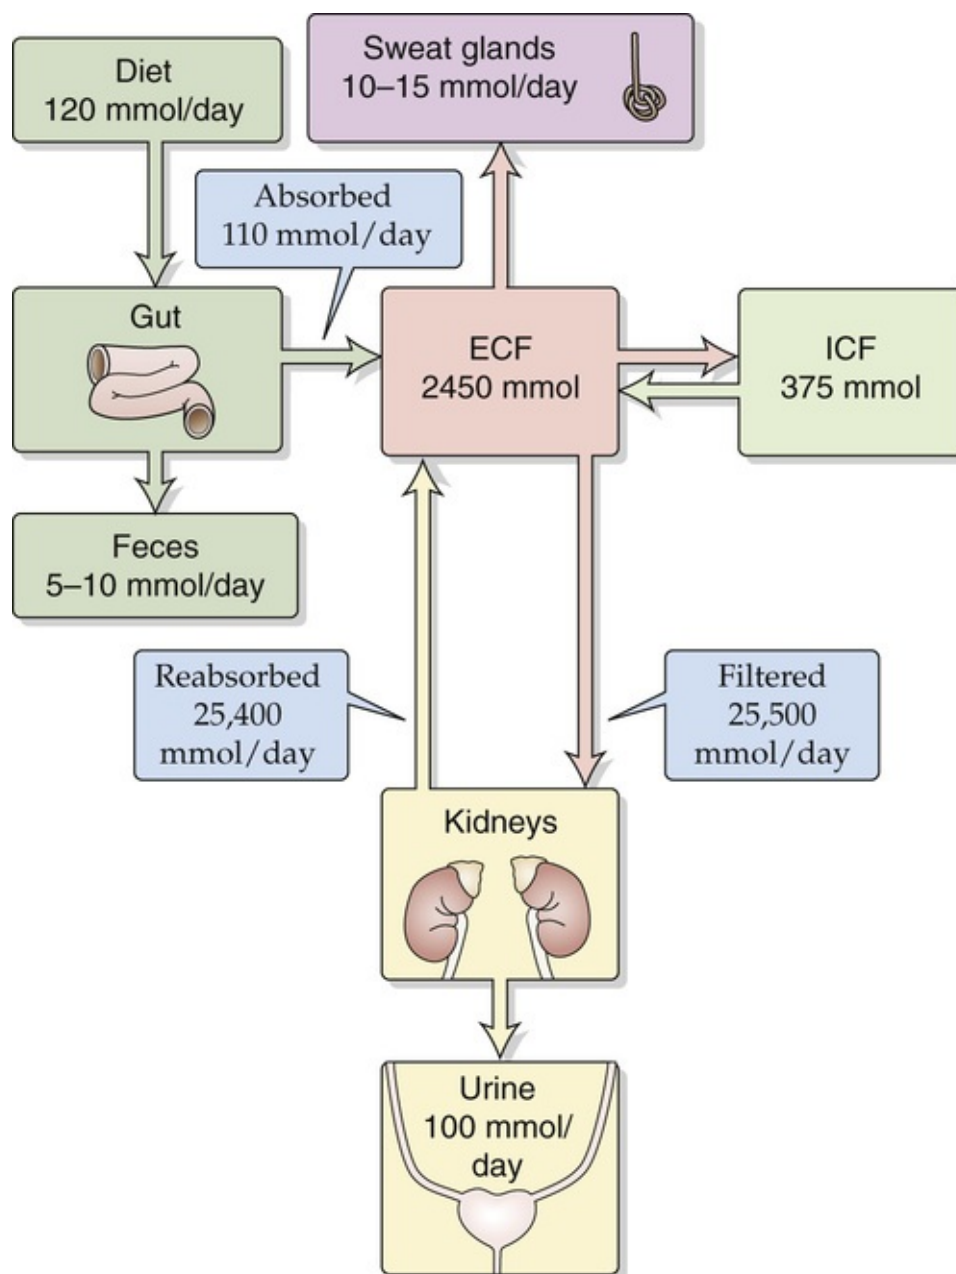

FIGURE 35-1 Distribution and balance of Na^+ throughout the body. The values in the boxes are approximations. ICF, intracellular fluid.

Na⁺ and Cl⁻ Transport by Different Segments of The Nephron

Na⁺ and Cl⁻ reabsorption decreases from proximal tubules to Henle's loops to classic distal tubules to collecting tubules and ducts

Figure 35-2 summarizes the segmental distribution of Na⁺ reabsorption along the nephron. The **proximal tubule** reabsorbs the largest fraction of filtered Na⁺ (~67%). Because [Na⁺] in *tubule fluid* (or TF_{Na} ; see p. 733) remains almost the same as that in *plasma* (i.e., $TF_{Na}/P_{Na} = 1.0$) throughout the length of the proximal tubule, it follows that the [Na⁺] in the *reabsorbate* is virtually the same as that in plasma. Because Na⁺ salts are the dominant osmotically active solutes in the filtrate, reabsorption must be a nearly isosmotic process. 🍷N35-1

FIGURE 35-2 Estimates of renal handling of Na^+ along the nephron. The numbered yellow boxes indicate the absolute amount of Na^+ —as well as the fraction of the filtered load—that various nephron segments reabsorb. The green boxes indicate the fraction of the filtered load that remains in the lumen at these sites. The values in the boxes are approximations. P_{Na} , plasma sodium concentration; U_{Na} , urine sodium concentration; \dot{V} , urine flow.

Investigators have found that the lumen of the proximal tubule becomes slightly *hypo*-osmolar as the reabsorption of salt and water proceeds. Because the ultrafiltrate in Bowman's space is truly *isosmotic* with blood plasma, the reabsorbate (i.e., the fluid that the tubule reabsorbed) must be slightly *hyperosmolar*. Once the tubule has reabsorbed a slightly hyperosmolar solution, it has established an osmotic gradient along which water can flow by osmosis. The osmotic water permeability (P_f) of the proximal tubule is so high—owing to the extremely high expression of the water channel AQP1 in both the apical and basolateral membranes—that the H_2O very nearly keeps up, so to speak, with the solutes, in an osmotic sense. A mathematical way of stating this fact is that the ratio of the NaCl reabsorptive flux (J_{NaCl}) to the reabsorptive volume or H_2O flux (J_v) is nearly the same as the osmolality of the lumen:

$$\frac{J_{NaCl}}{J_v} = \text{Osmolality of reabsorbate} \cong \text{Osmolality of lumen} \quad (\text{NE 35-1})$$

In mice lacking AQP1, the water permeability of the proximal tubule is so low that the diffusion of H_2O can no longer keep up with the active reabsorption of NaCl, $NaHCO_3$, and other solutes. As a result, the reabsorbate can become markedly hyperosmolar, and the fluid left behind becomes markedly hypo-osmolar. This situation is reminiscent of that in the TAL, which is sometimes called the *diluting segment*.

The **loop of Henle** reabsorbs a smaller but significant fraction of filtered Na^+ (~25%). Because of the low water permeability of the **thick ascending limb (TAL)**, this nephron segment reabsorbs Na^+ faster than it reabsorbs water, so that $[Na^+]$ in the tubule fluid entering the distal convoluted tubule has decreased substantially ($TF_{Na}/P_{Na} \cong 0.45$).

The **classic distal tubule** (see [p. 729](#)) and **collecting ducts** reabsorb smaller fractions of filtered Na^+ and water than do more proximal segments. The segments between the **distal convoluted tubule (DCT)** and the **cortical collecting tubule (CCT)**, inclusive, reabsorb ~5% of the filtered Na^+ load under normal conditions. Finally, the medullary collecting duct reabsorbs ~3% of the filtered Na^+ load. Although the distal nephron reabsorbs only small amounts of Na^+ , it can establish a steep transepithelial concentration gradient and can respond to several hormones, including mineralocorticoids and arginine vasopressin (AVP).

As discussed on [pages 763–769](#), most nephron segments reabsorb greater amounts of Na^+ when increased quantities of Na^+ are delivered due to increased filtered load or inhibition of upstream Na^+ reabsorption.

The tubule reabsorbs Na^+ via both the transcellular and the paracellular pathways

The tubule can reabsorb Na^+ and Cl^- via both transcellular and paracellular pathways (Fig. 35-3A). In the **transcellular pathway**, Na^+ and Cl^- sequentially traverse the apical and basolateral membranes before entering the blood. In the **paracellular pathway**, these ions move entirely by an extracellular route, through the tight junctions between cells. In the transcellular pathway, transport rates depend on the electrochemical gradients, ion channels, and transporters at the apical and basolateral membranes. However, in the paracellular pathway, transepithelial electrochemical driving forces and permeability properties of the tight junctions govern ion movements.

A PARACELLULAR AND TRANSCELLULAR ROUTES

B DRIVING FORCES FOR Na^+ TRANSPORT

FIGURE 35-3 Transcellular and paracellular mechanisms of Na^+ and Cl^- reabsorption. The example in **B** illustrates the electrochemical driving forces for Na^+ in the early proximal tubule. The equivalent circuit demonstrates that the flow of positive charge across the apical membrane slightly depolarizes the apical membrane (-67 mV) relative to the basolateral membrane (-70 mV).

Transcellular Na^+ Reabsorption

The basic mechanism of transcellular Na^+ reabsorption is similar in all nephron segments and is a variation on the classic two-membrane model of epithelial transport (see pp. 137–138). The *first step* is the passive entry of Na^+ into the cell across the **apical membrane**. Because the intracellular Na^+ concentration ($[\text{Na}^+]_i$) is low and the cell voltage is negative with respect to the lumen, the electrochemical gradient is favorable for passive Na^+ entry across the apical membrane (see Fig. 35-3B). However, different tubule segments use different mechanisms of passive Na^+ entry across the apical membrane. The proximal tubule, the TAL, and the DCT all use a combination of Na^+ -coupled cotransporters and exchangers to move Na^+ across the apical membrane; however, in the cortical and medullary collecting ducts, Na^+ enters the cell through epithelial Na^+ channels (ENaCs).

The *second step* of transcellular Na⁺ reabsorption is the active extrusion of Na⁺ out of the cell across the **basolateral membrane** (see Fig. 35-3B). This Na⁺ extrusion is mediated by the Na-K pump (see pp. 115–117), which keeps [Na⁺]_i low (~15 mM) and [K⁺]_i high (~120 mM). Because the basolateral membrane is primarily permeable to K⁺, it develops a voltage of ~70 mV, with the cell interior negative with respect to the interstitial space. Across the apical membrane, the cell is negative with respect to the lumen. The magnitude of the apical membrane voltage may be either lower or higher than that of the basolateral membrane, depending on the nephron segment and its transport activity.

Paracellular Na⁺ Reabsorption

The basic mechanism of paracellular Na⁺ transport is similar among nephron segments: the transepithelial electrochemical gradient for Na⁺ drives transport. However, both the **transepithelial voltage (V_{te})** and luminal [Na⁺] vary along the nephron (Table 35-1). As a result, the net driving force for Na⁺ is positive—favoring passive Na⁺ reabsorption—only in the S2 and S3 segments of the proximal tubule and in the TAL. In the other segments, the net driving force is negative—favoring passive Na⁺ diffusion from blood to lumen (“backleak”). In addition to undergoing purely passive, paracellular reabsorption in the S2 and S3 segments and TAL, Na⁺ can move uphill from lumen to blood via **solvent drag** across the tight junctions. In this case, the movement of H₂O from the lumen to the lateral intercellular space—energized by the active transport of Na⁺ into the lateral intercellular space—also sweeps Na⁺ and Cl[−] in the same direction.

TABLE 35-1
Transepithelial Driving Forces for Na⁺

	LUMINAL [Na ⁺]	TRANSEPITHELIAL CHEMICAL DRIVING FORCE*†	TRANSEPITHELIAL VOLTAGE (ELECTRICAL DRIVING FORCE)‡	TRANSEPITHELIAL ELECTROCHEMICAL DRIVING FORCE†
Proximal tubule, S1	142 mM	0 mV	−3 mV	−3 mV
Proximal tubule, S3	142 mM	0 mV	+3 mV	+3 mV
TAL	100 mM	−9 mV	+15 mV	+6 mV
DCT	70 mM	−19 mV	−5 to +5 mV	−24 to −14 mV
CCT	40 mM	−34 mV	−40 mV	−74 mV

*The chemical driving force is calculated assuming a plasma [Na⁺] of 142 mM and is given in mV.

†A negative value promotes passive Na⁺ movement from blood to lumen (i.e., backleak or secretion), whereas a positive value promotes passive Na⁺ movement from lumen to blood (i.e., reabsorption).

‡A negative value indicates that the lumen is negative with respect to the blood.

Nephron segments also vary in their **leakiness** to Na⁺ ions. This leakiness is largely a function of the varying ionic conductance of the paracellular pathway between cells across the tight junction, due to the expression of different claudins. In general, the leakiness of the paracellular pathway decreases along the nephron from the proximal tubule (the most leaky) to the papillary collecting ducts. However, even the tightest renal epithelia have what might be regarded as only a moderate degree of tightness compared with truly “tight” epithelia, such as in those the skin, the gastric mucosa, and the urinary bladder (see pp. 136–137).

The leakiness of an epithelium has serious repercussions for the steepness of the ion gradients that the epithelium can develop and maintain. For both Na⁺ and Cl[−], the ability of specific nephron segments to establish large concentration gradients correlates with the degree of tightness, which limits the backflux of ions between cells. Thus, the luminal fluid attains much lower concentrations of Na⁺ and Cl[−] in the distal

nephron than it does in the proximal tubule.

An important consequence of a highly leaky paracellular pathway is that it provides a mechanism by which the basolateral membrane voltage can generate a current that flows through the tight junctions and charges up the apical membrane, and vice versa (see [Fig. 35-3B](#)). For example, hyperpolarization of the basolateral membrane leads to a hyperpolarization of the apical membrane. A consequence of this **paracellular electrical coupling** is that the apical membrane of a leaky epithelium, such as the proximal tubule, has a membrane voltage that is negative (-67 mV in [Fig. 35-3B](#)) and close to that of the basolateral membrane (-70 mV in [Fig. 35-3B](#)), whereas one would expect that, based on the complement of channels and ion gradients at the apical membrane, the apical membrane would have a far less negative voltage. A practical benefit of this crosstalk is that it helps couple the activity of the basolateral electrogenic Na-K pump to the passive entry of Na^+ across the apical membrane. If the Na-K pump rate increases, not only does $[\text{Na}^+]_i$ decrease, enhancing the *chemical* Na^+ gradient across the apical membrane, but also the basolateral membrane hyperpolarizes (i.e., the cell becomes more negative with respect to the blood). Electrical coupling translates this basolateral hyperpolarization to a concomitant apical hyperpolarization, thus also enhancing the electrical gradient favoring apical Na^+ entry.

Na⁺ and Cl⁻, and Water Transport at the Cellular and Molecular Level

Na⁺ reabsorption involves apical transporters or ENaCs and a basolateral Na-K pump

Proximal Tubule

Along the first half of the tubule ([Fig. 35-4A](#)), a variety of cotransporters in the *apical membrane* couples the downhill uptake of Na⁺ to the uphill uptake of solutes such as glucose, amino acids, phosphate, sulfate, lactate, and citrate. Many of these Na⁺-driven cotransporters are electrogenic, carrying net positive charge into the cell. Thus, both the low [Na⁺]_i and the negative apical membrane voltage fuel the secondary active uptake of these other solutes, which we discuss in [Chapter 36](#). In addition to being coupled to the cotransporters, Na⁺ entry is also coupled to the extrusion of H⁺ through the electroneutral **Na-H exchanger 3 (NHE3)**. We discuss the role of NHE3 in renal acid secretion on [page 827](#).

FIGURE 35-4 Cell models of Na⁺ reabsorption. PCT, proximal convoluted tube.

Both cotransporters and exchangers exploit the downhill Na^+ gradient across the apical cell membrane that is established by the **Na-K pump** in the *basolateral membrane*. The Na-K pump—and, to a lesser extent, the **electrogenic Na/HCO₃ cotransporter 1 (NBCe1)**—are also responsible for the second step in Na^+ reabsorption, moving Na^+ from cell to blood. The presence of K^+ channels in the basolateral membrane is important for two reasons. First, these channels establish the negative voltage across the basolateral membrane and establish a similar negative voltage across the apical membrane via paracellular electrical coupling. Second, these channels permit the recycling of K^+ that had been transported into the cell by the Na-K pump.

Because of a lumen-negative V_{te} in the early proximal tubule, as well as a paracellular pathway that is permeable to Na^+ , approximately one third of the Na^+ that is transported from lumen to blood by the transcellular pathway diffuses back to the lumen by the *paracellular pathway* (“backleak”).

Thin Limbs of Henle's Loop

Na^+ transport by the thin descending and thin ascending limbs of Henle's loop is almost entirely passive and paracellular (see [p. 811](#)).

Thick Ascending Limb

Two major pathways contribute to Na^+ reabsorption in the TAL: transcellular and paracellular (see [Fig. 35-4B](#)). The *transcellular pathway* includes two major mechanisms for taking up Na^+ across the apical membrane. **Na/K/Cl cotransporter 2 (NKCC2)** couples the inward movement of 1 Na^+ , 1 K^+ , and 2 Cl^- ions in an electroneutral process driven by the downhill concentration gradients of Na^+ and Cl^- (see [p. 122](#)). The second entry pathway for Na^+ is an **NHE3**. As in the proximal tubule, the basolateral Na-K pump keeps $[\text{Na}^+]_i$ low and moves Na^+ to the blood.

Two features of the apical step of Na^+ reabsorption in the TAL are noteworthy. First, the **loop diuretics** (e.g., furosemide and bumetanide) inhibit Na/K/Cl cotransport. Second, a large fraction of the K^+ that NKCC2 brings into the cell recycles to the lumen via apical K^+ channels. These channels are essential for replenishing luminal K^+ and thus for maintaining adequate Na/K/Cl cotransport.

A key aspect of the *paracellular pathway* for Na^+ reabsorption in the TAL is a lumen-positive V_{te} (see [Fig. 35-4B](#)). Nearly all other epithelia have a lumen-negative V_{te} because the apical membrane voltage is less negative than the basolateral membrane voltage (see [Fig. 5-20B](#)). The TAL is just the opposite. Its lumen-positive V_{te} develops because of a substantial difference in the ion permeabilities of the apical and basolateral membranes. The *apical* membrane is K^+ selective, so that the apical membrane potential depends mainly on the cell-to-lumen $[\text{K}^+]$ gradient. In contrast, the TAL *basolateral* membrane is permeable to both K^+ and Cl^- . Hence, the basolateral membrane potential lies between the equilibrium potentials of Cl^- (approximately -50 mV) and K^+ (approximately -90 mV), so that it is less negative than if the basolateral membrane were permeable only to K^+ . Because the apical membrane potential is more negative than the basolateral membrane potential, the V_{te} is lumen positive.  **N37-9** Because the TAL has a low water permeability, removing luminal NaCl leaves the remaining tubule fluid *hypo-osmotic*. Hence, the TAL is sometimes referred to as the *diluting segment*.

The lumen-positive V_{te} provides the driving force for the diffusion of Na^+ across the tight junctions, accounting for approximately half of the Na^+ reabsorption by the TAL. The lumen-positive V_{te} also drives the passive reabsorption of K^+ (see [p. 798](#)), Ca^{2+} (see [p. 787](#)), and Mg^{2+} (see [p. 791](#)) via the paracellular pathway.

Distal Convoluted Tubule

Na^+ reabsorption in the DCT occurs almost exclusively by the transcellular route (see Fig. 35-4C). The *apical step* of Na^+ uptake is mediated by an electroneutral **Na/Cl cotransporter** (NCC; see p. 123) that belongs to the same family as NKCC2 in the TAL. However, the NCC differs from NKCC2 in being independent of K^+ and highly sensitive to **thiazide diuretics**. Although the thiazides produce less diuresis than do the loop diuretics, the thiazides are nevertheless effective in removing excess Na^+ from the body. The *basolateral step* of Na^+ reabsorption, as in other cells, is mediated by the Na-K pump. Because the DCT, like the TAL, has a low water permeability, removing luminal NaCl leaves the remaining tubule fluid even more hypo-osmotic. Hence, the DCT is also part of the “diluting segment.”

Initial and Cortical Collecting Tubules

Na^+ reabsorption in the connecting tubule, **initial collecting tubule (ICT)**, and CCT is transcellular and mediated by the majority cell type, the **principal cell** (see Fig. 35-4D). The neighboring β -intercalated cells are important for reabsorbing Cl^- , as discussed below. Na^+ crosses the *apical membrane* of the principal cell via the **epithelial Na^+ channel (ENaC)** (see Table 6-2, family No. 14), which is distinct from the voltage-gated Na^+ channels expressed by excitable tissues (see p. 187). ENaC is a trimer comprising homologous α , β , and γ subunits, each of which has two membrane-spanning segments. This channel is unique in that low levels of the diuretic drug **amiloride** specifically block it. This compound is a relatively mild diuretic because Na^+ reabsorption along the collecting duct is modest.  **N23-14** The *basolateral step* of Na^+ reabsorption is mediated by the Na-K pump, which also provides the electrochemical driving force for the apical entry of Na^+ .

The unique transport properties of the apical and basolateral membranes of the principal cells are also the basis for the lumen-negative V_{te} of approximately -40 mV in the CCT (see Table 35-1). In addition to ENaCs, the CCT has both apical and basolateral K^+ channels, which play a key role in K^+ transport (see p. 799). The apical entry of Na^+ (which tends to make the lumen negative) and the basolateral exit of K^+ (which tends to make the cell negative) are, in effect, two batteries of identical sign, arranged in series. In principle, these two batteries could add up to a V_{te} of ~ 100 mV (lumen negative). However, under most conditions, K^+ exit from cell to lumen partially opposes the lumen-negative potential generated by Na^+ entry. The net effect of these three batteries is a V_{te} of approximately -40 mV (lumen negative).

The V_{te} of the CCT can fluctuate considerably, particularly because of changes in the apical Na^+ battery owing to, for example, changes in luminal $[\text{Na}^+]$. In addition, changing levels of aldosterone or AVP may modulate the *number* of ENaCs that are open in the apical membrane and thus may affect the relative contribution of this Na^+ battery to apical membrane voltage.

Medullary Collecting Duct

The inner and outer medullary collecting ducts reabsorb only a minute amount of Na^+ , $\sim 3\%$ of the filtered load (see Fig. 35-2). It is likely that ENaC mediates the apical entry of Na^+ in these segments and that the Na-K pump extrudes Na^+ from the cell across the basolateral membrane (see Fig. 35-4D).

Cl^- reabsorption involves both paracellular and transcellular pathways

Most of the filtered Na^+ is reabsorbed with Cl^- . However, the segmental handling of Cl^- differs somewhat

from that of Na^+ . Both transcellular and paracellular pathways participate in Cl^- reabsorption.

Proximal Tubule

The proximal tubule reabsorbs Cl^- by both the transcellular and the paracellular routes, with the *paracellular* believed to be the dominant one in the early proximal tubule (Fig. 35-5A). The *transcellular pathway* is more appreciable in the late proximal tubule (see Fig. 35-5B), where the energetically uphill influx of Cl^- across the apical membrane occurs via an exchange of luminal Cl^- for cellular anions (e.g., formate, oxalate, HCO_3^- and OH^-), mediated at least in part by the anion exchanger SLC26A6. Cl-base exchange is an example of *tertiary* active transport: the apical NHE3, itself a *secondary* active transporter (see p. 115), provides the H^+ that neutralizes base in the lumen, thereby sustaining the gradient for Cl-anion exchange. The basolateral exit step for transcellular Cl^- movement may occur in part via a **Cl^- channel** that is analogous in function to the cystic fibrosis transmembrane conductance regulator (CFTR; see p. 120). In addition, the basolateral membrane of the proximal tubule expresses **K/Cl cotransporters** (KCC1, KCC3, KCC4), which are in the same family as the NKCCs and NCCs.

FIGURE 35-5 Cell models of Cl^- transport. In **B**, “Base” may include formate, oxalate, HCO_3^- , and OH^- . “HBase” represents the conjugate weak acid (e.g., formic acid). CA, carbonic anhydrase.

Passive Cl^- reabsorption via the *paracellular pathway* is driven by different electrochemical Cl^- gradients in the early versus the late proximal tubule. The S1 segment initially has no Cl^- concentration gradient between lumen and blood. However, the lumen-negative V_{te} (see [Table 35-1](#))—generated by electrogenic Na/glucose and Na/amino-acid cotransport—establishes a favorable *electrical* gradient for

passive Cl^- reabsorption. Solvent drag also makes a contribution in the S1 segment. Preferential HCO_3^- reabsorption in the S2 and S3 portions of the proximal tubule leaves Cl^- behind (see p. 825), so that $[\text{Cl}^-]$ in the lumen becomes higher than that in the blood (Fig. 35-6). This favorable lumen-to-blood *chemical* gradient of Cl^- provides a driving force for its passive paracellular reabsorption in the late proximal tubule, and generates a lumen-positive V_{te} (see Table 35-1) that drives a component of passive paracellular Na^+ reabsorption.

FIGURE 35-6 Changes in solute composition along the proximal tubule. In the upper panel, TF/P is the ratio of concentration or osmolality in tubule fluid to that in blood plasma. Because we assume that the proximal tubule reabsorbs half of the filtered water, $\text{TF}_{\text{In}}/\text{P}_{\text{In}}$ rises from 1 to 2. The lower panel shows the transition of V_{te} from a negative to a positive value.

The upper part of Figure 35-6 shows the profile of the ratio of concentration of various solutes X in tubule fluid versus plasma (TF_X/P_X ; see p. 733) for the major solutes in tubule fluid along the proximal tubule. Only minor changes occur in the TF/P for osmolality ($\text{TF}_{\text{Osm}}/\text{P}_{\text{Osm}}$) or $\text{TF}_{\text{Na}}/\text{P}_{\text{Na}}$. Because the tubule does not reabsorb inulin, the substantial increase in $\text{TF}_{\text{In}}/\text{P}_{\text{In}}$ indicates net fluid reabsorption. The fall in

$\text{TF}_{\text{HCO}_3^-}/\text{P}_{\text{HCO}_3^-}$ mirrors an increase in $\text{TF}_{\text{Cl}^-}/\text{P}_{\text{Cl}^-}$ because the tubule reabsorbs HCO_3^- more rapidly than it does Cl^- . The early proximal tubule avidly reabsorbs glucose and amino acids, which leads to sharp decreases in the concentrations of these substances in the tubule fluid.

An important characteristic of the proximal tubule is that the V_{te} reverses polarity between the S1 and the S2 segments (see Fig. 35-6, lower panel). The early proximal tubule is lumen negative because it reabsorbs Na^+ electrogenically, via both electrogenic apical Na^+ transporters (e.g., Na/glucose cotransporter) and the basolateral Na-K pump. The late proximal tubule reabsorbs Na^+ at a lower rate. Moreover, because TF_{Cl^-} is greater than P_{Cl^-} , the paracellular diffusion of Cl^- from lumen to blood generates a lumen-positive V_{te} that facilitates passive Na^+ reabsorption via the same paracellular route as discussed above.

Thick Ascending Limb

Cl^- reabsorption in the TAL takes place largely by Na/K/Cl cotransport across the apical membrane (see Fig. 35-5C), as we already noted in our discussion of Na^+ reabsorption (see Fig. 35-4B). The exit of Cl^- across the basolateral cell membrane via Cl^- channels of the ClC family (see Table 6-2, family No. 16) overwhelms any entry of Cl^- via the Cl- HCO_3^- exchanger. You may recall that only *half* of the Na^+ reabsorption by the TAL is transcellular, whereas *all* Cl^- reabsorption is transcellular. Overall, Na^+ and Cl^- reabsorption are identical because the apical NKCC2 cotransporter moves two Cl^- for each Na^+ .

Distal Convoluted Tubule

Cl^- reabsorption by the DCT (see Fig. 35-5D) occurs by a mechanism that is somewhat similar to that in the TAL, except the apical step occurs via NCC, as discussed above in connection with Na^+ reabsorption by the DCT (see Fig. 35-4C). Cl^- channels that are probably similar to those in the TAL mediate the basolateral Cl^- exit step.

Collecting Ducts

The ICT and the CCT reabsorb Cl^- by two mechanisms. First, the principal cell generates a V_{te} (~ 40 mV, lumen negative) that is favorable for *paracellular* diffusion of Cl^- (see Fig. 35-5E). Second, the β -type intercalated cells reabsorb Cl^- via a *transcellular* process in which pendrin (SLC26A4; see pp. 124–125) mediates Cl^- uptake across the apical membrane in exchange for HCO_3^- , and Cl^- exits via channels in the basolateral membrane (see Fig. 35-5F). Moreover, two cycles of Cl- HCO_3^- exchange via pendrin may operate in parallel with one cycle of Na-dependent Cl- HCO_3^- exchange via NDCBE (see p. 124) to produce net electroneutral NaCl entry across the apical membrane of β -intercalated cells (see Fig. 35-5F). Neither the α -type intercalated cells nor the principal cells participates in transcellular Cl^- reabsorption.

Water reabsorption is passive and secondary to solute transport

Proximal Tubule

If water reabsorption by the proximal tubule were to follow solute reabsorption *passively*, then one would expect the osmolality inside the peritubular capillaries to be greater than that in the luminal fluid.

Indeed, investigators have found that the lumen is slightly hypo-osmotic.

If, conversely, proximal-tubule water reabsorption were active, one might expect it to be independent of Na^+ reabsorption. Actually, the opposite was found by Windhager and colleagues in 1959. Using the stationary microperfusion technique, [N33-5](#) these investigators introduced solutions having various $[\text{Na}^+]$ values into the proximal-tubule lumen, and they kept luminal osmolality constant by adding mannitol (which is poorly reabsorbed). Because these experiments were performed on amphibian proximal tubules, the maximal $[\text{Na}^+]$ was only 100 mM, the same as that in blood plasma. After a known time interval, they measured the volume of fluid remaining in the tubule lumen and calculated the rate of fluid reabsorption (J_V). They also measured the $[\text{Na}^+]$ of the luminal fluid and calculated the rate of Na^+ reabsorption (J_{Na}). These experiments showed that both J_V and J_{Na} are directly proportional to the initial luminal $[\text{Na}^+]$ ([Fig. 35-7](#)). Moreover, the ratio J_{Na}/J_V is constant and equal to the osmolality of the lumen, which indicates that Na^+ reabsorption and secretion are approximately **isosmotic**. [N35-1](#)

FIGURE 35-7 Isosmotic water reabsorption in the proximal tubule. J_V and J_{Na} are the rates of fluid (or volume) and Na^+ reabsorption, respectively, in stationary microperfusion experiments.

Windhager and colleagues also found that at a luminal $[\text{Na}^+]$ of 100 mM, the J_{Na} and J_V were large and in the reabsorptive direction. When luminal $[\text{Na}^+]$ was only 65 mM, both J_{Na} and J_V were zero. At lower luminal $[\text{Na}^+]$ values, both J_{Na} and J_V reversed (i.e., the tubule secreted both Na^+ and water). At these low

luminal $[Na^+]$ values, active transcellular movement of Na^+ from lumen to blood cannot overcome the increasing paracellular backleak of Na^+ , which results in net secretion of an isosmotic NaCl solution. This experiment shows that Na^+ can move uphill from lumen to blood as long as the opposing Na^+ gradient is not too steep, and also suggests that the movement of water is not active but passively follows the reabsorption of Na^+ .

If water movement is passive, why is the difference in osmolality so small between the proximal-tubule lumen and blood? The answer is that, because the water permeability of the proximal-tubule epithelium to water is so high, the osmolality gradient needed to generate the observed passive reabsorption of water is only 2 to 3 mOsm. A somewhat greater osmolality gradient probably exists between the lumen and an inaccessible basolateral compartment comprising the lateral intercellular space and the microscopic unstirred layer that surrounds the highly folded basolateral membrane of the proximal-tubule cell.

The pathway for water movement across the proximal-tubule epithelium appears to be a combination of transcellular and paracellular transit, with the transcellular route dominating. The reason for the high rate of water movement through the proximal-tubule cell is the presence of a high density of aquaporin 1 (AQP1) **water channels** in both the apical and basolateral membranes. Indeed, in the AQP1-null mouse, the rates of solute and fluid reabsorption are reduced, and the fluid that the proximal tubule reabsorbs becomes hyperosmotic compared to normal conditions, resulting in marked luminal hypo-osmolality.

Loop of Henle and Distal Nephron

Two features distinguish water and Na^+ transport in the distal nephron. First, the TAL and all downstream segments have a relatively low water permeability in the absence of AVP (or antidiuretic hormone). We discuss the upregulation of this water permeability by AVP on [pages 817–818](#). Second, the combination of NaCl reabsorption and low water permeability allows these nephron segments to generate a low luminal $[Na^+]$ and osmolality with respect to the surrounding interstitial fluid. Given this large osmotic gradient across the epithelium, the distal nephron is poised to reabsorb water passively from a hypo-osmotic luminal fluid into the isosmotic blood when AVP increases the water permeability ([Box 35-1](#)).

Box 35-1

Osmotic Diuresis

Normally, luminal $[Na^+]$ does not change along the proximal tubule. The only exception is **osmotic diuresis**, a state in which poorly permeable substances are present in the plasma and, therefore, in the glomerular filtrate. Examples are the infusion of sucrose and mannitol. Another is untreated diabetes mellitus (see Box 51-5), when the blood glucose level exceeds the capacity of renal tubules to reabsorb the highly elevated glucose load. Glucose then acts as a poorly reabsorbed substance and as an osmotic diuretic. Because the proximal tubule must reabsorb isosmotic Na^+ salts from a luminal mixture of Na^+ salts and poorly reabsorbable solutes (e.g., mannitol), luminal $[Na^+]$ progressively falls and luminal [mannitol] rises, but luminal osmolality does not change (Fig. 35-8). Because the net rate of Na^+ and fluid reabsorption falls as the luminal $[Na^+]$ falls (see Fig. 35-7), the proximal tubule—with rising luminal [mannitol]—reabsorbs progressively less Na^+ and fluid as the fluid travels along the tubule. This decrease in Na^+ and water reabsorption leaves a larger volume of tubule fluid behind, thereby producing osmotic diuresis.

FIGURE 35-8 Osmotic diuresis and luminal $[\text{Na}^+]$ along the proximal tubule. In this example, blood and glomerular filtrate both contain 40 mM mannitol and have an osmolality of 300 mOsm. The isosmotic reabsorption of NaCl (but *not* mannitol) from proximal-tubule lumen to blood causes luminal [mannitol] to rise and $[\text{NaCl}]$ to fall, but causes no change in luminal osmolality. Once luminal $[\text{Na}^+]$ falls sufficiently, the Na^+ backleak from peritubular capillaries balances active Na^+ reabsorption, and net reabsorption of NaCl and water is zero. The absence of fluid absorption after this point causes osmotic diuresis. Viewed another way, the rising luminal [mannitol], with the osmotically obligated water the mannitol holds in the lumen, produces the diuresis. $\text{TF}_{\text{In}}/\text{P}_{\text{In}}$, the ratio of inulin concentrations in the tubule fluid to that in plasma.

Osmotic diuresis is of clinical use in several settings. For example, mannitol osmotically draws water out of brain tissue into the vascular system, for ultimate excretion by the kidneys. For this reason, osmotic diuresis is sometimes used in treating patients with acutely increased intracranial pressure from cerebral edema (e.g., from an embolic stroke), an expanding tumor or abscess, hematoma, or hemorrhage. In patients with severe hyperglycemia due to poorly controlled diabetes mellitus, pronounced osmotic diuresis can lead to a potentially life-threatening depletion of ECF volume.

It is common to distinguish between two types of diuresis, solute and water diuresis. The foregoing example of **solute or osmotic diuresis** is characterized by excretion of a larger-than-normal volume of urine that is rich in solutes. In contrast, **water diuresis** leads to excretion of larger-than-normal volumes of urine that is poor in solutes.

The kidney's high O_2 consumption reflects a high level of active Na^+ transport

Because virtually all Na^+ transport ultimately depends on the activity of the ATP-driven Na-K pump and, therefore, on the generation of ATP by oxidative metabolism, it is not surprising that renal O_2 consumption is large and parallels Na^+ reabsorption. Despite their low weight (<0.5% of body weight), the kidneys are responsible for 7% to 10% of total O_2 consumption. Although it would seem that the high O_2 consumption would necessitate a large arteriovenous difference in P_{O_2} , the renal blood flow is so large that the arteriovenous P_{O_2} difference is actually much smaller than that in cardiac muscle or brain.

If one varies Na^+ reabsorption experimentally and measures renal O_2 consumption, the result is a straight-line relationship (Fig. 35-9). However, the kidneys continue to consume a modest but significant amount of O_2 even in the complete absence of net Na^+ reabsorption. This transport-independent component reflects the basic metabolic needs for the maintenance of cell viability.

FIGURE 35-9 Dependence of O_2 consumption on Na^+ transport. Na^+ reabsorption (J_{Na}) was varied by changing GFR, administering diuretics, or imposing hypoxia. O_2 consumption was computed from the arteriovenous P_{O_2} difference.

Regulation of Na⁺ and Cl⁻ Transport

The body regulates Na⁺ excretion by three major mechanisms:

1. Changes in renal hemodynamics alter the Na⁺ load presented to the kidney and regulate Na⁺ reabsorption in the proximal tubule and distal nephron. We discuss these hemodynamic effects in the next four sections.
2. Three factors that respond to decreases in “effective circulating volume”—the renin-angiotensin-aldosterone axis, renal sympathetic nerve activity, and AVP (see [pp. 554–555](#))—do so in part by increasing Na⁺ reabsorption in various nephron segments. We discuss these factors in the fifth section.
3. Several factors that respond to increases in effective circulating volume—including atrial natriuretic peptide and dopamine—do so in part by reducing Na⁺ reabsorption in various segments of the nephron. That is, they produce a **natriuresis**. We discuss these factors in the final section of this chapter.

Glomerulotubular balance stabilizes fractional Na⁺ reabsorption by the proximal tubule in the face of changes in the filtered Na⁺ load

When hemodynamic changes (e.g., caused by a high-protein diet, intense exercise, severe pain, or anesthesia) alter GFR and thus the Na⁺ load presented to the nephron, *proximal* tubules respond by reabsorbing a relatively *constant fraction* of the Na⁺ load. This constancy of fractional Na⁺ reabsorption along the proximal tubule—**glomerulotubular (GT) balance**—is independent of external neural and hormonal control, and prevents spontaneous fluctuations in GFR from causing marked changes in Na⁺ excretion.

[Figure 35-10](#) shows how the *absolute reabsorption* of Na⁺ increases proportionally with increases in the filtered Na⁺ load, achieved by varying GFRs at constant plasma [Na⁺]. The amount of luminal Na⁺ remaining at the end of the proximal tubule also increases linearly with the filtered Na⁺ load. However, fractional reabsorption of Na⁺ and water in the proximal tubule is not always constant—that is, *proximal GT balance* is not always perfect—as we will see below. Moreover, at the level of the *whole kidney*, GT balance is not perfect, mainly because distal-nephron Na⁺ absorption is under neural and hormonal control (see [p. 765](#)).

FIGURE 35-10 Constancy of fractional Na⁺ reabsorption by the proximal tubule.

The proximal tubule achieves GT balance by both peritubular and luminal mechanisms

How do the proximal-tubule cells sense that the GFR has changed? Both peritubular and luminal control mechanisms contribute, although no agreement exists concerning their relative roles.

Peritubular Factors in the Proximal Tubule

As discussed in [Chapter 34](#), Starling forces across the peritubular capillary walls determine the uptake of interstitial fluid and thus the net reabsorption of NaCl and fluid from the tubule lumen into the peritubular capillaries (see [pp. 747–749](#)). These peritubular **physical factors** also play a role in GT balance. We can distinguish a sequence of three transport steps as reabsorbed fluid moves from the tubule lumen into the blood ([Fig. 35-11A](#)):

Step 1: Solutes and water enter a tubule cell across the apical membrane.

Step 2: Solutes and water from step 1 (i.e., “reabsorbate”) exit the tubule cell across the basolateral membrane and enter an *intercellular* compartment—the **lateral interspace**—that is bounded by the apical tight junction, the basolateral tubule-cell membranes, and a basement membrane that does not discriminate between solutes and solvent. Steps 1 and 2 constitute the *transcellular pathway*.

Step 3: The reabsorbate can either backleak into the lumen (step 3a) or move sequentially into the interstitial space and then into the blood (step 3b).

FIGURE 35-11 Peritubular mechanisms of GT balance. In **A**, P_{PC} and π_{PC} are, respectively, the hydrostatic and the oncotic pressures in the peritubular capillaries. At the level of the tubule, the net Na^+ reabsorption is the difference between active transcellular transport and passive backleak through the paracellular pathway. At the level of the peritubular capillary, net fluid absorption is the difference between fluid absorption (driven by π_{PC}) and fluid filtration (driven by P_{PC}). In **B**, increasing the filtered fraction has effects on both the tubule and the peritubular capillaries. At the level of the tubule, the increased concentrations of Na^+ -coupled solutes (e.g., glucose) increase active transport. At the level of the capillaries, the lower P_{PC} and higher protein concentration (π_{PC}) pull more fluid from the interstitium. The net effect is reduced passive backleak.

At normal GFR (see Fig. 35-11A), reabsorptive Starling forces—the low hydrostatic and high oncotic pressure in the capillaries—cause an extensive uptake of reabsorbate into the capillaries.

Because of GT balance, spontaneous alterations in GFR lead to changes in peritubular pressures (both hydrostatic and oncotic) that, in turn, modulate the forces that govern step 3. Peritubular mechanisms of GT balance come into play only when the changes in GFR are associated with alterations in **filtration fraction** ($\text{FF} = \text{GFR}/[\text{renal plasma flow}]$; see p. 746). Consider an example in which we increase GFR at constant glomerular plasma flow, thereby increasing FF (see Fig. 35-11B). We can produce this effect by increasing efferent arteriolar resistance while concomitantly decreasing afferent arteriolar resistance (see Fig. 34-8A, bottom section). The result is an increase in glomerular capillary pressure (i.e., net filtration pressure) without a change in overall arteriolar resistance. These changes have two important

consequences for peritubular capillaries. First, the increased GFR translates into less fluid remaining in the efferent arteriole, so that peritubular *oncotic pressure* (π_{PC}) rises. Second, the increased GFR also translates to slightly less blood flowing into the efferent arteriole, which slightly decreases *hydrostatic pressure* in the peritubular capillaries (P_{PC}). As a consequence, the net driving force increases for the transport of fluid from the lateral interspace into the capillaries; this results in a more effective absorption of fluid and NaCl. The opposite sequence of events occurs with a spontaneous fall in GFR, which leads to a decrease in FF. The response is a decrease in the net reabsorption of Na^+ and water by the proximal tubule that tends to maintain constancy of fractional Na^+ reabsorption and GT balance.

Luminal Factors in the Proximal Tubule

Luminal factors also contribute to GT balance, as evidenced by the observation that increased flow along the proximal tubule—without any peritubular effects—leads to an increase in fluid and NaCl reabsorption. The luminal concentrations of solutes such as glucose, amino acids, and HCO_3^- fall along the length of the proximal tubule as the tubule reabsorbs these solutes (see Fig. 35-6). Increasing luminal flow would, for instance, cause luminal [glucose] to fall less steeply along the tubule length, and more glucose would be available for reabsorption at distal sites along the proximal tubule. The net effect is that, integrated over the entire proximal tubule, higher luminal flows increase the reabsorption of Na^+ , glucose, and other Na^+ -coupled solutes.

A second luminal mechanism may revolve around flow sensing. Increased flow may cause increased bending of the **central cilium** or the microvilli on the apical membrane, which may signal increased fluid reabsorption. Third, humoral factors in the glomerular filtrate may also contribute to GT balance. If one harvests tubule fluid and injects it into a single proximal tubule, Na^+ reabsorption increases. **Angiotensin II (ANG II)**—a small peptide hormone that is both filtered in the glomeruli and secreted by proximal-tubule cells—increases Na^+ reabsorption in the proximal tubule.

ECF volume contraction or expansion upsets GT balance

As noted above, proximal GT balance is not always perfect. For instance, if excessive Na^+ loss (e.g., sweating or diarrhea) contracts the ECF volume—thereby reducing renal perfusion pressure, GFR, and the filtered Na^+ load—perfect GT balance would reduce renal Na^+ and water excretion. In fact, in volume contraction, the fractional reabsorption of Na^+ and water *increases* in the proximal tubule, so that renal Na^+ and water excretion fall beyond that expected for perfect GT balance. Conversely, if ingestion or administration of a high Na^+ load expands ECF, fractional reabsorption of Na^+ and water in the proximal tubule falls, which enhances renal Na^+ excretion beyond that expected for perfect GT balance. These effects result, in part, from the same hemodynamic factors maintaining GT balance, as well as from direct regulation of transcellular Na^+ reabsorption in the proximal tubule.

During ECF and plasma volume contraction, blood pressure and renal blood flow will tend to fall. Under these conditions, prostaglandins mediate afferent arteriolar dilation (see p. 753) and ANG II mediates efferent arteriolar constriction (see p. 752), thereby preventing GFR from falling in proportion to the reduction in renal blood flow. Thus, FF will increase. The resulting increase in peritubular protein concentration will raise peritubular oncotic pressure (π_{PC}), reducing backleak of reabsorbate and thereby enhancing net tubule reabsorption of Na^+ salts and water. In addition, ANG II—levels of which increase during volume contraction—binds to AT_1 receptors on proximal-tubule cells, which results in stimulation of transcellular Na^+ reabsorption. The converse series of events will take place during volume expansion.

The distal nephron also increases Na^+ reabsorption in response to an increased Na^+ load

The tubules of the distal nephron, like their proximal counterparts, also increase their absolute magnitude of Na^+ reabsorption in response to increased flow and Na^+ delivery. The principle is the same as that for glucose transport in the proximal tubule, except here it is luminal $[\text{Na}^+]$ that falls less steeply when flow increases (Fig. 35-12A). Because the transport mechanisms responsible for Na^+ reabsorption by the distal nephron are more effective at higher luminal $[\text{Na}^+]$ values, reabsorption at any site increases with flow (see Fig. 35-12B). In contrast to GT balance in the proximal tubule, increasing flow by a factor of 4 in the distal nephron may cause cumulative Na^+ reabsorption to rise by only a factor of 2 (see Fig. 35-12C).

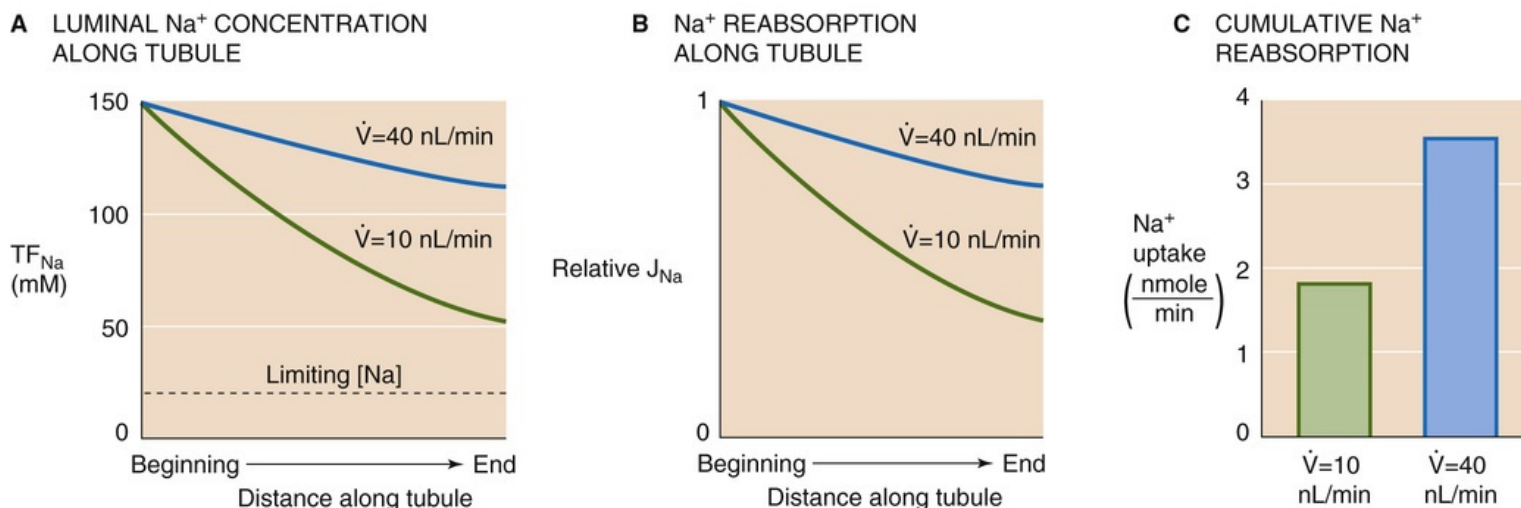

FIGURE 35-12 Flow dependence of Na^+ transport in the distal nephron. **A** and **B** are idealized representations of the effect of increased flow (\dot{V}) on luminal $[\text{Na}^+]$ and Na^+ reabsorption rate (J_{Na}) along the TAL. Limiting $[\text{Na}]$ is the theoretical minimal value that the tubule could achieve at zero flow. **C** summarizes the effect of flow on cumulative Na^+ reabsorption.

The load dependence of Na^+ reabsorption in the TAL is of clinical importance because it explains why diuretic agents acting on the proximal tubule are relatively less effective in enhancing Na^+ excretion than one would expect from the large fraction of filtered Na^+ that the proximal tubule reabsorbs. Thus, although carbonic anhydrase inhibitors are potent blockers of proximal Na^+ and water reabsorption, the increased delivery of Na^+ to the TAL and distal nephron results in a large increase in Na^+ reabsorption in these segments, greatly reducing the ultimate loss of Na^+ in the final urine.

Four parallel pathways that regulate effective circulating volume all modulate Na^+ reabsorption

GT balance is only one element in a larger, complex system for controlling Na^+ balance. As we see in Chapter 40, the control of effective circulating volume (i.e., Na^+ content) is under the powerful control of four parallel effectors (see pp. 554–555): the renin-angiotensin-aldosterone axis, the sympathetic nervous system, AVP, and atrial natriuretic peptide (ANP). In Chapter 34 we saw how these factors modulate renal blood flow and GFR (see pp. 752–753). Here, we briefly discuss how these four effectors modulate Na^+ reabsorption, a subject that we will treat more comprehensively beginning on page 836.

Renin-Angiotensin-Aldosterone Axis

ANG II—the second element in the renin-angiotensin-aldosterone axis (see [pp. 841–842](#))—binds to AT_1 receptors at the apical and basolateral membranes of proximal-tubule cells and, predominantly via protein kinase C, stimulates NHE3. ANG II also upregulates expression of NHE3 and NKCC2 in the TAL. Moreover, ANG II upregulates NCC activity in the DCT and stimulates apical Na^+ channels in the ICT. These effects promote Na^+ reabsorption. Complex interactions among intracellular kinases (e.g., WNK4 and SPAK) mediate the effects of ANG II on the DCT and ICT.

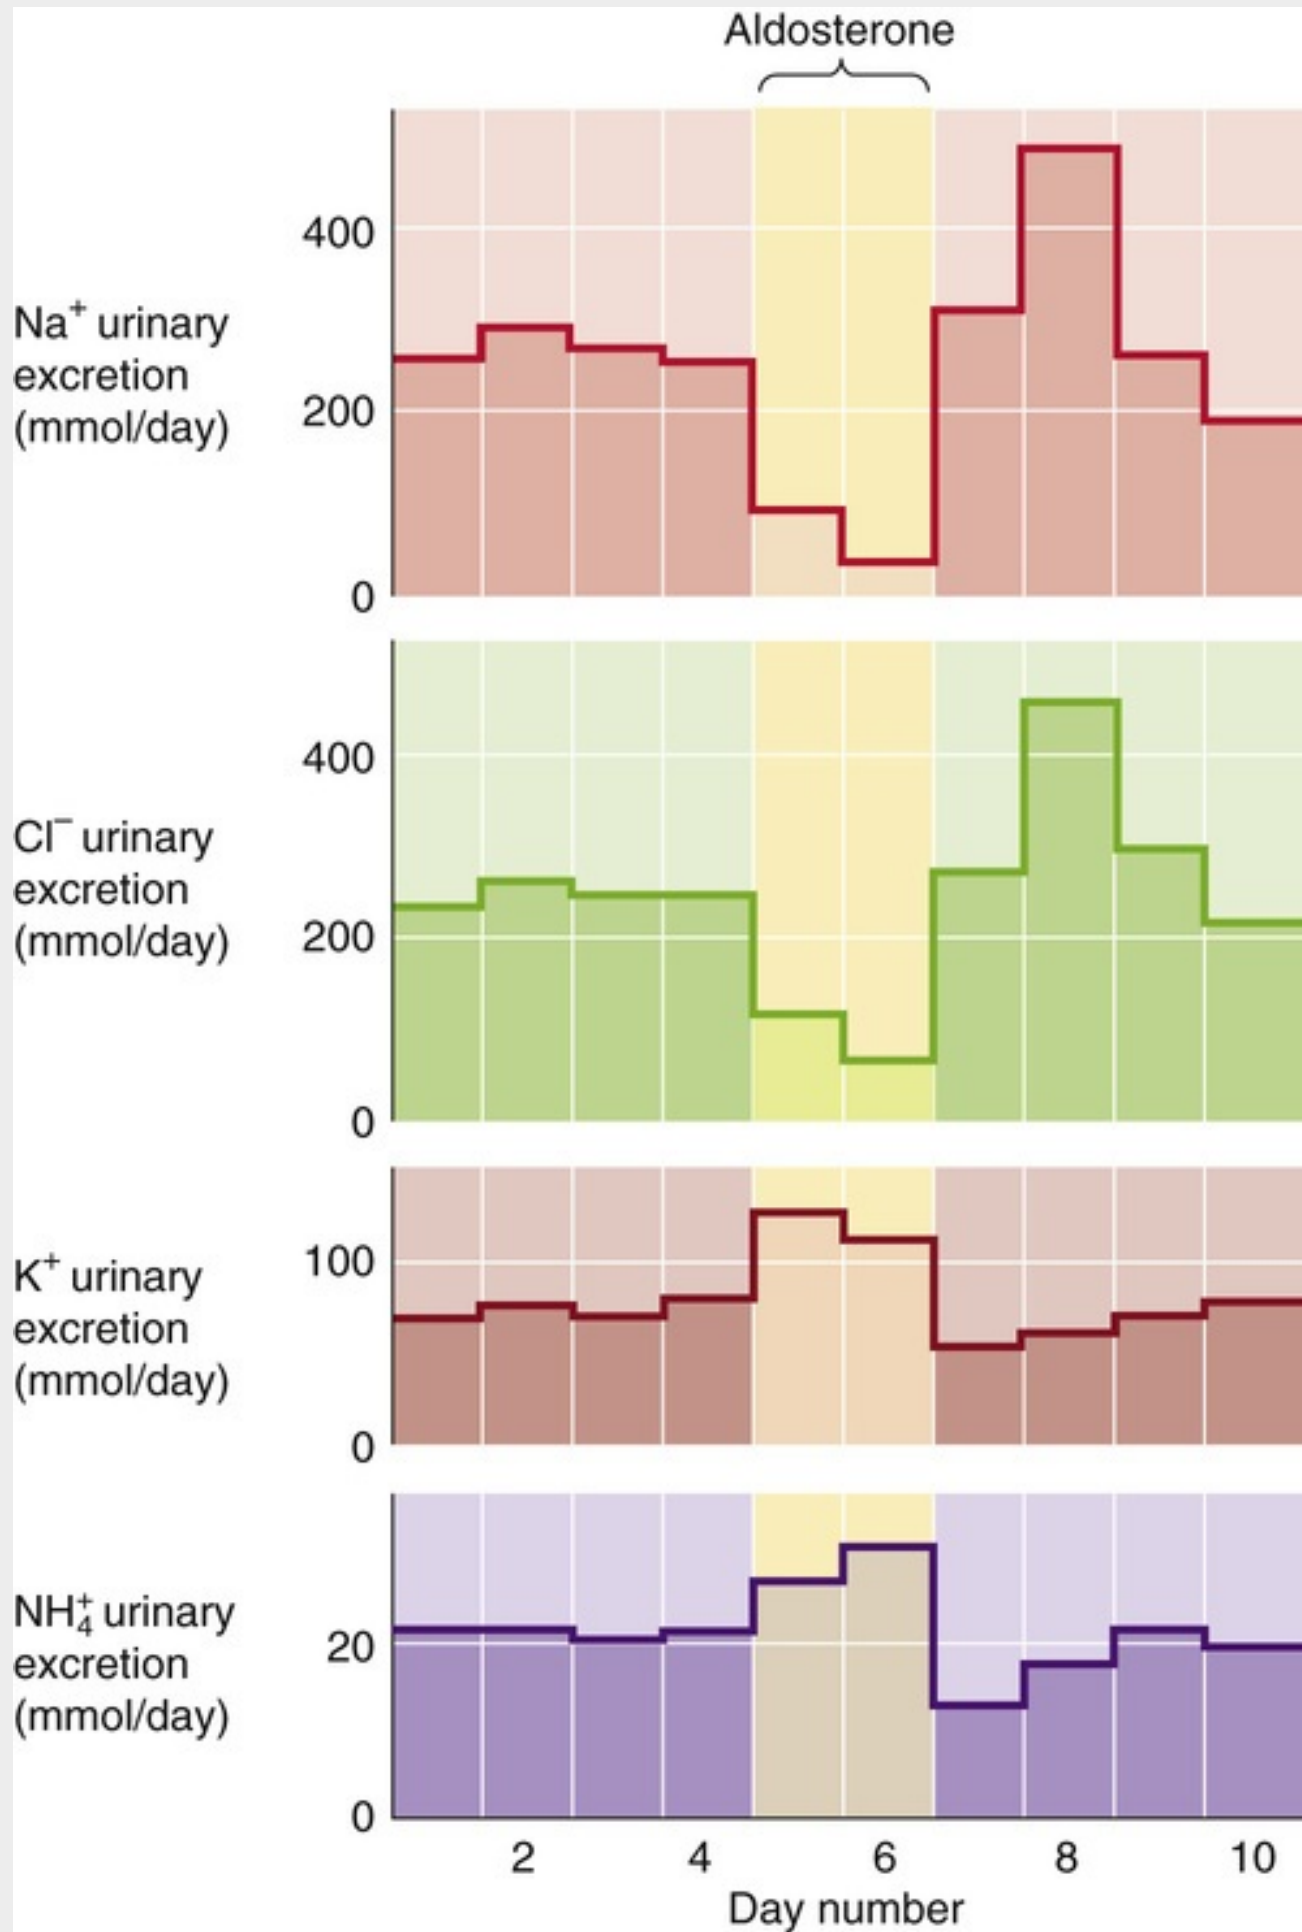

Aldosterone—the final element in the renin-angiotensin-aldosterone axis—stimulates Na^+ reabsorption by NCC in the DCT and by the ENaC in the late DCT, connecting tubule, and collecting ducts. Normally, <10% of the filtered Na^+ load is under humoral control by aldosterone. Nevertheless, the sustained loss of even a small fraction of the filtered Na^+ load would exceed the daily Na^+ intake significantly. Accordingly, the lack of aldosterone that occurs in adrenal insufficiency (Addison disease) can lead to severe Na^+ depletion, contraction of the ECF volume, low plasma volume, and hypotension. 📖 [N35-2](#)

N35-2

Acute Effects of Intravenous Aldosterone

Contributed by Gerhard Giebisch, Erich Windhager

eFigure 35-1 shows the renal effects of intravenously administered aldosterone. The acute effects include significant decreases in Na^+ and Cl^- excretion, as well as increases in K^+ and NH_4^+ excretion. The reverse changes occur in adrenalectomy, and the administration of **mineralocorticoids** (e.g., aldosterone) promptly reverses these deficiencies.

EFIGURE 35-1 Acute effects of intravenously administered aldosterone on electrolyte excretion in humans. (Data from Liddle GW: Aldosterone antagonists. *Arch Intern Med* 102:998–1005, 1958.)

Aldosterone acts on its target tissues by binding to cytoplasmic **mineralocorticoid receptors (MRs)** that then translocate to the nucleus and upregulate transcription (see [pp. 71–72](#)), as illustrated for the case of **principal cells** of the collecting ducts in [Figure 35-13A](#). Thus, the effects of aldosterone require a few hours to manifest themselves because they depend on the increased production of aldosterone-induced proteins. The ultimate cellular actions of aldosterone include upregulation of apical ENaCs, apical K⁺ channels, the basolateral Na-K pump, and mitochondrial metabolism. The effects on ENaC involve an increase in the product of channel number in the apical membrane and open probability (NP_o), and thus apical Na⁺ permeability. The simultaneous activation of apical Na⁺ entry and basolateral Na⁺ extrusion ensures that, even with very high levels of Na⁺ reabsorption, $[Na^+]_i$ and cell volume are stable. Long-term exposure to aldosterone leads to the targeting of newly synthesized Na-K pumps to the basolateral membrane and to amplification of the basolateral membrane area.

A GENOMIC EFFECTS OF ALDOSTERONE ON Na^+ TRANSPORT

B REGULATION OF ENaC

C ROLE OF 11β -HYDROXYSTEROID DEHYDROGENASE 2 (11β -HSD2)

11β -HSD2 metabolizes cortisol to a product that has little affinity for MR or GR. Aldosterone, which is not metabolized, occupies MR and GR.

D INHIBITION OF 11β -HSD2

Glycyrrhetic acid inhibits 11β -HSD2. Therefore cortisol is not metabolized and preferentially occupies MR and GR over aldosterone.

FIGURE 35-13 Cellular actions of aldosterone. The inset in **A** shows the upregulation of ENaC Na^+ channels, based on patch-clamp data from the rat CCT. N is the number of channels in the patch and P_O is the open probability. For simplicity, the blowup in **B** shows only the α subunit of the trimeric ENaC, which also has β and γ subunits. SGK1 not only phosphorylates Nedd4-2 but also Ser-621 of the α subunit (which is important for the rapid activation of the channel). In **C**, 11β -HSD2 prevents cortisol (a glucocorticoid), which is present at high plasma concentrations, from having mineralocorticoid effects in the target cell. In **D**, with the enzyme blocked, cortisol acts as a mineralocorticoid. mRNA, messenger RNA.

Aldosterone upregulates **serum- and glucocorticoid-induced kinase (SGK)**, which phosphorylates and thereby inhibits the ubiquitin ligase Nedd4-2 (see [Fig. 35-13B](#)). The net effect is reduced ubiquitination—and thus reduced endocytosis of ENaC—and increased apical membrane abundance of ENaC.

Because MRs distinguish poorly between glucocorticoids and mineralocorticoids, and because plasma concentrations of glucocorticoids greatly exceed those of aldosterone, one would expect glucocorticoids to exert a mineralocorticoid effect and cause Na⁺ retention. Under normal conditions, this does not happen because of the enzyme **11 β -hydroxysteroid dehydrogenase 2 (11 β -HSD2)**, [N35-3](#) which colocalizes with intracellular MRs (see [Fig. 35-13C](#)). This enzyme irreversibly converts cortisol into cortisone (see [p. 1021](#)), an inactive metabolite with low affinity for MRs. In sharp contrast, the enzyme does *not* metabolize aldosterone. Thus, 11 β -HSD2 enhances the apparent specificity of MRs by protecting them from illicit occupancy by cortisol. As may be expected, an 11 β -HSD2 deficiency may cause **apparent mineralocorticoid excess (AME)**, with abnormal Na⁺ retention, hypokalemia, and hypertension. Carbenoxolone, a specific inhibitor of 11 β -HSD2, prevents metabolism of cortisol in target cells, thus permitting abnormal activation of MRs by this glucocorticoid. Another inhibitor of 11 β -HSD2 is glycyrrhetic acid, a component of “natural” **licorice** (see [Fig. 35-13D](#)). [N35-4](#) Thus, natural licorice can also cause the symptoms of AME.

N35-3

Reaction Catalyzed by 11 β -Hydroxysteroid Dehydrogenase

Contributed by Eugene Barrett

Refer to Figure 50-2, specifically the **cortisol** molecule (4-pregnen-11 β ,17 α ,21-triol-3,20-dione), which has two highlighted hydroxyl groups—one on the C ring at position 11 and another on the D ring at position 17. The enzyme 11 β -hydroxysteroid dehydrogenase (11 β -HSD) removes one H from the hydroxyl group at position 11 and another H from the same carbon, yielding a ketone group (O=C) at position 11. The product of this reaction is **cortisone** (4-pregnen-17 α ,21-diol-3,11,20-trione). Thus, the enzyme converts a triol (three hydroxyl groups)/dione (two ketone groups) to a diol (two hydroxyl groups)/trione (three ketone groups).

N35-4

Licorice as a Cause of Apparent Mineralocorticoid Excess

Contributed by Emile Boulpaep, Walter Boron

Glycyrrhizic acid is a chemical that consists of **glycyrrhetic acid** (3- β -hydroxy-11-oxolean-12-en-30-oic acid) conjugated to two glucuronic acid moieties. Glycyrrhizic acid is 150-fold sweeter than sucrose. It is naturally produced by the plant *Glycyrrhiza glabra* (Leguminosae) and is also present in European licorice. American licorice manufacturers generally substitute anise for glycyrrhizic acid.

Glycyrrhetic acid and the glycyrrhetic acid moiety of glycyrrhizic acid have the curious property that they inhibit the enzyme **11 β -hydroxysteroid dehydrogenase (11 β HSD)**. This enzyme converts cortisol into cortisone. [N35-3](#) Because cortisol has a much higher affinity for the MR than does the breakdown product cortisone, inhibition of 11 β HSD produces the same symptoms as a bona fide excess of mineralocorticoids. As described on page 766, this excess leads to Na⁺ retention and hypertension.

These compounds also inhibit **15-hydroxyprostaglandin dehydrogenase** in the surface cells of the stomach and thereby increase levels of prostaglandins that protect the stomach from acid damage. This same action may also promote the release of mucus in the airway, which is why the active compounds of licorice have been used as expectorants.

True licorice has long been used as an herbal medicine.

Sympathetic Division of the Autonomic Nervous System

Sympathetic nerve terminals in the kidney release norepinephrine, which has two major *direct* effects on Na^+ reabsorption. First, high levels of sympathetic stimulation markedly reduce renal blood flow and, therefore, GFR (see [p. 752](#)). A decreased filtered load of Na^+ will tend to cause Na^+ excretion to fall. Second, even low levels of sympathetic stimulation activate α -adrenergic receptors in proximal tubules. This activation stimulates both the apical NHE3 and basolateral Na-K pump (see [Fig. 35-4A](#)), thereby increasing Na^+ reabsorption, independent of any hemodynamic effects. Conversely, surgical denervation of the kidneys can reduce blood pressure in patients with resistant hypertension.

Arginine Vasopressin (Antidiuretic Hormone)

Released by the posterior pituitary, AVP binds to a V_2 receptor at the basolateral membrane of target cells. Acting via G_s , the AVP increases $[\text{cAMP}]_i$ (see [pp. 56–57](#)). As discussed in [Chapter 38](#), the overall renal effect of AVP in humans is to produce urine with a high osmolality and thereby retain water (see [pp. 817–818](#)). However, AVP also stimulates Na^+ reabsorption. In the TAL, AVP stimulates the apical NKCC2 and K^+ channels (see [Fig. 35-4B](#)). In principal cells of the ICT and CCT, AVP stimulates Na^+ transport by increasing the number of open Na^+ channels (NP_o) in the apical membrane.  [N35-5](#)

N35-5

Effects of AVP on Na^+ Channels

Contributed by Gerhard Giebisch, Erich Windhager

As noted in the text, AVP increases the number of open Na^+ channels (NP_o) in the initial and cortical collecting tubules. This effect may reflect fusion of Na^+ channel-containing vesicles with the apical cell membrane or activation of pre-existing Na^+ channels in the membrane by cAMP-dependent protein kinase.

Atrial Natriuretic Peptide

Of the four parallel effectors that control effective circulating volume, ANP (see [p. 843](#)) is the only one that promotes natriuresis. A polypeptide released by atrial myocytes (see [p. 553](#)), ANP stimulates a receptor guanylyl cyclase to generate cGMP (see [p. 66](#)). The major effects of ANP are hemodynamic. 

N35-6 It causes renal vasodilation by increasing blood flow to both the cortex and the medulla. Increased blood flow to the *cortex* raises GFR and increases the Na^+ load to the proximal tubule and to the TAL (see pp. 752–753). Increased blood flow to the *medulla* washes out the medullary interstitium (see pp. 813–815), thus decreasing osmolality and ultimately reducing passive Na^+ reabsorption in the thin ascending limb (see p. 811). The combined effect of increasing cortical and medullary blood flow is to increase the Na^+ load to the distal nephron and thus to increase urinary Na^+ excretion. In addition to having hemodynamic effects, ANP directly inhibits Na^+ transport in the inner medullary collecting duct, perhaps by decreasing the activity of nonselective cation channels in the apical membrane.

N35-6

Renal Actions of ANP

Contributed by Gerhard Giebisch, Erich Windhager

eFigure 35-2 summarizes the effects of ANP on targets along the nephron.

Regarding **step 13** in the figure, patch-clamp studies show that cGMP directly decreases the activity of nonselective cation channels in the apical membrane of the medullary collecting duct.

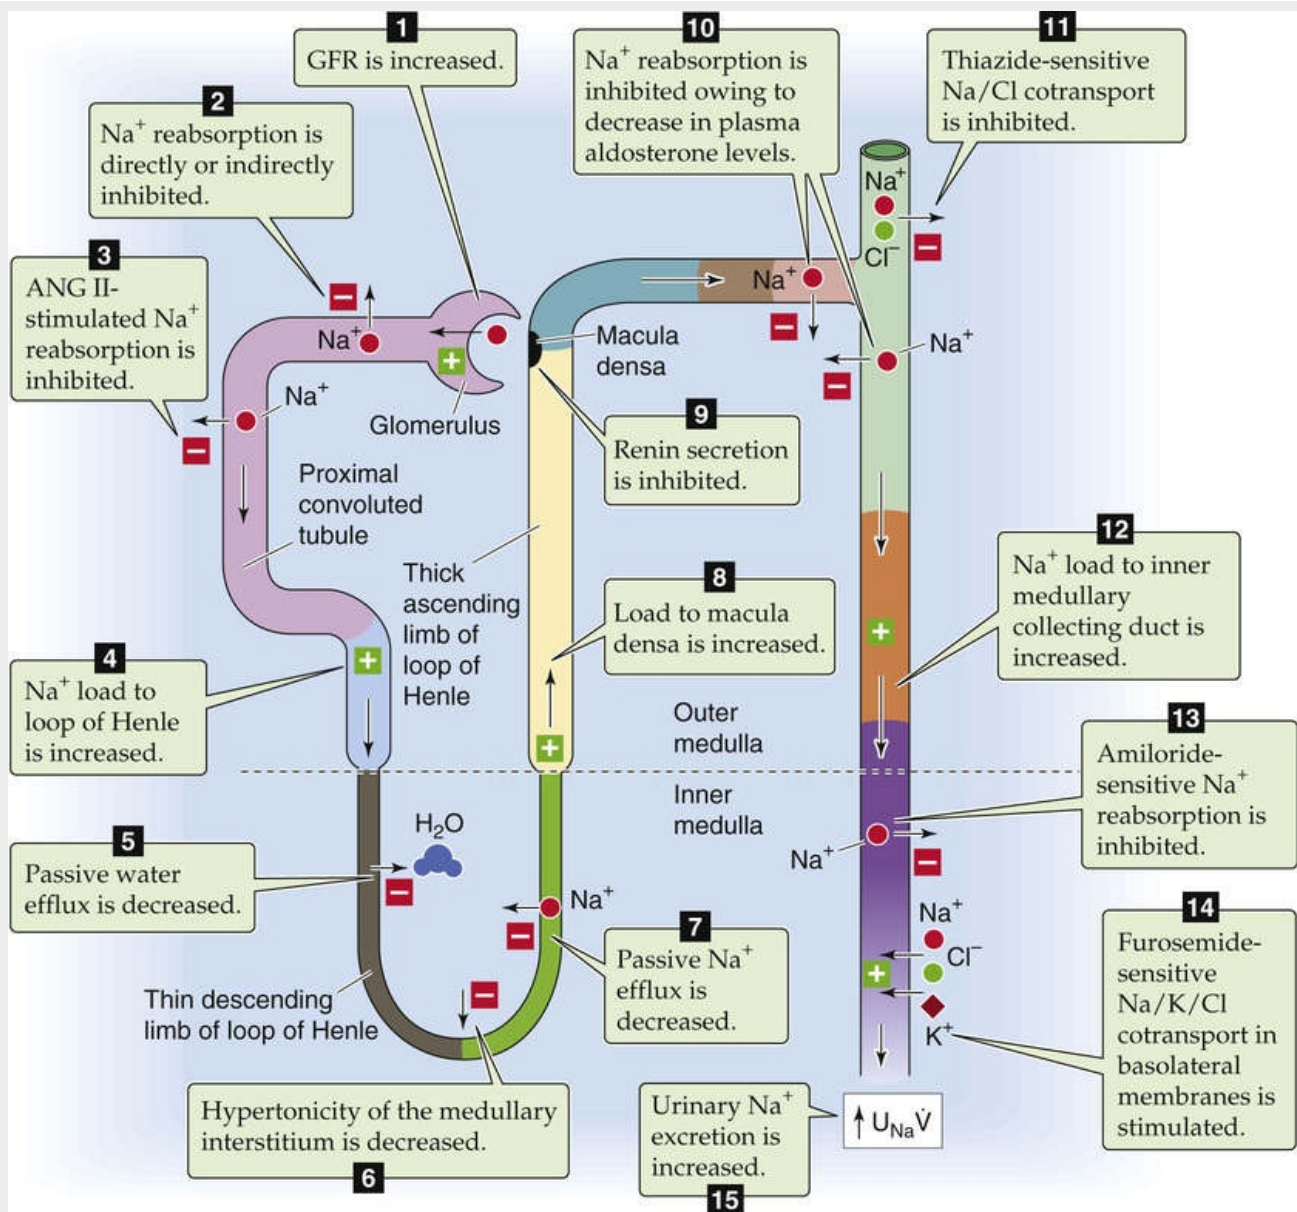

FIGURE 35-2 Sites of action of ANP. $U_{Na} \dot{V}$, urinary sodium excretion rate. (Data from Atlas SA, Maack T: Atrial natriuretic factor. In Windhager EE (ed): Handbook of Physiology, Section 8: Renal Physiology. New York, Oxford University Press, 1992, pp 1577–1674.)

Dopamine, elevated plasma $[Ca^{2+}]$, an endogenous steroid, prostaglandins, and bradykinin all decrease Na^+ reabsorption

Aside from ANP (see previous section), five humoral agents have significant natriuretic action, in part due to inhibition of Na^+ reabsorption at the level of the tubule cell.

Dopamine

From circulating L-dopa, proximal-tubule cells use L-amino acid decarboxylase (see Fig. 13-8C) to form dopamine, which they then secrete into the tubule lumen. Na^+ loading increases the synthesis and urinary excretion rate of dopamine, whereas a low Na^+ diet has the opposite effect. As noted above, dopamine causes renal vasodilation (see p. 753), which increases Na^+ excretion. Dopamine also directly inhibits Na^+ reabsorption at the level of tubule cells. Indeed, D1 dopamine receptors are present in the renal cortex, where they lead to an increase in $[cAMP]_i$. The result is an inhibition of apical NHE3 in the proximal tubule and inhibition of the basolateral Na-K pump in multiple tubule segments. In humans,

administering low doses of dopamine leads to natriuresis.

Elevated Plasma $[Ca^{2+}]$

The kidney, similar to the parathyroid gland (see pp. 1060–1061), responds directly to changes in extracellular $[Ca^{2+}]$. In the cortical TAL, an increase in basolateral $[Ca^{2+}]$ inhibits both the NKCC and K^+ channels on the apical membrane (see Fig. 35-4B), thereby decreasing the lumen-positive V_{te} and reducing paracellular Na^+ reabsorption. The mechanism appears to be the following (Fig. 35-14): Extracellular Ca^{2+} binds to a basolateral **Ca^{2+} -sensing receptor (CaSR)**, which couples to at least two G proteins. First, activation of G_{α_i} decreases $[cAMP]_i$, thus reducing stimulation of Na/K/Cl cotransport by cAMP (see p. 768). Second, activation of a member of the G_i/G_o family stimulates phospholipase A_2 (PLA_2 ; see p. 62), thereby increasing levels of arachidonic acid and one of its cytochrome P-450 metabolites, probably 20-hydroxyeicosatetraenoic acid (20-HETE). The latter inhibits apical NKCCs and K^+ channels. Third, CaSR activates G_{α_q} , elevating levels of inositol 1,4,5-trisphosphate (IP_3) and thus $[Ca^{2+}]_i$ (see p. 58) and also stimulating protein kinase C (PKC; see pp. 60–61), which also inhibits Na/K/Cl cotransport. Regardless of the mechanism, inhibition of apical Na/K/Cl cotransport (1) lowers $[Cl^-]_i$ and thus hyperpolarizes the basolateral membrane, and (2) lowers $[K^+]_i$ and thus depolarizes the apical membrane. Together, these two effects reduce the lumen-positive V_{te} , thereby inhibiting the paracellular reabsorption of Na^+ and, as we shall see below, Ca^{2+} (see p. 789) and Mg^{2+} (see p. 791). The CaSR is also present in the proximal tubule, the medullary TAL, the DCT, and the collecting ducts. 🧠N36-14

FIGURE 35-14 Role of CaSR in regulating Na^+ reabsorption by the TAL. AC, adenylyl cyclase.

Endogenous Na-K Pump Inhibitor

Human plasma contains an endogenous ouabain-like steroid (see p. 117) that inhibits Na-K pumps in a wide variety of cells. Levels of this natural Na-K pump inhibitor increase with salt loading and it is present in high levels in patients with hypertension. In response to Na^+ loading, the body may increase levels of this inhibitor, which presumably would bind preferentially to Na-K pumps of collecting-duct cells, thereby elevating $[\text{Na}^+]_i$ and enhancing Na^+ excretion.

Prostaglandins

Produced locally in the kidney, prostaglandin E_2 (PGE_2) inhibits Na^+ reabsorption and promotes natriuresis. In the TAL, PGE_2 inhibits both apical and basolateral K^+ channels, depolarizing both membranes and reducing passive Cl^- efflux across the basolateral membrane. $[\text{Cl}^-]_i$ therefore rises, impeding the turnover of the apical NKCC2 (see Fig. 35-4B) and reducing NaCl reabsorption. In addition, the V_{te} becomes less lumen positive, which decreases the driving force for passive paracellular reabsorption of Na^+ and other cations. In the CCT, both PGE_2 and bradykinin inhibit electrogenic reabsorption of Na^+ through principal cells (see Fig. 35-4D). Accordingly, drugs that inhibit prostaglandin synthesis (e.g., nonsteroidal anti-inflammatory drugs, or NSAIDs) tend to cause Na^+ retention, resistance to diuretic drugs, and exacerbation of hypertension in some patients.

Bradykinin

In the TAL, bradykinin—also made locally in the kidney—stimulates PGE_2 synthesis and release, which in turn inhibits NaCl reabsorption (see above). Moreover, in the CCT, bradykinin inhibits ENaC activity, thereby reducing Na^+ reabsorption and favoring natriuresis. Because angiotensin-converting enzyme (ACE) degrades bradykinin, one of the mechanisms by which ACE inhibitors enhance Na^+ excretion and reduce blood pressure is blocking bradykinin breakdown.

Transport of Urea, Glucose, Phosphate, Calcium, Magnesium, and Organic Solutes

Gerhard Giebisch, Erich E. Windhager, Peter S. Aronson

The kidney plays a central role in controlling the plasma levels of a wide range of solutes that are present at low concentrations in the body. The renal excretion of a solute depends on three processes—filtration, reabsorption, and secretion (see [pp. 732–733](#)). The kidney filters and then totally reabsorbs some of the substances we discuss in this chapter (e.g., glucose). Others, it filters and also secretes (e.g., the organic anion para-aminohippurate [PAH]). Still others, the kidney filters, reabsorbs, and secretes (e.g., urea).

Urea

The kidney filters, reabsorbs, and secretes urea

The liver generates urea from NH_4^+ , the primary nitrogenous end product of amino-acid catabolism (see [p. 965](#)). The primary route for urea excretion is the urine, although some urea exits the body through the stool and sweat. The normal plasma concentration of urea is 2.5 to 6 mM. Clinical laboratories report plasma urea levels as **blood urea nitrogen (BUN)** in the units (mg of elemental nitrogen)/(dL plasma); normal values are 7 to 18 mg/dL. For a 70-kg human ingesting a typical Western diet and producing 1.5 to 2 L/day of urine, the urinary excretion of urea is ~450 mmol/day.

The kidney freely filters urea at the glomerulus, and then it both reabsorbs and secretes it. Because the tubules reabsorb more urea than they secrete, the amount of urea excreted in the urine is less than the quantity filtered. In the example shown in [Figure 36-1A](#) (i.e., average urine flow), the kidneys excrete ~40% of the filtered urea. The primary sites for urea reabsorption are the proximal tubule and the medullary collecting duct, whereas the primary sites for secretion are the thin limbs of the loop of Henle.

A HANDLING OF UREA ALONG NEPHRON

B PROXIMAL TUBULE

C THIN DESCENDING LIMB (IDLH)

D THIN ASCENDING LIMB (IALH)

E INNER MEDULLARY COLLECTING DUCT (IMCD)

FIGURE 36-1 Urea handling by the kidney. In **A**, we assume a normal urine flow and thus a urea

excretion of 40% of the filtered load. The numbered yellow boxes indicate the fraction of the filtered load that various nephron segments *reabsorb*. The tALH and the tip of the tDLH in juxtamedullary nephrons secrete urea. In superficial nephrons, the entire tDLH may secrete urea. The red box indicates the fraction of the filtered load jointly *secreted* by both nephron types. The green boxes indicate the fraction of the filtered load that remains in the lumen at various sites. The values in the boxes are approximations. PCT, proximal convoluted tubule; PST, proximal straight tubule.

In the very early **proximal tubule** (see [Fig. 36-1B](#)), [urea] in the lumen is the same as in blood plasma. However, water reabsorption tends to increase [urea] in the lumen, thereby generating a favorable transepithelial gradient that drives urea reabsorption by **diffusion** via the transcellular or paracellular pathway. In addition, some urea may be reabsorbed by **solvent drag** (see [p. 467](#)) across the tight junctions. The greater the fluid reabsorption along the proximal tubule, the greater the reabsorption of urea via both diffusion and solvent drag.

In more distal urea-permeable nephron segments, urea moves via facilitated diffusion through the **urea transporters (UTs)**.  **N36-1** The *SLC14A2* gene encodes not only UT-A2 but also the splice variants UT-A1 and UT-A3. The prototypical member of the UT family, UT-A2, is a glycosylated 55-kDa integral membrane protein with 10 putative membrane-spanning segments (TMs). UT-A3 also has 10 TMs. The bacterial homolog has three monomers, each of which contains a urea pore, with the pores arranged as a triangle. UT-A1 is a 97-kDa protein with 20 TMs. UT-A1 is basically UT-A3 linked—via an intracellular loop—to UT-A2.

N36-1

Urea Transporters

Contributed by Walter Boron

The UTs belong to the SLC14 family of transporters. The family has two gene members, *SLC14A1* and *SLC14A2*. Both mediate **facilitated diffusion**. That is, the movement of urea is not coupled to that of another solute, but nevertheless exhibits saturation and other hallmarks of carrier-mediated transport.

***SLC14A1*:** This gene has at least two variants: UT-B1 (also known as UT3) and UT-B2 (also known as UT11). These are expressed in the descending vasa recta and red blood cells.

***SLC14A2*:** This gene has at least eight variants: UT-A1 (UT1), UT-A1b, UT-A2 (UT2), UT-A2b, UT-A3 (UT4), UT-A3b, UT-A4, and UT-A5. These are expressed predominantly in the kidney but also in other organs.

The putative fundamental topology of a UT protein is 5 membrane-spanning segments (TMs), a large extracellular loop, and an additional 5 TMs (for a total of 10 TMs). Somewhat paradoxically, the UT-A1 variant of *SLC14A2*—the first UT discovered—is a concatamer or two such units, linked by a long intracellular loop; it therefore has a total of 20 putative TMs.

In *juxtamedullary* nephrons, as the tubule fluid in the **thin descending limb (tDLH)** approaches the tip of the loop of Henle, [urea] is higher in the medullary interstitium than in the lumen (see [pp. 811–813](#)). Thus, the deepest portion of the tDLH *secretes* urea via facilitated diffusion (see [Fig. 36-1C](#)) mediated by the urea transporter **UT-A2**. As the fluid turns the corner to flow up the **thin ascending limb (tALH)**, the tubule cells continue to secrete urea into the lumen, probably also by facilitated diffusion (see [Fig. 36-1D](#)).

The tDLH of *superficial* nephrons is located in the inner stripe of the outer medulla. Here, the interstitial [urea] is higher than the luminal [urea] because the vasa recta carry urea from the inner medulla. Because the tDLH cells of these superficial nephrons appear to have UT-A2 along their entire length, these cells *secrete* urea. Thus, both superficial and probably also juxtamedullary nephrons contribute to urea secretion, raising urea delivery to ~110% of the filtered load at the level of the cortical collecting ducts.

Finally, the **inner medullary collecting duct (IMCD)** *reabsorbs* urea via a transcellular route involving apical and basolateral steps of facilitated diffusion (see [Fig. 36-1E](#)). The **UT-A1** urea transporter moves urea across the apical membrane of the IMCD cell, whereas **UT-A3** probably mediates urea movement across the basolateral membrane. Arginine vasopressin (AVP)—which is also known as antidiuretic hormone (ADH) and acts through cAMP (see [p. 57](#))—stimulates UT-A1 and UT-A3. We discuss the role of urea transport in the urinary concentrating mechanism beginning on [page 811](#).

UT-B1 and **UT-B2**, each encoded by *SLC14A1*, are present in the descending limb of the vasa recta (see [p. 814](#)).

Urea excretion rises with increasing urinary flow

Because urea transport depends primarily on urea concentration differences across the tubule epithelium, changes in urine flow unavoidably affect renal urea handling ([Fig. 36-2](#)). At low urine flow, when the tubule reabsorbs considerable water and, therefore, much urea, the kidneys excrete only ~15% of filtered urea (see [Fig. 38-5](#)). However, the kidneys may excrete as much as 70% of filtered urea at high urine flow, when the tubules reabsorb relatively less water and urea. During the progression of renal disease, the decline of glomerular filtration rate (GFR) leads to a low urine flow and urea retention, and thus an increase in BUN.

FIGURE 36-2 Urea excretion versus urine flow. P_{Urea} , plasma concentration of urea. (Data from Austin JH, Stillman E, Van Slyke DD: Factors governing the excretion rate of urea. J Biol Chem 46:91–112, 1921.)

In clinical conditions such as *volume depletion*, in which the urine flow declines sharply (see [Box 40-1](#)), urea excretion decreases out of proportion to the fall in GFR. The resulting high BUN can thus serve as laboratory confirmation of volume depletion. The flow dependence of urea clearance contrasts with the behavior of creatinine clearance, which, like inulin clearance (see [p. 740](#)), is largely independent of urine flow. Consequently, in patients with reduced effective circulating volume (see [pp. 554–555](#)), and hence low urine flow, the plasma [BUN]/[creatinine] ratio increases from its normal value of ~ 10 (both concentrations in mg/dL).

Glucose

The proximal tubule reabsorbs glucose via apical, electrogenic Na/glucose cotransport and basolateral facilitated diffusion

The fasting plasma glucose concentration is normally 4 to 5 mM (70 to 100 mg/dL; see [p. 1038](#)) and is regulated by insulin and other hormones. The kidneys freely filter glucose at the glomerulus and then reabsorb it, so that only trace amounts normally appear in the urine ([Fig. 36-3A](#)). The *proximal tubule* reabsorbs nearly all the filtered load of glucose, mostly along the first third of this segment. More distal segments reabsorb almost all of the remainder. In the proximal tubule, luminal [glucose] is initially equal to plasma [glucose]. As the early proximal tubule reabsorbs glucose, luminal [glucose] drops sharply, falling to levels far lower than those in the interstitium. Accordingly, glucose reabsorption occurs against a concentration gradient and must, therefore, be active.

FIGURE 36-3 Glucose handling by the kidney. The yellow box indicates the fraction of the filtered load that the proximal tubule reabsorbs. The green boxes indicate the fraction of the filtered load that remains in the lumen at various sites. The values in the boxes are approximations. PCT, proximal convoluted tubule; PST, proximal straight tubule.

Glucose reabsorption is transcellular; glucose moves from the lumen to the proximal tubule cell via Na/glucose cotransport, and from cytoplasm to blood via facilitated diffusion (see [Fig. 36-3B, C](#)). At the

apical membrane, **Na/glucose cotransporters (SGLT1, SGLT2;** see [pp. 121–122](#)) couple the movements of the electrically neutral D-glucose (but not L-glucose) and Na^+ . Phloridzin, extracted from the root bark of certain fruit trees (e.g., cherry, apple), inhibits the SGLTs. The basolateral Na-K pump maintains intracellular Na^+ concentration ($[\text{Na}^+]_i$) lower than that of the tubule fluid. Moreover, the electrically negative cell interior establishes a steep electrical gradient that favors the flux of Na^+ from lumen to cell. Thus, the electrochemical gradient of Na^+ drives the uphill transport of glucose into the cell (i.e., secondary active transport), thereby concentrating glucose in the cytoplasm.  **N36-2**

N36-2

Using Membrane Vesicles to Study Glucose Transport

Contributed by Gerhard Giebisch, Erich Windhager, Emile Boulpaep, Walter Boron

We describe the membrane-vesicle technique in  **N33-5**. Figure 5-12 illustrates the use of this technique to explore how the Na^+ gradient affects glucose uptake. The vesicles are made from brush-border membrane vesicles (i.e., made from the apical membrane of the proximal tubule). In the absence of Na^+ in the experimental medium, glucose enters renal brush-border membrane vesicles slowly until reaching an equilibrium value (green curve in the central graph of Fig. 5-12). At this point, internal and external glucose concentrations are identical. The slow increase in intravesicular [glucose] occurs by diffusion in the absence of Na^+ . In contrast, adding Na^+ to the external medium establishes a steep inwardly directed Na gradient, which dramatically accelerates glucose uptake (red curve in the central graph of Fig. 5-12). The result is a transient “overshoot” during which glucose accumulates above the equilibrium level. Thus, in the presence of Na^+ , the vesicle clearly transports glucose uphill. Similar gradients of other cations, such as K^+ , have no effect on glucose movement, beyond that expected from diffusion alone.

A negative cell voltage can also drive Na/glucose cotransport, even when there is no Na^+ gradient. In experiments in which the internal and external Na^+ concentrations are the same, making the inside of the vesicles electrically negative accelerates glucose uptake (not shown in Fig. 5-12).

In vesicle experiments performed on vesicles made from the basolateral membrane, the overshoot in intravesicular [glucose] does not occur, even in the presence of an inward Na^+ gradient. Thus, the Na/glucose cotransporter is restricted to the apical membrane.

In the early part of the proximal tubule (S1 segment), a high-capacity, low-affinity transporter called **SGLT2** (SLC5A2) mediates apical glucose uptake (see [Fig. 36-3B](#)). This cotransporter has an Na^+ -to-glucose stoichiometry of 1 : 1 and is responsible for 90% of the glucose reabsorption. Indeed, SGLT2 inhibitors have recently become available to treat patients with hyperglycemia due to diabetes mellitus.  **N36-3** In the later part of the proximal tubule (S3 segment), a high-affinity, low-capacity cotransporter called **SGLT1** (SLC5A1) is responsible for apical glucose uptake (see [Fig. 36-3C](#)). Because this cotransporter has an Na^+ -to-glucose stoichiometry of 2 : 1 (i.e., far more electrochemical energy per glucose molecule), it can generate a far larger glucose gradient across the apical membrane (see [Equation 5-20](#)). Paracellular glucose permeability progressively diminishes along the proximal tubule, which further contributes to the tubule's ability to maintain high transepithelial glucose gradients and to generate near-zero glucose concentrations in the fluid emerging from the proximal tubule.

Clinical Use of SGLT2 Inhibitors

Contributed by Emile Boulpaep

SGLT2 inhibitors are novel “glucuretics” that have been approved for the treatment of type 2 diabetes. The low-affinity, high-capacity cotransporter SGLT2 reabsorbs the bulk of the filtered glucose in the S1/S2 segments of the proximal convoluted tubule, whereas the low-affinity, high-capacity cotransporter SGLT1 in the S3 segment reabsorbs the remainder. Thus, specific SGLT2 inhibition causes the bulk of filtered glucose to be excreted in the urine, whereas about 10% of filtered glucose is still reabsorbed by SGLT1, so that $[\text{glucose}]_{\text{plasma}}$ is prevented from falling below normal. However, in clinical practice, SGLT2 inhibitors inhibit only 30% to 50% of renal glucose reabsorption.

Phlorizin, the 2'-glucoside of phloretin, is a natural compound in the bark of fruit trees and a competitive inhibitor of both SGLT1 and SGLT2. Before the discovery of insulin, phlorizin was used in the treatment of diabetes, although the compound is poorly absorbed by gastrointestinal tract and not stable. The U.S. Food and Drug Administration approved two specific SGLT2 inhibitors for oral use in the treatment of type 2 diabetes in adults: canagliflozin and dapagliflozin (Farxiga). Urinary tract infections and genital fungal infections are common adverse effects of this treatment due to chronically high glucose concentration in the urine.

Reference

Abdul-Ghani MA, DeFronzo RA. Lowering plasma glucose concentration by inhibiting renal sodium-glucose co-transport. *J Intern Med.* 2014;276(4):352–363.

Once inside the cell, glucose exits across the basolateral membrane via a member of the **GLUT** (SLC2) family of glucose transporters (see [p. 114](#)). These transporters—quite distinct from the SGLTs—are Na^+ -*independent* and move glucose by facilitated diffusion. Like the apical SGLTs, the basolateral GLUTs differ in early and late proximal-tubule segments, with GLUT2 in the early proximal tubule (see [Fig. 36-3B](#)) and GLUT1 in the late proximal tubule (see [Fig. 36-3C](#)). In contrast to the apical SGLTs, the basolateral GLUTs have a much lower sensitivity to phloridzin.

Glucose excretion in the urine occurs only when the plasma concentration exceeds a threshold

The relationship between plasma $[\text{glucose}]$ and the rate of glucose reabsorption is the **glucose titration curve**. [Figure 36-4A](#) shows how rates of glucose filtration (orange curve), excretion (green curve), and reabsorption (red curve) vary when plasma $[\text{glucose}]$ is increased by infusing intravenous glucose. As plasma $[\text{glucose}]$ rises—at constant GFR—from control levels to ~ 200 mg/dL, glucose excretion remains zero. It is only above a **threshold** of ~ 200 mg/dL (~ 11 mM) that glucose appears in the urine. Glucose excretion rises linearly as plasma $[\text{glucose}]$ increases further. Because the threshold is considerably higher than the normal plasma $[\text{glucose}]$ of ~ 100 mg/dL (~ 5.5 mM), and because the body effectively regulates plasma $[\text{glucose}]$ (see [p. 1038](#)), healthy people do not excrete any glucose in the urine, even after a meal. Likewise, patients with *diabetes mellitus*, who have chronically elevated plasma glucose

concentrations, do not experience glucosuria until the blood sugar level exceeds this threshold value.

A GLUCOSE TITRATION CURVE

B GLUCOSE CLEARANCE

FIGURE 36-4 Effect of increasing plasma glucose concentrations on glucose excretion and clearance. In **A**, T_m is the transport maximum for reabsorption. In **A** and **B**, the darker vertical bands represent the physiological range of plasma [glucose], which spans from a fasting [glucose] to the peak value after a meal.

The glucose titration curve shows a second property, **saturation**. The rate of glucose reabsorption reaches a plateau—the **transport maximum (T_m)**—at ~ 400 mg/min. The reason for the T_m value is that the SGLTs now become fully saturated. Therefore, these transporters cannot respond to further increases in filtered glucose.

Figure 36-4A also shows that the rate of glucose reabsorption reaches the T_m gradually, not abruptly. This **splay** in the titration curve probably reflects both anatomical and kinetic differences among nephrons. Therefore, a particular nephron's filtered load of glucose may be mismatched to its capacity to reabsorb glucose. For example, a nephron with a larger glomerulus has a larger load of glucose to reabsorb. Different nephrons may have different distributions and densities of SGLT2 and SGLT1 along the proximal tubule. Accordingly, saturation in different nephrons may occur at different plasma levels.  **N36-4**

N36-4

Clinical Correlates of Splay in the Glucose Titration Curve

Contributed by Erich Windhager, Gerhard Giebisch

Splay can be clinically important. Patients with proximal-tubule disease—mainly of hereditary nature and often observed in children—have a lower threshold, but a normal T_m . Thus, splay is exaggerated, presumably because some individual cotransporters have a low glucose affinity but normal maximal transport rate (see Equation 5-16). This abnormality results in glucose excretion at a lower-than-normal plasma [glucose]. Other patients have a normal threshold but a significantly reduced T_m (**primary renal glucosuria**). These patients, including those with Fanconi syndrome, have a reduced number of Na/glucose cotransporters. Thus, once plasma [glucose] exceeds the threshold, these patients excrete more glucose than normal. In addition, destruction of renal parenchyma by disease processes may diminish the activity of the basolateral Na-K pump and thus reduce the driving force for Na^+ across the brush-border membrane, resulting in glucosuria.

At low filtered glucose loads, when no glucose appears in the urine (see Fig. 36-4A), the *clearance* (see p. 731) of glucose is zero. As the filtered load increases beyond the threshold, and glucose excretion increases linearly with plasma [glucose], the clearance of glucose progressively increases. At extremely high glucose loads, when the amount of glucose reabsorbed becomes small compared with the filtered load, glucose behaves more like inulin (i.e., it remains in the tubule lumen). Thus, if we replot the glucose-excretion data in Figure 36-4A as *clearance* (i.e., excretion divided by plasma [glucose]), we see that, as the filtered glucose load rises, glucose clearance  **N36-5** (see Fig. 36-4B, red curve) approaches inulin clearance (orange curve).

N36-5

Glucose Clearance

As stated in the text, the glucose clearance is zero at plasma glucose values below the threshold and gradually rises as plasma glucose level rises. We can express the excretion of glucose quantitatively at plasma concentrations beyond the threshold, where the glucose reabsorption rate (T_m) has reached its maximum:

$$\underbrace{\overbrace{U_G}^{\text{Rate of glucose excretion}} \cdot \underbrace{\dot{V}}_{\text{Urine flow}}}_{\text{Urine [glucose]}} = \underbrace{\left(\overbrace{\text{GFR} \cdot P_G}^{\text{Rate of glucose filtration}} \right)}_{\text{Plasma [glucose]}} - \underbrace{\overbrace{T_G}_{\text{Maximal glucose reabsorption rate}}}_{\text{Rate of glucose reabsorption}}$$

(NE 36-1)

All three terms in the above equation are plotted in Figure 36-4A. The first term in the equation ($U_G \times \dot{V}$) is represented by the green curve. The second term ($\text{GFR} \times P_G$) is the yellow curve. The term (T_G) is the red curve. Dividing both sides of the equation by P_G yields the glucose clearance (C_G):

$$C_G = \frac{U_G \cdot \dot{V}}{P_G} = \text{GFR} - \frac{T_G}{P_G}$$

(NE 36-2)

Thus, as plasma [glucose] approaches infinity, the right-hand term reduces to GFR, and therefore glucose clearance approaches inulin clearance (see Fig. 36-4B). In patients with an extremely low threshold,  N36-4 glucose clearance even more closely approximates GFR.

The four key characteristics of glucose transport—(1) threshold, (2) saturation (T_m), (3) splay, and (4) clearance approaching GFR at infinite plasma concentrations—apply to several other solutes as well, including amino acids, organic-anion metabolites (e.g., lactate, citrate, and α -ketoglutarate [α -KG]), PAH, and phosphate.

Other Organic Solutes

The proximal tubule reabsorbs amino acids using a wide variety of apical and basolateral transporters

The total concentration of amino acids in the blood is ~2.4 mM. These L-amino acids are largely those absorbed by the gastrointestinal tract (see [p. 923](#)), although they also may be the products of protein catabolism or of the *de novo* synthesis of nonessential amino acids.

The glomeruli freely filter amino acids ([Fig. 36-5A](#)). Because amino acids are important nutrients, it is advantageous to retrieve them from the filtrate. The proximal tubule reabsorbs >98% of these amino acids via a transcellular route, using a wide variety of amino-acid transporters, some of which have overlapping substrate specificity ([Table 36-1](#)). At the *apical* membrane, amino acids enter the cell via Na⁺-driven or H⁺-driven transporters as well as amino-acid exchangers (see [Fig. 36-5B](#)). At the *basolateral* membrane, amino acids exit the cell via amino-acid exchangers—some of which are Na⁺ dependent—and also by facilitated diffusion (see [p. 114](#)). Particularly in the late proximal tubule and “postproximal” nephron segments, where the availability of luminal amino acids is low, SLC38A3 mediates the Na⁺-dependent uptake of amino acids across the *basolateral* membrane. This process is important for cellular nutrition or for metabolism. For example, in proximal-tubule cells SLC38A3 takes up glutamine—the precursor for NH₄⁺ synthesis and gluconeogenesis (see [pp. 829–831](#) and [Fig. 39-5A](#)).

FIGURE 36-5 Amino-acid handling by the kidney. In **A**, the yellow box indicates the fraction of the filtered load that the proximal tubule reabsorbs. The green boxes indicate the fraction of the filtered load that remains in the lumen at various sites. The values in the boxes are approximations. For **B**, the alternate protein names for the SLC designations of the amino-acid transporters are in the second column of [Table 36-1](#). AA, amino acid; PCT, proximal convoluted tubule; PST, proximal straight tubule.

TABLE 36-1
Amino-Acid Transporters*

A. Apical Uptake				
GENE NAME	PROTEIN NAMES	LUMINAL SUBSTRATES	OTHER TRANSPORTED SPECIES	LOCATION
	(System X _{AG} ⁻)			
<i>SLC1A1</i>	EAAT3, EAAC1	Anionic (or acidic) amino acids (Glu and Asp)	Cotransports 2 Na ⁺ and 1 H ⁺ inward, exchanges 1 K ⁺ outward (Electrogenic uptake of net + charge)	Kidney, small intestine, brain
Heterodimer: <i>SLC7A9</i> <i>SLC3A1</i>	(System b ⁰) b ⁰ ,+AT rBAT	Cationic (i.e., basic) amino acids (Lys ⁺ or Arg ⁺) or Cys (Cys-S-S-Cys)	Exchanges for neutral amino acid (Electrogenic uptake of + charge when substrate is Lys ⁺ or Arg ⁺)	Kidney—cystinuria
	(System B ⁰)	Neutral and cationic amino acids	Cotransports 2 Na ⁺ and 1 Cl ⁻	Small intestine
<i>SLC6A14</i>	ATB ⁰			
	(System Gly)			
<i>SLC6A18</i>	XT2	Gly	Cotransports with Na ⁺ and Cl ⁻	Kidney
	(System B ⁰)	Neutral amino acids (not Pro), including aromatic amino acids (Phe, Trp, Tyr)	Cotransports with Na ⁺ (No Cl ⁻)	
<i>SLC6A19</i>	B ⁰ AT1			Kidney—Hartnup disease
<i>SLC6A15</i>	B ⁰ AT2			Kidney, brain
	(System IMINO)			
<i>SLC6A20</i>	SIT, XT3	Pro, imino acids	Cotransports 2 Na ⁺ and 1 Cl ⁻	Kidney, small intestine, brain
<i>SLC36A1</i>	PAT1,	Pro, Ala, Gly, GABA	Cotransports with H ⁺	Small intestine, colon, kidney,

	LYAAT 1			brain
SLC36A2	PAT2	Pro, Gly, Ala, hydroxyproline	Cotransports with H ⁺	Kidney, heart, lung
B. Basolateral Exit				
GENE NAME	PROTEIN NAMES	CYTOSOLIC SUBSTRATES	OTHER TRANSPORTED SPECIES	LOCATION
	(System GLY)	Gly (also <i>N</i> -methylglycine, i.e., sarcosine)	Cotransports Na ⁺ and Cl ⁻	Small intestine
SLC6A5 SLC6A9	GLYT2 GLYT1			
SLC7A1	(System y ⁺) CAT-1	Cationic (i.e., basic) amino acids	None (facilitated diffusion)	Ubiquitous (not liver), basolateral in epithelia
Heterodimer:	(System y ⁺ L)			
SLC7A6 SLC3A2	y ⁺ LAT2 4F2hc	Cationic (i.e., basic) amino acids (Arg ⁺ , Lys ⁺ , ornithine ⁺)	Exchanges for extracellular neutral amino acid plus Na ⁺	Kidney, small intestine
Heterodimer:	(System y ⁺ L)			
SLC7A7 SLC3A2	y ⁺ LAT1 4F2hc	Cationic (i.e., basic) amino acids (Arg ⁺ , Lys ⁺ , ornithine ⁺)	Exchanges for extracellular neutral amino acid plus Na ⁺	Kidney, small intestine
Heterodimer:	(System L) LAT2 4F2hc	Neutral amino acids	Exchanges for neutral extracellular amino acid	Kidney
SLC16A10	TAT1 (MCT10)	Aromatic amino acids (Phe, Trp, Tyr)	None (facilitated diffusion)	Kidney
	(System A)	Gln, Ala, Asn, Cys, His, Ser	Cotransports Na ⁺	Small intestine
SLC38A1, 2, 4	SNAT1, 2, 4			
C. Basolateral Nutritional Uptake				
GENE NAME	PROTEIN NAMES	BASOLATERAL SUBSTRATES	OTHER TRANSPORTED SPECIES	LOCATION
	(System N)			Kidney
SLC38A3	SNAT3	Gln, Asn, His	Cotransports Na ⁺ inward, exchanges H ⁺ outward	
	(System ASC)		Exchanges for extracellular neutral amino acids; Na ⁺ dependent	Kidney, small intestine
SLC1A4 SLC1A5	ASCT1 ASCT2	Ala, Ser, Cys, Thr		
D. Uptake by Other Tissues				
GENE NAME	PROTEIN NAMES	EXTRACELLULAR SUBSTRATES	OTHER TRANSPORTED SPECIES	LOCATION
SLC1A2	EAAT2, GLT-1	Anionic (or acidic) amino acids (Glu and Asp)	Cotransports 2 Na ⁺ and 1 H ⁺ inward, exchanges 1 K ⁺ outward (Electrogenic uptake of net + charge)	Brain (astrocytes), liver
SLC1A3	EAAT1, GLAST			Brain (astrocytes), heart, skeletal muscle
SLC1A6	EAAT4			Brain (cerebellum)
SLC1A7	EAAT5			Retina
SLC6A1 SLC6A11	GAT1 GAT3	GABA (also betaine, β-alanine, taurine)	Cotransports Na ⁺ and Cl ⁻	Brain (GABAergic neurons)
SLC6A12	BGT1			Brain (GABAergic neurons), kidney
SLC6A13	GAT2			Kidney, brain
				Brain (choroid plexus), retina, liver, kidney

*The “System” designation is a historical classification based on functional characteristics in intact epithelia, intact cells, or membrane vesicles.

GABA, gamma-aminobutyric acid.

For an amino acid to cross the proximal-tubule epithelium, it must move through both an apical and a basolateral transporter (see [Table 36-1](#)). For example, **glutamate** enters the cell across the apical membrane via SLC1A1. This transporter simultaneously takes up Na⁺ and H⁺ in exchange for K⁺ (see [Fig. 36-5B](#)). Inside the cell, glutamate can be metabolized to α-KG in the synthesis of NH₄⁺ and gluconeogenesis, or it can exit across the basolateral membrane, perhaps by SLC1A4 or SLC1A5. The positively charged **lysine** and **arginine** cross the apical membrane in exchange for neutral amino acids, with their movement mediated by the heterodimeric transporter SLC7A9/SLC3A1. This process is driven by the cell-negative voltage and by relatively high intracellular concentrations of the neutral amino acids. Lysine and arginine exit across the basolateral membrane via the electroneutral, heterodimeric transporter SLC7A7/SLC3A2, which simultaneously takes up Na⁺ and a neutral amino acid. **Neutral amino acids** other than proline can cross the apical membrane via SLC6A19, driven by Na⁺, and exit across the basolateral membrane via the heterodimeric SLC7A8/SLC3A2, which exchanges neutral amino acids.

Neutral aromatic amino acids such as tyrosine can exit by facilitated diffusion, mediated by SLC16A10. **Proline** enters across the apical membrane together with H⁺ via SLC36A1 and exits across the basolateral membrane via the neutral amino-acid exchanger SLC7A8/SLC3A2.

Because the same carrier can reabsorb structurally similar amino acids, *competitive inhibition* may occur in the presence of two related amino acids. This effect may explain why the tubules do not fully reabsorb some amino acids (e.g., glycine, histidine, and some nonproteogenic amino acids, such as L-methylhistidine and taurine), even though the transporter itself is normal. Competition can also occur in patients with hyperargininemia (Table 36-2 and Box 36-1).

TABLE 36-2
Patterns of Hyperaminoacidurias

	DISEASE	AMINO ACIDS	MECHANISM
A. Prerenal hyperaminoaciduria (“overflow”)	Hyperargininemia	Arg	Elevated plasma concentration and thus elevated filtered load overwhelms T _m .
B. Competition	Side effect of hyperargininemia	Lys Ornithine	High filtered load of one amino acid (e.g., Arg) inhibits the reabsorption of another, both carried by SLC7A9 (b ⁰ +AT)/SLC3A1 (rBAT)
C. Renal aminoaciduria	Anionic aminoaciduria	Glu Asp	Defective SLC1A1 (EAAT3); autosomal recessive disease
	Hartnup disease (neutral aminoaciduria)	Neutral and ring-structure amino acids (e.g., phenylalanine)	Defective SLC6A19 (B ⁰ AT1); autosomal recessive disease
	Cystinuria (cationic aminoaciduria)	Cystine (Cys-S-S-Cys) and cationic amino acids	Defective SLC7A9 (b ⁰ +AT) or SLC3A1 (rBAT); autosomal recessive disease
	Lysinuric protein intolerance (cationic aminoaciduria)	Lys Arg	Defective SLC7A7 (y ⁺ LAT1) or SLC3A2 (4F2hc); autosomal recessive disease
D. Generalized proximal-tubule dysfunction	Fanconi syndrome	All amino acids	Metabolic, immune or toxic conditions (inherited or acquired) that impair function of proximal-tubule cell

Box 36-1
Hyperaminoacidurias

In general, an increase in the renal excretion of an amino acid (**hyperaminoaciduria**) may occur when the plasma concentration increases owing to any of several metabolic derangements or when the carrier-mediated reabsorption of the amino acid decreases abnormally.

Prerenal Hyperaminoacidurias (i.e., the Defect Is Before the Kidney)

Hyperargininemia (see Table 36-2, section A), an inherited condition in which a metabolic defect leads to an increase in plasma arginine (Arg) levels that, in turn, increases the filtered load of Arg. Although the reabsorption of Arg increases, the filtered load exceeds the T_m, and the renal excretion increases.

Competition

Because the same transporter (the heterodimeric SLC7A9/SLC3A1 in Table 36-1) that carries Arg across the apical membrane also transports lysine (Lys) and ornithine, competition from Arg decreases the reabsorption of the other two (see Table 36-2, section B). As a result, the urinary excretion of Lys and ornithine also increases. Because the metabolic production of Lys and ornithine does not change, plasma concentrations of these two amino acids, in contrast to that of Arg, usually fall.

Renal Aminoacidurias

The renal aminoacidurias result from an autosomal recessive defect in an amino-acid transporter (see Table 36-2, section C) and thus also affects absorption in the gastrointestinal tract (see Box 45-3). In

Hartnup disease, the defective apical transporter (SLC6A19) normally handles neutral amino acids (e.g., alanine, serine), including those with rings (i.e., phenylalanine, tryptophan, tyrosine). In **cystinuria**, the affected apical transporter is the heterodimeric SLC7A9/SLC3A1 that carries cystine (Cys-S-S-Cys) and cationic amino acids (i.e., Arg, Lys, ornithine). An increased filtered load of one of these amino acids leads to increased excretion of all of them. Nephrolithiasis (i.e., kidney stones) may be a consequence of the increased excretion of the poorly soluble cystine.

Probably the most severe renal hyperaminoaciduria is **lysineric protein intolerance (LPI)**, resulting from the reduced reabsorption of Lys and Arg. The resulting low blood [Arg] impairs the urea cycle and detoxification of ammonium (hyperammonemia). Other features include alveolar proteinosis (the leading cause of death), hepatosplenomegaly, and—in severe cases—mental deterioration. The defective proximal-tubule basolateral transporter (the heterodimeric SLC7A7/SLC3A2) normally mediates the efflux of Arg and Lys into blood in exchange for the uptake of Na^+ and neutral amino acids.

Generalized Proximal-Tubule Dysfunction

Fanconi syndrome (see Table 36-2, section D), which can be inherited or acquired, is characterized by a generalized loss of proximal-tubule function. As a result, several solutes—in addition to amino acids—inappropriately appear in the urine: low-molecular-weight filtered proteins, glucose, HCO_3^- , and phosphate.

Apparent competition between transported solutes occurs when they compete for the same energy source. Because the apical uptake of many organic and some inorganic solutes (e.g., phosphate, sulfate) depends on the electrochemical Na^+ gradient, increasing the activity of one such transporter can slow others. For example, glucose uptake via electrogenic $\text{Na}/\text{glucose}$ cotransport may compromise the reabsorption of some amino acids for two reasons: (1) raising $[\text{Na}^+]$ diminishes the chemical Na^+ gradient for other Na^+ -driven transporters, and (2) carrying net positive charge into the cell depolarizes the apical membrane and thus decreases the electrical gradient.

With a few exceptions, the kinetics of amino-acid reabsorption resembles that of glucose: the titration curves show saturation and transport maxima (T_m). In contrast to the case of glucose, in which the T_m is relatively high, the T_m values for amino acids are generally low. As a consequence, when plasma levels of amino acids increase, the kidneys excrete the amino acids in the urine, thus limiting the maximal plasma levels.

An H^+ -driven cotransporter takes up oligopeptides across the apical membrane, whereas endocytosis takes up proteins and other large organic molecules

Oligopeptides

The proximal tubules reabsorb ~99% of filtered oligopeptides (Fig. 36-6A). Segments beyond the proximal tubule contribute little to peptide transport.

A HANDLING OF OLIGOPEPTIDES ALONG NEPHRON

B PROXIMAL TUBULE: OLIGOPEPTIDES

FIGURE 36-6 Oligopeptide handling by the kidney. In **A**, the yellow box indicates the fraction of the filtered load that the proximal tubule reabsorbs. The green boxes indicate the fraction of the filtered load that remains in the lumen at various sites. The values in the boxes are approximations. PCT, proximal convoluted tubule; PST, proximal straight tubule.

Several peptidases are present at the outer surface of the brush-border membrane of proximal-tubule cells (see [Fig. 36-6B](#)), just as they are in the small intestine (see [p. 922](#)). These brush-border enzymes (e.g., γ -glutamyltransferase, aminopeptidases, endopeptidases, and dipeptidases) hydrolyze many peptides, including angiotensin II (see [p. 841](#)), thereby releasing into the tubule lumen the free constituent amino acids and oligopeptides. Tubule cells reabsorb the resulting free amino acids as described in the previous section. The cell also absorbs the resulting oligopeptides (two to five residues)—as well as other peptides (e.g., carnosine) that are resistant to brush-border enzymes—using the apical H/oligopeptide cotransporters **PepT1** (SLC15A1) and **PepT2** (SLC15A2; see [p. 123](#)). PepT1 is a low-affinity, high-capacity system in the early proximal tubule, whereas PepT2 is a high-affinity, low-capacity transporter in the late proximal segments—analogue in their properties to SGLT2 and SGLT1 (see [pp. 121–122](#)).

Once inside the cell, the oligopeptides undergo hydrolysis by cytosolic peptidases; this pathway is involved in the degradation of neurotensin and bradykinin. The distinction between which oligopeptides the cells fully digest in the lumen and which they take up via a PepT is not clear-cut. Oligopeptides that are more resistant to hydrolysis by peptidases are probably more likely to enter via a PepT.

Proteins

Although the glomerular filtration barrier (see [p. 726](#)) generally prevents the filtration of large amounts of protein, this restriction is incomplete (see [pp. 741–743](#)). For example, the albumin concentration in the filtrate is very low (4 to 20 mg/L), only 0.01% to 0.05% of the plasma albumin concentration. Nevertheless, given a GFR of 180 L/day, the filtered albumin amounts to 0.7 to 3.6 g/day. In contrast,

albumin excretion in the urine normally is only ~30 mg/day. Thus, the tubules reabsorb some 96% to 99% of filtered albumin (Fig. 36-7A). In addition to albumin, the tubules extensively reabsorb low-molecular-weight proteins that are relatively freely filtered (e.g., lysozyme, light chains of immunoglobulins, and β_2 -microglobulin), SH-containing peptides (e.g., insulin), and other polypeptide hormones (e.g., parathyroid hormone [PTH], atrial natriuretic peptide [ANP], and glucagon). It is therefore not surprising that tubule injury can give rise to proteinuria even in the absence of glomerular injury.

FIGURE 36-7 Protein handling by the kidney. In **A**, the yellow box indicates the fraction of the filtered load that the proximal tubule reabsorbs. The green boxes indicate the fraction of the filtered load that remains in the lumen at various sites. The values in the boxes are approximations.

Proximal-tubule cells use **receptor-mediated endocytosis** (see p. 42) to reabsorb proteins and polypeptides (see Fig. 36-7B). The first step is binding to receptors at the apical membrane (the receptor complex composed of megalin, cubilin, and amnionless), followed by internalization into clathrin-coated endocytic vesicles. Factors that interfere with vesicle formation or internalization, such as metabolic inhibitors and cytochalasin B, inhibit this selective absorption. The vesicles fuse with endosomes; this fusion recycles the vesicle membrane to the apical surface and targets the vesicle content for delivery to lysosomes. At the lysosomes, acid-dependent proteases largely digest the contents over a period that is on the order of minutes for peptide hormones and many hours or even days for other proteins. The cells ultimately release the low-molecular-weight end products of digestion, largely amino acids, across the basolateral membrane into the peritubular circulation. Although the proximal tubule hardly reabsorbs any protein in an intact state, a small subset of proteins avoids the lysosomes and moves by transcytosis for release at the basolateral membrane.

In addition to the apical absorption and degradation pathway, the kidney has two other pathways for protein degradation. The first may be important for several bioactive proteins, particularly those for which receptors are present on the basolateral membrane (e.g., insulin, ANP, AVP, and PTH). After

transcytosis, the proximal-tubule cell partially hydrolyzes peptide hormones at the basolateral cell membrane. The resulting peptide fragments re-enter the circulation, where they are available for glomerular filtration and ultimate handling by the apical absorption/degradation pathway. The second alternative pathway for protein degradation involves receptor-mediated endocytosis by endothelial cells of the renal vascular and glomerular structures. This pathway participates in the catabolism of small peptides, such as ANP.

In conclusion, the kidney plays a major role in the metabolism of small proteins and peptide hormones. Renal extraction rates may be large, and they account for as much as 80% of the total metabolic clearance. Thus, it is not surprising that end-stage renal disease can lead to elevated levels of glucagon, PTH, gastrin, and ANP. Under physiological conditions, glomerular filtration represents the rate-limiting step for the removal of low-molecular-weight proteins from the circulation—apical absorption by the tubules, intracellular hydrolysis, and peritubular hydrolysis do not saturate over a wide range of filtered loads.

Two separate apical Na^+ -driven cotransporters reabsorb monocarboxylates and dicarboxylates/tricarboxylates

The combined concentration of carboxylates in the blood plasma is 1 to 3 mM, of which lactate represents the largest fraction. The monocarboxylates pyruvate and lactate are products of anaerobic glucose metabolism (see pp. 1174–1176). The dicarboxylates and tricarboxylates include intermediates of the **citric acid cycle** (see p. 1185). Because these carboxylates are important for energy metabolism, their loss in the urine would be wasteful. Normally, the proximal tubule reabsorbs virtually all these substances (Fig. 36-8A). Nevertheless, carboxylates may appear in the urine when their plasma levels are elevated. Urinary excretion may occur when the filtered load of acetoacetate and β -hydroxybutyrate—ketone bodies (see p. 1185) produced during starvation or during low-insulin states (diabetes mellitus)—exceeds the T_m in the proximal tubule.

A HANDLING OF CARBOXYLATES ALONG NEPHRON

B PROXIMAL TUBULE

FIGURE 36-8 Monocarboxylate, dicarboxylate, and tricarboxylate handling by the kidney. **N36-18** In A, the yellow box indicates the fraction of the filtered load that the proximal tubule reabsorbs. The green boxes indicate the fraction of the filtered load that remains in the lumen at various sites. The values in the boxes are approximations. OAT1 and OAT3 in the Proximal Tubule

Contributed by Emile Boulpaep, Walter Boron

Note that the transporters labeled “OAT1 or OAT3” in Figures 36-8B and 36-9B are the same. Note that the “Organic anion” entering in Figure 36-8B could be PAH, and that the “Dicarboxylate” (DC²⁻) exiting in Figure 36-9B could be α-KG.

A HANDLING OF PAH ALONG NEPHRON

B LATE PROXIMAL TUBULE (S3)

FIGURE 36-9 PAH handling by the kidney. **N36-18** In **A**, the red box indicates the fraction of the filtered load secreted by the proximal tubule. The green boxes indicate the fraction of the filtered load that remains in the lumen at various sites when plasma [PAH] is low (<12 mg/dL). The values in the boxes are approximations. PCT, proximal convoluted tubule; PST, proximal straight tubule.

Two groups of Na⁺-dependent cotransporters carry carboxylates across the apical membranes (see Fig. 36-8B). First, SLC5A8 and SLC5A12 transport monocarboxylates, including lactate, pyruvate, acetoacetate, and β-hydroxybutyrate. Second, NaDC1 (SLC13A2) carries dicarboxylates and tricarboxylates, such as α-KG, malate, succinate, and citrate.

Once inside the cell, the monocarboxylates exit across the basolateral membrane via the H⁺/monocarboxylate cotransporter MCT2 (SLC16A7). Because monocarboxylates enter across the apical membrane coupled to Na⁺ and then exit across the basolateral membrane coupled to H⁺, monocarboxylate reabsorption leads to an accumulation of Na⁺ by the cell and a rise in intracellular pH.

Dicarboxylates exit the cell across the basolateral membrane via multiple organic anion–carboxylate exchangers; for example, the renal organic anion transporters OAT1 (SLC22A6) and OAT3 (SLC22A8; see p. 125). These exchangers may overlap in substrate specificity, or even carry anions of different valence. Moreover, the molecular identities and stoichiometries of some of these transporters are unknown.

The proximal tubule secretes PAH and a variety of other organic anions

The kidneys handle PAH, as well as many other organic anions (e.g., many metabolites of endogenous

compounds and administered drugs), by both filtration and secretion (Fig. 36-9A). The synthetic monovalent anion PAH (see p. 749) is somewhat unusual in that ~20% of it binds to plasma proteins, largely albumin. Thus, only ~80% of PAH is available for filtration. Assuming a filtration fraction (see p. 746) of 20%, only $80\% \times 20\%$, or 16%, of the arterial load of PAH appears in Bowman's space. Nevertheless, at low plasma [PAH], the kidneys excrete into the urine nearly all (~90%) of the PAH entering the renal arteries, so that very little PAH remains in the renal veins. Because the kidneys almost completely clear it from the blood in a single passage, PAH is useful for measuring renal plasma flow (see pp. 749–750).

The nephron secretes PAH mainly in the late proximal tubule (S3 segment) via the transcellular route, against a sizeable electrochemical gradient. PAH uptake across the *basolateral* membrane occurs via the high-affinity OAT1 (SLC22A6) and the lower-affinity OAT3 (SLC22A8) transporters, driven by the outward gradient of α -KG, **N36-6** which is a dicarboxylate (see Fig. 36-9B). This uptake of PAH is an example of *tertiary active transport* because the basolateral Na/dicarboxylate cotransporter NaDC3 (SLC13A3)—in a process of *secondary active transport*—elevates α -KG levels in the cell, creating the outward α -KG gradient. NaDC3 carries three Na^+ ions and one dicarboxylate into the cell. Finally, the basolateral Na-K pump—in a process of *primary active transport*—establishes the Na^+ gradient used to drive the accumulation of α -KG.

N36-6

Role of OAT1 and OAT3 in the Renal Transport of Organic Anions

Contributed by Emile Boulpaep, Walter Boron

OAT1 and OAT3 transporters are members of the SLC22 family of organic ion transporters (see Table 5-4). The OAT1 and OAT3 proteins shown in Figure 36-8B are in fact the same transporters as shown in Figure 36-9B. The “Organic anion” entering the cell across the basolateral membrane in Figure 36-8B could be any of several monovalent organic anions (including the nonphysiological PAH^-), and the “Dicarboxylate” exiting the cell across the basolateral membrane in Figure 36-9B could be any of several dicarboxylates, including α -KG.

Reference

Koepsell H, Endou H. The SLC22 drug transporter family. *Pflugers Arch.* 2004;447:666–676.

The *apical* step of PAH secretion probably occurs via exchange for luminal anions, electrogenic facilitated diffusion driven by the inside-negative membrane potential (e.g., via OATv1), or an ABC transporter (e.g., MRP4). Several anionic drugs (e.g., probenecid) that compete at the basolateral PAH-anion exchanger or the apical PAH-anion exchanger inhibit PAH secretion from blood to lumen.

The late proximal tubule secretes a wide variety of other organic anions in addition to PAH. These anions include the following (Table 36-3): (1) endogenous anions, such as oxalate and bile salts; (2) exogenous anions such as the drugs penicillin and furosemide; and (3) uncharged molecules *conjugated* to anionic groups such as sulfate or glucuronate (see pp. 955–956). The proximal tubule secretes these anions into the lumen using basolateral and apical anion exchangers that are similar to those involved in

PAH secretion (see [Fig. 36-9B](#)). At the apical membrane, the secreted anion appears to exchange for luminal Cl^- , urate, or OH^- .

PAH secretion is an example of a T_m -limited mechanism

Just as glucose reabsorption saturates at its T_m as one increases plasma [glucose], PAH secretion ([Fig. 36-10A](#), red curve) saturates at a sufficiently high plasma [PAH]. Starting from an initially low value, increasing plasma [PAH] causes excretion (green curve) to rise much faster than filtration (orange curve). Subtracting the amount filtered from the amount excreted, we see that the rate of PAH secretion at first rises rapidly with plasma [PAH]. However, as plasma [PAH] approaches ~20 mg/dL, the amount of secreted PAH reaches a plateau (T_m), typically 60 to 80 mg/min, indicating saturation of secretory mechanisms.

A PAH TITRATION CURVE

B PAH CLEARANCE

FIGURE 36-10 Effect of increasing plasma PAH concentrations on PAH excretion and clearance. In **A**, T_m is the transport maximum for reabsorption.

After plasma [PAH] has increased enough to reach the T_m , further increases in plasma [PAH] increase urinary excretion, but only as a consequence of the increase in the filtered load—not because of increased tubule secretion. At these high plasma PAH levels, the kidneys can no longer fully remove PAH from the blood in a single pass through the kidney, and therefore it is no longer appropriate to use PAH secretion to estimate renal plasma flow. At low plasma [PAH] values (<12 mg/dL), PAH extraction from plasma flowing through the kidney is nearly complete (~90%), which forms the basis for using PAH clearance as a measure of renal plasma flow.

Recall that as plasma [glucose] increases, glucose clearance *rises* to approach inulin clearance (see Fig. 36-4B). In contrast, PAH clearance (see Fig. 36-10B, red curve) *decreases* with increasing plasma [PAH] and falls to approach inulin clearance (orange curve). The reason is that, as plasma [PAH] increases, secreted PAH forms a progressively smaller fraction of the PAH appearing in the urine.

The proximal tubule both reabsorbs and secretes urate

Urate, a monovalent anion, is the end product of purine catabolism (Fig. 36-11A). Plasma [urate] is typically 3 to 7 mg/dL (0.2 to 0.4 mM) and is elevated in gout. The glomeruli filter urate, and then the proximal tubule both reabsorbs and secretes urate (see Fig. 36-11B). Reabsorption is the more important transport pathway in the human kidney, which excretes only ~10% of filtered urate under normal conditions.

A URIC ACID AND URATE

B HANDLING OF URATE ALONG NEPHRON

C PROXIMAL TUBULE: URATE TRANSPORT

FIGURE 36-11 Urate handling by the kidney. In **B**, the yellow arrows indicate reabsorption, whereas the red arrow indicates secretion. The green boxes indicate the fraction of the filtered load that remains in the lumen at various sites. The values in the boxes are approximations. In **C**, the upper portion of the cell illustrates transporters used in the reabsorption of urate, whereas the lower portion illustrates transporters used in the secretion of urate. DC²⁻, dicarboxylate; MC⁻, monocarboxylate; PCT, proximal convoluted tubule; PST, proximal straight tubule.

Reabsorption

The proximal tubule reabsorbs urate by both a paracellular route involving passive diffusion and a transcellular route involving active transport (see Fig. 36-11C, top portion). The contribution of the paracellular pathway can become apparent during extracellular volume depletion, which can lead to a compensatory enhancement of proximal-tubule fluid reabsorption. The resulting increase in luminal [urate] can then enhance paracellular urate reabsorption, thereby decreasing net urate excretion and raising plasma [urate].

The transcellular route involves an active apical uptake step, mediated by three different transporters. URAT1 (SLC22A12; see [p. 125](#)) exchanges luminal urate for intracellular monocarboxylates, whereas

OAT4 (SLC22A11) and OAT10 (SLC22A13; see [p. 125](#)) both exchange luminal urate for intracellular dicarboxylates.  **N36-7** Once inside the cell, urate exits across the basolateral membrane by facilitated diffusion via the voltage-driven transporter URATv1 (SLC2A9).

N36-7

Tertiary Active Transport of Urate

Contributed by Emile Boulpaep, Walter Boron

The apical uptake of urate in exchange for monocarboxylates (URAT1) or dicarboxylates (OAT4 or OAT10) in Figure 36-11C is an example of **tertiary active transport**.

In the case of **monocarboxylates**, an undefined Na/monocarboxylate cotransporter at the apical membrane mediates the uptake of monocarboxylates—an example of secondary active transport, energized by the inwardly directed Na^+ gradient.

In the case of **dicarboxylates**, NaDC1 at the apical membrane mediates the Na^+ -driven uptake of dicarboxylates—another an example of *secondary* active transport, energized by the inwardly directed Na^+ gradient.

In both cases, the Na-K pump at the basolateral membrane (a primary active transporter) extrudes Na^+ from the cell and thereby establishes the out-to-in Na^+ gradient.

Uricosuric agents such as probenecid, salicylate, and other nonsteroidal anti-inflammatory drugs inhibit URAT1 and thereby increase urate excretion. Indeed, probenecid is useful in the treatment of gout.

Secretion

Proximal-tubule cells are also capable of secreting urate. The basolateral step of urate *secretion* (see [Fig. 36-11C](#), bottom portion) occurs by organic anion exchange via OAT1 and OAT3 (which also mediate basolateral PAH uptake; see [Fig. 36-9B](#)) in exchange for intracellular dicarboxylates such as α -KG. Once inside the cell, urate exits across the apical membrane via two SLCs, NPT1 (SLC17A1) and the voltage-driven NPT4 (SLC17A3), and via two ABC transporters (see [Table 5-6](#)), MRP4 (ABCC4) and BCRP (ABCG2; see [Fig. 46-5D](#)). Under certain conditions, renal urate excretion can exceed the quantity filtered, which indicates net secretion.

The late proximal tubule secretes several organic cations

The late proximal tubule ([Fig. 36-12A](#)) is also responsible for secreting a wide range of both endogenous and exogenous organic *cations* (see [Table 36-3](#)). Some of the most important secreted endogenous organic cations are the monoamine neurotransmitters (e.g., dopamine, epinephrine, norepinephrine, and histamine; see [p. 315](#)) and creatinine, the breakdown product of phosphocreatine. Despite this modest secretion, creatinine is a useful index of GFR (see [p. 741](#)). Exogenous secreted organic cations include morphine, quinine, and the diuretic amiloride (see [pp. 758–759](#)).

A HANDLING OF ORGANIC CATIONS ALONG NEPHRON

B LATE PROXIMAL TUBULE (S3)

FIGURE 36-12 Organic cation handling by the kidney. In **A**, the red arrow indicates secretion. The green boxes indicate the fraction of the filtered load that remains in the lumen at various sites. The values in the boxes are approximations. OC, organic cation; PCT, proximal convoluted tubule.

At the *basolateral* membrane, the polyspecific organic cation transporter OCT2 (SLC22A2; see [p. 115](#)) mediates the uptake of these organic cations (see [Fig. 36-12B](#)) via facilitated diffusion. The driving force for this electrogenic process is the inside-negative membrane potential of the cell.

At the *apical* membrane, the organic cation–H exchangers **MATE1** (SLC47A1) and MATE2-K (SLC47A2) as well as the ABC transporter MDR1 (ABCB1; see [Table 5-6](#)) move these cations from the cell to the lumen (see [Fig. 36-12B](#)). The energy for the extrusion of the organic cations via the MATEs is the H⁺ electrochemical gradient across the apical membrane from lumen to cell. Because the apical Na-H exchanger (a *secondary* active transporter) is largely responsible for establishing this H⁺ gradient, the cation-H exchange is an example of *tertiary* active transport.

Nonionic diffusion of neutral weak acids and bases across tubules explains why their excretion is pH dependent

Many cations or anions are, in fact, weak acids or bases in equilibrium with a neutral species (see [pp. 628–629](#)), which generally diffuses across a membrane much faster than the corresponding cation or

anion. This rapid diffusion usually occurs because the neutral species is far more soluble in the lipid bilayer of cell membranes than is the charged species. **N36-8**

N36-8

Mechanism of Nonionic Diffusion

Contributed by Walter Boron

Nonionic diffusion refers to the passive flux across a membrane of the uncharged (i.e., neutral or “not ionic”) form of a buffer pair. Thus, for the HA/A⁻ buffer pair ($\text{HA} \rightleftharpoons \text{H}^+ + \text{A}^-$), HA is the nonionic component. For the BH⁺ or BH⁺/B buffer pair ($\text{BH}^+ \rightleftharpoons \text{B} + \text{H}^+$), B is the nonionic component. For buffer pairs in which *both* members are charged (e.g., $\text{H}_2\text{PO}_4^- \rightleftharpoons \text{H}^+ + \text{HPO}_4^{2-}$) then by definition neither of the members of the buffer pair can participate in nonionic diffusion.

In nonionic diffusion, the energy driving the net flux of HA or B across the membrane is the chemical or concentration gradient according to **Fick's law** (see p. 108):

$$J_{\text{HA}} = P_{\text{HA}} ([\text{HA}]_{\text{o}} - [\text{HA}]_{\text{i}}) \quad (\text{NE 36-3})$$

Here, the flux J_{HA} is positive when $[\text{HA}]_{\text{o}} > [\text{HA}]_{\text{i}}$ (i.e., the extracellular concentration exceeds the intracellular concentration) and HA diffuses passively into the cell. P_{HA} is the permeability of the cell membrane to HA. In the case of a neutral weak base, the flux would be

$$J_{\text{B}} = P_{\text{B}} ([\text{B}]_{\text{o}} - [\text{B}]_{\text{i}}) \quad (\text{NE 36-4})$$

Notice that we have not said anything about the *mechanism* by which HA or B moves across the cell membrane. Traditionally, people had thought that neutral species (e.g., acetic or lactic acids, CO₂, NH₃) would simply dissolve in the lipid phase of a biological membrane according to the oil/water partition coefficient of the species in question. This simple mechanism may account for a part of the membrane permeability to these neutral substances, but certainly not all, and in some carefully studied cases, very little. Many small neutral species cross biological membranes via transporters or channels. Examples of **transporters** that can carry lactic acid across the plasma membrane are the **MCT monocarboxylic acid transporters** (SLC16 family; see Table 5-4). Other membrane proteins can serve as channels for dissolved gases. The first example of such a **channel** was **aquaporin 1 (AQP1)**, which serves as a conduit for CO₂ and also NH₃. The **rhesus (Rh) protein** family also are channels for CO₂ and NH₃. Although the movement of the solute in question may occur via a transporter or a channel, the thermodynamic driving force is still the chemical gradient (i.e., the movement is still passive) and fits the description of nonionic diffusion.

Changing the luminal pH can substantially affect the overall transport of a buffer pair. For example, acidifying the tubule lumen promotes the reabsorption of a neutral weak acid and the secretion of a neutral weak base. In the case of a neutral weak acid such as salicylic acid ([Fig. 36-13A](#)), the glomerular filtrate contains both the neutral weak acid (HA) and its conjugate weak base, which is an anion (A^-). The secretion of H^+ into the lumen (see [pp. 827–828](#)) titrates the A^- to HA, thus raising luminal [HA] above intracellular [HA], so that HA rapidly diffuses across the apical membrane—by the process of **nonionic diffusion**—into the tubule cell and across the basolateral membrane into the blood. The more acidic the luminal fluid, the greater is the titration of A^- to HA, and the greater the nonionic diffusion of HA from lumen to blood.

A NONIONIC DIFFUSION OF NEUTRAL WEAK ACID

B NONIONIC DIFFUSION OF NEUTRAL WEAK BASE

C CLEARANCE OF NEUTRAL WEAK ACID AND CONJUGATE BASE

D CLEARANCE OF NEUTRAL WEAK BASE AND CONJUGATE ACID

FIGURE 36-13 Nonionic diffusion.

In the case of a weak base such as chloroquine (see [Fig. 36-13B](#)), the tubule filtrate contains both the neutral weak base (B) and the cationic species (BH^+). The permeant neutral weak base B is subject to reabsorption down its concentration gradient by nonionic diffusion. The more alkaline the luminal fluid, the greater the titration of BH^+ to B, the greater the nonionic diffusion of B from lumen to blood (i.e., reabsorption), which leaves less organic cation behind in the lumen for excretion. Thus, even though the proximal tubule may secrete the cation BH^+ , the final urinary excretion of the organic cation will be very dependent on urinary pH, with far less excretion at alkaline urinary pH and much more excretion at acidic urinary pH, as shown in [Figure 36-13D](#).

A striking example of how luminal pH affects the clearance of a weak acid is the renal handling of salicylic acid and its anion species, salicylate. At a urinary pH of ~ 7.5 , the amount of total salicylate (salicylic acid + salicylate anion) excreted is the same as the filtered load (see Fig. 36-13C); that is, the clearance of total salicylate ($C_{\text{Salicylate}}$) equals GFR. Lower urinary pH values favor the titration of luminal salicylate anion to salicylic acid, which the tubule readily reabsorbs. Hence, lowering pH causes the fractional excretion of total salicylate ($FE_{\text{Salicylate}} = C_{\text{Salicylate}}/\text{GFR}$; see p. 733) to fall to less than unity. At very low urinary pH values, the kidney reabsorbs virtually all salicylate, and $FE_{\text{Salicylate}}$ approaches zero. However, at urinary pH values higher than ~ 7.5 , $FE_{\text{Salicylate}}$ increases markedly because the alkalinity keeps luminal levels of the salicylate anion high and levels of salicylic acid low, so that the neutral weak acid now diffuses from blood to lumen.

It is possible to treat overdoses of salicylate or acetylsalicylate (i.e., aspirin) by alkalinizing the urine with HCO_3^- or by increasing urine flow with diuretics. **N36-9** The reason is that both high pH and high urine flow keep luminal levels of salicylic acid low, which maintains a sink for salicylic acid in the lumen. Both treatments enhance the urinary excretion of the drug and lower plasma concentrations.

N36-9

Treatment of Salicylate Poisoning

Contributed by Erich Windhager, Gerhard Giebisch

As noted in the text on page 785, physicians can treat salicylate poisoning by using the principle of nonionic diffusion of a neutral weak acid, outlined in Figure 36-13A. Alkalinizing the tubule lumen increases the trapping of the salicylate anion in the urine. The most common cause of salicylate poisoning is the accidental or suicidal overdose of aspirin. Signs of the poisoning include a severe metabolic acidosis and a compensatory respiratory alkalosis. The twofold purpose of the treatment is to neutralize the metabolic acidosis and to eliminate the salicylate. The treatment is to administer NaHCO_3 intravenously to alkalinize the urine above a pH of 7.5, while making sure that the plasma pH does not exceed 7.55.

The converse example of urinary pH dependence is seen in the excretion of a neutral weak base, such as chloroquine (see Fig. 36-13D). **N36-10**

N36-10

Treatment of a PCP Overdose

Contributed by Erich Windhager, Gerhard Giebisch

Phencyclidine hydrochloride—whose formal name is phenylcyclohexyl piperidine HCl (PCP) and whose street names include “angel dust”—can be thought of as the salt BH^+Cl^- . When dissolved in water, the BH^+ will equilibrate with the neutral form of the drug (B) as follows: $\text{BH}^+ \rightleftharpoons \text{B} + \text{H}^+$.

It is possible to treat PCP intoxication by using the principle shown in Figure 36-13B; namely, by decreasing the urinary pH and thereby increasing the trapping of the phencyclidine cation (BH^+) in the urine. Although PCP was originally developed as an intravenous anesthetic in the 1950s, its use was discontinued in 1965 because of its side effects, which include hallucinations and confusion. Today, the

most common cause of PCP intoxication is recreational drug use. The therapy has two goals: to promote the rapid urinary excretion of the drug, and to treat the neurological symptoms with antidotes that target the neurotransmitter systems most activated in a particular patient. Regarding the urinary excretion, acidification of the urine can increase the rate of excretion 100-fold. Acidification of the urine can be promoted by administering vitamin C (ascorbic acid) or ammonium chloride. By the effect shown in Figure 36-13D, this maneuver increases the excretion of the drug. In the absence of urinary acidification, the slow clearance of PCP means that screening for substance abuse can produce a positive urine test result as long as 7 days after casual use and 30 days after habitual use.

The same approach can be used to increase the clearance of other weak bases, such as the psychotropic drug remoxipride.

Phosphate

The metabolism of **inorganic phosphate (P_i)** depends on bone, the gastrointestinal tract, and the kidneys (see [p. 1054](#)). About half of total plasma phosphate ([Table 36-4](#)) is in an ionized form, and the rest is either complexed to small solutes (~40%) or bound to protein (10% to 15%). The plasma concentration of total P_i varies rather widely, between 0.8 and 1.5 mM (2.5 to 4.5 mg/dL of elemental phosphorus). Thus, the filterable phosphate (i.e., both the ionized and complexed) varies between ~0.7 and 1.3 mM. At a normal blood pH of 7.4, 80% of the ionized plasma phosphate is HPO_4^{2-} and the rest is $H_2PO_4^-$. Assuming that the total plasma phosphate concentration is 4.2 mg/dL, that only the free and complexed phosphate is filterable, and that the GFR is 180 L/day, each day the kidneys filter ~7000 mg of phosphate. Because this amount is more than an order of magnitude greater than the total extracellular pool of phosphate (see [pp. 1054–1056](#)), it is clear that the kidney must reabsorb most of the phosphate filtered in the glomerulus.

TABLE 36-4
Components of Total Plasma Phosphate

	mg/dL	mM	% OF TOTAL
Ionized $H_2PO_4^-$ and HPO_4^{2-}	2.1	0.7	50
Diffusible phosphate complexes	1.5	0.5	40
Nondiffusible (protein-bound) phosphate	0.6	0.2	10
Total phosphate	4.2	1.4	100

The proximal tubule reabsorbs phosphate via apical Na/phosphate cotransporters

The proximal tubule reabsorbs 80% to 95% of the filtered phosphate ([Fig. 36-14A](#)). More distal nephron segments reabsorb a negligible fraction of the filtered phosphate. Thus, the kidneys excrete 5% to 20% of the filtered load of phosphate in the urine under normal conditions.

A HANDLING OF PHOSPHATE ALONG NEPHRON

B PROXIMAL TUBULE

FIGURE 36-14 Phosphate handling by the kidney. In **A**, the numbered yellow boxes indicate the fraction of the filtered load that various nephron segments reabsorb. The green boxes indicate the fraction of the filtered load that remains in the lumen at various sites. The values in the boxes are approximations. In **B**, the top path illustrates reabsorption of divalent phosphate (HPO_4^{2-}), and the bottom path illustrates the

reabsorption of monovalent phosphate (H_2PO_4^-). PCT, proximal convoluted tubule; PST, proximal straight tubule.

The proximal tubule reabsorbs most of the filtered phosphate by the transcellular route (see Fig. 36-14B). Phosphate ions enter the cell across the *apical* membrane by secondary active transport, energized by the apical electrochemical Na^+ gradient. At least three separate Na/phosphate cotransporters contribute: NaPi-IIa (SLC34A1; see Table 5-4), NaPi-IIc (SLC34A3) and PiT-2 (SLC20A2).

NaPi-IIa translocates three Na^+ ions and one divalent phosphate ion (HPO_4^{2-}). Thus, the process is electrogenic (net positive charge into the cell). **N36-11** In contrast, NaPi-IIc is electroneutral, with a stoichiometry of two Na^+ ions per one HPO_4^{2-} . Because HPO_4^{2-} rather than H_2PO_4^- is the preferred substrate of NaPi-IIc, low luminal pH inhibits phosphate reabsorption by shifting the phosphate equilibrium toward H_2PO_4^- . Of the three transporters, NaPi-IIc is most important in humans, based on the phosphate wasting and hypophosphatemia that occurs in patients with NaPi-IIc mutations. Finally, PiT-2 is electrogenic, with a stoichiometry of 2 Na^+ ions per monovalent phosphate (H_2PO_4^-).

N36-11

The Type II Na/Phosphate Cotransporter NaPi-IIa

Contributed by Jürg Biber

As noted in the text, the apical Na/phosphate cotransporter NaPi-IIa (SLC34A1; see Table 5-4) translocates three Na^+ ions and one divalent phosphate ion (HPO_4^{2-}), and thus the process is electrogenic. As pH along the lumen of the proximal tubule falls, the relative concentration of H_2PO_4^- falls as well, so that one might expect that the uptake of inorganic phosphate by NaPi-IIa would become less effective. On the other hand, the affinity of NaPi-IIa for HPO_4^{2-} is so high ($K_i \cong 50 \mu\text{M}$) that the effect should not be severe.

The passive exit of phosphate across the *basolateral* membrane occurs by mechanisms that are still unknown (see Fig. 36-14B).

Phosphate excretion in the urine already occurs at physiological plasma concentrations

Phosphate handling by the kidney shares some of the properties of renal glucose handling, including threshold, saturation with T_m kinetics, and splay (Fig. 36-15). However, important differences exist. First, some phosphate excretion (green curve) occurs even at normal levels of plasma [phosphate]. Thus, a small increment in the plasma [phosphate] results in significant acceleration of phosphate excretion (i.e., to higher values along the green curve), whereas plasma [glucose] must double before glucose excretion even commences. Second, the kidney reaches the T_m for phosphate (red curve) at the high end of normal plasma [phosphate] values, whereas the kidney reaches the T_m for glucose at levels that are far higher than physiological plasma [glucose] levels. Third, the renal phosphate T_m is sensitive to a variety of stimuli, including hormones and acid-base balance, whereas the glucose T_m is insensitive to regulators of glucose

metabolism, such as insulin. Accordingly, the kidney plays an important role in the regulation of plasma [phosphate] but does not normally modulate plasma [glucose].

FIGURE 36-15 Phosphate titration curves. T_m is the transport maximum for reabsorption. The plasma phosphate concentration is the filterable phosphate (i.e., ionized plus complexed to small solutes). The dark vertical band is the approximate range of normal filterable values.

PTH inhibits apical Na/phosphate uptake, promoting phosphate excretion

Table 36-5 summarizes the major hormones and other factors that regulate phosphate transport by the proximal tubule.

TABLE 36-5
Factors that Modulate Phosphate Excretion

↓ REABSORPTION ↑ EXCRETION	↑ REABSORPTION ↓ EXCRETION
PTH	Parathyroidectomy
PTHrP	1,25-dihydroxyvitamin D
ECF volume expansion	ECF volume contraction
Dopamine	
High dietary phosphate	Phosphate deprivation
High plasma [phosphate]	
Glucocorticoids	Insulin
Acidosis	Alkalosis
	Thyroid hormone
ANP	Growth hormone
Acetazolamide	
Phosphatonins (FGF23, sFRP4, MEPE)	Stanniocalcin-1 (STC1)
Estrogen	
Hypercalcemia	Hypocalcemia
Hypokalemia	

ECF, extracellular fluid; PTHrP, parathyroid hormone–related protein.

The most important hormonal regulator is **PTH**, which inhibits phosphate reabsorption (see [p. 1062](#)) and thus promotes phosphate excretion. PTH is a classic example of a rapid regulator that does *not* require protein synthesis. PTH binds to **PTH 1 receptors (PTH1Rs)**, which appear to couple to *two* heterotrimeric G proteins (see [p. 1061](#)). The first (G α_s) activates adenylyl cyclase and, via cAMP, stimulates protein kinase A (PKA; see [p. 57](#)). The second (G α_q), particularly at low PTH levels, activates phospholipase C (PLC), and then protein kinase C (PKC; see [pp. 60–61](#)). Once activated, PKA and PKC promote endocytotic removal of NaPi from the apical membrane with targeting for degradation in lysosomes, which reduces phosphate reabsorption.

Another inhibitor of phosphate reabsorption is dopamine, which acts via D1 receptors and, like PTH, activates the cAMP/PKA pathway. High dietary phosphate intake decreases phosphate reabsorption, even without changes in PTH levels. Changes in plasma [phosphate], such as those that occur in phosphate depletion or loading, also modulate the surface expression of NaPi cotransporters. Both phosphate depletion and 1,25-dihydroxy-vitamin D (see [pp. 1063–1065](#)) upregulate the cotransporter. Glucocorticoid excess and metabolic acidosis downregulate the cotransporter; the latter effect is synergistic with the direct effects of H⁺ on the NaPi protein (see above). Because phosphate is the primary pH buffer in normal urine, factors that increase urinary [phosphate] (e.g., acidosis) increase the titratable acidity component of renal acid excretion (see [p. 823](#)).

Fibroblast growth factor 23 and other phosphatonins also inhibit apical Na/phosphate uptake, promoting phosphate excretion

Phosphatonins are the circulating factors that cause renal phosphate wasting in diseases such as oncogenic osteomalacia, autosomal dominant hypophosphatemic rickets, and X-linked hypophosphatemic rickets. In these diseases, phosphatonins—including fibroblast growth factor 23 (FGF23), secreted frizzled-related protein 4 (sFRP4), and matrix extracellular phosphoprotein (MEPE)—cause the kidneys to excrete more phosphate.

FGF23 has emerged as a particularly important phosphate-regulating hormone. In response to *hyperphosphatemia*, osteocytes release FGF23, which acts via the receptor tyrosine kinase FGFR1 (see [p. 787](#)) and the coreceptor **Klotho** [N36-12](#) to reduce the expression of Na/phosphate cotransporters

and thereby augment renal phosphate excretion. In addition, FGF23 decreases the renal production of 1,25-dihydroxyvitamin D and thus results in reduced phosphate absorption by the small intestine (see [p. 1065](#)).

N36-12

Klotho

Contributed by Emile L. Boulpaep, Walter F. Boron

The *KL* gene encodes two transcripts: a membrane protein with a single transmembrane segment (and related to β -glucosidase) and a secretory form. The transmembrane variant of Klotho associates with FGFR1 and acts as a coreceptor for FGF23. The secreted variant of Klotho, which is important in the resistance to aging (see p. 1247), is the result of ectodomain shedding.

Calcium

Binding to plasma proteins and formation of Ca^{2+} -anion complexes influence the filtration and reabsorption of Ca^{2+}

We discuss whole-body calcium balance—as well as the hormonal control of free, ionized plasma calcium (Ca^{2+}) levels—on [page 1054](#). Here we consider the role of the kidney in calcium balance. The *total* calcium concentration in plasma is normally 2.2 to 2.6 mM (8.8 to 10.6 mg/dL). [Table 36-6](#) summarizes the forms of calcium in the plasma. Some 40% binds to plasma proteins, mainly albumin, and constitutes the nonfilterable fraction. The **filterable** portion, ~60% of total plasma calcium, consists of two moieties. The first, ~15% of the total, complexes with small anions such as carbonate, citrate, phosphate, and sulfate. The second, ~45% of total calcium, is the ionized calcium (Ca^{2+}) that one may measure with Ca^{2+} -sensitive electrodes or dyes. It is the concentration of this free, ionized calcium that the body tightly regulates; plasma $[\text{Ca}^{2+}]$ normally is 1.0 to 1.3 mM (4.0 to 5.2 mg/dL).

TABLE 36-6
Components of Total Plasma Calcium

	mg/dL	mM	% OF TOTAL
Ionized Ca^{2+}	4.7	1.2	~45%
Diffusible calcium complexes	1.4	0.3	~15%
Nondiffusible (protein-bound) calcium	3.9	1.0	~40%
Total calcium	10.0	2.5	100%

The distribution of the various forms of total calcium is not fixed. Because H^+ competes with Ca^{2+} for binding to anionic sites on proteins or small molecules, acidosis generally increases plasma $[\text{Ca}^{2+}]$ and alkalosis acutely reduces it. Thus, acute alkalosis can cause signs and symptoms mimicking hypocalcemia. In addition, Ca^{2+} binding to proteins in the plasma depends on the concentrations of the proteins, particularly albumin. Thus, at a given $[\text{Ca}^{2+}]$, the total measured calcium will vary with serum albumin concentration. For example, in patients with low plasma albumin, total measured plasma calcium may be low despite a normal $[\text{Ca}^{2+}]$. [N36-13](#)

N36-13

Corrections for Plasma Calcium

Contributed by Gerhard Giebisch, Erich Windhager, Peter S. Aronson

Clinical laboratories routinely report total plasma calcium levels (8.8 to 10.6 mg/dL or 2.2. to 2.6 mM), not the ionized $[\text{Ca}^{2+}]_{\text{plasma}}$ that the body tightly regulates. Because the fraction of total plasma calcium that is ionized varies greatly with the $[\text{albumin}]_{\text{plasma}}$, the measured total plasma calcium is corrected for the patient's $[\text{albumin}]_{\text{plasma}}$ to obtain a **corrected $[\text{Ca}]_{\text{plasma}}$** or adjusted $[\text{Ca}]_{\text{plasma}}$.

$$\underbrace{\text{Corrected}[\text{Ca}]_{\text{plasma}}}_{\text{mg/dL}} = \underbrace{\text{Measured}[\text{Ca}]_{\text{plasma}}}_{\text{mg/dL}} + 0.8 \cdot \left[4.0 - \underbrace{[\text{Albumin}]_{\text{plasma}}}_{\text{g/dL}} \right]$$

(NE 36-5)

The equation assumes a normal $[\text{albumin}]_{\text{plasma}}$ of 4 g/dL.

Thus, the corrected $[\text{Ca}]_{\text{plasma}}$ in a patient with hypoalbuminemia (e.g., $[\text{albumin}]_{\text{plasma}}$ of 3 g/dL) is 0.8 mg/dL higher than the measured $[\text{Ca}]_{\text{plasma}}$. The physician then applies the theoretical fractional distribution of the different calcium Ca^{2+} entities to the corrected $[\text{Ca}]_{\text{plasma}}$.

A change in the level of the anions with which Ca^{2+} can form complexes also affects the distribution of different calcium Ca^{2+} entities. Tubule cells probably reabsorb Ca^{2+} -anion complexes poorly. However, because the concentration of these anions declines along the nephron owing to anion reabsorption, free Ca^{2+} becomes available for transport.

The proximal tubule reabsorbs two thirds of filtered Ca^{2+} , with more distal segments reabsorbing nearly all of the remainder

The kidney reabsorbs ~99% of the filtered load of calcium, principally at the proximal tubule, the thick ascending limb (TAL), and the distal convoluted tubule (DCT) ([Fig. 36-16A](#)).

A HANDLING OF Ca^{2+} ALONG NEPHRON

B PROXIMAL TUBULE

D DISTAL CONVOLUTED TUBULE (DCT)

C THICK ASCENDING LIMB (TAL)

FIGURE 36-16 Calcium handling by the kidney. In **A**, the numbered yellow boxes indicate the approximate fraction of the filtered load that various nephron segments *reabsorb*. The green boxes indicate the fraction of the filtered load that remains in the lumen at various sites. The values in the boxes are approximations. AC, adenylyl cyclase; HETE, hydroxyeicosatetraenoic acid; PCT, proximal convoluted tubule; PST, proximal straight tubule.

Proximal Tubule

The proximal tubule reabsorbs ~65% of the filtered calcium, a process that is *not* subject to hormonal control. Virtually all proximal-tubule Ca^{2+} reabsorption occurs via the paracellular route (see [Fig. 36-16B](#)). The evidence for a large component of *paracellular Ca^{2+} transport* is the high Ca^{2+} permeability of the tubule, as well as the sensitivity of net Ca^{2+} transport to changes in the transepithelial electrochemical gradient for Ca^{2+} . For example, imposing a lumen-negative transepithelial voltage induces Ca^{2+} secretion, whereas a lumen-positive voltage induces reabsorption. The passive paracellular reabsorption of calcium

is very dependent on luminal $[Ca^{2+}]$. Water reabsorption tends to increase luminal $[Ca^{2+}]$, generating a favorable transepithelial gradient that drives passive Ca^{2+} reabsorption by diffusion via the paracellular pathway. In addition, some calcium reabsorption may occur via solvent drag across the tight junctions. The greater the fluid reabsorption along the proximal tubule, the greater the reabsorption of Ca^{2+} via both diffusion and solvent drag. For this reason, a high-NaCl diet—which increases extracellular volume and thus lowers proximal-tubule Na^+ and water reabsorption—reduces Ca^{2+} reabsorption and increases urinary Ca^{2+} excretion. One consequence is an elevated risk of calcium kidney stones.

Thick Ascending Limb

The TAL reabsorbs ~25% of the filtered calcium (see Fig. 36-16C). Most of the Ca^{2+} reabsorption in the TAL occurs passively via a paracellular route, driven by the lumen-positive voltage. Thus, it is not surprising that loop diuretics (see p. 757), which block the generation of the lumen-positive transepithelial voltage, acutely inhibit Ca^{2+} reabsorption.

Distal Convoluted Tubule

The DCT reabsorbs ~8% of the filtered Ca^{2+} load (see Fig. 36-16D). Despite the relatively small amount of Ca^{2+} delivered, the DCT is a major regulatory site for Ca^{2+} excretion. In contrast to the proximal tubule and TAL, the DCT reabsorbs Ca^{2+} predominantly via an active, transcellular route (see next section).

The quantitative contribution of the collecting ducts and tubules to Ca^{2+} reabsorption is quite small (~1% of the filtered load), and their role in regulating renal Ca^{2+} excretion is not well defined.

Transcellular Ca^{2+} movement is a two-step process, involving passive Ca^{2+} entry through apical channels and basolateral extrusion by electrogenic Na/Ca exchange and a Ca pump

Because $[Ca^{2+}]_i$ is only ~100 nM (~10,000-fold less than in extracellular fluid), and because the membrane voltage across the apical membrane is approximately -70 mV, a steep electrochemical gradient favors Ca^{2+} entry across *the apical membrane*. Work on the DCT shows that apical Ca^{2+} entry is passive, mediated by the epithelial Ca^{2+} channels TRPV5 and TRPV6 (ECaC1 and ECaC2).

As Ca^{2+} enters the tubule cell across the apical membrane, the Ca^{2+} -binding proteins (i.e., calbindins) buffer the Ca^{2+} , helping to keep $[Ca^{2+}]_i$ low and maintaining a favorable gradient for Ca^{2+} influx. In addition, Ca^{2+} may temporarily enter certain organelles, particularly the endoplasmic reticulum and mitochondria. In the steady state, however, the cell must extrude across the basolateral membrane all the Ca^{2+} that enters across the apical membrane. Both primary and secondary active transporters participate in this Ca^{2+} extrusion against a steep electrochemical gradient. The primary active transporter is an ATP-driven plasma-membrane Ca^{2+} ATPase or pump (PMCA1b; see p. 118).

In addition to the Ca pump, an Na-Ca exchanger (NCX1; see pp. 123–124) also extrudes Ca^{2+} across the basolateral membrane of tubule cells. At physiologically low $[Ca^{2+}]_i$ levels, when NCX1 is not very active, the major pathway for Ca^{2+} extrusion is the Ca pump. Only when $[Ca^{2+}]_i$ increases does the NCX1 begin to make a significant contribution. Conversely, if the $[Ca^{2+}]_i$ is normal and the inward Na^+ electrochemical gradient falls (e.g., $[Na^+]_i$ rises), the NCX1 can reverse direction and load the cell with Ca^{2+} .

PTH and vitamin D stimulate—whereas high plasma Ca^{2+} inhibits— Ca^{2+} reabsorption

Table 36-7 summarizes factors that modulate Ca^{2+} handling by various segments of the nephron.

TABLE 36-7
Factors Affecting Ca^{2+} Reabsorption Along the Nephron  **N36-16**

SITE	INCREASE REABSORPTION	DECREASE REABSORPTION
Proximal tubule	Volume contraction	Volume expansion

DCT	Alkalosis PTH Vitamin D Estrogens Thiazide diuretics	Acidosis

N36-16

Regulation of Ca^{2+} Reabsorption

Contributed by Gerhard Giebisch, Erich Windhager

In addition to the factors discussed beginning on page 789, several other factors modulate the handling of Ca^{2+} .

Effective Circulating Volume

A reduction in effective circulating volume triggers four parallel effector pathways (see p. 836) that act to restore volume. One of these pathways—the sympathetic division of the autonomic nervous system—increases Na^+ reabsorption by the proximal tubule (see pp. 766–768). Because proximal-tubule Ca^{2+} reabsorption depends largely on transepithelial voltage and solvent drag (see p. 787), which in turn depend on Na^+ reabsorption, it is not surprising that volume contraction, which increases Na^+ reabsorption, also increases Ca^{2+} reabsorption. Volume expansion has the opposite effects on both Na^+ and Ca^{2+} reabsorption.

Acid-Base Balance

Metabolic alkalosis increases renal Ca^{2+} reabsorption (i.e., decreases excretion) at the level of the DCT, probably by relieving the inhibition of apical TRPV5/TRPV6 Ca^{2+} channels by H^+ . This effect is independent of PTH status as well as of Na^+ transport. The latter observation suggests that factors such as solvent drag and diffusion are not involved.

Phosphate Depletion

Chronic phosphate depletion impairs Ca^{2+} reabsorption at both proximal and distal sites. The effects are independent of the decrease in PTH secretion that follows phosphate depletion; the basis for the effect is otherwise unknown.

Parathyroid Hormone

The most important regulator of renal Ca^{2+} reabsorption is **PTH**, which stimulates Ca^{2+} reabsorption in

the DCT and the connecting tubule. Regarding TRPV5, PTH increases transcription and open probability, and inhibits endocytosis, thereby stimulating Ca^{2+} reabsorption. In addition to its effects to stimulate apical Ca^{2+} entry, PTH also upregulates expression of calbindin and NCX1.

As we saw in our discussion of phosphate handling (see pp. 786–787), PTH acts by binding to the PTH1R receptor, which apparently couples to two heterotrimeric G proteins and activates two kinases (see p. 1061), PKA (see p. 57) and PKC (see pp. 60–61). Both pathways are essential for the action of PTH on apical Ca^{2+} entry.

Vitamin D

Acting on gene transcription, vitamin D (see pp. 1063–1067) increases Ca^{2+} reabsorption in the distal nephron; this renal reabsorption complements the major Ca^{2+} -retaining action of vitamin D, Ca^{2+} absorption in the gastrointestinal tract (see p. 938). In renal tubule cells, vitamin D upregulates TRPV5 Ca^{2+} -binding proteins, which contribute to enhanced Ca^{2+} reabsorption by keeping $[\text{Ca}^{2+}]_i$ low during increased Ca^{2+} traffic through the cell.

Plasma Ca^{2+} Levels

As discussed on page 768, extracellular Ca^{2+} binds to a basolateral **Ca^{2+} -sensing receptor (CaSR)** in the TAL, which leads to a reduction in the lumen-positive transepithelial potential. CaSR activation also leads to a reduction in paracellular Ca^{2+} permeability in this nephron segment. Because Ca^{2+} reabsorption in the TAL is predominantly passive and paracellular (see p. 787), these CaSR-mediated decreases in driving force and permeability lead to reduced Ca^{2+} reabsorption and thus increased Ca^{2+} excretion, tending to compensate for hypercalcemia.  **N36-14**

N36-14

Effect of Hypercalcemia on Ability to Create a Concentrated Urine

Contributed by Gerhard Giebisch, Erich Windhager

As noted on page 791, **hypercalcemia** (i.e., high plasma $[\text{Ca}^{2+}]$), acting via the CaSR, reduces Na^+ reabsorption by the TAL. One result of this action is reduced osmolality in the renal medulla, which in turn impairs the kidney's ability to generate concentrated urine (see p. 811). Indeed, chronic hypercalcemia results in a dilute urine, a form of **nephrogenic diabetes insipidus** (see Box 38-1). By keeping urine $[\text{Ca}^{2+}]$ relatively low, this effect may help avoid Ca^{2+} stones under conditions of high Ca^{2+} excretion.

An interesting consequence of reduced Na^+ reabsorption induced by high plasma $[\text{Ca}^{2+}]$ is an inhibition of the kidney's ability to generate a concentrated urine (see p. 811). Indeed, chronic hypercalcemia results in a dilute urine, a form of nephrogenic diabetes insipidus (see p. 819). By keeping urine $[\text{Ca}^{2+}]$ relatively low, this effect may help avoid Ca^{2+} stones under conditions of high Ca^{2+} excretion.

Diuretics

Among diuretics, those acting on the TAL, such as furosemide, acutely *decrease* Ca^{2+} reabsorption,

whereas those acting on the distal nephron, such as thiazides and amiloride, *increase* Ca^{2+} reabsorption. Thus, of these drugs, only the powerful loop diuretic furosemide is appropriate for treating hypercalcemic states. In the TAL, **furosemide** (see [p. 757](#)) reduces the lumen-positive voltage, and thus the driving force for passive, paracellular Ca^{2+} reabsorption. Accordingly, with furosemide, urinary Ca^{2+} excretion increases in parallel with Na^+ excretion.

In contrast to furosemide, thiazides and amiloride *increase* Ca^{2+} reabsorption. **Thiazide diuretics** (see [p. 758](#)) inhibit Na/Cl cotransport and stimulate Ca^{2+} reabsorption in the DCT. Inhibiting apical Na/Cl cotransport lowers $[\text{Cl}^-]_i$ in the DCT cell, thus hyperpolarizing the cell. The steeper electrical gradient increases apical Ca^{2+} entry, secondarily stimulating basolateral Ca^{2+} extrusion. **Amiloride** (see [pp. 758–759](#)) inhibits apical Na^+ channels in the initial and cortical collecting tubules and hyperpolarizes the apical membrane. Thus, like the thiazides, amiloride augments Ca^{2+} reabsorption by enhancing the gradient for apical Ca^{2+} entry.

Volume depletion induced by any of these diuretics will increase Na^+ reabsorption by the proximal tubule and thus secondarily increase passive proximal Ca^{2+} reabsorption (see [p. 787](#)). In the case of thiazides and amiloride, volume depletion further decreases Ca^{2+} excretion. Physicians exploit the ability of thiazides to reduce Ca^{2+} excretion, particularly in a state of mild volume contraction, to lower urinary $[\text{Ca}^{2+}]$ in patients with calcium-containing kidney stones. In the case of furosemide, if the patient is allowed to become volume depleted, the proximal effect will blunt the primary calciuric effect.

Magnesium

Most Mg^{2+} reabsorption takes place along the TAL

Approximately 99% of the total body stores of magnesium reside either within bone (~54%) or within the intracellular compartment (~45%), mostly muscle. Renal magnesium excretion plays an important role in maintaining physiological plasma magnesium levels. The body maintains the total magnesium concentration in blood plasma within narrow limits, 0.8 to 1.0 mM (1.8 to 2.2 mg/dL). Of this total, ~30% is protein bound ([Table 36-8](#)). The remaining ~70% of total magnesium, which is filterable, is made up of two components. Less than 10% is complexed to anions such as phosphate, citrate, and oxalate, thus leaving ~60% of the total as free, ionized magnesium (Mg^{2+}).

TABLE 36-8
Components of Total Plasma Magnesium

	mg/dL	mM	% OF TOTAL
Ionized Mg^{2+}	1.3	0.56	62
Diffusible magnesium complexes	0.1	0.06	7
Nondiffusible (protein-bound) magnesium	0.6	0.28	31
Total magnesium	2.0	0.90	100

Disturbances of Mg^{2+} metabolism usually involve abnormal *losses*, and these occur most frequently during gastrointestinal malabsorption (see [p. 939](#)) and diarrhea, in the course of renal disease, and following the administration of diuretics. Clinical manifestations of Mg^{2+} depletion include neurological disturbances such as tetany (especially when associated with hypocalcemia), cardiac arrhythmias, and increased peripheral vascular resistance. Conversely, increased Mg^{2+} intake may lower blood pressure and may reduce the incidence of hypertension. Severe hypermagnesemia, which may occur following excessive intake or renal failure, results in a toxic syndrome involving nausea, hyporeflexia, respiratory insufficiency, and cardiac arrest.

Normally, 5% or less of the filtered magnesium load appears in the urine ([Fig. 36-17A](#)). In contrast to the predominantly “proximal” reabsorption pattern of the major components of the glomerular filtrate, Mg^{2+} reabsorption occurs mainly along the TAL.

A HANDLING OF Mg^{2+} ALONG NEPHRON

C THICK ASCENDING TUBULE (TAL)

D DISTAL CONVOLUTED TUBULE (DCT)

B PROXIMAL TUBULE

FIGURE 36-17 Magnesium handling by the kidney. In **A**, the numbered yellow boxes indicate the fraction of the filtered load that various nephron segments reabsorb. The green boxes indicate the fraction of the filtered load that remains in the lumen at various sites. The values in the boxes are approximations. CCT, cortical collecting tubule; ICT, initial collecting tubule; OMCD, outer medullary collecting duct; PCT, proximal convoluted tubule; PST, proximal straight tubule.

Normally, the **proximal tubule** reabsorbs only ~15% of the filtered magnesium load (see [Fig. 36-17B](#)). Water reabsorption along the proximal tubule causes luminal $[Mg^{2+}]$ to double compared with the value in Bowman's space, thereby establishing a favorable Mg^{2+} electrochemical gradient for passive, paracellular Mg^{2+} reabsorption. Solvent drag may also contribute to the paracellular reabsorption of Mg^{2+} . Because proximal paracellular permeability to Mg^{2+} is significantly less than that to Ca^{2+} , Mg^{2+} reabsorption is not as sensitive to changes in extracellular volume as is Ca^{2+} reabsorption.

The **TAL** absorbs ~70% of the filtered magnesium load (see Fig. 36-17C). The driving force for paracellular Mg^{2+} reabsorption is the lumen-positive voltage of the TAL (see p. 758).

In the TAL, the tight-junction proteins **claudin 16** and **claudin 19** (see pp. 43–44) account for the high paracellular cation permeability that is necessary for paracellular Mg^{2+} reabsorption. Mutations of *CLDN16* or *CLDN19* genes cause an autosomal recessive disorder of severe renal Mg^{2+} wasting with hypomagnesemia.

Mg^{2+} reabsorption along the **DCT**, which is predominantly transcellular (see Fig. 36-17D), accounts for only ~10% of the filtered load. Mg^{2+} entry across the apical membrane may take place via the TRPM6 cation channel (see Table 6-2, family No. 5). Because both luminal and intracellular Mg^{2+} are in the millimolar range, the key driving force is the inside-negative membrane potential. The efflux of K^+ through apical $Kv1.1$ K^+ channels neutralizes the entry of positive charge via Mg^{2+} uptake. The mechanism of Mg^{2+} extrusion across the basolateral membrane may be secondary active transport by Na-Mg exchange (SLC41A1).  **N36-15**

N36-15

Regulation of Magnesium Reabsorption in the DCT

Contributed by Gerhard Giebisch, Erich Windhager, Peter Aronson

Active Mg reabsorption is tonically stimulated by the epidermal growth factor receptor (EGFR). Identification of patients with syndromes including renal Mg wasting and hypomagnesemia due to mutations in TRPM6, *Kv1.1*, and EGF support this model. In addition, renal Mg wasting due to mutations in the Na/Cl cotransporter, the γ subunit of the Na-K pump, the transcription factor HNF1B that affects γ subunit expression, or the basolateral K^+ channel Kir 4.1/5.1 suggest that these processes are also required for normal Mg reabsorption.

Mg²⁺ reabsorption increases with depletion of Mg²⁺ or Ca²⁺, or with elevated PTH levels

Table 36-9 shows the site of action of factors modulating renal Mg^{2+} excretion.

TABLE 36-9

Factors Affecting Mg^{2+} Reabsorption Along the Nephron  **N36-17**

SITE	INCREASE REABSORPTION	DECREASE REABSORPTION
Proximal tubule	Volume contraction	Volume expansion
TAL	PTH, calcitonin, glucagon, AVP Low plasma $[Mg^{2+}]$ Metabolic alkalosis	Furosemide and related loop diuretics Mannitol High plasma $[Mg^{2+}]$ or $[Ca^{2+}]$
DCT	PTH, calcitonin, glucagon, estrogens, vitamin D Metabolic alkalosis Low plasma $[Mg^{2+}]$ Amiloride	High plasma $[Mg^{2+}]$ or $[Ca^{2+}]$ Metabolic acidosis K^+ or phosphate depletion

N36-17

Regulation of Mg^{2+} Reabsorption

In addition to the factors discussed beginning on page 791, other factors modulate the handling of Mg^{2+} , of which we discuss two.

Effective Circulating Volume

As is true for Ca^{2+} , a decrease in effective circulating volume leads to an increase in Na^+ reabsorption and an increase in the forces that drive Mg^{2+} reabsorption via paracellular pathways. Thus, volume contraction increases Mg^{2+} reabsorption, whereas volume expansion has the opposite effect.

Acid-Base Balance

As is the case for Ca^{2+} , alkalosis increases Mg^{2+} reabsorption. However, for Mg^{2+} , the effect is at the level of the TAL.

Mg^{2+} Depletion

In response to low plasma $[\text{Mg}^{2+}]$, the kidney reduces fractional excretion of Mg^{2+} to very low levels (<2%). This adaptive response is due to upregulation of Mg^{2+} reabsorption in the TAL and DCT.

Hypermagnesemia and Hypercalcemia

The kidney seems to discriminate poorly between increases in plasma $[\text{Mg}^{2+}]$ and $[\text{Ca}^{2+}]$. Thus, *each* of these disturbances inhibits the reabsorption of both Mg^{2+} and Ca^{2+} in the TAL, thereby leading to increased urinary excretion of both Mg^{2+} and Ca^{2+} . It is thought that high plasma $[\text{Mg}^{2+}]$ and $[\text{Ca}^{2+}]$ each diminish Mg^{2+} reabsorption because each cation can bind to the CaSR.

Hormones

PTH is the most important hormone for Mg^{2+} regulation, increasing distal Mg^{2+} reabsorption. When tested separately in hormone-depleted animals, AVP, glucagon, and calcitonin all stimulate Mg^{2+} reabsorption in the TAL, acting via cAMP and PKA. Many of these hormones probably act by modulating passive Mg^{2+} movement through the paracellular pathway, either by changing NaCl transport and transepithelial voltage or by increasing paracellular permeability.

Diuretics

In general, diuretics decrease Mg^{2+} reabsorption and thus enhance Mg^{2+} excretion. Loop diuretics have effects on Mg^{2+} similar to those on Ca^{2+} and act by depressing the lumen-positive voltage in the TAL and thus the gradient for passive, paracellular Mg^{2+} reabsorption. Osmotic diuretics, such as mannitol, also reduce Mg^{2+} reabsorption along the loop of Henle. Thiazide diuretics reduce Mg^{2+} reabsorption in the DCT, at least in part by indirectly downregulating expression of TRPM6 Mg^{2+} channels.

CHAPTER 37

Transport of Potassium

Gerhard Giebisch, Erich E. Windhager, Peter S. Aronson

Potassium Balance and the Overall Renal Handling of Potassium

Changes in K⁺ concentrations can have major effects on cell and organ function

The distribution of K⁺ in the body differs strikingly from that of Na⁺. Whereas Na⁺ is largely extracellular, K⁺ is the most abundant intracellular cation. Some 98% of the total-body K⁺ content (~50 mmol/kg body weight) is inside cells; only 2% is in the extracellular fluid (ECF). The body tightly maintains the plasma [K⁺] at 3.5 to 5.0 mM.

Table 37-1 summarizes the most important physiological functions of K⁺ ions. A *high* [K⁺] inside cells and mitochondria is essential for maintenance of cell volume, for regulation of intracellular pH and control of cell-enzyme function, for DNA and protein synthesis, and for cell growth. The relatively *low* extracellular [K⁺] is necessary for maintaining the steep K⁺ gradient across cell membranes that is largely responsible for the membrane potential of excitable and nonexcitable cells. Therefore, changes in extracellular [K⁺] can cause severe disturbances in excitation and contraction. As a general rule, either doubling the normal plasma [K⁺] or reducing it by half results in severe disturbances in skeletal and cardiac muscle function. The potentially life-threatening disturbances of cardiac rhythmicity that result from a rise in plasma [K⁺] are particularly important (Box 37-1).

TABLE 37-1
Physiological Role of Potassium Ions

A. Roles of Intracellular K ⁺	
Cell volume maintenance	Net loss of K ⁺ → cell shrinkage
	Net gain of K ⁺ → cell swelling
Intracellular pH regulation	Low plasma [K ⁺] → cell acidosis
	High plasma [K ⁺] → cell alkalosis
Cell enzyme functions	K ⁺ dependence of enzymes: e.g., some ATPases, succinic dehydrogenase
DNA/protein synthesis, growth	Lack of K ⁺ → reduction of protein synthesis, stunted growth
B. Roles of Transmembrane [K ⁺] Ratio	
Resting cell membrane potential	Reduced [K ⁺] _i /[K ⁺] _o → membrane depolarization
	Increased [K ⁺] _i /[K ⁺] _o → membrane hyperpolarization
Neuromuscular activity	Low plasma [K ⁺]: muscle weakness, muscle paralysis, intestinal distention, respiratory failure
	High plasma [K ⁺]: increased muscle excitability; later, muscle weakness (paralysis)
Cardiac activity	Low plasma [K ⁺]: prolonged repolarization; slowed conduction; abnormal pacemaker activity, leading to tachyarrhythmias
	High plasma [K ⁺]: enhanced repolarization; slowed conduction, leading to bradyarrhythmias and cardiac arrest
Vascular resistance	Low plasma [K ⁺]: vasoconstriction
	High plasma [K ⁺]: vasodilation

Chronic K⁺ depletion leads to several metabolic disturbances. These include the following: (1) inability of the kidney to form a concentrated urine (Box 38-1); (2) a tendency to develop metabolic alkalosis (pp. 834–835); and, closely related to this acid-base disturbance, (3) a striking enhancement of renal ammonium excretion (pp. 834–835).

K⁺ homeostasis involves external K⁺ balance between environment and body, and internal K⁺ balance between

intracellular and extracellular compartments

Figure 37-1 illustrates processes that govern K^+ balance and the distribution of K^+ in the body: (1) gastrointestinal (GI) intake, (2) renal and extrarenal excretion, and (3) the internal distribution of K^+ between the intracellular and extracellular fluid compartments. The first two processes accomplish external K^+ balance (i.e., body versus environment), whereas the last achieves internal K^+ balance (i.e., intracellular versus extracellular fluids).

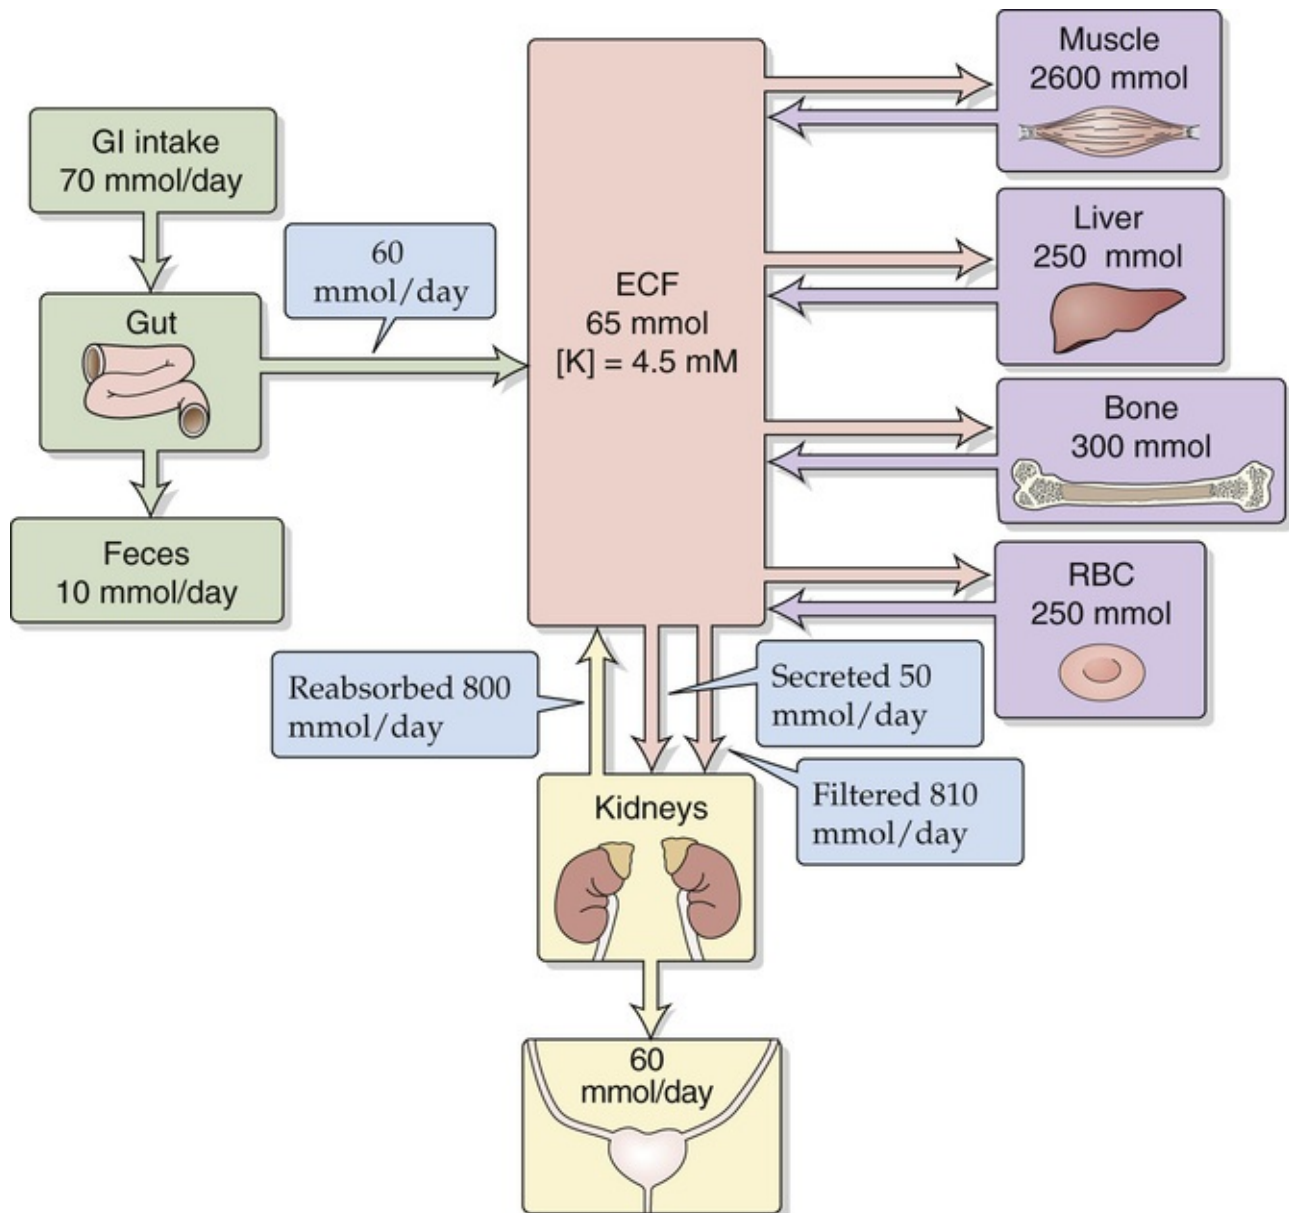

FIGURE 37-1 Distribution and balance of K^+ throughout the body. Intracellular K^+ concentrations are similar in all tissues in the four purple boxes. The values in the boxes are approximations. RBC, red blood cell.

External K^+ Balance

The relationship between dietary K^+ intake and K^+ excretion determines external K^+ balance. The *dietary intake* of K^+ is approximately equal to that of Na^+ , 60 to 80 mmol/day. This K^+ intake is approximately equal to the entire K^+ content of the ECF, which is only about 65 to 75 mmol. For the plasma K^+ content to remain constant, the body must excrete K^+ via renal and extrarenal mechanisms at the same rate as K^+

ingestion. Moreover, because dietary K^+ intake can vary over a wide range, it is important that these K^+ -excretory mechanisms be able to adjust appropriately to variable K^+ intake. The kidney is largely responsible for K^+ excretion, although the GI tract plays a minor role. The kidneys excrete 90% to 95% of the daily K^+ intake; the colon excretes 5% to 10%. Although the colon can adjust its K^+ excretion in response to some stimuli (e.g., adrenal hormones, changes in dietary K^+ , decreased capacity of the kidneys to excrete K^+), the colon—by itself—is incapable of increasing K^+ secretion sufficiently to maintain external K^+ balance.

Internal K^+ Balance

Maintaining normal intracellular and extracellular $[K^+]$ requires not only the *external* K^+ balance just described, but also the appropriate distribution of K^+ within the body. Most of the K^+ is inside cells—particularly muscle cells, which represent a high fraction of body mass—with smaller quantities in liver, bone, and red blood cells. The markedly unequal distribution between the intracellular and extracellular K^+ content has important quantitative implications. Of the total intracellular K^+ content of ~ 3000 mmol, shuttling as little as 1% to or from the ECF would cause a 50% change in extracellular $[K^+]$, with severe consequences for neuromuscular function (see [Table 37-1](#)).

Ingested K^+ moves transiently into cells for storage before excretion by the kidney

What happens when the body is presented with a K^+ load? By far, the most common source of a K^+ load is dietary K^+ . When one ingests K^+ salts, both the small intestine ([p. 908](#)) and the colon ([p. 910](#)) absorb the K^+ . Not only can K^+ come from external sources, but substantial amounts of K^+ may enter the ECF from damaged tissues ([Box 37-2](#)). Such K^+ release from intracellular to extracellular fluid can lead to a severe, even lethal, increase in plasma $[K^+]$ (i.e., **hyperkalemia**). However, even a large meal presents the body with a K^+ load that could produce hyperkalemia if it were not for mechanisms that buffer and ultimately excrete this K^+ .

N37-8

Causes of Hypoaldosteronism

Contributed by Emile Boulpaep, Walter Boron

The reason that hypoaldosteronism can cause hyperkalemia is that renal K^+ excretion largely depends on K^+ secretion by the CCT. There, aldosterone is responsible for maintaining high levels of the apical ENaC. Decreased expression of ENaC leads to decreased Na^+ uptake across the apical membrane, less depolarization of the apical membrane, and thus less driving force for the passive diffusion of K^+ out across the apical membrane (see [Fig. 37-7C](#)).

Bear in mind that aldosterone is synthesized by the glomerulosa cells in the adrenal cortex (see [Figs. 50-1 and 50-2](#) and the discussion of mineralocorticoids beginning on [p. 1026](#)). Causes of hypoaldosteronism include the following:

- Addison disease (in which part of the adrenal gland is destroyed)
- Congenital adrenal hypoplasia

- Deficiency in the enzyme aldosterone synthase (see Fig. 50-2)
- Low-renin states (because the renin–ANG II axis is the major stimulant for aldosterone secretion—see pp. 1027–1029). Examples of patients with low-renin states include otherwise normal older patients (who may have a reduced renin response to orthostasis) and diabetic patients. Another class of low-renin state is drug induced (e.g., secondary to the inhibition of the sympathetic division of the autonomic nervous system, which is a major stimulant of renin release).
- Pseudohypoaldosteronism types 1 and 2. Both cases represent defects in the ability of aldosterone to exert its effects (e.g., defects in the mineralocorticoid receptor or ENaC). In these syndromes, plasma levels of aldosterone are actually higher than normal.

Some four fifths of an ingested K^+ load temporarily moves into cells, so that plasma $[K^+]$ rises only modestly, as shown in the upper panel of Figure 37-2. Were it not for this translocation, plasma $[K^+]$ could reach dangerous levels. The transfer of excess K^+ into cells is rapid and almost complete after an hour (lower panel of Fig. 37-2, gold curve). With a delay, the kidneys begin to excrete the surfeit of K^+ (lower panel of Fig. 37-2, brown curve), removing from the cells the excess K^+ that they had temporarily stored.

FIGURE 37-2 K^+ handling following an acute K^+ load. (Data from Cogan MG: Fluid and Electrolytes: Physiology and Pathophysiology. Norwalk, CT, Appleton & Lange, 1991.)

What processes mediate the temporary uptake of K^+ into cells during K^+ loading? As shown in Figure

37-3, the hormones insulin, epinephrine (a β -adrenergic agonist), and aldosterone all promote the transfer of K^+ from extracellular to intracellular fluid via the ubiquitous Na-K pump. 🍌N37-1 Indeed, the lack of insulin or a deficient renin-angiotensin-aldosterone system can significantly compromise tolerance to K^+ loading and can predispose to hyperkalemia. Similarly, administering β -adrenergic blockers (in treatment of hypertension) impairs sequestration of an acute K^+ load.

FIGURE 37-3 K^+ uptake into cells in response to high plasma $[K^+]$.

Hormonal Response to Acute K^+ Loading

Contributed by Emile Boulpaep, Walter Boron

As noted in the text, ingestion of a K^+ -rich meal leads to only small increases in extracellular $[K^+]_o$ because of the actions of insulin, epinephrine, and aldosterone on target tissues (see Fig. 37-3).

As discussed on p. 1039 of the text, increases in $[K^+]_o$ depolarize β cells in the pancreatic islets, leading to the release of **insulin**.

As discussed on page 1031, chromaffin cells in the adrenal medulla secrete **epinephrine** and to a lesser extent norepinephrine. Extremely large increases in $[K^+]_o$ —so large that they would be fatal—do indeed promote the secretion of the aforementioned catecholamines. Physiological increases in $[K^+]_o$ do not. Thus, physiological levels of epinephrine are permissive for K^+ sequestration.

As discussed on page 1028, increases in $[K^+]_o$ depolarize glomerulosa cells in the adrenal cortex, promoting the secretion of **aldosterone**.

Acid-base disturbances also affect internal K^+ distribution. As a rule, *acidemia* leads to hyperkalemia as tissues release K^+ . One can think of this K^+ release as an “exchange” of intracellular K^+ for extracellular H^+ , although a single transport protein generally does not mediate this exchange (p. 645). Rather, apparent K-H exchange is most likely the indirect result of two effects of low pH_o (Fig. 37-4). *Extracellular* acidosis inhibits Na-H exchange and Na/HCO_3 cotransport, both raising $[H^+]_i$ (i.e., lowering pH_i) and lowering $[Na^+]_i$. The *intracellular* acidosis compromises both the Na-K pump and the Na/K/Cl cotransporter NKCC2, both of which move K^+ into cells. In addition, low pH_i lessens the binding of K^+ to nondiffusible intracellular anions, promoting K^+ efflux. In parallel, the low $[Na^+]_i$ reduces the supply of intracellular Na^+ to be extruded by the Na-K pump and thus inhibits K^+ uptake by the Na-K pump. These mechanisms all promote hyperkalemia. 🍌N37-2

FIGURE 37-4 Effect of acidosis on K⁺ uptake into cells.

N37-2

Ability of Inorganic Versus Organic Acids to Cause Hyperkalemia

Contributed by Gerhard Giebisch, Erich Windhager, Peter Aronson

Interestingly, for the same degree of acidemia, mineral acids produce a greater degree of hyperkalemia than do organic acids. This difference occurs because organic anions like lactate enter the cell by H⁺ cotransport. The resulting intracellular acidosis and fall in intracellular bicarbonate will tend to stimulate Na/HCO₃ cotransporters (NBCs; see p. 122) and Na-H exchangers (NHEs; see pp. 123–124) and thereby oppose the inhibitory effects of extracellular acidosis.

Conversely, *alkalemia* causes cells to take up K^+ and thus leads to hypokalemia. High extracellular pH and $[HCO_3^-]$ enhance Na^+ entry into the cell via Na-H exchange and Na/HCO₃ cotransport. The resulting stimulation of the Na-K pump then causes hypokalemia by stimulating K^+ transfer into cells. The opposite side of the coin, also appearing as the exchange of K^+ for H^+ , is the effect of changes in extracellular $[K^+]$ on acid-base homeostasis. For example, hyperkalemia causes intracellular alkalosis (p. 645) and extracellular acidosis (p. 835). Conversely, K^+ depletion causes intracellular acidosis and extracellular alkalosis (pp. 834–835).

In some clinical conditions, an increase in extracellular osmolality induces a transfer into the extracellular space not only of water but also of K^+ . An example of this phenomenon occurs in diabetic patients in whom severe hyperglycemia leads to cell shrinkage and thus a regulatory volume increase (p. 131), resulting in a rise in plasma $[K^+]$.  **N37-3**

N37-3

Hyperkalemia During Hyperosmolality

Contributed by Emile Boulpaep

In the text, we introduce the example of hyperglycemia-induced hyperkalemia in diabetics. The insulin deficiency, by itself (even without cell shrinkage), will reduce K^+ uptake into cells by the Na-K pump and thus lead to hyperkalemia.

In addition, hypertonicity will contribute to hyperkalemia by two possible mechanisms, one likely to be minor and the other major. In the first mechanism (i.e., presumably the minor one), we assume no regulation of cell volume after cell shrinkage. In isosmolal solutions, the net driving force for K^+ in mammalian skeletal muscle is $(V_m - E_K) = (-80 - [-95]) = +15$ mV (see Fig. 6-10), where V_m is membrane potential and E_K is the equilibrium potential for K^+ . An increase in extracellular osmolality from 300 to 315 mOsm (i.e., a 5% increase in osmolality)—for example, caused by raising plasma [glucose] from 100 to 400 mg/dL (or from 5 to 20 mM), which is a large increase—would cause the cell to shrink by 5% of its initial volume. As a result, intracellular $[K]$ would rise by 5%, thereby causing E_K to shift by ~1.3 mV in the negative direction and increasing the net electrochemical driving force for K^+ (i.e., $V_m - E_K$) from +15 mV to +16.3 mV. Assuming V_m and K^+ conductance are unaffected by shrinkage,* K^+ efflux would increase by an unimpressive 9%. Thus, this direct effect of cell shrinkage on $[K^+]_o$ is likely to be relatively small.

In the second mechanism, we assume that the skeletal muscle cell undergoes a **regulatory volume increase (RVI; see p. 131)**. If the cell responds to the initial 5% shrinkage in 315 mOsm by returning cell volume to its initial level, the cell will gain 15 mOsm of NaCl (i.e., adding 7.5 mM of Na^+ and 7.5 mM of Cl^-). Note that the normal $[Cl^-]_i$ in mammalian skeletal muscle is only ~4.2 mM (see Table 6-1) and E_{Cl} is -89 mV (see Fig. 6-10). Thus, $[Cl^-]_i$ will rise from 4.2 mM to $(4.2 + 7.5) = 11.7$ mM, which is sufficient to shift E_{Cl} from -89 mV to -61 mV. Because the Cl^- conductance of skeletal muscle is high (approximately one half of total membrane conductance), this shift in E_{Cl} will cause a major depolarization of skeletal muscle and thereby promote the efflux of K^+ into the ECF, contributing in a major way to hyperkalemia.

*In fact, V_m probably would shift slightly in the negative direction, inasmuch as V_m depends on the K^+ gradient. Thus, the increase in outward K^+ driving force would be less than in this example.

The kidney excretes K^+ by a combination of filtration, reabsorption, and secretion

At a normal glomerular filtration rate and at physiological levels of plasma $[K^+]$, the kidney filters ~800 mmol/day of K^+ , far more than the usual dietary intake of 60 to 80 mmol/day. Therefore, to achieve K^+ balance, the kidneys normally need to excrete 10% to 15% of the filtered K^+ . Under conditions of low dietary K^+ intake, the kidneys excrete 1% to 3% of filtered K^+ , so that—with a normal- or low- K^+ diet—the kidneys could in principle achieve K^+ balance by *filtration* and *reabsorption* alone. Considering only the filtered K^+ load and external K^+ balance, we would have no reason to suspect that the kidneys would be capable of K^+ secretion. However, with a chronic high intake of dietary K^+ , when the kidneys must rid the body of excess K^+ , urinary K^+ excretion may exceed 150% of the total amount of filtered K^+ . Therefore, even if the tubules reabsorb none of the filtered K^+ , they must be capable of secreting an amount equivalent to at least 50% of the filtered K^+ load.

As discussed below, even in the absence of a large dietary K^+ load, K^+ *secretion* by the tubules is an important component of urinary K^+ excretion. Therefore, K^+ handling is a complex combination of K^+ filtration at the glomerulus as well as both K^+ reabsorption and secretion by the renal tubules.

Potassium Transport by Different Segments of the Nephron

The proximal tubule reabsorbs most of the filtered K^+ , whereas the distal nephron reabsorbs or secretes K^+ , depending on K^+ intake

Figure 37-5 summarizes the pattern of K^+ transport along the nephron under conditions of low or normal/high K^+ intake. In either case, the kidney filters K^+ in the glomerulus and then extensively reabsorbs it along the proximal tubule (~80%) and the loop of Henle (~10%), so that only ~10% of the filtered K^+ enters the distal convoluted tubule (DCT). Moreover, in either case, the **medullary collecting duct (MCD)** reabsorbs K^+ . The K^+ handling depends critically on dietary K^+ in five nephron segments: the DCT, the connecting tubule (CNT), the initial collecting tubule (ICT), the cortical collecting tubule (CCT), and the MCD.

A LOW DIETARY K^+ INTAKE

B NORMAL TO HIGH DIETARY K^+ INTAKE

FIGURE 37-5 K^+ handling along the nephron. In **A** and **B**, the numbered yellow boxes indicate the fraction of the filtered load that various nephron segments reabsorb, whereas the red box in **B** indicates the fraction of the filtered load secreted by the ICT and CCT. The green boxes indicate the fraction of the filtered load that remains in the lumen at these sites. The values in the boxes are approximations that reflect the joint contributions of both juxtamedullary and superficial nephrons.

Low Dietary K^+

Normal or High Dietary K^+

When the body is trying to conserve K^+ , the “classic distal tubule” (i.e., DCT, CNT, and ICT) and CCT all reabsorb K^+ , so that only a small fraction of the filtered load (1% to 3%) appears in the urine (see Fig. 37-5A). In states of K^+ depletion, this additional K^+ reabsorption can be lifesaving by retrieving from the tubule lumen precious K^+ that escaped reabsorption along the proximal tubule and loop of Henle. Despite the degree to which the kidneys can enhance K^+ reabsorption, they cannot restrict K^+ loss in the urine as effectively as they can restrict Na^+ loss. Therefore, a negative K^+ balance and hypokalemia may develop when K^+ intake has been abnormally low for prolonged periods of time.

When external K^+ balance demands that the kidneys excrete K^+ , the ICT, CCT, and the more proximal portion of the MCD secrete K^+ into the tubule lumen (see Fig. 37-5B). Together, these segments, known as the **distal K^+ secretory system**, account for most of the urinary excretion of K^+ . It is also this distal K^+

secretory system that responds to many stimuli that modulate K^+ excretion. Even at normal rates of K^+ excretion (10% to 15% of the filtered load), the proximal tubules and loop of Henle first absorb very large amounts of K^+ (~90% of the filtered load), so that the K^+ appearing in the urine may largely represent K^+ secreted by more distal segments of the nephron.

Medullary trapping of K^+ helps to maximize K^+ excretion when K^+ intake is high

The kidney traps K^+ in the medullary interstitium, with the interstitial $[K^+]$ being highest at the tip of the papilla and falling toward the cortex. This **medullary K^+ trapping** is the result of three steps along the nephron. First, because interstitial $[K^+]$ rises toward the tip of the papilla, **juxtamedullary nephrons**, whose long loops of Henle dip into the inner medulla ([p. 724](#)), secrete K^+ *passively* into the thin descending limb of the loop of Henle (tDLH). Indeed, analysis of fluid collected from the hairpin bend of the long loops of Henle of juxtamedullary nephrons shows that the amount of K^+ delivered to the collection site at the hairpin bend can exceed not only the amount of K^+ present at the end of the proximal tubule, but also the amount of K^+ filtered. This K^+ secretion by the tDLH is the *first step* of a process known as **medullary K^+ recycling** ([Fig. 37-6](#)).

FIGURE 37-6 Medullary recycling of K^+ by juxtamedullary nephrons. IMCD, inner medullary collecting duct; OMCD, outer medullary collecting duct.

The second step of medullary K^+ recycling is K^+ reabsorption by the thin (tALH) and thick (TAL) ascending limbs, which deposit K^+ in the medullary interstitium. This newly deposited interstitial K^+ contributes to the high interstitial $[K^+]$. Together, the tALH and TAL of a juxtamedullary loop reabsorb more K^+ than the *descending* limb secretes, so that net K^+ reabsorption occurs along the loop and thereby contributes to medullary K^+ trapping.

The third step of medullary K^+ recycling is the reabsorption of K^+ by the MCDs. Regardless of whether the distal K^+ -secretory system (ICT, CCT, early MCD) reabsorbs K^+ (see [Fig. 37-5A](#)) or secretes K^+ (see [Fig. 37-5B](#)), the *medullary* collecting ducts reabsorb some K^+ and thereby contribute to medullary K^+ trapping.

One would think that—with respect to K^+ excretion—medullary K^+ recycling is inefficient because K^+ exits the ascending limb and MCD only to re-enter the nephron upstream, in the tDLH. However, medullary recycling and concomitant K^+ trapping may be important in maximizing the excretion of K^+ when K^+ intake is high. Under these conditions, K^+ secretion by the distal K^+ -secretory system is intense, so that luminal $[K^+]$ in the MCD may rise to ≥ 200 mM. Thus, enhanced K^+ trapping in the medullary interstitium minimizes the $[K^+]$ difference between the MCD lumen and its peritubular environment, thus reducing the passive loss of K^+ from the MCD.

Potassium Transport at the Cellular and Molecular Levels

Passive K^+ reabsorption along the proximal tubule follows Na^+ and fluid movements

The proximal tubule reabsorbs most of the filtered K^+ , a process occurring via two paracellular mechanisms (Fig. 37-7A): electrodiffusion and solvent drag. The passive paracellular reabsorption of K^+ by **electrodiffusion** (pp. 146–147) is very dependent on the luminal $[K^+]$ and transepithelial voltage (V_{te}). Water reabsorption tends to increase $[K^+]$ in the lumen, generating a favorable transepithelial gradient that drives passive absorption by diffusion across the paracellular pathway from lumen to blood. Moreover, as fluid flows down the proximal tubule, V_{te} shifts from lumen negative to lumen positive (see Table 35-1 and p. 759), which also favors K^+ reabsorption by electrodiffusion via the low-resistance paracellular pathway.

FIGURE 37-7 Cellular models of K^+ transport along the nephron.

In addition, some K^+ may be reabsorbed by solvent drag (p. 467) across tight junctions. The greater the

fluid reabsorption along the proximal tubule, the greater the reabsorption of K^+ via both electrodiffusion and solvent drag. Indeed, one of the distinguishing features of proximal-tubule K^+ reabsorption is its strong dependence on net fluid reabsorption. Thus, interventions that depress fluid reabsorption almost always inhibit K^+ reabsorption.

Although the proximal tubule reabsorbs K^+ via paracellular pathways, the proximal tubule has several cellular pathways for K^+ movement that do not directly participate in K^+ reabsorption (see Fig. 37-7A): (1) a basolateral Na-K pump, a feature common to all tubule cells; (2) apical and basolateral K^+ channels; and (3) a basolateral K/Cl cotransporter (KCC).

The K^+ conductance of the basolateral membrane greatly exceeds that of the apical membrane, and it appears that different channels are responsible for the K^+ conductances in these two membranes. The open probability of the *basolateral* K^+ channel increases sharply with the turnover rate of the Na-K pump. Accordingly, most of the K^+ taken up via the Na-K pump recycles across the basolateral membrane via K^+ channels and a KCC, and does not appear in the lumen. This basolateral K^+ channel belongs to the class of inwardly rectifying K^+ channels—ROMK—characterized by ATP sensitivity: a decrease in $[ATP]_i$ enhances channel activity (p. 198). This regulation by $[ATP]_i$ is most likely involved in the coupling between basolateral Na-K pumps and K^+ channels. An increase in pump rate—which could occur when increased apical Na^+ entry increases $[Na^+]_i$ —would lower $[ATP]_i$, relieving inhibition of the K^+ channels. Were it not for this crosstalk between the basolateral Na-K pump and apical K^+ channels, the K^+ content of proximal-tubule cells would fluctuate dramatically during alterations in net Na^+ transport.

In contrast to the high state of activity of the basolateral K^+ channels, *apical* K^+ channels are largely quiescent under normal conditions. They appear to become active, however, when tubule cells swell, possibly when entry of Na^+ from the lumen increases rapidly, such as by Na/glucose cotransport. These channels, which may respond to membrane stretch, then allow K^+ to leave the cell, hyperpolarizing the apical membrane and thereby sustaining the driving force for inward Na/glucose cotransport.  **N37-4**

N37-4

Absence of Transcellular K^+ Reabsorption in the Proximal Tubule

Contributed by Gerhard Giebisch, Erich Windhager, Peter Aronson

Even if the apical K^+ channels were open more often, uptake of K^+ across the apical membrane would not occur, because the electrochemical K^+ gradient favors K^+ movement from cell to lumen. Because K^+ cannot enter across the apical membrane, no transcellular reabsorption of K^+ can take place. Thus, proximal-tubule K^+ reabsorption must occur exclusively via the paracellular pathway.

K^+ reabsorption along the TAL occurs predominantly via a transcellular route that exploits secondary active Na/K/Cl cotransport

As discussed on page 796, the **tDLH** of the loops of Henle, particularly those originating from juxtamedullary nephrons, *secrete* K^+ (see Fig. 37-6). This secretion of K^+ from the medullary interstitium into the tDLH lumen is passive, driven by the high $[K^+]$ of the medullary interstitium and made possible by a substantial K^+ permeability. Both the tDLH lumen and the interstitium become increasingly K^+ rich

toward the tip of the papilla.

In the tALH, K^+ moves from lumen to interstitium passively, via the paracellular pathway. The major driving force for this passive reabsorption of K^+ is the lumen-to-interstitium K^+ gradient, which becomes progressively larger as the fluid moves toward the cortex because interstitial $[K^+]$ becomes progressively lower toward the cortex.

The TAL of the loop of Henle reabsorbs K^+ predominantly by a transcellular mechanism (see Fig. 37-7B). The lumen-positive V_{te} (pp. 757–758), **N37-9** together with the relatively high paracellular K^+ permeability, could in principle allow passive K^+ reabsorption to occur via the *paracellular* pathway. However, the high interstitial $[K^+]$ due to medullary K^+ trapping opposes this process. Thus, it is uncertain how much K^+ the TAL reabsorbs via the paracellular pathway.

N37-9

Electrical Profile Across an Epithelial Cell in the TAL

Contributed by Emile Boulpaep, Walter Boron

Figure 5-20B shows the electrical profile typical of a cell from the renal proximal tubule. There, V_{te} (the transepithelial potential difference) is -3 mV with reference to the interstitial space because the membrane potential of -67 mV across the apical membrane (V_a) is *less negative* than the membrane potential of -70 mV across the basolateral membrane (V_{bl}).

The situation in the TAL is a right-to-left mirror image of that in Figure 5-20B. A typical V_{te} in the TAL would be $+15$ mV (see Table 35-1) with reference to the interstitial space. The reason for this lumen-positive V_{te} is that the membrane potential across the apical membrane (e.g., -70 mV) is *more negative* than the membrane potential across the basolateral membrane (e.g., -55 mV).

Most of the K^+ reabsorption by the TAL occurs via a *transcellular* pathway using the apical NKCC2 (p. 122). The major evidence for such a mechanism is the mutual interdependence of Na^+ , Cl^- , and K^+ transport. Removing any of the three cotransported ions from the lumen abolishes transcellular K^+ reabsorption. However, because inhibiting NKCC2 also abolishes the lumen-positive V_{te} (p. 757), this inhibition also blocks passive, paracellular K^+ reabsorption.

The apical NKCC2 is a typical example of a secondary active transporter (p. 115). Expressed in electrical terms, the apical membrane potential is some 10 to 12 mV more positive than the K^+ equilibrium potential, so that K^+ would tend to diffuse passively from cell to lumen. Because the combined inward gradients of Na^+ and Cl^- across the apical membrane greatly exceed that of K^+ , the energy is adequate for the coupled uptake of all three ion species. Ultimately, a primary active transporter (i.e., Na-K pump) at the basolateral membrane drives the secondary active transport of K^+ in the apical membrane. Inhibiting the basolateral Na-K pump leads to an increase in $[Na^+]_i$ and $[Cl^-]_i$, so that apical Na/K/Cl transport ceases. A characteristic feature of NKCC2 is its sensitivity to a class of diuretics that have their main site of action in the TAL. Therefore, administering so-called loop diuretics such as furosemide or bumetanide blocks net reabsorption of Na^+ , Cl^- , and K^+ .

The apical K^+ conductance mentioned above—which mainly reflects ROMK (see Table 6-2, family No. 2) and BK_{Ca} (see Table 6-2, family No. 2)—is also important for the function of NKCC2 (see Fig. 37-7B). The major function of the apical K^+ channel is to provide a mechanism for recycling much of the K^+ from cell to lumen, so that luminal $[K^+]$ does not fall so low as to jeopardize Na/K/Cl cotransport (p.

757). Nevertheless, some of the K^+ entering the cell via NKCC2 exits across the basolateral membrane, which accounts for transcellular K^+ reabsorption. The presence of apical K^+ channels also explains why inhibiting Na/K/Cl cotransport—either with loop diuretics (e.g., furosemide) or by deletion from the lumen of any of the cotransported ions—causes the TAL to engage in net K^+ secretion. Active K^+ uptake no longer opposes the K^+ leak from the cell to lumen.

K^+ secretion by principal and intercalated cells of the ICT and CCT involves active K^+ uptake across the basolateral membrane

The *early* portion of the classic distal tubule (i.e., DCT) secretes K^+ but at a relatively low rate. However, a high rate of K^+ secretion into the tubule fluid is one of the distinguishing features of *late* portions of the classic distal tubule (i.e., CNT and ICT) and of the CCT. Of the two cell types in the ICT and CCT, it is the **principal cell** that is mainly responsible for secretion of K^+ , and it does so by a transcellular process (see Fig. 37-7C). The three key elements of the principal cell are (1) an Na-K pump for active K^+ uptake at the basolateral membrane, (2) a relatively high (and variable) apical K^+ permeability due to the ROMK channel, and (3) a favorable electrochemical driving force for K^+ exit across the apical membrane. In addition, K^+ may move from cell to lumen via an apical KCC (p. 123). The net effects are the active movement of K^+ from blood to cell and the passive movement of K^+ from cell to lumen. Changes in any of the three elements can affect the secretion of K^+ .

States of high luminal flow (e.g., osmotic diuresis, or administration of thiazide or loop diuretic drugs) increase K^+ secretion via a transcellular mechanism involving α - and β -intercalated cells (p. 729) and principal cells.  **N37-5** Most of this flow-dependent K^+ moves from cell to lumen via BK_{Ca} channels, which are more active when luminal flow increases. This flow dependence of K^+ secretion helps explain the urinary K^+ wasting that frequently occurs during states of high distal flow.

N37-5

Basolateral K^+ Uptake by Intercalated Cells

Contributed by Gerhard Giebisch, Peter Aronson

In intercalated cells, basolateral K^+ uptake mainly takes place by Na/K/Cl cotransport. Because these cells have a very low activity of the Na-K pump, a K^+ -independent Na pump may be involved in maintaining the Na^+ gradient needed to drive Na/K/Cl cotransport at the basolateral membrane.

Reference

Liu W, Schreck C, Coleman RA, et al. Role of NKCC in BK channel-mediated net K^+ secretion in the CCD. *Am J Physiol Renal Physiol*. 2011;301:F1088–F1097.

K^+ reabsorption by intercalated cells involves apical uptake via an H-K pump

Ultrastructurally, the ICT and CCT are nearly identical (p. 729); they are made up of ~70% principal

cells (which secrete K^+) and ~30% intercalated cells (some of which reabsorb K^+).

As discussed above, the ICT, CCT, and MCD reabsorb K^+ in response to K^+ depletion (see Fig. 37-5A). This K^+ reabsorption is transcellular (see Fig. 37-7D), mediated by both α - and β -intercalated cells in two steps: (1) an *active step* mediated by an apical ATP-driven H-K pump (pp. 117–118) similar to that present at the apical membrane of parietal cells in gastric glands (pp. 865–866), and (2) a *passive step* mediated by a basolateral K^+ channel, which allows K^+ to leak out. K^+ depletion produces a marked increase in the abundance of H-K pumps, thereby enhancing K^+ reabsorption. However, this increase in H-K pump activity tends to accelerate H^+ secretion, which contributes to the development of hypokalemic alkalosis.

K^+ reabsorption along the MCD is both passive and active

The capacity for K^+ secretion diminishes from the cortical to the MCD. Indeed, the MCD is responsible for K^+ reabsorption, which contributes to medullary K^+ recycling (see Fig. 37-6). This K^+ loss from the MCD lumen can occur by passive movement via the paracellular pathway—which has a significant K^+ permeability—driven by a favorable K^+ concentration gradient. The luminal $[K^+]$ of the MCD is high for two reasons. First, the segments just upstream (i.e., distal K^+ -secretory system) may have secreted K^+ . Second, the continuing reabsorption of fluid in the medullary collecting tubules, particularly in the presence of high arginine vasopressin (AVP) levels, further increases luminal $[K^+]$. In addition to passive K^+ reabsorption, apical H-K pumps (similar to those in intercalated cells, such as the α -intercalated cell in Fig. 37-7D) may mediate active K^+ reabsorption, especially during low K^+ intake.

Regulation of Renal Potassium Excretion

Table 37-2 summarizes factors that modulate K^+ secretion. These may be grouped into luminal and peritubular (i.e., bathing basolateral membrane) factors.

*ICT and CCT, and proximal portion of MCD.

Increased luminal flow increases K^+ secretion

One of the most potent stimuli of K^+ secretion is the rate of fluid flow along the distal K^+ -secretory system (i.e., ICT and CCT). Under almost all circumstances, an increase in luminal flow increases K^+ secretion (Fig. 37-8) and a similar relationship holds between final urine flow and K^+ excretion. Accordingly, the increased urine flow that occurs with extracellular volume expansion, osmotic diuresis, or administration of several diuretic agents (e.g., acetazolamide, furosemide, thiazides) leads to enhanced K^+ excretion —**kaliuresis**.

FIGURE 37-8 Effect of flow (i.e., Na^+ delivery) on K^+ excretion. (Data from Stanton BA, Giebisch G: Renal potassium transport. In Windhager EE [ed]: Handbook of Physiology, Section 8: Renal Physiology. New York, Oxford University Press, 1992, pp 813–874.)

The strong flow dependence of distal K^+ secretion is a consequence of enhancements in both the cell-to-lumen K^+ gradient and apical K^+ permeability of α -intercalated cells (see Fig. 37-7D), β -intercalated cells, and principal cells (see Fig. 37-7C). When luminal flow is low, the movement of K^+ from cell to lumen causes luminal $[\text{K}^+]$ to rise, which opposes further K^+ diffusion from the cell and limits total K^+ secretion. When luminal flow increases and sweeps newly secreted K^+ downstream, the resulting fall in luminal $[\text{K}^+]$ steepens the K^+ gradient across the apical membrane and consequently increases passive K^+ flux from cell to lumen. In addition to producing this enhanced gradient, increased luminal flow activates apical BK_{Ca} channels, which enhances apical K^+ permeability, as noted above (p. 799).

Increased luminal flow also increases the Na^+ delivery to tubule cells, thus raising luminal $[\text{Na}^+]$ and enhancing Na^+ uptake by principal cells (p. 765). This incremental supply of Na^+ to the principal cell stimulates its Na-K pump, increases basolateral K^+ uptake, and further increases K^+ secretion. The Na^+ sensitivity of K^+ secretion is most pronounced when luminal $[\text{Na}^+]$ is $<35 \text{ mM}$, as is often the case in the CCT. Almost uniformly, increased urinary flow is associated with increased Na^+ excretion (natriuresis), so that the urinary excretion of both K^+ and Na^+ increases.

An increased lumen-negative transepithelial potential increases K^+ secretion

The apical step of K^+ secretion in the ICT and CCT occurs by diffusion of K^+ from the principal cell to the lumen, a process that depends on the apical electrochemical K^+ gradient (see Fig. 37-7C). Increases in luminal $[\text{Na}^+]$ —enhancing apical Na^+ entry through **epithelial Na^+ channels (ENaCs)** (pp. 758–759)—

depolarize the apical membrane, favoring the exit of K^+ from cell to lumen (i.e., K^+ secretion). Conversely, a fall in luminal $[Na^+]$ hyperpolarizes the apical membrane, thereby inhibiting K^+ secretion. The diuretic amiloride (pp. 758–759) has the same effect on K^+ secretion as decreasing luminal $[Na^+]$. By blocking apical ENaCs, amiloride hyperpolarizes the apical membrane and reduces the electrochemical gradient for K^+ secretion. Moreover, by inhibiting apical Na^+ entry, amiloride lowers intracellular Na^+ and reduces the activity of the basolateral Na-K pump. Thus, amiloride is a K^+ -sparing diuretic.

Low luminal $[Cl^-]$ enhances K^+ secretion

Lowering luminal Cl^- —replacing it with an anion (e.g., SO_4^{2-} or HCO_3^-) that the tubule reabsorbs poorly—promotes K^+ loss into the urine, independent of changes in the lumen-negative V_{te} . Underlying this effect may be a KCC in the apical membrane of the principal cell of the ICT and CCT (see Fig. 37-7C). Lowering luminal $[Cl^-]$ increases the cell-to-lumen Cl^- gradient, which presumably stimulates K/Cl cotransport, and thus K^+ secretion.  N37-6

N37-6

Paradoxical Inhibition of K^+ Secretion by Thiazide Diuretics in Low- Cl^- States

Contributed by Erich Windhager, Gerhard Giebisch

As noted on pages 799–800, K^+ secretion in the distal nephron is strongly flow dependent as a result of the high K^+ permeability of the apical membrane. Figure 37-8 illustrates this effect. Accordingly, all diuretics (e.g., furosemide, thiazides, and acetazolamide) that act proximal to the collecting duct—and thus increase the luminal flow at the level of the collecting duct—enhance K^+ secretion by the collecting duct. Thus, these diuretics enhance K^+ excretion and are termed **kaliuretic agents** (i.e., they are *not* “ K^+ -sparing” diuretics).

An exception to this general rule is the administration of thiazide diuretics in low- Cl^- states (hypochloremia), in which the diuretic *inhibits* K^+ secretion. The basis of this paradox is that because luminal $[Cl^-]$ is low all along the nephron—including the CCT—the apical K/Cl cotransporter (KCC) in the CCT (see Fig. 37-7C) makes an unusually large contribution to K^+ secretion in a low- Cl^- state. When a patient with hypochloremia takes a thiazide diuretic, the drug inhibits the Na/Cl cotransporter (NCC) in the apical membrane of the DCT, which is illustrated in Figure 35-4C. As a result, luminal $[Cl^-]$ is higher than it otherwise would be in the DCT and also downstream in the CCT. In the CCT, the higher-than-otherwise luminal $[Cl^-]$ now acts as a brake on the apical KCC, thereby decreasing K^+ secretion.

Aldosterone increases K^+ secretion

Both mineralocorticoids (p. 1026) and glucocorticoids (pp. 1018–1019) cause kaliuresis. Primary hyperaldosteronism leads to K^+ wasting and hypokalemia, whereas adrenocortical insufficiency (i.e., deficiency of both mineralocorticoids and glucocorticoids) leads to K^+ retention and hyperkalemia.

Mineralocorticoids

Aldosterone, the main native mineralocorticoid, induces K^+ secretion in the ICT and CCT, **N37-7** particularly when its effects are prolonged. Aldosterone and desoxycorticosterone acetate (DOCA), a powerful synthetic mineralocorticoid, increase the transcription of genes that enhance Na^+ reabsorption and, secondarily, K^+ secretion in the *principal cells* of the ICT and CCT (p. 766). Three factors act in concert to promote K^+ secretion. First, over a period of a few hours, aldosterone increases the basolateral K^+ uptake by stimulating the Na-K pump. Over a few days, elevated aldosterone levels also lead to a marked amplification of the area of the basolateral membrane of principal cells, as well as to a corresponding increase in the number of Na-K pump molecules. Conversely, adrenalectomy causes a significant reduction in basolateral surface area and Na-K pumps in principal cells. Second, mineralocorticoids stimulate apical ENaCs (p. 766), thus depolarizing the apical membrane and increasing the driving force for K^+ diffusion from cell to lumen. Third, aldosterone increases the K^+ conductance of the apical membrane.

N37-7

Acute Effects of Intravenous Aldosterone

Contributed by Erich Windhager, Gerhard Giebisch

eFigure 37-1 shows the renal effects of intravenously administered aldosterone. The acute effects include significant decreases in Na^+ and Cl^- excretion, as well as increases in K^+ and NH_4^+ excretion. The reverse changes occur in adrenalectomy, and the administration of **mineralocorticoids** (e.g., aldosterone) promptly reverses these deficiencies.

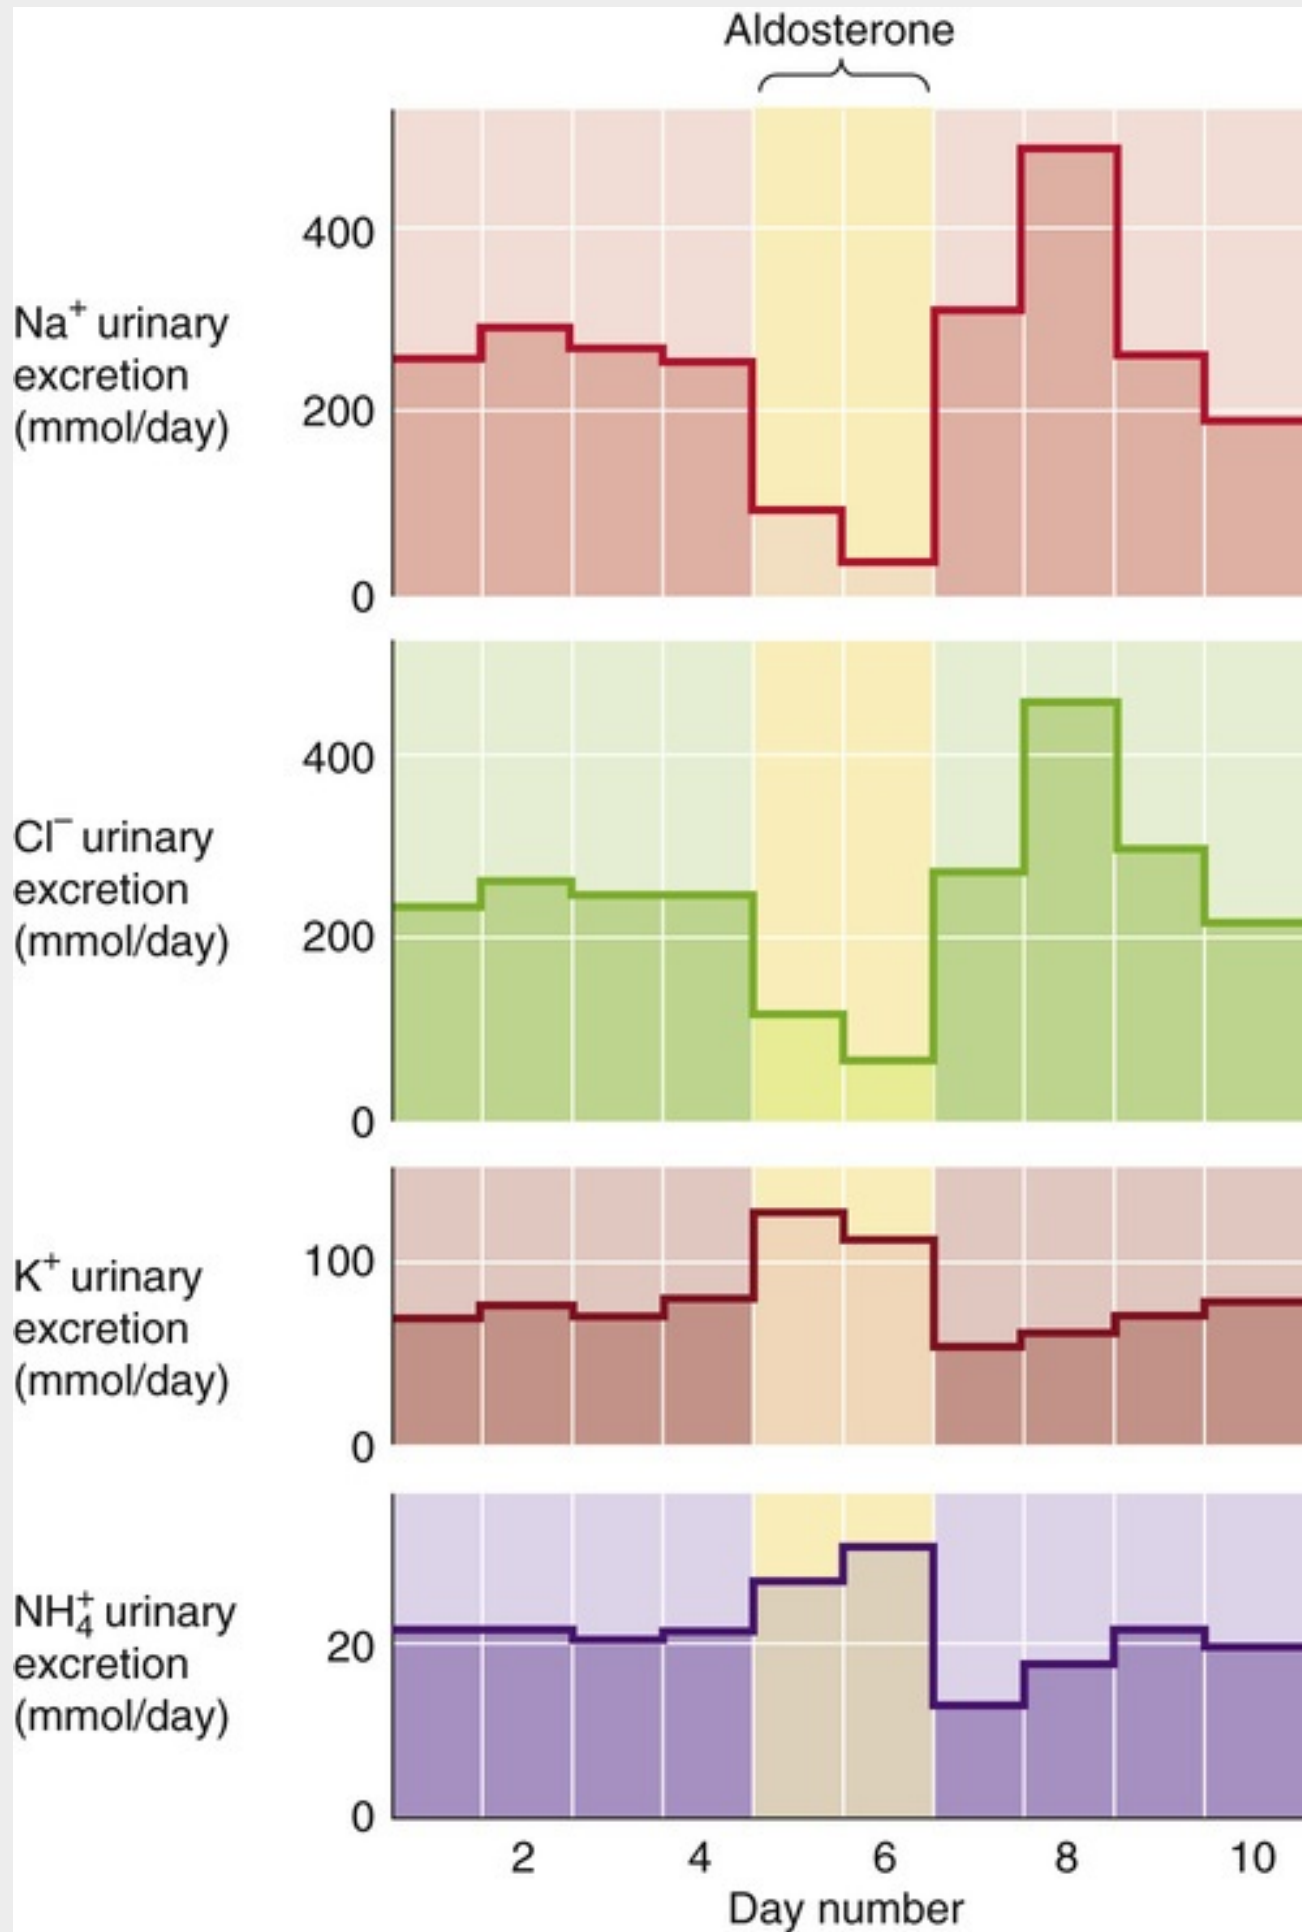

FIGURE 37-1 Acute effects of intravenously administered aldosterone on electrolyte excretion in humans. (Data from Liddle GW: Aldosterone antagonists. *Arch Intern Med* 102:998–1005, 1958.)

Given aldosterone's mechanisms of action, one would think that the renal excretion of K^+ and Na^+ should always be inversely related. However, the extent to which aldosterone increases K^+ excretion depends strongly on Na^+ excretion. For example, when Na^+ intake and excretion are low, the Na^+ retention induced by aldosterone reduces luminal flow and Na^+ delivery to such low levels that K^+ excretion fails to increase. In contrast, under high-flow conditions (e.g., with a high Na^+ load or following administration of diuretics that act on the TAL or the DCT), aldosterone increases K^+ excretion.

Simultaneous elevation of both aldosterone and angiotensin II (ANG II) is another example of a case in which K^+ and Na^+ excretion are not inversely related. In *hypovolemia*, when both ANG II and aldosterone levels are high, intracellular kinases, including WNK4 and SPAK, cause activation of ENaC but inhibition of ROMK, so that Na^+ reabsorption is enhanced without a large increase in K^+ secretion—an appropriate adaptive response that tends to restore Na^+ content with minimal K^+ loss. In contrast, when it is *hyperkalemia* rather than hypovolemia that increases aldosterone secretion ([pp. 1027–1029](#)), ANG II levels do not rise. Here, cell-signaling mechanisms activate both ENaC and ROMK, and appropriately enhance K^+ secretion.

Long-term administration of mineralocorticoids or untreated primary hyperaldosteronism leads to a sequence of events known as aldosterone escape. Aldosterone leads to Na^+ retention and hence volume expansion. Eventually, the volume expansion causes proximal Na^+ reabsorption to fall (see [Fig. 34-10](#)), which increases Na^+ delivery to the ICT and CCT, and ultimately raises Na^+ excretion toward prealdosterone levels. Thus, the kidney can escape the Na^+ -retaining effect of aldosterone, albeit at the price of expanding the extracellular volume and causing *hypertension*. However, the increased Na^+ delivery to the principal cells continues to stimulate K^+ secretion. Once the body has become depleted of K^+ , the aldosterone-stimulated K^+ secretion eventually wanes, and the distal nephron may return to net K^+ reabsorption, but at the price of *continued hypokalemia*.

Glucocorticoids

Under physiological conditions, glucocorticoids enhance K^+ excretion ([Fig. 37-9](#)). Corticosterone and dexamethasone, a synthetic glucocorticoid, produce this effect largely by increasing flow along the distal K^+ -secretory system (i.e., ICT and CCT). Because glucocorticoids increase the glomerular filtration rate and probably lower the water permeability of the distal K^+ -secretory system, they increase the amounts of fluid and Na^+ remaining in these segments. These two flow effects, by themselves, increase K^+ secretion. Indeed, when one perfuses the distal K^+ -secretory system at a *constant rate*, glucocorticoids have no effect on K^+ transport.

In addition, administering unphysiologically high doses of glucocorticoids may stimulate K^+ transport directly as glucocorticoids bind to *mineralocorticoid* receptors, despite the presence of 11β -hydroxysteroid dehydrogenase 2 in aldosterone target cells (p. 766).

Box 37-1

Hyperkalemia and the Heart

An electrocardiogram (ECG)—a measure of the electrical activity of the myocardial cells (pp. 493–496)—can be clinically useful for detecting rising plasma $[K^+]$.

As plasma $[K^+]$ begins to rise (Fig. 37-9, ECG tracing for 6 mM), the T wave becomes tall and peaked, assuming a symmetric, “tenting” shape. The PR interval becomes prolonged, and the P wave gradually flattens. Eventually, the P wave disappears (see Fig. 37-9, tracing for 8 mM). Moreover, the QRS complex, which represents depolarization of the ventricles, widens and merges with the T wave, forming a sine-wave pattern. At higher concentrations, ventricular fibrillation, a lethal arrhythmia, may develop (see Fig. 37-9, tracing for 10 mM). These ECG changes do not always occur in this precise order, and some patients with hyperkalemia may progress very rapidly to ventricular fibrillation. Any change in the ECG resulting from hyperkalemia requires immediate clinical attention.

Decreases in plasma $[K^+]$ also affect the ECG. For example, moderate decreases in $[K^+]$ to ~3 mM cause the QT interval to lengthen and the T wave to flatten. Lower values of $[K^+]$ lead to the appearance of a U wave (see Fig. 37-9, tracing for 1.5 mM), which represents the delayed repolarization of the ventricles. The most severe manifestation of hypokalemia is ventricular tachycardia or fibrillation (not shown).

Box 37-2

Clinical Implications

Evaluating Hypokalemia and Hyperkalemia in the Patient

We can directly apply the physiological principles discussed in this chapter to understanding the common causes and treatment of hypokalemia and hyperkalemia.

Hypokalemia

The body can lose K^+ from three sites: the kidneys, the GI tract, and the skin. Renal losses occur most commonly in patients taking diuretics (e.g., furosemide and thiazides) that act at sites upstream to the distal K^+ -secretory system (i.e., ICT, CCT, and proximal portion of MCD). K^+ losses can also occur in individuals with renal tubule disorders or alterations in the renin-angiotensin-aldosterone system (e.g., hyperaldosteronism). Because intestinal secretions have a high $[K^+]$, severe diarrhea is a common cause of hypokalemia. Significant K^+ depletion through the skin can occur in two situations: (1) strenuous exercise on a hot, humid day can cause dehydration and hypokalemia from the loss of many liters of perspiration; and (2) severe and extensive burns can result in the transudation of vast amounts of K^+ -containing fluid through the skin. In both cases, the lost fluid is K^+ rich compared with plasma.

Low plasma $[K^+]$ can also develop as the result of altered K^+ distribution within the body without any net loss of whole-body K^+ . Common causes include alkalosis, a catecholamine surge (e.g., as during any acute stress to the body, such as an acute myocardial infarction), and insulin administration without K^+ repletion during the treatment of diabetic ketoacidosis.

Patients may develop hypokalemia because of inadequate dietary K^+ intake. Patients receiving large amounts of intravenous saline (which lacks K^+) may also waste K^+ . Some persons in rural areas ingest clay (a behavior called pica), which binds K^+ in the GI tract and prevents K^+ absorption.

Hyperkalemia

Probably the most common cause of a high laboratory value for plasma $[K^+]$ is **pseudohyperkalemia**, a falsely elevated value that results from traumatic hemolysis of red blood cells during blood drawing. Red blood cells release their intracellular stores of K^+ in the blood sample, and the laboratory reports a falsely elevated plasma $[K^+]$. Patients with myeloproliferative disorders associated with greatly increased numbers of platelets or white blood cells can also show a falsely elevated $[K^+]$ because of K^+ released during clot formation within the blood-sample tube.

Excessive intake of K^+ rarely causes hyperkalemia in persons with healthy kidneys. However, even in these individuals, a large K^+ bolus can cause transient hyperkalemia (see Fig. 37-2, top panel), often from ill-advised use of an inappropriate intravenous fluid. Altered distribution of K^+ can lead to elevated plasma levels in patients with acidosis and, rarely, as a result of β -adrenergic blockade. Intoxication with digitalis, a cardiac glycoside that inhibits the Na-K pump (p. 117), is another rare cause of hyperkalemia resulting from K^+ redistribution. Massive breakdown of cells can release large amounts of K^+ into the extracellular space. This release can occur in patients with intravascular hemolysis (e.g., from a mismatched blood transfusion), burns, crush injuries, rhabdomyolysis (massive muscle destruction such as can be seen with trauma or sepsis), GI bleeding with subsequent intestinal absorption of K^+ -rich fluid, or destruction of tumor tissue or leukemic blood cells by chemotherapy.

Impaired renal excretion of K^+ is the primary cause of a sustained increase in plasma $[K^+]$. Hypoaldosteronism  **N37-8** and high doses of amiloride can be responsible, but advanced renal failure itself, from any myriad of disorders, is the most common cause.

The treatment of hyperkalemia depends on the severity of the problem. For severe hyperkalemia (i.e., $[K^+] > 8$ mM) with accompanying ECG changes, the physician immediately infuses calcium gluconate intravenously to counter the electrophysiological effects of the hyperkalemia. (Ca^{2+} raises the threshold for action potentials and lessens membrane excitability). The simultaneous administration of glucose and insulin leads to the uptake of some of the K^+ from the extracellular to the intracellular space. In addition, if the patient is acidotic, administration of $NaHCO_3$ can promote cellular uptake of K^+ . These are all temporizing measures. To remove the excess K^+ from the body, the physician administers an oral nonabsorbable Na-K cation exchange resin (e.g., sodium polystyrene sulfonate). The resin binds the K^+ and carries it out of the body via the GI tract. However, the resin takes several hours to work. Thus, for patients with hyperkalemia and ECG changes, the temporizing measures buy time for the resin to act. For patients with renal failure, dialysis is often necessary to return the plasma $[K^+]$ to normal.

High K^+ intake promotes renal K^+ secretion

Dietary K^+ Loading

An increase in dietary K^+ intake causes, after some delay, an increase in urinary K^+ excretion (see Fig. 37-5B). If the period of high- K^+ intake is prolonged, a condition of tolerance (K^+ adaptation) develops in

which the kidneys become able to excrete large doses of K^+ —even previously lethal doses—with only a small rise in plasma $[K^+]$.

The kaliuresis following an acute or chronic K^+ load is the result of increased K^+ secretion in the ICT and CCT (compare the three curves in [Fig. 37-8](#) at a single flow), a process that occurs by three mechanisms. First, a transient rise in plasma $[K^+]$, even if maintained for only short periods, is an effective stimulus for K^+ excretion. The mechanism is increased K^+ uptake across the basolateral membrane of principal cells by the Na-K pump, a response shared by most of the cells of the body. As is the case with mineralocorticoid stimulation, the ultrastructure of the ICT and CCT correlates with changes in the rate of K^+ transport induced by high dietary K^+ . Therefore, a high- K^+ diet—independent of the effects of aldosterone—causes surface amplification of the basolateral membrane of principal cells. Second, the increased plasma $[K^+]$ stimulates glomerulosa cells in the adrenal cortex to synthesize and release aldosterone ([p. 1028](#)). This mineralocorticoid is a potent stimulus for K^+ secretion both in the kidney by principal cells ([p. 799](#)) and in the colon ([p. 909](#)). Third, acute K^+ loading inhibits proximal Na^+ and fluid reabsorption and increases flow and Na^+ delivery to the distal K^+ -secretory system, processes that stimulate K^+ secretion. In addition, independent of a rise in plasma K^+ or aldosterone, dietary K^+ ingestion can stimulate renal K^+ excretion, which suggests a feed-forward mechanism, perhaps involving the sensing of ingested K^+ by the gut, and the release of humoral factors.

Dietary K^+ Deprivation

In response to K^+ restriction, the kidneys retain K^+ (see [Fig. 37-5A](#)). The rate of urinary K^+ excretion may fall to 1% to 3% of the filtered load, via three mechanisms.

First, the low plasma $[K^+]$ suppresses K^+ secretion by the principal cells in the ICT and CCT (see [Fig. 37-8](#), lower curve) both by reducing basolateral K^+ uptake by principal cells and by reducing aldosterone secretion.

Second, low plasma $[K^+]$ stimulates K^+ reabsorption via H-K pumps of intercalated cells of the ICT and CCT (see [Fig. 37-7D](#)). Whereas states of high K^+ secretion (i.e., aldosterone or high- K^+ diet) amplify the basolateral membrane area of principal cells, K^+ deprivation amplifies the *apical* membrane of α -*intercalated* cells. Moreover, K^+ depletion causes an increased incorporation of rod-shaped particles (presumably representing H-K pumps) in the apical membrane of α -intercalated cells, and the density of these particles correlates well with enhanced K^+ reabsorption.

Third, the MCD responds to K^+ depletion by increasing its reabsorption of K^+ by enhancing both the activity of its apical K-H pump and its paracellular K^+ permeability. As a result, the $[K^+]$ of the final urine falls sharply, sometimes to levels below that of the plasma. Nevertheless, when the diet is extremely low in K^+ , it may be impossible to maintain K^+ balance and a normal plasma $[K^+]$ because urinary K^+ excretion cannot fall to less than ~15 meq/day.

Acidosis decreases K^+ secretion

Acid-base disturbances have marked effects on renal K^+ transport. In general, either metabolic alkalosis ([p. 635](#)) or respiratory alkalosis ([p. 634](#)) leads to increased K^+ excretion. Conversely, acidosis reduces K^+ excretion, although this response is more variable than that to alkalosis. Changes in systemic acid-base parameters affect K^+ transport mainly by acting on the distal K^+ -secretory system.

Alkalosis leads to hypokalemia ([p. 794](#)), owing to K^+ uptake by cells throughout the body. Despite this fall in plasma $[K^+]$, alkalosis *stimulates* K^+ secretion in the distal K^+ -secretory system, thereby worsening the hypokalemia. Conversely, K^+ secretion falls acutely in acidosis despite the shift of K^+ from cells to

ECF and the concomitant rise in plasma $[K^+]$.

The cellular events underlying the renal response to acid-base disturbances most likely involve effects of pH_i on both the basolateral Na-K pump and the apical K^+ channels of the principal cells in the ICT and CCT. Tubule perfusion studies with ^{42}K indicate that decreasing basolateral pH—which also decreases pH_i —inhibits the Na-K pump and thus K^+ secretion. A fall in pH_i also inhibits ENaC activity. Even more important is that the decrease in pH_i also markedly decreases the open probability of apical ROMK (p. 198) K^+ channels (Fig. 37-10). The reverse changes occur in alkalosis.

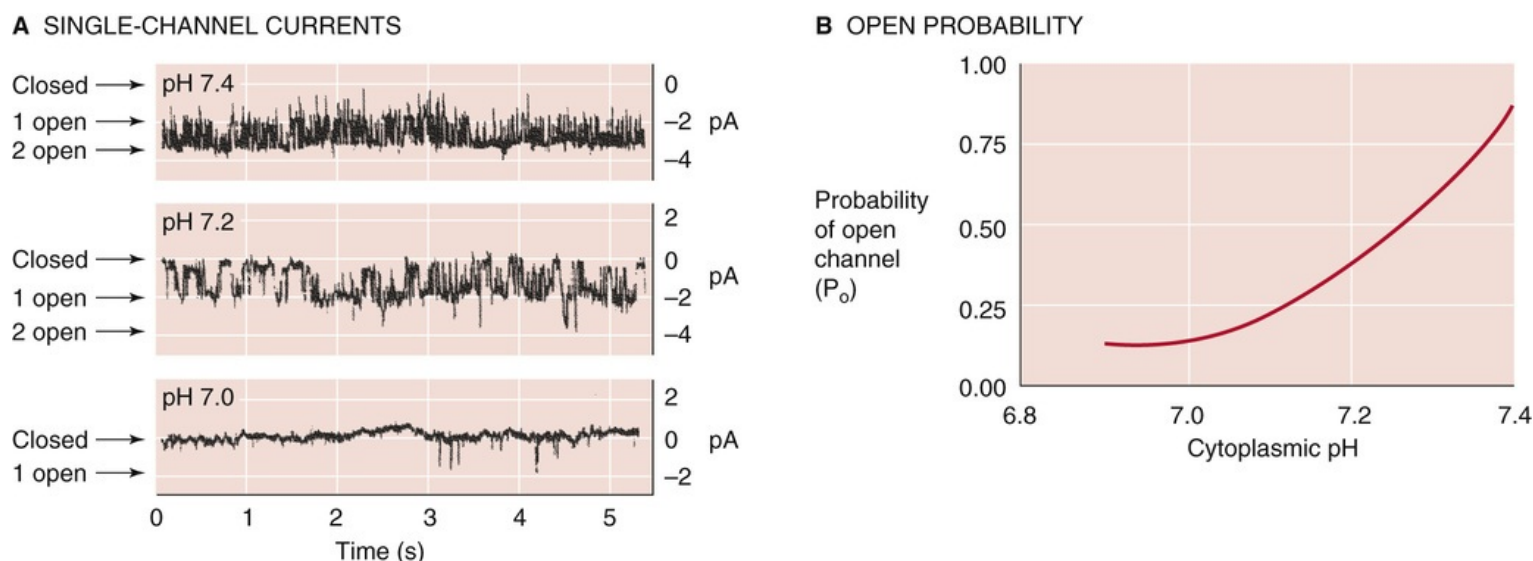

FIGURE 37-10 Effect of intracellular acidosis on K^+ channel activity in the apical membrane of a principal cell. In **A**, the recordings show single channel K^+ currents from inside-out patches, with different pH values on the “cytoplasmic” side. As shown in **B**, channels are almost never open at pH values of 7.0 or below. (Data from Wang W, Geibel J, Giebisch G: Regulation of small conductance K channel in the apical membrane of rat cortical collecting tubule. *Am J Physiol* 259:F494–F502, 1990.)

Changes in tubule flow (i.e., fluid delivery to the distal K^+ -secretory system) that occur in acid-base disturbances may modulate the effects of pH changes per se. For example, metabolic alkalosis increases the flow by delivering an HCO_3^- -rich solution to the ICT and CCT. By itself, this increased flow enhances K^+ secretion and thus *potentiates* the effect of alkalosis per se. Acidosis also increases distal flow, but in this case by inhibiting proximal fluid reabsorption, with the consequence that the tendency of increased flow to increase K^+ secretion *opposes* the effect of acidosis per se to decrease it. Indeed, chronic acidosis, as with inherited renal tubule defects in acid secretion, tends to cause renal K^+ wasting and hypokalemia (see Box 37-2).

Epinephrine reduces and AVP enhances K^+ excretion

By both extrarenal and renal mechanisms, **epinephrine** lowers K^+ excretion. First, epinephrine enhances K^+ uptake by extrarenal tissues (p. 794), thereby lowering plasma $[K^+]$ and reducing the filtered K^+ load. Second, catecholamines directly inhibit K^+ secretion in nephron segments downstream of the ICT.

Although it is not a major regulator of K^+ excretion, AVP (also known as antidiuretic hormone, or ADH) can stimulate the distal K^+ -secretory system by two mechanisms (see Fig. 37-7C): (1) AVP increases the apical Na^+ conductance, thus depolarizing the apical membrane and providing a larger driving force for K^+ efflux from cell to lumen; and (2) AVP increases apical K^+ permeability. However,

AVP also reduces urine flow, and thus inhibits K^+ secretion. Therefore, the two opposing effects—a direct stimulation of K^+ secretion and a flow-related reduction of K^+ secretion—may cancel each other.

Opposing factors stabilize K^+ secretion

The net effect of a specific disturbance on K^+ excretion in the final urine often represents a result of two or more interacting factors. Changes in flow often indirectly amplify or attenuate the direct response of the distal K^+ -secretory system to a given stimulus.

Attenuating Effects

Figure 37-11 shows four examples of disturbances affecting K^+ excretion, the first three of which (acidosis, volume expansion, and high water intake) are characterized by the competition between a direct inhibitory effect on K^+ secretion and an indirect stimulatory effect of increased flow (see Fig. 37-11A–C). The fourth example, extracellular volume contraction (see Fig. 37-11D), also has two effects on K^+ secretion. First, volume contraction increases ANG II levels, which in turn *increases* aldosterone release and hence K^+ secretion. However, the combination of high angiotensin with high aldosterone (p. 801) may lower ROMK activity, resulting in less K^+ secretion than when aldosterone alone is elevated. Second, hypovolemia decreases distal flow and distal Na^+ delivery, which inhibits the distal K^+ -secretory system. Thus, during hypovolemia, K^+ excretion tends to remain constant despite the high aldosterone level.

FIGURE 37-11 Effects of interaction of opposing factors on K^+ secretion. GFR, glomerular filtration rate.

Additive Effects

In the following three examples, the direct actions of an agent and flow-related effects are additive.

First, metabolic alkalosis—as discussed—directly stimulates the distal K^+ -secretory system. In addition, the delivery of the poorly reabsorbable HCO_3^- in metabolic alkalosis increases distal flow, thereby potentiating K^+ excretion.

Second, hyperkalemia directly stimulates the distal K^+ -secretory system. In addition, because increased plasma $[K^+]$ inhibits Na^+ and fluid reabsorption in the proximal tubule, distal flow increases, again potentiating K^+ excretion.

Third, administration of diuretics that act on a site upstream of the ICT and CCT increases Na^+ delivery to the distal K^+ -secretory system and thereby stimulates K^+ secretion. In addition, the volume contraction induced by the diuretic raises aldosterone levels, which again potentiates K^+ excretion. Hypokalemia is thus a possible harmful side effect of diuretic treatment.

Water Balance and the Overall Renal Handling of Water

The kidney can generate a urine as dilute as 40 mOsm (one seventh of plasma osmolality) or as concentrated as 1200 mOsm (four times plasma osmolality)

In the steady state, water intake and output must be equal ([Table 38-1](#)). The body's three major sources of water are (1) ingested water, (2) water contained in the foods eaten, and (3) water produced by aerobic metabolism as mitochondria convert foodstuffs and O₂ to CO₂ and H₂O (see [p. 1185](#)).

TABLE 38-1
Input and Output of Water

Input	
SOURCE	AMOUNT (mL)
Ingested fluids	1200
Ingested food	1000
Metabolism	300
Total	2500
Output	
ROUTE	AMOUNT (mL)
Urine	1500
Feces	100
Skin/sweat	550
Exhaled air	350
Total	2500

Modified from Valtin H: Renal Dysfunction: Mechanisms Involved in Fluid and Solute Imbalance. Boston, Little, Brown, 1979, p 21.

The major route of water loss is usually through the kidneys, the organs that play the central role in regulating water balance. The feces are usually a minor route of water output (see [p. 901](#)). Although the production of sweat can increase markedly during exercise or at high temperatures, sweat production is geared to help regulate body core temperature (see [p. 1201](#)), not body water balance. Water also evaporates from the skin and is lost in the humidified air exhaled from the lungs and air passages. The figures summarized in [Table 38-1](#) will obviously vary, depending on diet, physical activity, and the environment (e.g., temperature and humidity).

The kidney adjusts its water output to compensate for either abnormally high or abnormally low water intake, or for abnormally high water losses via other routes. The kidney excretes a variable amount of solute, depending especially on salt intake. However, with consumption of a normal diet, the excreted solute is ~600 milliosmoles/day. For average conditions of water and solute intake and output, these 600 milliosmoles are dissolved in a daily urine output of 1500 mL. A key principle is that, regardless of the volume of water they excrete, the kidneys must excrete ~600 milliosmoles/day. Stated somewhat differently, the product of urine osmolality and urine output is approximately constant:

$$\text{Osmoles excreted/day} = \underbrace{U_{\text{Osm}}}_{\text{Urine osmolality}} \times \underbrace{\dot{V}}_{\text{Urine output/day}}$$

(38-1)

Therefore, to excrete a wide range of water volumes, the human kidney must produce urine having a wide range of osmolalities. For example, when the kidney excretes the 600 milliosmoles dissolved in 1500 mL of urine each day, urine osmolality must be 400 milliosmolar (i.e., 400 mOsm):

$$U_{\text{Osm}} = \frac{\text{osmoles excreted/day}}{\dot{V}} = \frac{600 \text{ milliosmoles/day}}{15 \text{ L/day}}$$

$$= 400 \text{ mOsm}$$

(38-2)

When the intake of water is especially high, the human kidney can generate urine having an osmolality as low as ~40 mOsm. Because the kidneys must still excrete 600 milliosmoles of solutes, the urine volume in an extreme **water diuresis** would be as high as ~15 L/day.

$$\dot{V} = \frac{\text{osmoles excreted/day}}{U_{\text{Osm}}} = \frac{600 \text{ milliosmoles/day}}{40 \text{ mOsm}}$$

$$= 15 \text{ L/day}$$

(38-3)

However, when it is necessary to conserve water (e.g., with restricted water intake or excessive loss by sweat or stool), the kidney is capable of generating urine with an osmolality as high as ~1200 mOsm. Therefore, with an average solute load, the minimal urine volume can be as low as ~0.5 L/day:

$$\dot{V} = \frac{\text{osmoles excreted/day}}{U_{\text{Osm}}} = \frac{600 \text{ milliosmoles/day}}{1200 \text{ mOsm}}$$

$$= 0.5 \text{ L/day}$$

(38-4)

Therefore, the kidney is capable of diluting the urine ~7-fold with respect to blood plasma, but it is capable of concentrating the urine only ~4-fold. Renal failure reduces both the concentrating and diluting ability.

Free-water clearance ($C_{\text{H}_2\text{O}}$) is positive if the kidney produces urine that is less concentrated than plasma and negative if the kidney produces urine that is more concentrated than plasma

A urine sample can be thought of as consisting of two moieties: (1) the volume that would be necessary to dissolve all the excreted solutes at a concentration that is isosmotic with blood plasma, and (2) the volume of pure or **solute-free water**—or, simply, **free water**—that one must add (or subtract) to the previous volume to account for the entire urine volume. As discussed below, the kidney generates free water in the tubule lumen by reabsorbing solutes, mainly NaCl, in excess of water along nephron segments with low water permeability. When the kidney generates free water, the urine becomes dilute (hypo-osmotic). Conversely, when the kidney removes water from an isosmotic fluid, the urine becomes concentrated (hyperosmotic). When the kidney neither adds nor subtracts free water from the isosmotic moiety, the urine is isosmotic with blood plasma.

The urine output is the sum of the rate at which the kidney excretes the isosmotic moiety of urine (**osmolal clearance**, C_{Osm}) and the rate at which it excretes free water—**free-water clearance** ($C_{\text{H}_2\text{O}}$):

$$\dot{V} = C_{\text{Osm}} + C_{\text{H}_2\text{O}} \quad (38-5)$$

Of course, $C_{\text{H}_2\text{O}}$ is negative (i.e., excretion of negative free water) if the kidney removes free water and produces a concentrated urine. We compute C_{Osm} in the same way we would compute the clearance of any substance from the blood (see p. 731):

$$C_{\text{Osm}} = \frac{U_{\text{Osm}} \cdot \dot{V}}{P_{\text{Osm}}} \quad (38-6)$$

P_{Osm} is the osmolality of blood plasma. The osmolal clearance is the hypothetical volume of blood that the kidneys fully clear of solutes (or osmoles) per unit time. For example, if the daily solute excretion ($U_{\text{Osm}} \cdot \dot{V}$) is fixed at 600 milliosmoles/day, and P_{Osm} is 300 milliosmoles/L, then Equation 38-6 tells us that C_{Osm} has a fixed value of 2 L/day.

We can obtain the $C_{\text{H}_2\text{O}}$ only by subtraction:

$$C_{\text{H}_2\text{O}} = \dot{V} - C_{\text{Osm}} \quad (38-7)$$

Indeed, $C_{\text{H}_2\text{O}}$ does not conform to the usual definition of “clearance” because $C_{\text{H}_2\text{O}}$ is not $(U_{\text{H}_2\text{O}} \cdot \dot{V})/P_{\text{H}_2\text{O}}$. Nevertheless, this apparent misnomer has been accepted by renal physiologists and nephrologists.  **N38-1**

N38-1

“Effective Osmolal-less” versus “Osmolal-less” Water

Clearance

Contributed by Emile Boulpaep, Walter Boron

In the text, we define **free-water clearance** as the clearance of water that is devoid of *all* solutes. However, if you were interested in how a gain or loss of water would affect cell volume, you would really be interested in the clearance of water that is devoid of *impermeant* or *effective* solutes (see discussion of effective osmolality on pp. 132–133). These effective osmoles do not include **urea** because cells are generally highly permeable to urea, owing to the presence of transport pathways for urea (see p. 770). Therefore, it may be useful to consider the clearance of water that is devoid of all effective osmoles. We will—tongue in cheek—define this as **effective osmolal-less water clearance**, to distinguish it from classical free-water clearance, which is **osmolal-less water clearance**.

Urea can be one of the major contributors to urine osmolality (U_{Osm}) and thus an important contributor to **osmolal clearance** (C_{Osm}):

$$C_{\text{Osm}} = \frac{U_{\text{Osm}} \cdot \dot{V}}{P_{\text{Osm}}} \quad \text{(NE 38-1)}$$

Equation NE 38-1 above is also Equation 38-6. Because urea equilibrates freely across cell membranes, it does not influence the *effective plasma osmolality* ($P_{\text{effective-Osm}}$) nor the distribution of water between cells and the extracellular fluid. Thus, we could convert Equation NE 38-1 to an expression for *effective osmolal* clearance by substituting $U_{\text{effective-Osm}}$ for U_{Osm} and $P_{\text{effective-Osm}}$ for P_{Osm} in Equation NE 38-1. The resulting new expression for **effective osmolal clearance** ($C_{\text{effective-Osm}}$) is

$$C_{\text{effective-Osm}} = \frac{U_{\text{effective-Osm}} \cdot \dot{V}}{P_{\text{effective-Osm}}} \quad \text{(NE 38-2)}$$

Note that in both the numerator and the denominator, we are considering only the *effective osmoles* in urine and plasma.

By analogy to Equation 38-7, the effective osmolal-less water clearance is

$$\begin{aligned} C_{\text{H}_2\text{O}}^* &= \dot{V} - C_{\text{effective-Osm}} && \text{(NE 38-3)} \\ &\text{or} \\ C_{\text{H}_2\text{O}}^* &= \dot{V} - \frac{U_{\text{effective-Osm}} \cdot \dot{V}}{P_{\text{effective-Osm}}} \end{aligned}$$

Because plasma levels of urea are generally quite low (i.e., $P_{\text{effective-Osm}} \cong P_{\text{Osm}}$), the important issue is the extent to which urea contributes to the total osmolality of the urine (i.e., the extent to which U_{Osm} exceeds $U_{\text{effective-Osm}}$).

The range of C_{H_2O} values for the human kidney is related to the extremes in urine osmolality, as shown in the three examples that follow.

Isosmotic Urine

If the osmolalities of the urine and plasma are the *same* ($U_{Osm} = P_{Osm}$), then osmolal clearance equals urine flow:

$$\begin{aligned}C_{Osm} &= \frac{U_{Osm} \cdot \dot{V}}{P_{Osm}} = \frac{300 \text{ milliosmoles/L} \times 2 \text{ L/day}}{300 \text{ milliosmoles/L}} \\&= 2 \text{ L/day} = \dot{V}\end{aligned}\quad (38-8)$$

Therefore, [Equation 38-7](#) tells us that the C_{H_2O} must be zero.

Dilute Urine

If the urine is more dilute than plasma ($\dot{V} > C_{Osm}$), the difference between \dot{V} and C_{Osm} is the **positive** C_{H_2O} . When the kidney *maximally dilutes* the urine to ~40 mOsm, the total urine flow (\dot{V}) must be ~15 L/day, and C_{H_2O} is a positive 13 L/day (see [Equation 38-3](#)):

$$\begin{aligned}C_{H_2O} &= \dot{V} - C_{Osm} \\ \text{Maximal dilution: } C_{H_2O} &= 15 \text{ L/day} - 2 \text{ L/day} \\ &= +13 \text{ L/day}\end{aligned}\quad (38-9)$$

Concentrated Urine

If the urine is more concentrated than plasma ($\dot{V} < C_{Osm}$), then the difference between \dot{V} and C_{Osm} is a negative number, the **negative** C_{H_2O} . When the kidney *maximally concentrates* the urine to 1200 mOsm, the total urine flow must be 0.5 L/day, and C_{H_2O} is a negative 1.5 L/day (see [Equation 38-4](#)):

$$\begin{aligned}C_{H_2O} &= \dot{V} - C_{Osm} \\ \text{Maximal concentration: } C_{H_2O} &= 0.5 \text{ L/day} - 2 \text{ L/day} \\ &= -1.5 \text{ L/day}\end{aligned}\quad (38-10)$$

Thus, the kidneys can generate a C_{H_2O} of as much as +13 L/day under maximally diluting conditions, or

as little as -1.5 L/day under maximally concentrating conditions. This wide range of C_{H_2O} represents the kidneys' attempt to stabilize the osmolality of extracellular fluid in the face of changing loads of solutes or water.

Water Transport by Different Segments of the Nephron

The kidney concentrates urine by driving water via osmosis from the tubule lumen into a hyperosmotic interstitium

The kidney generates *dilute* urine by pumping salts out of the lumen of tubule segments that are relatively impermeable to water. What is left behind is tubule fluid that is hypo-osmotic (dilute) with respect to the blood.

How does the kidney generate *concentrated* urine? One approach could be to pump water actively out of the tubule lumen. However, water pumps do not exist (see [pp. 127–128](#)). Instead, the kidney uses osmosis as the driving force to concentrate the contents of the tubule lumen. The kidney generates the osmotic gradient by creating a hyperosmotic interstitial fluid in a confined compartment, the renal medulla. The final step for making a hyperosmotic urine—controlled by regulated water permeability—is allowing the lumen of the medullary collecting duct (MCD) to equilibrate with the hyperosmotic interstitium, resulting in a concentrated urine.

Although net absorption of H_2O occurs all along the nephron, not all segments alter the osmolality of the tubule fluid. The proximal tubule, *regardless of the final osmolality of the urine*, reabsorbs two thirds of the filtered fluid isosmotically (i.e., the fluid reabsorbed has nearly the same osmolality as plasma). The loop of Henle and the distal convoluted tubule (DCT) reabsorb salt in excess of water, so that the tubule fluid leaving the DCT is hypo-osmotic. *Whether the final urine is dilute or concentrated* depends on whether water reabsorption occurs in more distal segments: the initial and cortical collecting tubules (ICT and CCT) and the outer and inner medullary collecting ducts (OMCD and IMCD). **Arginine vasopressin (AVP)**—also called **antidiuretic hormone (ADH)**—regulates the variable fraction of water reabsorption in these four nephron segments. [Figure 13-9](#) shows the structure of AVP.

Tubule fluid is isosmotic in the proximal tubule, becomes dilute in the loop of Henle, and then either remains dilute or becomes concentrated by the end of the collecting duct

[Figure 38-1](#) shows two examples of how tubule-fluid osmolality (expressed as the ratio TF_{Osm}/P_{Osm}) changes along the nephron. The first is a case of water restriction, in which the kidneys maximally concentrate the urine and excrete a minimal volume of water (**antidiuresis**). The second is a case of ingestion of excess water, in which the kidneys produce a large volume of dilute urine (**water diuresis**). In both cases, the tubule fluid does not change in osmolality along the proximal tubule, and it becomes hypotonic to plasma by the end of the thick ascending limb of the loop of Henle (TAL), also known as the diluting segment (see [pp. 757–758](#)). The fluid exiting the DCT is hypo-osmotic with respect to plasma, regardless of the final urine osmolality (see [Fig. 38-1](#)).

FIGURE 38-1 Relative osmolality of the tubule fluid along the nephron. Plotted on the y-axis is the ratio of the osmolality of the tubule fluid (TF_{Osm}) to the osmolality of the plasma (P_{Osm}); plotted on the x-axis is a representation of distance along the nephron. The red record is the profile of relative osmolality (i.e., TF_{Osm}/P_{Osm}) for water restriction, whereas the blue record is the profile for high water intake. (Data from Gottschalk CW: Micropuncture studies of tubular function in the mammalian kidney. *Physiologist* 4:33–55, 1961.)

Under conditions of restricted water intake or **hydropenia**, elevated levels of AVP increase the water permeability of the nephron from the ICT to the end of the IMCD. As a result, the osmolality of the tubule fluid increases along the ICT (see Fig. 38-1, red curve), achieving the osmolality of the cortical interstitium—which is the same as the osmolality of plasma (~290 mOsm)—by the end of this nephron segment (also the end of the classic distal tubule in Fig. 38-1). No additional increase in osmolality occurs along the CCT, because the tubule fluid is already in osmotic equilibrium with the surrounding cortical interstitium. However, in the MCDs, the luminal osmolality rises sharply as the tubule fluid equilibrates with the surrounding medullary interstitium, which becomes increasingly more hyperosmotic from the corticomedullary junction to the papillary tip. Eventually the tubule fluid reaches osmolalities that are as much as four times higher than the plasma. Thus, the MCDs are responsible for concentrating

the final urine.

In summary, the two key elements in producing a concentrated urine are (1) the hyperosmotic medullary interstitium that provides the osmotic gradient, and (2) the AVP that raises the water permeability of the distal nephron. How the kidney generates this interstitial hyperosmolality is discussed in the next subchapter, and the role of AVP is discussed in the last subchapter.

Under conditions of **water loading**, depressed AVP levels cause the water permeability of the distal nephron to remain low. However, the continued reabsorption of NaCl along the distal nephron effectively separates salt from water and leaves a relatively hypo-osmotic fluid behind in the tubule lumen. Thus, the tubule fluid becomes increasingly hypo-osmotic from the DCT throughout the remainder of the nephron (see [Fig. 38-1](#), blue curve).

Generation of a Hyperosmotic Medulla and Urine

Understanding the mechanisms involved in forming a hyperosmotic or hypo-osmotic urine requires knowing (1) the solute and water permeability characteristics of each tubule segment, (2) the osmotic gradient between the tubule lumen and its surrounding interstitium, (3) the active transport mechanisms that generate the hyperosmotic medullary interstitium, and (4) the “exchange” mechanisms that sustain the hyperosmotic medullary compartment.

The renal medulla is hyperosmotic to blood plasma during both antidiuresis (low urine flow) and water diuresis

The loop of Henle plays a key role in both the dilution and the concentration of the urine. The main functions of the loop are to remove NaCl—more so than water—from the lumen and deposit this NaCl in the interstitium of the renal medulla. By separating tubule NaCl from tubule water, the loop of Henle participates *directly* in forming dilute urine. Conversely, because the TAL deposits this NaCl into the medullary interstitium, thus making it hyperosmotic, the loop of Henle is *indirectly* responsible for elaborating concentrated urine. As discussed below, urea also contributes to the hyperosmolality of the medulla.

Figure 38-2A shows approximate values of osmolality in the tubule fluid and interstitium during an *antidiuresis* produced, for example, by water restriction. Figure 38-2B illustrates the comparable information during a *water diuresis* produced, for example, by high water intake. In *both* conditions, interstitial osmolality progressively rises from the cortex to the tip of the medulla (corticomedullary osmolality gradient). The difference between the two conditions is that the maximal interstitial osmolality during antidiuresis, ~1200 mOsm (see Fig. 38-2A), is more than twice that achieved during water diuresis, ~500 mOsm (see Fig. 38-2B).

A WATER RESTRICTION (ANTIDIURESIS)

B HIGH WATER INTAKE (WATER DIURESIS)

FIGURE 38-2 Nephron and interstitial osmolalities. **A**, Water restriction (antidiuresis). **B**, High water

intake (water diuresis). The numbers in the boxes are osmolalities (in mOsm) along the lumen of the nephron and along the corticomedullary axis of the interstitium. In **A**, the interstitial osmolality values in the green boxes come from [Figure 38-7](#). The outflow of blood from the vasa recta is greater than the inflow, which reflects the uptake of water reabsorbed from the collecting ducts. Blue arrows indicate passive water movements. Green arrows indicate passive solute movements. Red arrows indicate active solute movements. NKCC2, Na/K/Cl cotransporter 2.

Because of the NaCl pumped out of the rather water-impermeable TAL, the tubule fluid at the end of this segment is hypo-osmotic to the cortical interstitium during both antidiuresis and water diuresis. However, beyond the TAL, luminal osmolalities differ considerably between antidiuresis and diuresis. In *antidiuresis*, the fluid becomes progressively more concentrated from the ICT to the end of the nephron (see [Fig. 38-2A](#)). In contrast, during *water diuresis*, the hypo-osmolality of the tubule fluid is further accentuated as the fluid passes along segments from the DCT to the end of the nephron segments that are relatively water impermeable and continue to pump NaCl out of the lumen (see [Fig. 38-2B](#)). During *antidiuresis*, the tubule fluid in the ICT, CCT, OMCD, and IMCD more or less equilibrates with the interstitium, but it fails to do so during *water diuresis*. This marked difference in osmotic equilibration reflects the action of AVP, which increases water permeability in each of the previously mentioned four segments.

NaCl transport generates only a ~200-mOsm gradient across any portion of the ascending limb, but countercurrent exchange can multiply this single effect to produce a 900-mOsm gradient between cortex and papilla

Developing and maintaining the hyperosmolality of the medullary interstitium depends on the net transport of NaCl across the rather water-impermeable wall of the ascending limb of the loop of Henle, from lumen to interstitium. This salt reabsorption increases the osmolality of the interstitium and decreases the osmolality of the fluid within the lumen. The limiting NaCl concentration gradient that the tubule can develop at any point along its length is only ~200 mOsm, and this concentration alone could not explain the ability of the kidney to raise the osmolality of the papilla to 1200 mOsm. The kidney can achieve such high solute levels only because the hairpin loops of Henle create a countercurrent flow mechanism that multiplies the “single” *transverse* gradient of 200 mOsm. The result is an osmotic gradient of 900 mOsm along both the axis of the lumen of the ascending limb and the corticomedullary axis of the interstitium. In addition to the hairpin shape of the loop of Henle, a distinct pattern of salt and water permeabilities along the loop of Henle also contributes to osmotic multiplication.

[Figure 38-3](#) illustrates a simplified, schematized model of a **countercurrent-multiplier** system. **N38-2** The kidney in this example establishes a longitudinal osmotic gradient of 300 mOsm from cortex (300 mOsm) to the papilla (600 mOsm) by iterating (i.e., multiplying) a single effect that is capable of generating a transepithelial osmotic gradient of only 200 mOsm. Of course, if we had used more cycles, we could have generated a corticomedullary gradient that was even greater. For example, after 39 cycles in our example, the interstitial osmolality at the tip of the loop of Henle would be ~1200 mOsm. Therefore, the countercurrent arrangement of the loop of Henle magnifies the osmotic work that a single ascending-limb cell can perform. Among mammals, the length of the loop of Henle—compared with the thickness of the renal cortex—determines the maximal osmolality of the medulla. **N38-3**

FIGURE 38-3 Stepwise generation of a high interstitial osmolality by a countercurrent multiplier. This example illustrates in a stepwise fashion how a countercurrent-multiplier system in the loop of Henle increases the osmolality of the medullary interstitium. Heavy boundaries of ascending limb and early DCT indicate that these nephron segments are rather impermeable to water, even in the presence of AVP. The numbers refer to the osmolality (in mOsm) of tubule fluid and interstitium. The top panel shows the starting condition (step 0) with isosmotic fluid (~300 mOsm) throughout the ascending and descending limbs and in the interstitium. Each cycle comprises two steps. **N38-2** Step 1 is the “single effect”: NaCl transport from the lumen of the ascending limb to the interstitium, which instantaneously equilibrates with the lumen of the descending limb (steps 1, 3, 5, and 7). Step 2 is an “axial shift” of tubule fluid along the loop of Henle (steps 2, 4, and 6), with an instantaneous equilibration between the lumen of the descending limb and the interstitium. Beginning with the conditions in step 0, the first single effect is NaCl absorption across the rather water-impermeable *ascending* limb. At each level, we assume that this single effect creates a 200-mOsm *difference* between the ascending limb (which is water *impermeable*) and a second compartment: the combination of the interstitium and descending limb (which is water *permeable*). Thus, the osmolality of the ascending limb falls to 200 mOsm, whereas the osmolality of the interstitium and descending limb rise to 400 mOsm (step 1). The shift of new isosmotic fluid (~300 mOsm) from the proximal tubule in the cortex into the descending limb pushes the column of tubule fluid along the loop of Henle, *decreasing* osmolality at the top of the descending limb and *increasing* osmolality at the bottom of the ascending limb. Through instantaneous equilibration, the interstitium—with an assumed negligible volume—acquires the osmolality of the descending limb, thereby diluting the top of the interstitium (step 2). A second cycle starts with net NaCl transport out of the ascending limb (step 3), which again generates an osmotic gradient of 200 mOsm—at each transverse level—between the ascending limb on the one hand and the interstitium and descending limb on the other. After the axial shift of tubule fluid and instantaneous equilibration of the descending limb with the interstitium (step 4), osmolality at the bottom of the ascending limb exceeds that in the preceding cycle. With successive cycles, interstitial osmolality at the tip of the loop of Henle rises progressively from 300 (step 0) to 400 (step 1) to 500 (step 3) to 550 (step 5) and then to 600 mOsm (step 7). Thus, in this example, the kidney establishes a longitudinal osmotic gradient of 300 mOsm from the cortex (300 mOsm) to the papilla (600 mOsm) by iterating (i.e., multiplying) a single effect that is capable of generating a transepithelial osmotic gradient of only 200 mOsm. Step 7A adds the collecting duct and shows the final event of urine concentration: allowing the fluid in the collecting duct to osmotically equilibrate with the hyperosmotic interstitium, which produces a concentrated urine. (Based on a model in Pitts RF: Physiology of the Kidney and Body Fluids. Chicago, Year Book, 1974.)

N38-2

Simplifications in the Countercurrent-Multiplier Model in Figure 38-3

Contributed by Emile Boulpaep, Walter Boron

The model shown in Figure 38-3 is simplified in several respects.

- Perhaps the most significant simplification is that we regard the ascending limb as being functionally uniform from bottom to top. In fact, the bottom of the ascending limb is “thin” (tALH), whereas the top is “thick” (TAL). Both the tALH and the TAL separate salt from water, but by very different mechanisms. As discussed in the text, the “single effect” is the result of passive NaCl reabsorption in the *thin* and active NaCl reabsorption in the *thick* ascending limb (see p. 811).
- We assume that at every site, the ascending limb establishes a transepithelial gradient of 200 mOsm.
- In Figure 38-3, we separate the generation of the single effect (left column) from the axial movement of fluid along the loop (right column). In fact, the two occur simultaneously.

- Figure 38-3 considers only four cycles rather than the essentially limitless number of cycles in the real kidney. Thus, in our example, we reached an osmolality of only 600 mOsm at the tip of the loop, whereas 1200 mOsm would be a more realistic maximal value. More iterations would generate a larger tip osmolality.
- The model does not include any dissipation of the gradient along the corticomedullary axis by either diffusion or by washout via medullary blood flow. In the text, we noted that after 39 cycles of our model, we would eventually achieve an osmolality of 1200 mOsm at the tip of the loop. What we did *not* say is that if we had continued with even *more* iterations, we would have achieved even higher, unrealistic osmolalities. In the real kidney, a balance between the single effect and washout would create a stable corticomedullary gradient of osmolality.

N38-3

Spectrum of Urinary Concentrating Abilities among Different Mammals

Contributed by Erich Windhager, Gerhard Giebisch

The countercurrent-multiplication theory accounts for the observation that the osmolality of the final urine in different species is roughly proportional to the *relative* length of the loop of Henle. Comparing the *absolute* lengths of loops of Henle is a gross simplification because of the large variation in the absolute size of kidneys in different species. A better correlation exists between maximal concentrating ability and the ratio of medullary thickness to cortical thickness. For instance, the beaver, whose kidney has no papilla, maximally concentrates the final urine to ~600 mOsm and has a medullary/cortical ratio of 1.3. Humans, on the other hand, achieve a maximal concentration of ~1200 mOsm and have a medullary/cortical ratio of 3.0. Finally, the desert rodent *Psammomys*, which can achieve a urine osmolality of almost 6000 mOsm, has a medullary/cortical ratio of 10.7.

Another important factor for explaining interspecies differences in concentrating ability is the fraction of nephrons that have long loops of Henle. This fraction varies from 0% (i.e., long loops are totally absent) in the beaver to ~14% in humans to 100% in the desert rodent *Psammomys*.

In the last panel of [Figure 38-3](#), we include the collecting duct in the model to show the final event of urine concentration: allowing the fluid in the collecting duct to equilibrate osmotically with the hyperosmotic interstitium produces a concentrated urine.

The single effect is the result of passive NaCl reabsorption in the thin ascending limb and active NaCl reabsorption in the TAL

So far, we have treated the ascending limb as a functionally uniform epithelium that is capable of generating a 200-mOsm gradient between lumen and interstitium across a relatively water-impermeable barrier. However, the bottom of the ascending limb is “thin” (tALH), whereas the top is “thick” (TAL). Both the tALH and the TAL separate salt from water, but they transport the NaCl by very different mechanisms. The **TAL** moves NaCl from lumen out to interstitium via transcellular and paracellular

pathways (see [Fig. 35-4B](#)). For the transcellular pathway, the TAL cell takes up Na^+ and Cl^- via an apical Na/K/Cl cotransporter and exports these ions to the blood using basolateral Na-K pumps and Cl^- channels. For the paracellular pathway, the lumen-positive transepithelial voltage drives Na^+ from lumen to blood via the tight junctions. Using these two pathways, the TAL can generate a **single effect** as large as 200 mOsm.

In contrast, the movement of Na^+ and Cl^- from the lumen to the interstitium of the **tALH** appears to be an entirely passive process. During the debate on the mechanism of NaCl reabsorption in the tALH, several investigators pointed out that it was difficult to imagine how the extraordinarily thin cells of the tALH, with their paucity of mitochondria, could perform intensive active solute transport. Because the concentration of NaCl in the lumen exceeds that of the interstitium of the inner medulla, NaCl is reabsorbed passively. The key question for this model is: How did the luminal [NaCl] in the tALH become so high?

The work of concentrating the NaCl in the lumen was performed earlier, when the fluid was in the **thin descending limb (tDLH)** of juxtamedullary nephrons. This tDLH has three features that allow it to concentrate luminal NaCl: (1) the tDLH has a high water permeability owing to a high expression of aquaporin 1 (AQP1), (2) the tDLH has a very low permeability to NaCl and a finite urea permeability resulting from the presence of the UT-A2 urea transporter, and (3) the interstitium of the inner medulla has a very high [NaCl] and [urea]. The high interstitial concentrations of NaCl and urea provide the osmotic energy for passively reabsorbing water, which secondarily concentrates NaCl in the lumen of the tDLH.

In the interstitium, $[\text{Na}^+]$, $[\text{Cl}^-]$, and [urea] all rise along the axis from the cortex to the papillary tip of the renal medulla ([Fig. 38-4](#)). In the *outer* medulla, a steep rise in interstitial $[\text{Na}^+]$ and $[\text{Cl}^-]$ —owing to the pumping of NaCl out of the TAL (see [p. 731](#))—is largely responsible for producing the hyperosmolality. Although urea makes only a minor contribution in the outermost portion of the outer medulla, [urea] rises steeply from the middle of the outer medulla to the papilla. At the tip of the papilla, urea and NaCl each contribute half of the interstitial osmolality. As discussed in the next section, this steep interstitial [urea] profile in the inner medulla (see [Fig. 38-4](#)) is the result of the unique water and urea permeabilities of the collecting tubules and ducts (see [Fig. 38-2A](#)).

FIGURE 38-4 Concentration profiles of Na^+ , Cl^- , and urea along the corticomedullary axis. The data are from hydropenic dogs. (Data from Ullrich KJ, Kramer K, Boylan JW: Present knowledge of the counter-current system in the mammalian kidney. *Progr Cardiovasc Dis* 3:395–431, 1961.)

Knowing that NaCl and urea contribute to the high osmolality of the inner medullary interstitium, we can understand how the tDLH passively elevates $[\text{NaCl}]$ in the lumen above that in the interstitium. NaCl is the main solute in the lumen at the tip of the papilla but urea contributes to the luminal osmolality. As the luminal fluid turns the corner and moves up the tALH, it encounters a very different epithelium, one that is now impermeable to water but permeable to NaCl. The Cl^- channel ClC-K1 , selectively localized to the tALH, likely plays a pivotal role in this passive NaCl reabsorption. Indeed, mice lacking this channel have a urinary concentration defect. At the tip of the papilla interstitial $[\text{Na}^+]$ and $[\text{Cl}^-]$ are each ~300 mM (see Fig. 38-4). Luminal $[\text{Na}^+]$ and $[\text{Cl}^-]$, each in excess of 300 mM, provide a substantial gradient for passive transcellular reabsorption of Na^+ and Cl^- . As we see in the next section, urea enters the tALH passively due to a favorable urea gradient and a urea permeability of the tALH larger than that of the tDLH. The entry of urea opposes the osmotic work achieved by the passive reabsorption of NaCl. Even though the mechanism and magnitude of the single effect is different in the tALH and the TAL, the result is the same. At any level, osmolality in the lumen of the ascending limb is lower than it is in the interstitium.

The IMCD reabsorbs urea, producing high levels of urea in the interstitium of the inner medulla

Because urea comes from protein breakdown, urea delivery to the kidney—and, therefore, the contribution of urea to the medullary hyperosmolality—is larger with consumption of protein-rich diets. Indeed, investigators have long known that the higher the dietary protein content, the greater the

concentrating ability.

Urea Handling

The renal handling of urea is complex (see pp. 770–772). The kidney filters urea in the glomerulus and reabsorbs about half in the proximal tubule (Fig. 38-5, step 1). In juxtamedullary nephrons, the tDLH and the tALH secrete urea into the tubule lumen (see Fig. 38-5, step 2). Some urea reabsorption occurs along the TAL up through the CCT (see Fig. 38-5, step 3). Finally, the IMCD reabsorbs urea (see Fig. 38-5, step 4). The net effect is that the kidney excretes less urea into the urine than it filters. Depending on urine flow (see Fig. 36-2), the fractional excretion may be as low as ~15% (minimal urine flow) or as high as ~65% or more (maximal urine flow). Because we are interested in understanding the role of urea in establishing a hyperosmotic medullary interstitium, in Figure 38-5 we consider an example in which maximal AVP produces minimal urine flow (i.e., antidiuresis), a condition already illustrated in Figure 38-2A.

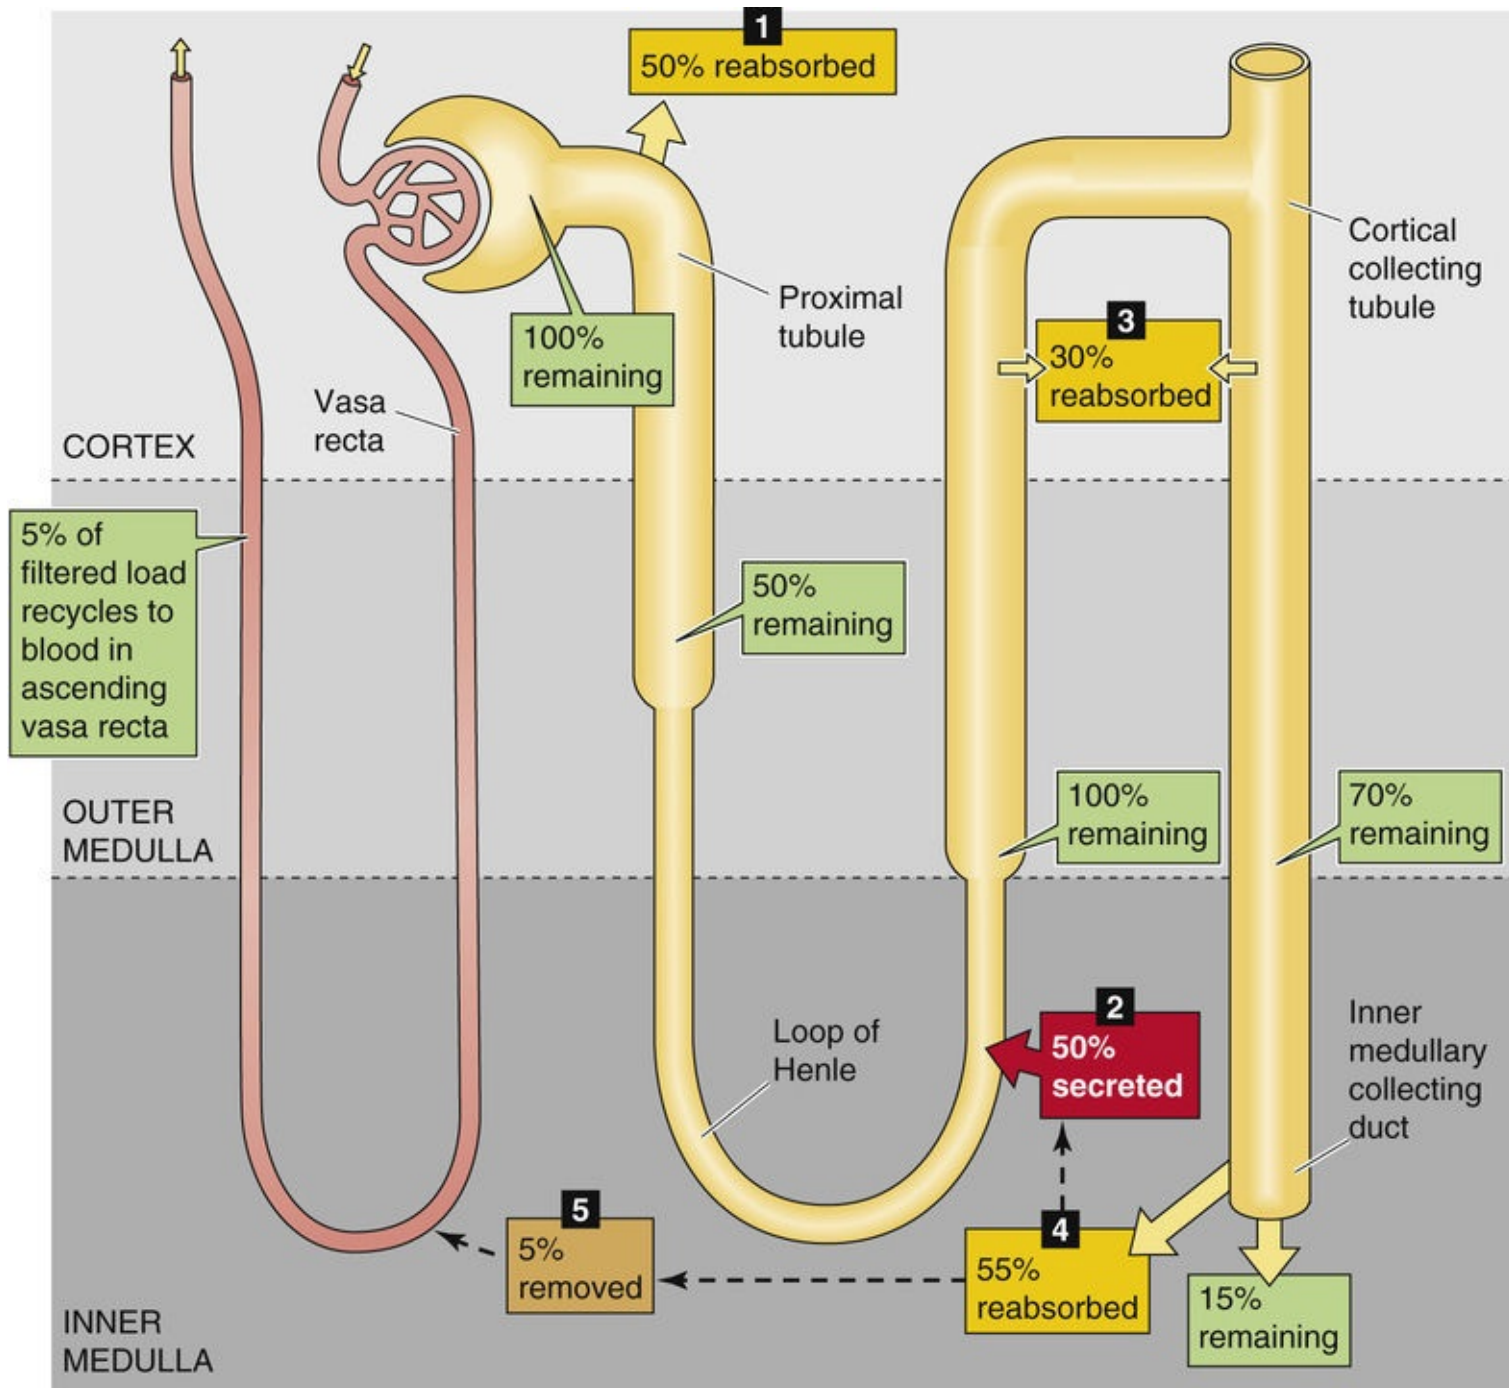

FIGURE 38-5 Urea recycling. Under conditions of water restriction (antidiuresis), the kidneys excrete ~15% of the filtered urea. The numbered yellow boxes indicate the fraction of the filtered load that various nephron segments *reabsorb*. The red box indicates the fraction of the filtered load *secreted* by the tALH and the brown box indicates the fraction of the filtered load *carried away* by the vasa recta. The green boxes indicate the fraction of the filtered load that remains in the lumen at various sites. The values in the boxes are approximations. **N38-8**

N38-8

Urea Reabsorption in the Distal Nephron

Contributed by Erich Windhager, Gerhard Giebisch

Of the urea filtered in the glomerulus, the proximal tubule reabsorbs ~50% by solvent drag (see p. 770), leaving ~50% remaining in the nephron lumen as the fluid enters the tDLH. As the thin limbs of juxtamedullary nephrons (which make up ~10% of all nephrons) dip into the inner medulla (remember,

these are the *only* nephrons whose loops of Henle dip into the inner medulla—see Figure 33-2), they secrete—under maximal antidiuretic conditions—an amount of urea equivalent to ~50% of the total filtered load of urea summed over all of the nephrons. In other words, by the time the luminal fluid of juxtamedullary nephrons reaches the beginning of the TAL, the luminal urea content must be an extremely high fraction of the filtered load of these nephrons. The *superficial nephrons*, on the other hand, have ~50% of their filtered load of urea remaining (the fraction not reabsorbed by their proximal tubules) by the time their fluid reaches the beginning of their TAL. Averaging over all nephrons—the juxtamedullary nephrons with high urea levels and superficial nephrons with low urea levels—the fluid entering the “average” TAL has an amount of urea that corresponds to 100% of the total filtered load of urea for the entire kidney. This is the 100% in the green box that points to the TAL in Figure 38-5.

Figure 38-5 indicates that, by time the tubule fluid reaches the junction of the outer and inner medulla, only 70% of the total filtered load of urea remains. Because the TAL, DCT, CNT, and CCT all have low urea permeabilities, it is perhaps somewhat surprising that 30% should have disappeared. Box 3 in the figure shows 30% of the total filtered load of urea being reabsorbed. Two events contribute to this 30%: (1) In the relatively few nephrons that are juxtamedullary, the [urea] in the TAL and CCT is very high, providing a gradient for passive urea loss in the cortex, where the interstitial [urea] is little more than that in plasma (i.e., ~5 mM). (2) In the collecting-duct system, fluid from the many superficial nephrons (each of which has a relatively low amount of its filtered load of urea remaining) admixes with that from the few juxtamedullary nephrons (each of which has far more than its filtered load of urea remaining), producing a blend with an intermediate level of urea remaining. Thus, the admixture of a few hundred percent remaining (from the juxtamedullary nephrons) with 50% remaining (from the superficial nephrons) contributes to the overall decrease in the percent of urea remaining to 70%.

As the tubule fluid enters the TAL, the [urea] is several-fold higher than it is in the plasma because ~100% of the filtered load of urea remains, even though earlier nephron segments have reabsorbed water. All nephron segments from the TAL to the OMCD, inclusive, have low permeabilities to urea. In the presence of AVP, however, all segments from the ICT to the end of the nephron have high water permeabilities and continuously reabsorb fluid. As a result, luminal [urea] gradually rises, beginning at the ICT and reaching a concentration as much as 8-fold to 10-fold higher than that in blood plasma by the time the tubule fluid reaches the end of the OMCD.

The **IMCD** differs in an important way from the three upstream segments: Although AVP increases *only water permeability* in the ICT, CCT, and OMCD, AVP increases water *and urea permeability* in the IMCD. In the IMCD, the high luminal [urea] and the high urea permeabilities of the apical membrane (via the urea transporter **UT-A1**; see [p. 770](#)) and basolateral membrane (via **UT-A3**) promote the outward facilitated diffusion of urea from the IMCD lumen, through the IMCD cells, and into the medullary interstitium (see [Fig. 38-5](#), step 4). As a result, urea accumulates in the interstitium and contributes about half of the total osmolality in the deepest portion of the inner medulla. In addition, in the outer portion of the inner medulla, active urea reabsorption occurs via an Na/urea cotransporter in the apical membrane of the early IMCD.

Because of the accumulation of urea in the inner medullary interstitium, [urea] is higher in the interstitium than it is in the lumen of the **tDLH** and **tALH** of juxtamedullary (i.e., long-loop) nephrons. This concentration gradient drives urea into the tDLH via UT-A2 and into the tALH via an unidentified transporter (see [Fig. 38-5](#), step 2). The secretion of urea into the tDLH and tALH accounts for two important observations: First, more urea (i.e., a greater fraction of the filtered load) emerges from the tALH than entered the tDLH. Second, as noted above, [urea] in the TAL is considerably higher than that in

blood plasma.

Urea Recycling

The processes that we have just described—(1) absorption of urea from IMCD into the interstitium (see Fig. 38-5, step 4), (2) secretion of urea from the interstitium into the thin limbs (see Fig. 38-5, step 2), and (3) delivery of urea up into the cortex and back down via nephron segments from the TAL to the IMCD—are the three elements of a loop. This **urea recycling** is responsible for the buildup of a high [urea] in the inner medulla. A small fraction of the urea that the IMCD deposits in the interstitium moves into the vasa recta (see Fig. 38-5, step 5), which removes it from the medulla and returns it either to superficial nephrons or to the general circulation.

The preceding discussion focused on the situation in *antidiuresis*, in which AVP levels are high and the kidney concentrates urea in the inner medulla. The converse situation pertains in *water diuresis*, when circulating levels of AVP are low. The kidney reabsorbs *less* water along the ICT, CCT, OMCD, and IMCD. Furthermore, with low AVP levels, the IMCD has *lower* permeability to both urea and water. In addition, urea may be actively secreted by an apical Na-urea exchanger located in the apical membrane of the most distal portions of the IMCD. Therefore, during water diuresis, the interstitial [urea] is lower, and more urea appears in the urine.

The vasa recta's countercurrent exchange and relatively low blood flow minimize washout of medullary hyperosmolality

The simplified scheme for the countercurrent multiplier presented in Figure 38-3 did not include blood vessels. If we were simply to introduce a straight, permeable blood vessel running from papilla to cortex, or vice versa, the blood flow would soon wash away the papillary hyperosmolality that is critical for concentrating urine. Figure 38-6A shows a hypothetical kidney with only *descending* vasa recta. Here, blood would flow from cortex to papilla and then exit the kidney. Because the blood vessel wall is permeable to small solutes and water, the osmolality of the blood would gradually increase from 300 to 1200 mOsm during transit from cortex to papilla, reflecting a loss of water or a gain of solutes. Because these movements occur at the expense of the medullary interstitium, the blood would wash out the interstitium's hyperosmolality. The greater the blood flow through this straight/unlooped blood vessel, the greater would be the medullary washout.

A HYPOTHETICAL STRAIGHT-TUBE EXCHANGER

B HYPOTHETICAL COUNTERCURRENT EXCHANGER

FIGURE 38-6 Model of countercurrent exchange. **A**, If blood simply flows from the cortex to the medulla through a straight tube, then the blood exiting the medulla will have a high osmolality (750 mOsm), washing out the osmolality gradient of the medullary interstitium. The numbers in the yellow boxes indicate the osmolality (in mOsm) inside the vasa recta, and the numbers in the green boxes indicate the osmolality of the interstitial fluid. **B**, If blood flows into and out of the medulla through a hairpin loop, then the water will leave the vessel and solute will enter along the entire descending vessel and part of the ascending vessel. Along the rest of the ascending vessel, the fluxes of water and solute are reversed. The net effect is that the blood exiting the medulla is less hyperosmotic than that in **A** (450 versus 750 mOsm), so that the kidney better preserves the osmotic gradient in the medulla. The values in the boxes are approximations. (Data from a model in Pitts RF: Physiology of the Kidney and Body Fluids. Chicago, Year Book, 1974.)

The kidney solves the medullary-washout problem in two ways. First, compared with the blood flow in the renal cortex, which is one of the highest (per gram of tissue) of any tissue in the body, the blood flow through the medulla is relatively low, corresponding to no more than 5% to 10% of total renal plasma flow. This low flow represents a compromise between the need to deliver nutrients and oxygen to the medulla and the need to avoid washout of medullary hyperosmolality.

Second, and far more significant, the kidney uses a hairpin configuration, with the descending and ascending vasa recta both entering and leaving through the same region, which creates an efficient **countercurrent exchange mechanism** (see [Fig. 38-6B](#)) in the blood vessels. The vasa recta have a hairpin configuration, but no capacity for active transport. We start with the osmotic stratification in the

medullary interstitium that the countercurrent multiplier generated in the presence of high AVP levels. This osmotic stratification results in part from a gradient of $[\text{Na}^+] + [\text{Cl}^-]$, but also from a similarly directed cortex-to-papilla gradient of [urea] (see Fig. 38-4). As isosmotic blood enters the hyperosmotic milieu of the medulla, which has high concentrations of NaCl and urea, NaCl and urea diffuse into the lumen of the descending vasa recta, whereas water moves in the opposite direction. This entry of urea into the descending vasa recta occurs via facilitated diffusion, mediated by the **UT-B1** and **UT-B2** urea transporters (see p. 770). The result is that the osmolality of the blood increases as the blood approaches the tip of the hairpin loop. As the blood rounds the curve and heads up toward the cortex inside the ascending vasa recta, that blood eventually develops a higher solute concentration than the surrounding interstitium. As a consequence, NaCl and urea now diffuse from the lumen of the vasa recta into the interstitium, whereas water moves into the ascending vasa recta.

Viewed as a whole, these passive exchange processes not only cause the *descending* vasa recta to gain solute and lose water, but also cause the *ascending* vessels to lose solute and gain water. Thus, at any level, the descending and ascending vessels exchange solutes and water via—and at the expense of—the medullary interstitium. Solute recirculates from the ascending vessel, through the interstitium, to the descending vessel. Conversely, the countercurrent exchange mechanism also “short-circuits” the water but in the opposite direction, from the descending vessel, through the interstitium, to the ascending vessel. The net effect is that the countercurrent exchanger tends to trap solutes in and exclude water from the medulla, thereby minimizing dissipation of the corticomedullary osmolality gradient. **N38-4**

N38-4

Anatomical Arrangements between the Vasa Recta and Thin Limbs in the Medulla

Contributed by Erich Windhager, Gerhard Giebisch

Although in some species, the ascending and descending vasa recta are closely intermingled in vascular bundles within the medulla, such close contact between the ascending and descending vessels is not necessary to create an effective countercurrent exchanger. It is only necessary that vessels at the same level equilibrate with the same interstitial fluid.

The total mass of solute and water leaving the medulla each minute via the *ascending* vasa recta must exceed the total inflow of solute and water into the medulla via the *descending* vasa recta. With regard to *solute balance*, the renal tubules continuously deposit NaCl and urea in the medullary interstitium. Thus, in the steady state, the vasa recta must remove these solutes lest they form crystals of NaCl and urea in the medullary interstitium. Almost all the urea in the interstitium of the inner medulla comes from the IMCD (see Fig. 38-5, step 4), and in the steady state most of this leaves the interstitium by way of the tALH (see Fig. 38-5, step 2). The blood of the vasa recta carries away the balance or excess urea (see Fig. 38-5, step 5). The vasa recta also carry off the excess NaCl that enters the interstitium from the ascending limb of the loop of Henle and, to some extent, from the MCDs (see Fig. 38-2).

With regard to *water balance* within the medulla, the descending limb of the loop of Henle and—in the presence of AVP—the MCD continuously give up water to the medullary interstitium (see Fig. 38-2). The ascending vasa recta carry off this excess water from the medulla.

The net effect of managing both solute and water balance in the medulla is that the ascending vasa recta

carry out more salt and more water than the descending vasa recta carry in.  **N38-5**

N38-5

Osmolality of the Ascending versus Descending Vasa Recta

Contributed by Gerhard Giebisch, Eric Windhager

As shown in Figure 38-2A, the net effect of managing both solute and water balance in the medulla is that the ascending vasa recta carry out greater *amounts* of salt and water than the descending vasa recta carry in. Although no precise measurements have been made, it is likely that the salt *concentration*—and therefore osmolality—of blood leaving the ascending vasa recta exceeds that of the blood entering the descending vessels by a fairly small amount, perhaps 10 to 30 mOsm.

The MCD produces a concentrated urine by osmosis, driven by the osmotic gradient between the medullary interstitium and the lumen

Whereas the loop of Henle acts as a *countercurrent multiplier* and the loop-shaped vasa recta act as a *countercurrent exchanger*, the MCD acts as an unlooped or *straight-tube exchanger*. The wall of the MCD has three important permeability properties: (1) in the absence of AVP, it is relatively impermeable to water, urea, and NaCl along its entire length; (2) AVP increases its water permeability along its entire length; and (3) AVP increases its urea permeability along just the terminal portion of the tube (IMCD). The collecting duct traverses a medullary interstitium that has a stratified, ever-increasing osmolality from the cortex to the tip of the papilla. Thus, along the entire length of the tubule, the osmotic gradient across the collecting-duct epithelium favors the reabsorption of water from lumen to interstitium.

A complicating factor is that two solutes—NaCl and urea—contribute to the osmotic gradient across the tubule wall. As fluid in the collecting-duct lumen moves from the corticomedullary junction to the papillary tip, the [NaCl] gradient across the tubule wall always favors the osmotic reabsorption of water (Fig. 38-7). For urea, the situation is just the opposite. However, because the ICT, CCT, and OMCD are all relatively impermeable to urea, water reabsorption predominates in the presence of AVP and gradually causes luminal [urea] to increase in these segments. Because the interstitial [urea] is low in the cortex, a rising luminal [urea] in the ICT and CCT *opposes* water reabsorption in these segments. Even when the tubule crosses the corticomedullary junction, courses toward the papilla, and is surrounded by interstitial fluid with an ever-increasing [urea], the transepithelial urea gradient still favors water movement into the lumen, which is a handicap for the osmotic concentration of the tubule fluid.

FIGURE 38-7 Opposing effects of NaCl and urea gradients on urine concentrating ability during antidiuresis. The numbers in the green boxes indicate the osmolalities (in mOsm) of the interstitial fluid.

The IMCD partially compensates for this problem by acquiring, in response to AVP, a high permeability to urea. The result is a relatively low reflection coefficient for urea (σ_{urea} ; see p. 468), which converts any transepithelial difference in [urea] into a smaller difference in effective osmotic pressure (see pp. 132–133). Thus, water reabsorption continues from the IMCD even though [urea] in tubule fluid exceeds that in the interstitium. The combination of a high interstitial [NaCl] and high σ_{NaCl} ($\sigma_{\text{NaCl}} = 1.0$), along with a low σ_{urea} ($\sigma_{\text{urea}} = 0.74$), promotes NaCl-driven water *reabsorption*. The high AVP-induced urea permeability has the additional effect of raising interstitial [urea], which further reduces the adverse effect of the high luminal [urea] on water reabsorption.

If luminal urea opposes the formation of a concentrated urine, why did the mammalian kidney evolve to have high levels of urea in the lumen of the collecting tubules and ducts? At least two reasons are apparent. First, because urea is the body's major excretable nitrogenous waste, the kidney's ability to achieve high urinary [urea] reduces the necessity to excrete large volumes of water to excrete nitrogenous waste. Second, as we have already seen, the kidney actually takes advantage of urea—*indirectly*—to generate maximally concentrated urine. In the presence of AVP, the permeability of the IMCD to urea is

high, so that large amounts of urea can enter the medullary interstitium. The high interstitial [urea] energizes the increase in luminal [NaCl] in the tDLH, which, in turn, fuels the single effect in the tALH, thus creating the high inner-medullary [NaCl] that is *directly* responsible for concentrating the urine.

As discussed above in this section, the composition of the inner medullary interstitium determines the composition of the final urine. However, to some extent, the composition of the final urine, as well as the rate of urine flow, also influences the composition of the interstitium. [Figure 38-2](#) shows that the medullary interstitial osmolality is much lower, and the stratification of osmolality from cortex to papillary tip is much less, during water diuresis than during antidiuresis. Two factors contribute to the lesser degree of osmotic stratification under conditions of water diuresis, when levels of AVP are low. First, less urea moves from the IMCD lumen to the interstitium, both because of the low urea permeability of the IMCD and because of the low water permeability of the upstream segments that would otherwise concentrate urea. Second, the MCDs reabsorb some water despite the low AVP levels, and this water dilutes the medullary interstitium. The reasons for this apparent paradox are as follows: (1) even when AVP is low, the water permeability is not zero; (2) the ICT and CCT present a much larger fluid volume to the MCD, because they reabsorb less water when AVP levels are low; and (3) the tubule fluid is more hypo-osmotic, which results in a larger osmotic gradient for transepithelial water movement. With low AVP levels, this larger osmotic gradient overrides the effect of the lower water permeability.

[Table 38-2](#) summarizes factors that modulate urinary concentration ability.

TABLE 38-2
Factors that Modulate Urinary Concentration and Dilution

<div>1. Osmotic gradient of medullary interstitium from corticomedullary junction to papilla:<div>a. Length of loops of Henle: Species with long loops (e.g., desert rodents) concentrate more than those with short loops (e.g., beaver).</div><div>b. Rate of active NaCl reabsorption in the TAL: Increased luminal Na⁺ delivery to the TAL (high GFR or filtration fraction, and low proximal-tubule Na⁺ reabsorption) enhances NaCl reabsorption, whereas low Na⁺ delivery (low GFR, increased proximal Na⁺ and fluid reabsorption) reduces concentrating ability. High Na-K pump turnover enhances NaCl reabsorption, whereas inhibiting transport (e.g., loop diuretics) reduces concentrating ability.</div><div>c. Protein content of diet: High-protein diet, up to a point, promotes urea production and thus accumulation in the inner medullary interstitium, and increased concentrating ability.</div></div> <div>2. Medullary blood flow: Low blood flow promotes high interstitial osmolality. High blood flow washes out medullary solutes.</div> <div>3. Osmotic permeability of the collecting tubules and ducts to water: AVP enhances water permeability and thus water reabsorption.</div> <div>4. Luminal flow in the loop of Henle and the collecting duct: High flow (osmotic diuresis) diminishes the efficiency of the countercurrent multiplier, and thus reduces the osmolality of the medullary interstitium. In the MCD, high flow reduces the time available for equilibration of water and urea.</div> <div>5. Pathophysiology: Central diabetes insipidus (DI) reduces plasma AVP levels, whereas nephrogenic DI reduces renal responsiveness to AVP (see Box 38-1).</div>

GFR, glomerular filtration rate.

Regulation by Arginine Vasopressin

Large-bodied neurons in the paraventricular and supraoptic nuclei of the hypothalamus synthesize AVP, a nonapeptide also known as ADH. These neurons package the AVP and transport it along their axons to the posterior pituitary, where they release AVP through a breach in the blood-brain barrier into the systemic circulation (see pp. 844–845). In Chapter 40, we discuss how increased plasma osmolality and decreased effective circulating volume increase AVP release. AVP has synergistic effects on two target organs. First, at rather high circulating levels, such as those seen in hypovolemic shock, AVP acts on vascular smooth muscle to cause *vasoconstriction* (see p. 553) and thus to increase blood pressure. Second, and more importantly, AVP acts on the kidney, where it is the major regulator of water excretion. AVP increases water reabsorption by increasing (1) the water permeabilities of the collecting tubules and ducts, (2) NaCl reabsorption in the TAL, and (3) urea reabsorption by the IMCD.

AVP increases water permeability in all nephron segments beyond the DCT

Of the water remaining in the DCT, the kidney reabsorbs a variable fraction in the segments from the ICT to the end of the nephron. Absorption of this final fraction of water is under the control of circulating AVP.

Figure 38-8 summarizes the water permeability of various nephron segments. The water permeability is highest in the proximal tubule and tDLH. The constitutively high water permeability in these segments reflects the abundant presence of **AQP1** water channels (see p. 110) in the apical and basolateral cell membranes.

FIGURE 38-8 Water permeability in different nephron segments. Note that the x-axis scale is logarithmic. (Modified from Knepper MA, Rector FC: Urine concentration and dilution. In Brenner BM [ed]: The Kidney. Philadelphia, WB Saunders, 1996, pp 532–570.)

AQP2 and additional proteins that play a role in the trafficking of intracellular vesicles containing AQP2 and the fusion of these vesicles with the apical membrane. These water channels are AVP sensitive, not in the sense that AVP increases their single channel water conductance, but rather that it increases their *density* in the apical membrane. **N38-6** In conditions of low AVP, AQP2 water channels are mainly in the membrane of intracellular vesicles just beneath the apical membrane. In the membrane of these vesicles, the AQP2 water channels are present as **aggregophores**—aggregates of AQP2 proteins. Under the influence of AVP, the vesicles containing AQP2 move to the apical membrane of principal cells of the collecting tubules and ducts. By exocytosis (see pp. 34–35), these vesicles fuse with the apical membrane, thus increasing the density of AQP2. When AVP levels in the blood decline, endocytosis retrieves the water channel–containing aggregates from the apical membrane and shuttles them back to the cytoplasmic vesicle pool.

Multiple Effects of Arginine Vasopressin on AQP2 Activity

Contributed by Erich Windhager, Gerhard Giebisch

On page 818, we mentioned that AVP acts through cAMP and protein kinase A (PKA) to phosphorylate AQP2 and other proteins. One result of these phosphorylation events is to increase the trafficking of AQP2 from vesicular pools to the apical membrane of the collecting-duct cells. Thus, AVP increases **AQP2 density** in the apical membrane; that is, the number of water channels per unit area of apical membrane.

In addition, PKA also phosphorylates AQP2 itself as well as cAMP response element-binding protein (CREB; see p. 89). The phosphorylation of CREB, in the longer term, stimulates AQP2 synthesis, as indicated in Figure 38-9.

The apical water permeability of principal cells depends not only on AVP levels but also on certain other factors. For example, high $[Ca^{2+}]_i$ and high $[Li^+]$ both inhibit adenylyl cyclase, thus decreasing $[cAMP]_i$, reducing water permeability, and producing a diuresis. A similar inhibition of AQP2 insertion, and hence a decrease in water permeability, occurs when agents such as colchicine disrupt the integrity of the cytoskeleton. Conversely, inhibitors of phosphodiesterase (e.g., theophylline), which increase $[cAMP]_i$, tend to increase the osmotic water permeability. In addition to regulating AQP2 trafficking in and out of the apical membrane in the short term, AVP regulates AQP2 protein abundance over the longer term.

AVP increases NaCl reabsorption in the outer medulla and urea reabsorption in the IMCD, enhancing urinary concentrating ability

AVP promotes water reabsorption not only by increasing the water permeability of the collecting tubules and ducts, but also by enhancing the osmotic gradients across the walls of the IMCD and perhaps the OMCD. In the *outer* medulla, AVP acts through the cAMP pathway to increase NaCl reabsorption by the TAL. AVP acts by stimulating apical Na/K/Cl cotransport and K^+ recycling across the apical membrane (see p. 768). The net effect is to increase the osmolality of the outer medullary interstitium and thus enhance the osmotic gradient favoring water reabsorption by the OMCD. In addition, AVP stimulates the growth of TAL cells in animals that are genetically devoid of AVP. This hormone also stimulates Na^+ reabsorption in the CCT, largely by activating apical Na^+ channels (ENaCs). These observations on the TAL and CCT were all made on rodents. In humans these TAL and CCT mechanisms may have only minor significance.

In the *inner* medulla, AVP enhances the urea permeability of the terminal two thirds of the IMCD (see pp. 811–813). The AVP-dependent increase in $[cAMP]_i$ that triggers the apical insertion of AQP2-containing vesicles also leads to a phosphorylation of apical UT-A1 and basolateral UT-A3 urea transporters (see p. 770), increasing their activity. The result is a substantial increase in urea reabsorption and thus the high interstitial [urea] that is indirectly responsible (see p. 816) for generating the osmotic gradient that drives water reabsorption in the inner medulla (Boxes 38-1, 38-2, and 38-3).

Box 38-1

Diabetes Insipidus

Diabetes insipidus (DI) is a fairly rare disorder that occurs in two varieties. The first, neurogenic or **central DI**, is caused by failure of AVP secretion. The lesion can be at the level of either the hypothalamus (where neurons synthesize AVP) or the pituitary gland (where neurons release AVP). Central DI can be idiopathic, familial, or caused by any disorder of the hypothalamus or pituitary, such as injury, a tumor, infection, or autoimmune processes. In the second variety, **nephrogenic DI (NDI)**, the kidneys respond inadequately to normal or even elevated levels of circulating AVP due to familial or acquired defects. Ninety percent of the familial cases are due to mutations in the X-linked *AVPR2* gene that encodes the V_2 receptor, and 10%, to mutations in the *AQP2* gene. Acquired NDI may be associated with electrolyte abnormalities (e.g., states of K^+ depletion or high plasma $[Ca^{2+}]$ **N36-14**), the renal disease associated with sickle cell anemia, and various drugs (notably Li^+ salts and colchicine).

In both central and nephrogenic DI, patients present with polyuria and polydipsia. If patients cannot gain access to water on their own (e.g., infants, bedridden elderly), the disorder can result in marked hypernatremia, hypotension, and shock. Often the physician first suspects the diagnosis when the patient is deprived of access to water or other fluids. The patient may then quickly become dehydrated, and a random determination of plasma $[Na^+]$ may yield a very high value.

The physician can confirm the diagnosis of DI most easily by a fluid-deprivation test. The patient will continue to produce a large output of dilute urine, despite the need to conserve fluids. If the patient has **central DI**, administering a subcutaneous dose of AVP will rapidly increase urine osmolality by $>50\%$. In patients with **nephrogenic DI**, on the other hand, the increase in urine osmolality will be less.

The treatment for central DI is **desmopressin acetate (DDAVP)** (see Fig. 56-10), a synthetic AVP analog that patients can take intranasally. Nephrogenic DI, in which the kidneys are resistant to the effects of the hormone, does not respond to DDAVP therapy. In these patients, it is best to treat the underlying disease. It can also be helpful to administer a diuretic (to produce natriuresis) and restrict dietary Na^+ to induce a state of volume depletion, which in turn enhances proximal NaCl and water reabsorption and thereby moderates the polyuria.

The high urine flow in DI is associated with low rates of solute excretion. Therefore, the physician must distinguish DI from states of **polyuria** accompanied by high rates of solute excretion in the urine (**osmotic diuresis**). The most frequent cause of the latter is untreated **diabetes mellitus**. In that case, the polyuria occurs because the high plasma [glucose] leads to the filtration of an amount of glucose that exceeds the capacity of the proximal tubule to retrieve it from the lumen (see pp. 772–773). Another cause of osmotic diuresis is the administration of poorly reabsorbable solutes, such as mannitol.

In an entirely distinct class of polyurias is **primary polydipsia**, a psychoneurotic disorder in which patients drink large amounts of fluid. Whereas simple water deprivation benefits a patient with primary polydipsia, it aggravates the condition of a patient with DI.

Box 38-2

Role of Aquaporins in Renal Water Transport

Whereas AQP1 is the water channel responsible for a large amount of transcellular fluid movement in the proximal tubule and the tDLH, three related isoforms of the water channel protein—AQP2, AQP3, and AQP4—are present in the principal cells of the collecting ducts. These channels regulate water transport

in collecting tubules and ducts. Apical AQP2 is the basis for AVP-regulated water permeability. AQP3 and AQP4 are present in the basolateral membrane of principal cells, where they provide an exit pathway for water movement into the peritubular fluid.

Short-term and long-term regulation of water permeability depends on an intact AQP2 system. In short-term regulation, AVP—via cAMP—causes water channel-containing vesicles from a subapical pool to fuse with the apical membrane (see Fig. 38-9). As a result, the number of channels and the water permeability sharply increase. In long-term regulation, AVP—by enhancing transcription of the AQP2 gene—increases the abundance of AQP2 protein in principal cells.

Mutations of several AQP genes lead to loss of function and marked abnormalities of water balance. Examples include sharply decreased fluid absorption along the proximal tubule in AQP1 knockout animals and nephrogenic diabetes insipidus (see Box 38-1) in patients with mutations of the gene for AQP2. An interesting situation may develop during the third trimester of pregnancy, when elevated plasma levels of vasopressinase—a placental aminopeptidase that degrades AVP—may lead to a clinical picture of central diabetes insipidus.

An acquired increase of AQP2 expression often accompanies states of abnormal fluid retention, such as congestive heart failure, hepatic cirrhosis, nephrotic syndrome, and pregnancy. In addition, some conditions—including acute and chronic renal failure, primary polydipsia, consumption of a low-protein diet, and syndrome of inappropriate antidiuretic hormone secretion (see Box 38-3)—are associated with increased AQP2 levels in the apical membrane.

Box 38-3

Syndrome of Inappropriate Antidiuretic Hormone Secretion

The **syndrome of inappropriate ADH secretion (SIADH)** is the opposite of diabetes insipidus. Patients with SIADH secrete ADH (i.e., AVP) or AVP-like substances at levels that are inappropriately *high*, given the low plasma osmolality and lack of hypovolemia. Thus, the urine osmolality is inappropriately high and patients are unable to excrete ingested water loads normally. As a result, total-body water increases, the blood becomes hypo-osmolar, plasma $[\text{Na}^+]$ drops (**hyponatremia**), and cells swell. If plasma $[\text{Na}^+]$ falls substantially, cell swelling can cause headaches, nausea, vomiting, and behavioral changes. Eventually, stupor, coma, and seizures may ensue.

Before making the diagnosis of SIADH, the physician must rule out other causes of hyponatremia in which AVP levels may be appropriate. In Chapter 40, we discuss how plasma osmolality (see p. 844) and effective circulating volume (see p. 843) *appropriately* regulate AVP secretion. SIADH has four major causes:

1. Certain **malignant tumors** (e.g., bronchogenic carcinoma, sarcomas, lymphomas, and leukemias) release AVP or AVP-like substances.
2. **Cranial disorders** (e.g., head trauma, meningitis, and brain abscesses) can increase AVP release.
3. **Nonmalignant pulmonary disorders** (e.g., tuberculosis, pneumonia, and abscesses) and positive-pressure ventilation also can cause SIADH.  **N38-7**
4. Several **drugs** can either stimulate AVP release (e.g., clofibrate, phenothiazines), increase the sensitivity of renal tubules to AVP (e.g., chlorpropamide), or both (e.g., carbamazepine).

Treatment is best directed at the underlying disorder, combined, if necessary and clinically appropriate, with fluid restriction. Patients with severe hyponatremia and marked symptoms must receive urgent attention. Infusion of hyperosmotic Na^+ is usually effective, but the correction must be gradual or severe neurological damage can result owing to rapid changes in the volume of neurons, especially in the pontine area of the brainstem.

N38-7

Pulmonary Disorders Causing Syndrome of Inappropriate Antidiuretic Hormone Secretion

Contributed by Emile Boulpaep, Walter Boron

Several chronic, nonmalignant pulmonary conditions, including positive-pressure ventilation, impede venous return. The result is reduced stretch of the atrial receptors (see Fig. 23-7). As discussed on page 547, the afferent fibers from these stretch receptors project not only to the medulla (where they produce cardiovascular effects) but also to the hypothalamic neurons that synthesize and release AVP. Decreased atrial stretch increases AVP release. Thus, the aforementioned pulmonary conditions result in a syndrome of inappropriate AVP (ADH) release—SIADH.

Transport of Acids and Bases

Gerhard Giebisch, Erich E. Windhager, Peter S. Aronson

The lungs and the kidneys are largely responsible for regulating the acid-base balance of the blood (see [Chapter 28](#)). They do so by independently controlling the two major components of the body's major buffering system: CO_2 and HCO_3^- ([Fig. 39-1](#)). [Chapter 31](#) focuses on how the lungs control plasma $[\text{CO}_2]$. In this chapter we see how the kidneys control plasma $[\text{HCO}_3^-]$.

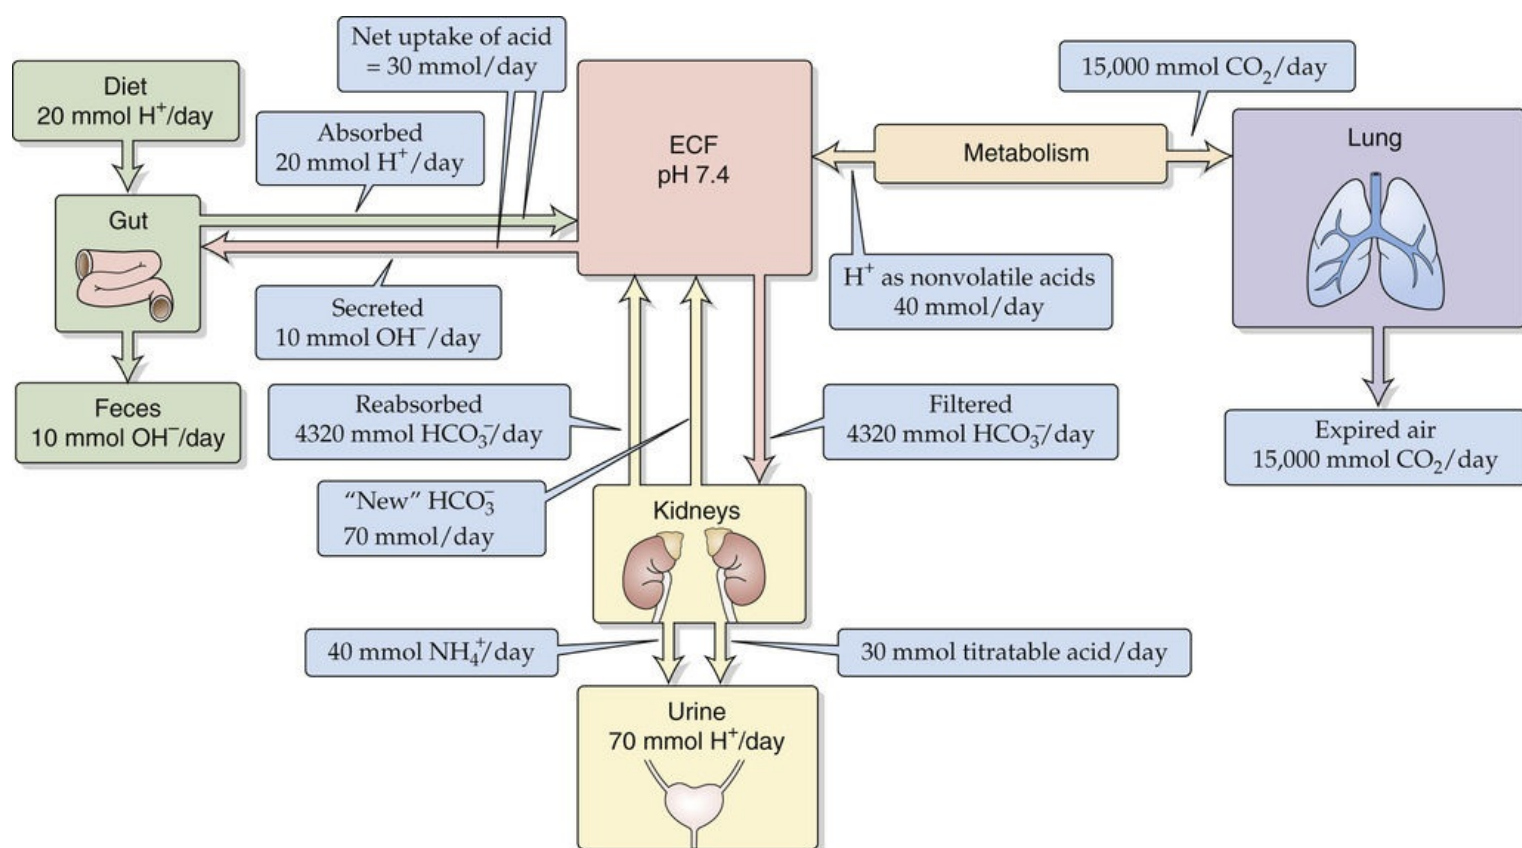

FIGURE 39-1 Acid-base balance. All values are for a 70-kg human consuming a typical Western acid-ash diet. The values in the boxes are approximations.

Acid-Base Balance and the Overall Renal Handling of Acid

Whereas the lungs excrete the large amount of CO₂ formed by metabolism, the kidneys are crucial for excreting nonvolatile acids

The kidneys play a critical role in helping the body rid itself of excess acid that accompanies the intake of food or that forms in certain metabolic reactions. By far, the largest potential source of acid is CO₂ production (Table 39-1, section A), which occurs during oxidation of carbohydrates, fats, and most amino acids (see pp. 1185–1187). An adult ingesting a typical Western diet produces ~15,000 mmol/day of CO₂. This CO₂ would act as an acid if it went on to form H⁺ and HCO₃⁻ (see p. 630). Fortunately, the lungs excrete this prodigious amount of CO₂ by diffusion across the alveolar-capillary barrier (see p. 673), preventing the CO₂ from forming H⁺.

TABLE 39-1
Metabolic Sources of Nonvolatile Acids and Bases

A. Reactions Producing CO₂ (merely a potential acid)
1. Complete oxidation of neutral carbohydrate and fat → CO ₂ + H ₂ O
2. Oxidation of <i>most</i> neutral amino acids → Urea + CO ₂ + H ₂ O
B. Reactions Producing Nonvolatile Acids
1. Oxidation of sulfur-containing amino acids → Urea + CO ₂ + H ₂ O + H ₂ SO ₄ → 2 H ⁺ + SO ₄ ²⁻ (Examples: methionine, cysteine)
2. Metabolism of phosphorus-containing compounds → H ₃ PO ₄ → H ⁺ + H ₂ PO ₄ ⁻
3. Oxidation of <i>cationic</i> amino acids → Urea + CO ₂ + H ₂ O + H ⁺ (e.g., lysine ⁺ , arginine ⁺)
4. Production of nonmetabolizable organic acids → HA → H ⁺ + A ⁻ (e.g., uric acid, oxalic acid)
5. Incomplete oxidation of carbohydrate and fat → HA → H ⁺ + A ⁻ (e.g., lactic acid, keto acids)
C. Reactions Producing Nonvolatile Bases
1. Oxidation of <i>anionic</i> amino acids → Urea + CO ₂ + H ₂ O + HCO ₃ ⁻ (e.g., glutamate ⁻ , aspartate ⁻)
2. Oxidation of organic anions → CO ₂ + H ₂ O + HCO ₃ ⁻ (e.g., lactate ⁻ , acetate ⁻)

However, metabolism also generates **nonvolatile acids**—such as sulfuric acid, phosphoric acid, and various organic acids—that the lungs cannot handle (see Table 39-1, section B). In addition, metabolism generates **nonvolatile bases**, which end up as HCO₃⁻ (see Table 39-1, section C). Subtracting the metabolically generated base from the metabolically generated acid leaves a net endogenous H⁺ production of ~40 mmol/day for a person weighing 70 kg. The strong acids contained in a typical Western acid-ash diet (20 mmol/day of H⁺ gained) and the obligatory loss of bases in stool (10 mmol/day of OH⁻ lost) represent an additional acid load to the body of 30 mmol/day. Thus, the body is faced with a total load of nonvolatile acids (i.e., not CO₂) of ~70 mmol/day—or ~1 mmol/kg body weight—derived from metabolism, diet, and intestinal losses. The kidneys handle this acid load by “dividing” 70 mmol/day of carbonic acid (H₂CO₃): excreting ~70 mmol/day of H⁺ into the urine and simultaneously transporting 70 mmol/day of new HCO₃⁻ into the blood. Once in the blood, this new HCO₃⁻ neutralizes the daily load of 70 mmol of nonvolatile acid.

Were it not for the tightly controlled excretion of H^+ by the kidney, the daily load of ~ 70 mmol of nonvolatile acids would progressively lower plasma pH and, in the process, exhaust the body's stores of bases, especially HCO_3^- . The result would be death by relentless acidification. Indeed, one of the characteristic symptoms of renal failure is severe acidosis caused by acid retention.  **N39-1** The kidneys continuously monitor the acid-base parameters of the extracellular fluid (ECF) and adjust their rate of acid secretion to maintain the pH of ECF within narrow limits.

N39-1

Acidoses of Renal Origin

Contributed by Erich Windhager, Gerhard Giebisch

Any overall decrease in the ability of the kidneys to excrete the daily load of ~ 70 mmol of nonvolatile acids will lead to metabolic acidosis. In the strict sense of the term, renal tubular acidosis (RTA) is an acidosis that develops secondary to the dysfunction of renal tubules. In addition, an overall decrease in useful renal mass and GFR—as occurs in end-stage renal disease—also leads to an acidosis of renal origin. One system of organizing these maladies recognizes five types of RTAs:

- **Uremic acidosis** or RTA of glomerular insufficiency. The fundamental problem is a decrease in the total amount of NH_3 that the proximal tubule can synthesize from glutamine (see pp. 829–831).
- **Proximal (type 2) RTA.** A specific dysfunction of the proximal tubule reduces the total amount of HCO_3^- that these nephron segments reabsorb.
- **Classical distal (type 1) RTA.** A specific dysfunction of the distal tubule reduces the total amount of HCO_3^- that these nephron segments reabsorb. The mechanisms can include mutations of key proteins involved in distal H^+ secretion, such as H^+ pumps and Cl-HCO_3 exchangers.
- **Generalized (type 4) RTA.** A global dysfunction of the distal tubule—secondary to aldosterone deficiency or aldosterone resistance (see p. 835)—leads to a reduced net excretion of acid.
- **Type 3 RTA.** Rare defects in CAII lead to defects in both proximal and distal H^+ secretion.

In summary, although the lungs excrete an extremely large amount of a *potential* acid in the form of CO_2 , the kidneys play an equally essential role in the defense of the normal acid-base equilibrium, because they are the sole effective route for neutralizing *nonvolatile* acids.

To maintain acid-base balance, the kidney must not only reabsorb virtually all filtered HCO_3^- but also secrete generated nonvolatile acids

In terms of acid-base balance, the major task of the kidney is to secrete acid into the urine and thus to neutralize the nonvolatile acids that metabolism produces. However, before the kidney can begin to achieve this goal, it must deal with a related and even more serious problem: retrieving from the tubule

fluid virtually all HCO_3^- filtered by the glomeruli.

Each day, the glomeruli filter 180 L of blood plasma, each liter containing 24 mmol of HCO_3^- , so that the daily filtered load of HCO_3^- is $180 \text{ L} \times 24 \text{ mM} = 4320 \text{ mmol}$. If this filtered HCO_3^- were all left behind in the urine, the result would be equivalent to an acid load in the blood of 4320 mmol, or a catastrophic metabolic acidosis (see p. 635). The kidneys avoid this problem by reclaiming virtually all the filtered HCO_3^- through secretion of H^+ into the tubule lumen and titration of the 4320 mmol/day of filtered HCO_3^- to CO_2 and H_2O .

After the kidney reclaims virtually all the filtered HCO_3^- (i.e., 4320 mmol/day), how does it deal with the acid load of 70 mmol/day produced by metabolism, diet, and intestinal losses? If we simply poured 70 mmol of nonvolatile acid into the ~1.5 L of “unbuffered” urine produced each day, urinary $[\text{H}^+]$ would be $0.070 \text{ mol}/1.5 \text{ L} = 0.047 \text{ M}$, which would correspond to a pH of ~1.3. The lowest urine pH that the kidney can achieve is ~4.4, which corresponds to an $[\text{H}^+]$ that is three orders of magnitude lower than required to excrete the 70 mmol/day of nonvolatile acids. The kidneys solve this problem by binding the H^+ to buffers that the kidney can excrete within the physiological range of urinary pH values. Some of these buffers the kidney *filters*—for example, phosphate, creatinine, and urate. Because of its favorable pK of 6.8 and its relatively high rate of excretion, phosphate is the most important nonvolatile filtered buffer. The other major urinary buffer is $\text{NH}_3/\text{NH}_4^+$, which the kidney *synthesizes*. After diffusing into the tubule lumen, the NH_3 reacts with secreted H^+ to form NH_4^+ . Through adaptive increases in the synthesis of NH_3 and excretion of NH_4^+ , the kidneys can respond to the body's need to excrete increased loads of H^+ .

The kidney does not simply eliminate the 70 mmol/day of nonvolatile acids by filtering and then excreting them in the urine. Rather, the body deals with the 70-mmol/day **acid challenge** in three steps:

Step 1: Extracellular HCO_3^- neutralizes *most* of the H^+ load:

Thus, HCO_3^- decreases by an amount that is equal to the H^+ it consumes, and an equal amount of CO_2 is produced in the process. Non- HCO_3^- buffers (see p. 635) in the blood neutralize most of the remaining H^+ load:

Thus, B^- , too, decreases by an amount that is equal to the H^+ it consumes. A very tiny fraction of the H^+

load (<0.001%; see Fig. 28-7, panel 2A) escapes buffering by either HCO_3^- or B^- . This remnant H^+ is responsible for a small drop in the extracellular pH.

Step 2: The lungs excrete the CO_2 formed by the process in Equation 39-1. The body does not excrete the HB generated by the process in Equation 39-2, but rather converts it back into B^- , as discussed below.

Step 3: The kidneys regenerate the HCO_3^- and B^- in the ECF by creating new HCO_3^- at a rate that is equal to the rate of H^+ production (i.e., ~70 mmol/day). Thus, over the course of a day, 70 mmol more HCO_3^- exits the kidneys via the renal veins than entered via the renal arteries. Most of this new HCO_3^- replenishes the HCO_3^- consumed by the neutralization of nonvolatile acids, so that extracellular $[\text{HCO}_3^-]$ is maintained at ~24 mM. The remainder of this new HCO_3^- regenerates B^- :

Again, the lungs excrete the CO_2 formed as indicated in Equation 39-3, just as they excrete the CO_2 formed by the process in Equation 39-1. Thus, by generating new HCO_3^- , the kidneys maintain constant levels of both HCO_3^- and the deprotonated forms of non- HCO_3^- buffers (B^-) in the ECF.

Table 39-2 lists the three components of net urinary acid excretion. Historically, component 1 is referred to as **titratable acid**, the amount of base one must add to a sample of urine to bring its pH back up to the pH of blood plasma. The titratable acid does *not* include the H^+ the kidneys excrete as NH_4^+ , which is component 2. Because the pK of the $\text{NH}_3/\text{NH}_4^+$ equilibrium exceeds 9, almost all of the total ammonium buffer in the urine is in the form of NH_4^+ , and titrating urine from an acid pH to a pH of 7.4 will not appreciably convert NH_4^+ to NH_3 . If no filtered HCO_3^- were lost in component 3, the generation of new HCO_3^- by the kidneys would be the sum of components 1 and 2. To the extent that filtered HCO_3^- is lost in the urine, the new HCO_3^- must exceed the sum of components 1 and 2. **N39-2**

TABLE 39-2
Components of Net Urinary Acid Excretion

	1	2	3
Net urinary acid excretion	= Excreted H^+ bound to phosphate (as H_2PO_4^-), creatinine, and uric acid	+ Excreted H^+ bound to NH_3 (as NH_4^+)	- Excretion of filtered HCO_3^-

N39-2

Urinary Excretion of Carboxylates

In addition to the loss of filtered HCO_3^- in the urine, the excretion of organic anions that can undergo conversion to HCO_3^- (e.g., lactate, citrate) would represent a loss of alkali into the urine, which in principle would need to be taken into account in computing net renal acid excretion. Because the proximal tubule normally reabsorbs nearly all of these carboxylates (see p. 779), this component of alkali loss is minor under most circumstances.

The kidneys also can control HCO_3^- and B^- following an **alkaline challenge**, produced, for example, by ingesting alkali or by vomiting (which leads to a loss of HCl, equivalent to a gain in NaHCO_3). The kidney responds by decreasing net acid excretion—that is, by sharply reducing the excretion rates of titratable acid and NH_4^+ . The result is a decrease in the production of new HCO_3^- . With an extreme alkali challenge, the excretion of urinary HCO_3^- also increases and may exceed the combined rates of titratable acid and NH_4^+ excretion. In other words, *component 3* in [Table 39-2](#) exceeds the sum of components 1 and 2, so that “net acid excretion” becomes negative, and the kidney becomes a net excretor of alkali. In this case, the kidneys return less HCO_3^- to the ECF via the renal veins than entered the kidneys via the renal arteries.

Secreted H^+ titrates HCO_3^- to CO_2 (HCO_3^- reabsorption) and also titrates filtered non-HCO_3^- buffers and endogenously produced NH_3

As we have seen, the kidney can reabsorb nearly all of the filtered HCO_3^- and excrete additional acid into the urine as both titratable acid and NH_4^+ . The common theme of these three processes is **H^+ secretion** from the blood into the lumen. Thus, the secreted H^+ can have three fates. It can titrate (1) filtered HCO_3^- , (2) filtered phosphate (or other filtered buffers that contribute to the “titratable acid”), and (3) NH_3 , both secreted and, to a lesser extent, filtered.

Titration of Filtered HCO_3^- (“ HCO_3^- Reabsorption”)

Extensive reabsorption reclaims almost all of the filtered HCO_3^- (>99.9%). As discussed beginning on [page 825](#), the kidney reabsorbs HCO_3^- at specialized sites along the nephron. However, regardless of the site, the basic mechanism of HCO_3^- reabsorption is the same ([Fig. 39-2A](#)): H^+ transported into the lumen by the tubule cell titrates filtered HCO_3^- to CO_2 plus H_2O . One way that this titration can occur is by H^+ interacting with HCO_3^- to form H_2CO_3 , which in turn dissociates to yield H_2O and CO_2 . However, the reaction $\text{H}_2\text{CO}_3 \rightarrow \text{H}_2\text{O} + \text{CO}_2$ is far too slow to convert the entire filtered load of HCO_3^- to CO_2 plus H_2O . The enzyme carbonic anhydrase (CA) [N18-3](#)—which is present in many tubule segments—bypasses this slow reaction by splitting HCO_3^- into CO_2 and OH^- (see [Table 39-1](#)). The secreted H^+ neutralizes this OH^- so that the net effect is to accelerate the production of H_2O and CO_2 .

B FORMATION OF TITRATABLE ACID

C AMMONIUM EXCRETION

FIGURE 39-2 Titration of luminal buffers by secreted H^+ . **A** and **B**, Generic models of H^+ secretion at various sites along the nephron. The red arrows represent diverse transport mechanisms. **C**, Ammonium handling by the proximal tubule.

The apical membranes of these H^+ -secreting tubules are highly permeable to CO_2 , so that the CO_2 produced in the lumen, as well as the H_2O , diffuses into the tubule cell. Inside the tubule cell, the CO_2 and H_2O regenerate intracellular H^+ and HCO_3^- with the aid of CA. Finally, the cell exports these two products, thereby moving the H^+ out across the apical membrane into the tubule lumen and the HCO_3^- out across the basolateral membrane into the blood. Thus, for each H^+ secreted into the lumen, one HCO_3^- disappears from the lumen, and one HCO_3^- appears in the blood. However, the HCO_3^- that disappears from the lumen and the HCO_3^- that appears in the blood are *not* the same molecule! To secrete H^+ and yet keep intracellular pH within narrow physiological limits (see pp. 644–645), the cell closely coordinates the apical secretion of H^+ and the basolateral exit of HCO_3^- .

Two points are worth re-emphasizing. First, HCO_3^- reabsorption does not represent net H^+ excretion into the urine. It merely prevents the loss of the filtered alkali. Second, even though HCO_3^- reabsorption is simply a reclamation effort, this process consumes by far the largest fraction of the H^+ secreted into the tubule lumen. For example, reclaiming the 4320 mmol of HCO_3^- filtered each day requires 4320 mmol of H^+ secretion, far more than the additional 70 mmol/day of H^+ secretion necessary for neutralizing nonvolatile acids.

Titration of Filtered Non- HCO_3^- Buffers (Titratable-Acid Formation)

The H^+ secreted into the tubules can interact with buffers other than HCO_3^- and NH_3 . The titration of the non- NH_3 , non- HCO_3^- buffers (B^-)—mainly HPO_4^{2-} , creatinine, and urate—to their conjugate weak acids (HB) constitutes the titratable acid discussed on page 823.

The major proton acceptor in this category of buffers excreted in the urine is HPO_4^{2-} , although creatinine also makes an important contribution; urate and other buffers contribute to a lesser extent. Figure 39-2B shows the fate of H^+ as it protonates phosphate from its divalent form (HPO_4^{2-}) to its monovalent form ($H_2PO_4^-$). Because low luminal pH inhibits the apical Na/phosphate cotransporter (NaPi) in the proximal tubule, and NaPi carries $H_2PO_4^-$ less effectively than HPO_4^{2-} (see pp. 785–786), the kidneys tend to excrete H^+ -bound phosphate in the urine. For each H^+ it transfers to the lumen to titrate HPO_4^{2-} , the tubule cell generates one new HCO_3^- and transfers it to the blood (see Fig. 39-2B).

How much does the “titratable acid” contribute to net acid excretion? The following three factors determine the rate at which these buffers act as vehicles for excreting acid:

1. The amount of the buffer in the glomerular filtrate and final urine. The filtered load (see p. 732) of HPO_4^{2-} , for example, is the product of plasma $[\text{HPO}_4^{2-}]$ and glomerular filtration rate (GFR). Plasma phosphate levels may range from 0.8 to 1.5 mM (see p. 1054). Therefore, increasing plasma $[\text{HPO}_4^{2-}]$ allows the kidneys to excrete more H^+ in the urine as H_2PO_4^- . Conversely, decreasing the GFR (as in chronic renal failure) reduces the amount of HPO_4^{2-} available for buffering, lowers the excretion of titratable acid, and thus contributes to metabolic acidosis. Ultimately, the key parameter is the amount of buffer excreted in the urine. In the case of phosphate, the fraction of the filtered load that the kidney excretes increases markedly as plasma [phosphate] exceeds the maximum saturation (T_m ; see p. 786). For a plasma [phosphate] of 1.3 mM, the kidneys reabsorb ~90%, and ~30 mmol/day appear in the urine.

2. The pK of the buffer. To be most effective at accepting H^+ , the buffer (e.g., phosphate, creatinine, urate) should have a pK value that is between the pH of the glomerular filtrate and the pH of the final urine. For example, if blood plasma has a pH of 7.4, then only ~20% of its phosphate (pK = 6.8) will be in the form of H_2PO_4^- (Table 39-3). Even if the final urine were only mildly acidic, with a pH of 6.2, ~80% of the phosphate in the urine would be in the form of H_2PO_4^- . In other words, the kidney would have titrated ~60% of the filtered phosphate from HPO_4^{2-} to H_2PO_4^- . Because creatinine has a pK of 5.0, lowering the pH of the tubule fluid from 7.4 to 6.2 increases the fractional protonation of creatinine from ~0.4% to only ~6%. However, urate has a pK of 5.8, so lowering pH from 7.4 to 6.2 would increase its fractional protonation from 2.5% to 28.5%.

TABLE 39-3
Titration of Buffers

	% PROTONATED BUFFER		
pH	PHOSPHATE (pK = 6.8)	URATE (pK = 5.8)	CREATININE (pK = 5.0)
7.4	20.1	2.5	0.4
6.2	79.9	28.5	5.9
4.4	99.6	96.2	79.9

3. The pH of the urine. Regardless of the pK of the buffer, the lower is the urinary pH, the more protonated is the buffer and the greater is the amount of acid excreted with this buffer. As discussed, lowering the pH of the tubule fluid from 7.4 to 6.2 increases the protonation of creatinine from 0.4% to only ~6%. However, if the pH of the final urine is 4.4, the fractional protonation of creatinine increases to ~80% (see Table 39-3). Thus, creatinine becomes a much more effective buffer during acidosis, when the kidney maximally acidifies the urine.

Titration of Filtered and Secreted NH_3 (Ammonium Excretion)

The third class of acceptors of luminal H^+ is NH_3 . However, unlike either HCO_3^- or the bases that give rise to “titratable acid” (e.g., HPO_4^{2-}), glomerular filtration contributes only a negligible quantity of NH_3 because plasma $[\text{NH}_3]$ concentration is exceedingly low. Instead, urinary NH_3 derives mainly from diffusion into the lumen from the proximal-tubule cell (see Fig. 39-2C), with some NH_4^+ entering the lumen directly via the apical Na-H exchanger NHE3. In the case of the proximal tubule, the conversion of

glutamine to α -ketoglutarate (α -KG) generates two NH_4^+ ions, which form two NH_3 and two H^+ ions. In addition, the metabolism of α -KG generates two OH^- ions, which CA converts to HCO_3^- ions. This new HCO_3^- then enters the blood. 🍷N39-3

N39-3

Ammonium Secretion by the Medullary Collecting Duct

Contributed by Erich Windhager, Gerhard Giebisch, Emile Boulpaep, Walter Boron

Ammonium secretion by the medullary collecting duct is critical for renal NH_4^+ excretion. As described in Figure 39-5C, the TAL of juxtamedullary nephrons reabsorbs some NH_4^+ and deposits this NH_4^+ in the medullary interstitium, where it is partitioned between ammonium and ammonia according to the equilibrium $\text{NH}_4^+ \rightleftharpoons \text{NH}_3 + \text{H}^+$. As pointed out in Figure 39-5D, this interstitial NH_4^+ (and NH_3) can have three fates: (1) some recycles back to the late proximal tubule and descending thin limb of Henle, (2) some bypasses the cortex by being secreted into the medullary collecting duct, and (3) some is washed out by the blood for export to the liver.

The mechanism of pathway (2) is depicted in Figure 39-5E. NH_3 diffuses from the medullary interstitium, through the tubule cell and into the lumen. The NH_3 moves via members of the Rh family at both the basolateral and apical membranes. The parallel extrusion of H^+ across the apical membrane of the collecting-duct cell provides the luminal H^+ that then titrates the luminal NH_3 to NH_4^+ , which is excreted. This luminal H pumping also generates OH^- inside the cells. Although not shown in Figure 39-5E, intracellular CA converts this newly created OH^- (along with H_2O) to HCO_3^- , and basolateral $\text{Cl}^-/\text{HCO}_3^-$ exchangers then export this newly created HCO_3^- to the interstitium. The HCO_3^- , of course, ultimately is washed out by the blood. Thus, for each NH_4^+ formed in the lumen of the collecting duct by this route, the tubule cell transfers one “new” HCO_3^- to the blood.

Figure 39-5E also shows that the Na-K pump can also transport NH_4^+ directly into the collecting-duct cell. This intracellular NH_4^+ can then dissociate into NH_3 (which can diffuse into the lumen) and H^+ (which moves into the lumen via the apical H pump), with the ultimate formation of NH_4^+ in the lumen. The NH_4^+ that enters the collecting-duct lumen by this route *does not* generate a new HCO_3^- ion.

eFigure 39-1 shows the most recent model for how the TAL handles NH_3 and CO_2 .

EFigure 39-1 Proposed model for CO_2 and NH_3 transport across the apical and basolateral membranes of TAL and α -intercalated cells in the collecting duct. Dashed arrows represent the possible diffusion of CO_2 or NH_3 across plasma membranes. NKCC2, Na/K/Cl cotransporter 2. In summary, when renal-tubule cells secrete H^+ into the lumen, this H^+ simultaneously titrates three kinds of buffers: (1) HCO_3^- , (2) HPO_4^{2-} and other buffers that become the “titratable acid,” and (3) NH_3 . Each of these three buffers competes with the other two for available H^+ . In our example, the kidneys secrete 4390 mmol/day of H^+ into the tubule lumen. The kidneys use most of this secreted acid—4320 mmol/day or ~98% of the total—to reclaim filtered HCO_3^- . The balance of the total secreted H^+ , 70 mmol/day, the kidneys use to generate new HCO_3^- .

Acid-Base Transport by Different Segments of the Nephron

Most nephron segments secrete H^+ to varying degrees.

The nephron reclaims virtually all the filtered HCO_3^- in the proximal tubule (~80%), thick ascending limb (~10%), and distal nephron (~10%)

The kidney reabsorbs the largest fraction of filtered HCO_3^- (~80%) along the proximal tubule (Fig. 39-3A). By the end of the proximal tubule, luminal pH falls to ~6.8, which represents only a modest transepithelial H^+ gradient compared with the plasma pH of 7.4. Thus, the proximal tubule is a high-capacity, low-gradient system for H^+ secretion. The thick ascending limb of the loop of Henle (TAL) reabsorbs an additional 10% of filtered HCO_3^- , so that by the time the tubule fluid reaches the distal convoluted tubule (DCT), the kidney has reclaimed ~90% of the filtered HCO_3^- . The rest of the distal nephron—from the DCT to the inner medullary collecting duct (IMCD)—reabsorbs almost all the remaining ~10% of the filtered HCO_3^- . Although the latter portion of the nephron reabsorbs only a small fraction of the filtered HCO_3^- , it can lower luminal pH to ~4.4. Thus, the collecting tubules and ducts are a low-capacity, high-gradient system for H^+ transport.

A RECLAMATION OF FILTERED HCO_3^- ALONG THE NEPHRON

B GENERATION OF NEW HCO_3^-

FIGURE 39-3 Acid-base handling along the nephron. In **A**, the numbered yellow boxes indicate the fraction of the filtered load reabsorbed by various nephron segments. The green boxes indicate the fraction of the filtered load that remains in the lumen at various sites. In **B**, the red boxes indicate the moieties of acid secretion associated with either the formation of titratable acid (TA) or the secretion of NH_4^+ . The yellow boxes indicate the formation of new HCO_3^- or NH_4^+ reabsorption by the TAL. The values in the boxes are approximations.

The amount of HCO_3^- lost in the urine depends on urine pH. If the $[\text{CO}_2]$ in the urine were the same as that in the blood, and if urine pH were 5.4, the $[\text{HCO}_3^-]$ in the urine would be 0.24 mM, which is 1% of the 24 mM in blood (see p. 630). For a urine production of 1.5 L/day, the kidneys would excrete 0.36 mmol/day of HCO_3^- . For a filtered HCO_3^- load of 4320 mmol/day, this loss represents a fractional excretion of ~0.01%. In other words, the kidneys reclaim ~99.99% of the filtered HCO_3^- . Similarly, at a nearly maximally acidic urine pH of 4.4, urine $[\text{HCO}_3^-]$ would be only 0.024 mM. Therefore, the kidneys

would excrete only 36 $\mu\text{mol/day}$ of filtered HCO_3^- and would reabsorb $\sim 99.999\%$.

The nephron generates new HCO_3^- , mostly in the proximal tubule

The kidney generates new HCO_3^- in two ways (see Fig. 39-3B). It titrates filtered buffers such as HPO_4^{2-} to produce “titratable acid,” and it titrates secreted NH_3 to NH_4^+ . In healthy people, NH_4^+ excretion is the more important of the two and contributes $\sim 60\%$ of *net* acid excretion or new HCO_3^- .

Formation of Titratable Acid

The extent to which a particular buffer contributes to titratable acid (see Fig. 39-2B) depends on the amount of buffer in the lumen and luminal pH. The titratable acid due to *phosphate* is already substantial at the end of the proximal tubule (Table 39-4), even though the proximal tubule reabsorbs $\sim 80\%$ of the filtered phosphate. The reason is that the luminal pH equals the pK of the buffer at the end of the proximal tubule. The titratable acid due to phosphate rises only slightly along the classical distal tubule (i.e., DCT, connecting tubule [CNT], and initial collecting tubule [ICT]), because acid secretion slightly exceeds phosphate reabsorption. The titratable acid due to phosphate rises further as luminal pH falls to 4.4 along the collecting ducts in the absence of significant phosphate reabsorption.

TABLE 39-4
Titratable Acidity of Creatinine and Phosphate Along the Nephron*

	pH	PHOSPHATE		CREATININE		SUM OF TITRATABLE ACID DUE TO PHOSPHATE AND CREATININE (mmol/day)
		FILTERED LOAD REMAINING (%)	TITRATABLE ACID DUE TO P_i (mmol/day)	FILTERED LOAD REMAINING (%)	TITRATABLE ACID DUE TO CREATININE (mmol/day)	
Bowman's space	7.4	100	0	100	0	0
End of PT	6.8	20	14.0	120 [†]	0.2	14.2
End of ICT	6.0	10	15.5	120	1.7	17.2
Final urine	5.4	10	17.8	120	5.5	23.3

*Note that other buffers in the urine contribute to the *total* titratable acid, which increases with the excreted amount of each buffer and with decreases in urine pH. In this example, we assume a plasma [phosphate] of 1.3 mM, a plasma [creatinine] of 0.09 mM, and a GFR of 180 L/day.

[†]We assume that the proximal tubule secretes an amount of creatinine that is equivalent to 20% of the filtered load.

P_i , inorganic phosphate; PT, proximal tubule.

Although the late proximal tubule secretes creatinine, the titratable acid due to *creatinine* (see Table 39-4) is minuscule at the end of the proximal tubule, because luminal pH is so much higher than creatinine's pK . However, the titratable acidity due to creatinine increases substantially along the collecting ducts as luminal pH plummets. The urine contains the protonated form of other small organic acids (e.g., uric, lactic, pyruvic, and citric acids) that also contribute to titratable acid.

NH_4^+ Excretion

Of the new HCO_3^- that the nephron generates, $\sim 60\%$ (~ 40 mmol/day) is the product of net NH_4^+ excretion (see Fig. 39-3B), which is the result of five processes: (1) the proximal tubule actually secretes slightly

more than ~40 mmol/day of NH_4^+ , (2) the TAL reabsorbs some NH_4^+ and deposits it in the interstitium, (3) some of this interstitial NH_4^+ recycles back to the proximal tubule and thin descending limb (tDLH), (4) some of the interstitial NH_4^+ enters the lumen of the collecting duct, and finally, (5) some of the interstitial NH_4^+ enters the vasa recta and leaves the kidney. As we shall see on [p. 831](#), the liver uses some of this NH_4^+ to generate urea, a process that consumes HCO_3^- . Thus, the net amount of new HCO_3^- attributable to NH_4^+ excretion is $(1) - (2) + (3) + (4) - (5)$.

Acid-Base Transport at the Cellular and Molecular Levels

The secretion of acid from the blood to the lumen—whether for reabsorption of filtered HCO_3^- , formation of titratable acid, or NH_4^+ excretion—shares three steps: (1) transport of H^+ (derived from H_2O) from tubule cell to lumen, which leaves behind intracellular OH^- ; (2) conversion of intracellular OH^- to HCO_3^- , catalyzed by CA; and (3) transport of newly formed HCO_3^- from tubule cell to blood. In addition, because the buffering power of filtered non-HCO_3^- buffers is not high enough for these buffers to accept sufficient luminal H^+ , the adequate formation of new HCO_3^- requires that the kidney generate buffer de novo. This buffer is NH_3 .

H^+ moves across the apical membrane from tubule cell to lumen by Na-H exchange, electrogenic H pumping, and K-H pumping

Although the kidney could, in principle, acidify the tubule fluid either by secreting H^+ or by reabsorbing OH^- or HCO_3^- , the secretion of H^+ appears to be solely responsible for acidifying tubule fluid. At least three mechanisms can extrude H^+ across the apical membrane; not all of these are present in any one cell.

Na-H Exchanger

Of the known NHE isoforms (see [p. 124](#)), **NHE3** is particularly relevant for the kidney because it moves more H^+ from tubule cell to lumen than any other transporter.  **N39-4** NHE3 is present not only throughout the proximal tubule ([Fig. 39-4A, B](#)) but also in the TAL (see [Fig. 39-4C](#)) and DCT.

FIGURE 39-4 Cell models of H^+ secretion.

N39-4

Renal NHEs

Contributed by Peter Aronson, Emile Boulpaep, Walter Boron

As described on page 124 of the text, several related genes encode NHEs. **N5-20**

In the renal proximal tubule, Na-H exchange is blocked by the removal of Na^+ from the lumen. Although all NHEs are far less sensitive to amiloride than the ENaC epithelial Na^+ channels (see pp. 758–759 and Fig. 35-4D), the apical **NHE3 isoform** in the proximal tubule is even less amiloride sensitive than the ubiquitous or “housekeeping” NHE1. The **NHE1 isoform** is present in the basolateral membranes of several nephron segments. The role of basolateral NHEs in acid-secreting nephron segments, such as the proximal tubule, is unclear; they may help regulate pH_i independently of transepithelial H^+ secretion.

Given a 10 : 1 concentration gradient for Na^+ from the proximal tubule lumen to the cell interior, a maximal pH gradient of 1 pH unit can be achieved by this gradient. Indeed, the late proximal tubule may have a luminal pH as low as ~6.4.

The **NHE2 isoform** is present at the apical membrane of the DCT, where it may participate in the apical step of H^+ secretion.

The apical NHE3 secretes H^+ in exchange for luminal Na^+ . Because a steep lumen-to-cell Na^+ gradient

drives this exchange process (see [p. 115](#)), apical H^+ secretion ultimately depends on the activity of the basolateral Na-K pump.

The carboxyl termini of the NHEs have phosphorylation sites for various protein kinases. For example, protein kinase A (PKA) phosphorylates apical NHE in the proximal tubule, inhibiting it. Both parathyroid hormone and dopamine inhibit NHE3 via PKA.

Electrogenic H Pump

A second mechanism for apical H^+ secretion by tubule cells is the electrogenic H pump, a vacuolar-type ATPase (see [pp. 118–119](#)). The ATP-driven H pump can establish steep transepithelial H^+ concentration gradients, thus lowering the urine pH to ~ 4.0 to 5.0 . In contrast, NHE3, which depends on the 10-fold Na^+ gradient across the apical membrane, cannot generate an H^+ gradient in excess of ~ 1 pH unit.

The apical electrogenic H pumps are located mainly in a subpopulation of intercalated cells (α cells) of the CNT, ICT, and cortical collecting tubule (CCT) and in cells of the IMCD and outer medullary collecting duct (OMCD; [Fig. 39-4D](#)). However, H pumps are also present in the apical membrane of the proximal tubule (see [Fig. 39-4A, B](#)), the TAL (see [Fig. 39-4C](#)), and the DCT. In addition, an electrogenic H pump is also present in the basolateral membrane of β -intercalated cells. [N39-5](#) Mutations in genes encoding subunits of this H pump cause a metabolic acidosis (see [p. 635](#)) in the blood—a **distal renal tubular acidosis (dRTA)**.

N39-5

The β -Intercalated Cell

Contributed by Walter Boron, Peter Aronson, Emile Boulpaep

Electrogenic H pumps are present in β -intercalated cells (see [Fig. 39-9B](#)), which, to a first approximation, are backward α -intercalated cells (see [Fig. 39-4D](#)). We discuss β -intercalated cells (β -ICs) in the text on page 834.

In β -ICs, the electrogenic H pump is present in the basolateral membrane, and the $Cl-HCO_3$ exchanger is in the apical membrane. Thus, unlike the α -ICs, which engage in net HCO_3^- reabsorption, the β -ICs engage in net HCO_3^- secretion.

An interesting difference between the α -ICs and the β -ICs is that in the α cells, the $Cl-HCO_3$ exchanger is a variant of AE1 (the $Cl-HCO_3$ exchanger in red blood cells, and a member of the SLC4 family), whereas in the β cells the $Cl-HCO_3$ exchanger is molecularly quite different, being a member of the SLC26 family.

In addition to the switch from α -IC to β -IC, HCO_3^- secretion can also be stimulated by increased luminal delivery of Cl^- , which promotes the exchange of luminal Cl^- for intracellular HCO_3^- via the apical $Cl-HCO_3$ exchanger.

A molecule by the name of **hensin** controls the conversion from β - to α -intercalated cells. Genetic deletion of hensin in the tubule causes a **distal renal tubular acidosis (dRTA)** because the mice secrete HCO_3^- inappropriately and therefore become HCO_3^- deficient in the blood.

Reference

The regulation of the apical H pump involves several mechanisms. First, the transepithelial electrical potential may modulate the H pump rate. For instance, aldosterone induces increased apical Na^+ uptake by the principal cells in the CCT (see pp. 765–766), thus causing an increase in the lumen-negative potential, which in turn stimulates the H pump. Second, aldosterone stimulates the H pump independently of changes in voltage. Third, acidosis increases the recruitment and targeting of pump molecules to the apical membranes of α -intercalated cells in the CNT, ICT and CCT, whereas alkalosis has the opposite effect.

H-K Exchange Pump

A third type of H^+ -secretory mechanism is present in the ICT, the CCT, and the OMCD (see Fig. 39-4D): an electroneutral H-K pump (see pp. 117–118) that is related to the Na-K pump. Several isoforms of the H-K pump are present in the kidney and exhibit differential sensitivities to inhibition by drugs such as omeprazole, SCH-28080, and ouabain. The H-K pump probably does not contribute significantly to acid secretion under normal conditions. However, K^+ depletion (see p. 803) induces expression of the H-K pump, which retrieves luminal K^+ and, as a side effect, enhances H^+ secretion. This H^+ secretion contributes to the metabolic alkalosis often observed in patients with hypokalemia—hypokalemic metabolic alkalosis.

CAs in the lumen and cytosol stimulate H^+ secretion by accelerating the interconversion of CO_2 and HCO_3^-

The CAs  N18-3 play an important role in renal acidification by catalyzing the interconversion of CO_2 to HCO_3^- . Inhibition of CAs by sulfonamides, such as acetazolamide, profoundly slows acid secretion. CAs may act at three distinct sites of acid-secreting tubule cells (see Fig. 39-4): the extracellular face of the apical membrane, the cytoplasm, and the extracellular face of the basolateral membrane. Two CAs are especially important for tubule cells. The soluble CA II is present in the cytoplasm, whereas CA IV is coupled via a GPI linkage (see p. 13) to the outside of the apical and basolateral membranes, predominantly in proximal-tubule cells.

Apical CA (CA IV)

In the absence of apical CA, the H^+ secreted accumulates in the lumen, and Na-H exchange and H^+ secretion are inhibited. By promoting the conversion of luminal HCO_3^- to CO_2 plus OH^- , apical CA prevents the lumen from becoming overly acidic and thus substantially relieves this inhibition. Thus, CA promotes high rates of HCO_3^- reabsorption along the early proximal tubule (see Fig. 39-4A).

In the distal nephron (see Fig. 39-4D), H^+ secretion is less dependent on luminal CA than it is in the early proximal tubule for two reasons. First, the H^+ secretion rate is lower than that in the proximal tubule. Thus, the uncatalyzed conversion of luminal H^+ and HCO_3^- to CO_2 and H_2O can more easily keep up with the lower H^+ secretion rate. Second, in the collecting tubules and ducts the electrogenic H pump can extrude H^+ against a very high gradient. Therefore, even in the absence of CA, the collecting ducts can

raise luminal $[H^+]$ substantially, thereby accelerating the uncatalyzed reaction by mass action.

Cytoplasmic CA (CA II)

Cytoplasmic CA accelerates the conversion of intracellular CO_2 and OH^- to HCO_3^- (see Fig. 39-4). As a result, CA II increases the supply of H^+ for apical H^+ extrusion and the supply of HCO_3^- for the basolateral HCO_3^- exit step. In the CNT, ICT, and CCT, the intercalated cells (which engage in acid-base transport) contain CA II, whereas the principal cells do not.

Basolateral CA (CA IV and CA XII)

The role played by basolateral CA IV and CA XII (an integral membrane protein with an extracellular catalytic domain) is not yet understood.  [N39-6](#)

N39-6

Carbonic Anhydrase at the Basolateral Membrane

Contributed by Walter Boron

Although it has been known for years that carbonic anhydrases (CAs) are present at the basolateral membrane of the proximal tubule (CA IV, CA XII), only recently has research begun to shed light on the significance of this observation. Two distinct classes of CAs are present near or at the basolateral membrane: (1) the cytosolic or soluble CA II, and (2) one or more membrane-bound CAs (e.g., CA IV, CA XII) with the catalytic domain facing the interstitial fluid. Renal CA XIV is abundant in rodents but is virtually undetectable in human and rabbit kidneys. The role of CA XIV in rodents may be an adaptation to the relatively low activity of rodent CA IV, owing to a G63Q substitution.

CA II

According to several reports, the soluble CA II binds reversibly to a site on the cytosolic carboxyl termini of certain HCO_3^- transporters in the SLC4 family. Among these is the electrogenic Na/HCO_3 cotransporter NBCe1, which is responsible for the vast majority of HCO_3^- efflux across the basolateral membrane of the proximal tubule (see Fig. 39-4A). According to one viewpoint, the function of the bound CA II is to provide HCO_3^- as a substrate for the NBCe1 to export to the basolateral side of the tubule cell according to the reaction

Published data are consistent with the hypothesis that bound—but not free—CA II increases HCO_3^- transport.

According to an alternate view that is emerging from the laboratory of Walter Boron, the role of CA II is very different. Preliminary data suggest that NBCe1 transports CO_3^{2-} . Thus, when operating with an apparent $Na^+ : HCO_3^-$ stoichiometry of 1 : 3, as it appears to do in the proximal tubule, NBCe1 might

actually transport 1 Na^+ , 1 CO_3^{2-} , and 1 HCO_3^- out of the cell across the basolateral membrane. You might imagine that 1 Na^+ and 3 HCO_3^- ions approach the basolateral membrane from the bulk cytosol. NBCe1 directly extrudes the Na^+ and 1 HCO_3^- . The second HCO_3^- dissociates to provide the CO_3^{2-} that NBCe1 will export:

The third HCO_3^- , in a reaction catalyzed by CA II, produces an OH^- ,

and this OH^- neutralizes the newly formed H^+ :

As a result, NBCe1 would export 1 Na^+ , 1 HCO_3^- , and 1 CO_3^{2-} . Of the original 3 HCO_3^- ions that approached the basolateral membrane, 1 carbon atom, 2 hydrogen atoms, and 3 oxygen atoms would be left behind in the cytosol in the form of $\text{CO}_2 + \text{H}_2\text{O}$. According to the alternate view proposed by the Boron laboratory, the CO_2 and H_2O would exit across the basolateral membrane via another route. Also according to the alternate view, the role of the bound CA II would be to buffer the H^+ ions that accumulate on the intracellular side of the membrane as CO_3^{2-} forms from HCO_3^- . Preliminary data from the Boron laboratory indicate that the presence of CA II does *not* stimulate the electrical current carried by NBCe1, at least as expressed in *Xenopus* oocytes.

Extracellular CAs

According to the classical view, the role of CAs that face the basolateral ECF would be to consume the HCO_3^- exported by NBCe1 according to the following reaction:

According to this view, in consuming the newly exported HCO_3^- , the CA would stimulate the NBCe1.

According to the alternate hypothesis put forward by the Boron laboratory, the role of these extracellular CAs is just the opposite of that of the cytoplasmic CA II. Recall that this hypothesis proposes that NBCe1 directly exports 1 Na^+ , 1 HCO_3^- , and 1 CO_3^{2-} , and that 1 CO_2 and 1 H_2O exit by a

parallel route. The extracellular CA would assist in the reassembly of 1 CO_2 , 1 H_2O , and 1 CO_3^{2-} to form 2 HCO_3^- ions, which would then diffuse away from the membrane into the bulk ECF. Indeed, preliminary data show that expressing CA IV on the surface of a *Xenopus* oocyte greatly reduces the magnitude of the alkalization produced as NBCe1 exports “ HCO_3^- ” from the cell. Moreover, blocking the CA IV with acetazolamide increases the magnitude of the alkalization by more than twofold. Finally, preliminary data show that blockade of the CA IV has virtually no effect on the current carried by NBCe1. Thus, it may be that the role of the extracellular CA is not to stimulate NBCe1, but to minimize the size of pH changes on the extracellular surface of the cell.

Inhibition of CA

The administration of drugs that block CAs, such as acetazolamide, strongly inhibits HCO_3^- reabsorption along the nephron, leading to the excretion of an alkaline urine. Because acetazolamide reduces the reabsorption of Na^+ , HCO_3^- , and water, this drug is also a **diuretic** (i.e., it promotes urine output). **N39-7** However, a small amount of H^+ secretion and HCO_3^- reabsorption remains despite the complete inhibition of CA. This remaining transport is related in part to the slow uncatalyzed hydration-dehydration reactions and in part to a buildup of luminal H_2CO_3 , which may diffuse into the cell across the apical membrane (mimicking the uptake of CO_2 and H_2O).

N39-7

Diuretic Action of the CA Inhibitor Acetazolamide

Contributed by Gerhard Giebisch, Erich Windhager

As described in Box 40-3 and in Table 40-3, the drug acetazolamide (a potent inhibitor of CAs) produces diuresis by inhibiting the component of proximal-tubule Na^+ reabsorption that is coupled to HCO_3^- reabsorption.

For further discussion of CAs, consult **N18-3**.

HCO_3^- efflux across the basolateral membrane takes place by electrogenic Na/HCO_3 cotransport and $\text{Cl}-\text{HCO}_3$ exchange

The regulation of the intracellular pH of acid-secreting tubule cells requires that H^+ secretion across the apical membrane be tightly linked to, and matched by, the extrusion of HCO_3^- across the basolateral membrane. Two mechanisms are responsible for HCO_3^- transport from the cell into the peritubular fluid: electrogenic Na/HCO_3 cotransport and $\text{Cl}-\text{HCO}_3$ exchange.

Electrogenic Na/HCO_3 Cotransport

In proximal-tubule cells, the electrogenic Na/HCO_3 cotransporter NBCe1 (see p. 122) is responsible for much of the HCO_3^- transport across the basolateral membrane. NBCe1 (SLC4A4) is expressed at highest levels in the S1 portion of the proximal tubule (see Fig. 39-4A) and gradually becomes less abundant in the more distal proximal-tubule segments (see Fig. 39-4B). NBCe1 is a 1035–amino-acid protein with a

molecular weight of ~130 kDa. 4,4'-Diisothiocyanostilbene-2,2'-disulfonate (DIDS), an inhibitor of most HCO_3^- transporters, also inhibits NBCe1. Because, in proximal-tubule cells, this transporter usually transports three HCO_3^- ions for each Na^+ ion, the electrochemical driving forces cause it to carry these ions from cell to blood. Renal NBCe1 carries two *net* negative charges and is thus electrogenic. Human mutations that reduce either NBCe1 activity or NBCe1 targeting to the basolateral membrane cause a severe metabolic acidosis—**proximal renal tubular acidosis (pRTA)**.  **N39-8**

N39-8

The Electrogenic Na/HCO_3 Cotransporter NBCe1

Contributed by Walter Boron

NBCe1 is a member of the SLC4 family of solute transporters. It is believed that all of the family members have the same topology: (1) a large cytoplasmic N terminus (Nt) that comprises about 40% of the protein, (2) a large transmembrane domain (TMD) that includes 10 to 14 transmembrane segments (TMs) and comprises ~50% of the protein, and (3) a short cytoplasmic C terminus (Ct) that comprises ~10% of the protein.

The gene *SLC4A4* encodes three known variants of NBCe1, which differ from one another at their extreme Nt and Ct. The proximal tubule expresses the variant NBCe1-A, which has a very high functional activity. The other variants—the more ubiquitous NBCe1-B and the “brain” form NBCe1-C—have a different Nt. This difference endows these transporters with a low functional activity—due to either reduced trafficking to the membrane or reduced intrinsic activity. However, a soluble protein called IRBIT appear to reverse this inhibition. The NBCe1-A variant in the proximal tubule, however, is the fast variant.

In the proximal tubule, NBCe1-A appears to operate with a stoichiometry of 1 Na^+ for 3 HCO_3^- ions. Thus, each transport event moves two negative charges out of the cell and thereby makes the basolateral membrane potential (V_{bl}) more positive. The reversal potential for NBCe1-A is very close to V_{bl} . Accordingly, cell depolarization inhibits Na/HCO_3 efflux or can even reverse the direction of transport and cause basolateral Na/HCO_3 uptake.

At least 10 naturally occurring human mutations of NBCe1 are known. From a molecular perspective, these mutations cause poor function or poor targeting to the appropriate plasma membrane (i.e., the basolateral membrane in the case of NBCe1-A in the proximal-tubule cell). From a clinical perspective, these naturally occurring mutations have a devastating effect on the patient, causing a severe **pRTA** and other problems that may—depending on the mutation—lead to short stature, mental retardation, and ocular deficits.

Chronic metabolic and respiratory acidosis, hypokalemia, and hyperfiltration all increase NBCe1 activity. As would be expected, several factors cause parallel changes in the activities of the apical NHE3 and basolateral Na/HCO_3 cotransporter, minimizing changes in cell pH and $[\text{Na}^+]$. Thus, angiotensin II (ANG II) and protein kinase C (PKC) stimulate both transporters, whereas parathyroid hormone and PKA markedly inhibit both.

Cl- HCO_3 Exchange

In the S3 segment of the proximal tubule, as well as in the TAL and collecting tubules and ducts, $\text{Cl}-\text{HCO}_3$ exchangers participate in transepithelial acid-base transport. The AE1 anion exchanger (see pp. 124–125) is found in the basolateral membranes of α -intercalated cells of the CNT, the ICT, and the CCT (see Fig. 39-4D). Basolateral AE2 is present in the TAL (see Fig. 39-4C) and the DCT.

NH_4^+ is synthesized by proximal tubules, partly reabsorbed in the loop of Henle, and secreted passively into papillary collecting ducts

As we saw in our discussion of the segmental handling of NH_4^+ (see pp. 826–827 and Fig. 39-3B), the **proximal tubule** is the main site of renal NH_4^+ synthesis, although almost all other tubule segments have the capacity to form NH_4^+ . The proximal tubule forms NH_4^+ largely from glutamine (Fig. 39-5A), which enters tubule cells both from luminal and peritubular fluid via Na^+ -coupled cotransporters. Inside the mitochondria, glutaminase splits glutamine into NH_4^+ and glutamate, and then glutamate dehydrogenase splits the glutamate into α -KG and a second NH_4^+ . Ammonium is a weak acid that can dissociate to form H^+ and NH_3 . Because the pK of the $\text{NH}_3/\text{NH}_4^+$ equilibrium is ~ 9.2 , the $\text{NH}_3/\text{NH}_4^+$ ratio is 1 : 100 at a pH of 7.2. Whereas the cationic NH_4^+ does not rapidly cross most cell membranes, the neutral NH_3 readily diffuses through most, but not all, cell membranes via gas channels.  **N39-3** When NH_3 diffuses from a relatively alkaline proximal-tubule or collecting-duct cell into the more acidic lumen, the NH_3 becomes “trapped” in the lumen after buffering the newly secreted H^+ to form the relatively impermeant NH_4^+ (see Fig. 39-5A). Not only does NH_3 diffuse across the apical membrane, but the apical NHE3 directly secretes some NH_4^+ into the proximal tubule lumen (with NH_4^+ taking the place of H^+).

A EARLY PROXIMAL TUBULE

B DESCENDING LIMB OF HENLE (tDLH)

C THICK ASCENDING LIMB (TAL)

D FATES OF MEDULLARY $\text{NH}_3/\text{NH}_4^+$

E MEDULLARY COLLECTING DUCT

FIGURE 39-5 Ammonium handling. **B**, In juxtamedullary nephrons, the secretion of NH_4^+ into the tubule lumen of the tDLH occurs mainly in the outer portion of the medulla. In **D**, the three numbered boxes indicate the three fates of the NH_4^+ reabsorbed by the TAL. GLUT, glucose transporter; NBC, Na/HCO_3 cotransporter; PEP, phosphoenolpyruvate.

A second consequence of NH_4^+ synthesis is that the byproduct $\alpha\text{-KG}$ participates in gluconeogenesis, which indirectly generates HCO_3^- ions. As shown in [Figure 39-5A](#), the metabolism of two glutamines generates four NH_3 and two $\alpha\text{-KG}$. Gluconeogenesis of these two $\alpha\text{-KG}$, along with four H^+ , forms one glucose and four HCO_3^- ions. Accordingly, for each NH_4^+ secreted into the tubule lumen, the cell secretes one new HCO_3^- into the peritubular fluid.

In juxtamedullary nephrons, which have long loops of Henle, the **tDLH** may both reabsorb and secrete NH_3 , with the secretion dominating. Tubule fluid may become alkaline along the tDLH, titrating NH_4^+ to NH_3 and promoting NH_3 reabsorption. On the other hand, reabsorption of NH_4^+ by the TAL (see following paragraph) creates a gradient favoring NH_3 diffusion from the interstitium into the lumen of the tDLH. Modeling of these processes predicts net secretion of NH_3 into the tDLH in the outer medulla (see [Fig. 39-5D](#)). In the **thin ascending limb**, NH_4^+ reabsorption may occur by diffusion of NH_4^+ into the interstitium.

In contrast to the earlier segments, the **TAL** *reabsorbs* NH_4^+ (see [Fig. 39-5C](#)). Thus, much of the NH_4^+ secreted by the proximal tubule and tDLH does not reach the DCT. Because the apical membrane of the TAL is unusual in having a very low NH_3 permeability, the TAL takes up NH_4^+ across the apical membrane by using two transport mechanisms, the $\text{Na}/\text{K}/\text{Cl}$ cotransporter and the K^+ channels. Indeed, inhibiting the $\text{Na}/\text{K}/\text{Cl}$ cotransporter blocks a significant fraction of NH_4^+ reabsorption, which suggests that NH_4^+ can replace K^+ on the cotransporter. Ammonium leaves the cell across the basolateral membrane—probably as NH_3 , via a gas channel, and as NH_4^+ carried by the NHE—which leads to accumulation of NH_4^+ in the renal medulla.

The NH_4^+ that has accumulated in the interstitium of the medulla has three possible fates (see [Fig. 39-5D](#)). First, some dissociates into H^+ and NH_3 , which then enters the lumen of the late proximal tubule and the early tDLH (see [Fig. 39-5D](#)). This NH_3 probably diffuses across the aquaporin 1 (AQP1) water channel (see [Chapter 5](#)) that is present in both the basolateral and apical membranes of these tubules. Luminal H^+ then traps the NH_3 as NH_4^+ (see [Fig. 39-5B](#)). Thus, NH_4^+ **recycles** between the proximal tubule/tDLH and the TAL.

Second, some of the interstitial NH_4^+ dissociates into H^+ and NH_3 , which then enters the lumen of the medullary collecting ducts (see [Fig. 39-5D](#)). NH_3 diffuses into the cell across the basolateral membrane via the gas channels RhBG and RhCG, and then enters the lumen via RhCG, where the NH_3 combines with secreted H^+ to form NH_4^+ (see [Fig. 39-5E](#)). In addition, the Na-K pump may carry NH_4^+ (in place of K^+) into cells of the medullary collecting ducts. To the extent that NH_4^+ moves directly from the TAL to the medullary collecting duct, it engages in a **bypass** of the cortical portions of the distal nephron. This bypass prevents cortical portions of the distal nephron from losing NH_3 by diffusion from the lumen into the cortical interstitium, and thus minimizes the entry of the toxic NH_3 into the circulation.

Third, a small fraction of medullary NH_4^+ enters the vasa recta. This NH_4^+ **washout** returns the nitrogen to the systemic circulation for eventual detoxification by the liver. In the steady state, the buildup of NH_4^+ in the medulla leads to a sharp increase in $[\text{NH}_4^+]$ along the corticomedullary axis.

Because the liver synthesizes glutamine (see [p. 965](#)), the main starting material for NH_4^+ production in the kidney, hepatorenal interactions are important in the overall process of NH_4^+ excretion ([Fig. 39-6](#)). The liver disposes of ~ 1000 mmol/day of amino groups during the catabolism of amino acids. Some of these amino groups become NH_4^+ via deamination reactions, and some end up as amino groups on either glutamate or aspartate via transamination reactions.

FIGURE 39-6 Cooperation between the liver and kidney in excreting nitrogen derived from amino-acid breakdown. In this example, we assume a release of 940 mmol/day of amino groups, resulting in the urinary excretion of 450 mmol/day of urea (900 mmol/day of amino nitrogen) and 40 mmol/day of NH₄⁺. The values in the boxes are approximations.

Of the ~1000 mmol/day of catabolized amino groups, the liver detoxifies ~95% by producing urea (see

p. 965), which the kidneys excrete (see p. 770). One -NH_2 in urea comes from an NH_4^+ that had dissociated to form NH_3 and H^+ , the other -NH_2 comes from aspartate, and the C=O comes from HCO_3^- (see Fig. 39-6). The net result is the generation of urea and—considering that the generated H^+ consumes another HCO_3^- —the consumption of two HCO_3^- .

The liver detoxifies the remaining ~5% of catabolized amino groups by converting NH_4^+ and glutamate to glutamine (see Fig. 39-6). This reaction does not generate acid-base equivalents. The proximal-tubule cells take up this hepatic glutamine and use it as the source of the NH_4^+ that they secrete into the tubule lumen as they generate one new HCO_3^- (see Fig. 39-5A).

Thus, the two hepatorenal mechanisms for disposing of catabolized amino groups have opposite effects on HCO_3^- . For each catabolized amino group excreted as urea, the liver *consumes* the equivalent of one HCO_3^- . For each catabolized amino group excreted as NH_4^+ via the glutamine pathway, the proximal tubule *produces* one new HCO_3^- (see Fig. 39-6). To the extent that the kidney excretes NH_4^+ , the liver consumes less HCO_3^- as it synthesizes urea (Box 39-1). **N39-9**

Box 39-1

Renal Tubular Acidosis

Contributed by Mark D. Parker

Renal tubular acidosis (RTA) is a broad label applied to a group of disorders that compromise renal acid-base handling. RTA is characterized by a reduced ability to eliminate H^+ in the urine or by HCO_3^- wasting, both of which can result in a lowered plasma pH (i.e., metabolic acidosis) and, in children, severe impairment of physical and intellectual development. RTA can follow a more generalized disruption of renal function (e.g., as a side effect of medication, autoimmune disease, multiple myeloma) or can result from mutations in genes that encode renal acid-base-handling proteins. RTA is classified into four types, each of which has a different set of causes and clinical manifestations. In addition, we can define a fifth type of RTA that is associated with end-stage renal disease.

Type 1 or Distal RTA

Distal RTA (dRTA) results from defective H^+ excretion by distal segments of the nephron. Consequently, dRTA patients cannot appropriately acidify their urine and may exhibit a metabolic acidosis. Genetic causes of dRTA include mutations in the **Cl-HCO_3 exchanger AE1** and in subunits of the **H pump**, both of which are key components of the H^+ -secretory machinery in α -intercalated cells (see Fig. 39-4D). In patients with **incomplete dRTA**, blood pH is unaffected because compensatory mechanisms (e.g., proximal-tubule function) remain intact; in these individuals, metabolic acidosis occurs only following an acid load. Manifestations of dRTA can include hypokalemia, kidney stones, hemolytic anemia (due to loss of AE1 function in red cells), and hearing loss (due to loss of H pump function in the cochlea).

Type 2 or Proximal RTA

Proximal RTA (pRTA) results from the inability of proximal-tubule cells to reabsorb filtered HCO_3^- or to generate new HCO_3^- . Consequently, pRTA patients exhibit a severe metabolic acidosis and a wasting of HCO_3^- into the urine. Genetic defects in the **Na/HCO_3 cotransporter NBCe1** cause pRTA because of the

key role of that protein in mediating HCO_3^- movement into the bloodstream (see Fig. 39-4A). Other causes include Fanconi syndrome (e.g., due to multiple myeloma, lead poisoning) and acetazolamide toxicity. Manifestations of pRTA can include hypokalemia and—in children—developmental defects, including ocular problems and poor dentition (considered in part to be due to loss of NBCe1 function in the eye and enamel organ).

Type 3 RTA

Type 3 RTA is a rare combination of type 1 and type 2 RTAs and is associated with defects in **CA II**, a shared component of the acid-base–handling mechanisms in the distal and proximal tubules. Clinical manifestations include osteopetrosis due to loss of CA II function in osteoclasts (see p. 1056).

Type 4 or Hyperkalemic RTA (Hypoaldosteronism)

Hyperkalemic RTA is a mild form of acidosis caused by aldosterone insufficiency or renal insensitivity to aldosterone. Insufficient stimulation of mineralocorticoid receptors in α -intercalated cells reduces H^+ directly (see p. 835); insufficient stimulation of these receptors in principal cells reduces K^+ secretion, leading to hyperkalemia, which causes metabolic acidosis by several mechanisms (see p. 835).

Uremic Acidosis

In end-stage renal disease, a loss of functional renal mass compromises total ammoniagenesis. **N39-1**

Treatment

Treatments for RTA vary depending on the clinical signs in each case but generally focus on correcting the metabolic acidosis by administration of HCO_3^- or citrate salts (**oral base therapy**). Additional therapies include administration of diuretics (e.g., hydrochlorothiazide) to stimulate renal H^+ secretion.

N39-9

Net Renal Ammonium Excretion

Contributed by Peter Aronson, Gerhard Giebisch

As noted in the text, one component of the “new HCO_3^- ” created by the proximal tubule parallels the generation of NH_4^+ in the proximal-tubule lumen. However, this generation of new HCO_3^- is reversed to the extent that the NH_4^+ reabsorbed by the TAL into the medullary interstitium is then picked up by the vasa recta and carried back to the liver for urea production (see Fig. 39-6). Thus, the resecretion of NH_4^+ from the medullary interstitium into the collecting-duct lumen (for excretion into the urine) is crucial to optimize the efficiency of new-HCO_3^- generation by the kidney and thus to balance net acid production.

Regulation of Renal Acid Secretion

A variety of physiological and pathophysiological stimuli can modulate renal H^+ secretion as well as NH_3 synthesis. Most of these factors produce coordinated changes in apical and basolateral acid-base transport, as well as in NH_3 production.

Respiratory acidosis stimulates renal H^+ secretion

The four fundamental pH disturbances are respiratory acidosis and alkalosis, and metabolic acidosis and alkalosis (see Fig. 28-11A). In each case, the initial and almost instantaneous line of defense is the action of buffers—both in the extracellular and intracellular compartments—to *minimize* the magnitude of the pH changes (see pp. 628–629). However, *restoring* the pH to a value as close to “normal” as possible requires slower compensatory responses from the lungs or kidneys.

In respiratory acidosis, in which the primary disturbance is an increase in arterial P_{CO_2} , the compensatory response is an increase in renal H^+ secretion, which translates to increased production of new HCO_3^- via NH_4^+ excretion. The opposite occurs in respiratory alkalosis. These changes in H^+ secretion tend to correct the distorted $[\text{HCO}_3^-]/[\text{CO}_2]$ ratios that occur in primary respiratory acid-base derangements.

Respiratory acidosis stimulates H^+ secretion in at least three ways. First, an *acute* elevated P_{CO_2} directly stimulates proximal-tubule cells to secrete H^+ , as shown by applying solutions in which it is possible to change P_{CO_2} without altering basolateral pH or $[\text{HCO}_3^-]$. **N39-10** Thus, proximal-tubule cells directly sense basolateral CO_2 . In part, the mechanism is the exocytotic insertion of H pumps into the apical membranes of proximal-tubule cells. Second, acute respiratory acidosis also causes exocytotic insertion of H pumps into the apical membranes of intercalated cells in distal nephron segments. Third, *chronic* respiratory acidosis leads to adaptive responses that upregulate acid-base transporters. For example, respiratory acidosis increases the activities of apical NHE3 and basolateral NBCe1 in proximal tubule. These adaptive changes allow the kidney to produce a metabolic compensation to the respiratory acidosis (see p. 641).

N39-10

Use of Out-of-Equilibrium Solutions to Probe the Chemosensitivity of the Proximal Tubule

Contributed by Walter Boron

As described in **N28-4**, the laboratory of Walter Boron developed a rapid-mixing technique that makes it possible to generate out-of-equilibrium (OOE) $\text{CO}_2/\text{HCO}_3^-$ solutions with virtually any combination of $[\text{CO}_2]$, $[\text{HCO}_3^-]$, and pH—as long as the desired pH is not more than a few pH units from neutrality.

Recently, the laboratory has applied the OOE $\text{CO}_2/\text{HCO}_3^-$ solutions to learn more about how the proximal tubule senses acute acid-base disturbances and translates that information to alter the rate at which the tubule reabsorbs HCO_3^- (i.e., moves HCO_3^- from the lumen to the basolateral side of the tubule).

The approach was to isolate a single proximal tubule and perfuse its lumen with a solution of 5% $\text{CO}_2/22 \text{ mM } \text{HCO}_3^-/\text{pH } 7.4$ as well as ^3H -methoxyinulin as a volume marker. By collecting the fluid after it had flowed down the lumen and then analyzing this fluid for $[\text{HCO}_3^-]$ and $[^3\text{H}\text{-methoxyinulin}]$, the investigators were able to compute the rate of volume reabsorption (J_V —that is, the rate at which the tubule moves water from the lumen to the basolateral surface of the tubule, measured in nanoliters per minute per millimeter of tubule length) and the rate of HCO_3^- reabsorption ($J_{\text{HCO}_3^-}$ —measured in picomoles per minute per millimeter of tubule length). The investigators superfused the basolateral (bl) surface of the tubule with a rapidly flowing solution that was either the “standard” equilibrated 5% $\text{CO}_2/22 \text{ mM } \text{HCO}_3^-/\text{pH } 7.4$ solution or an OOE solution in which they varied—one at a time— $[\text{CO}_2]_{\text{bl}}$, $[\text{HCO}_3^-]_{\text{bl}}$, or pH_{bl} . Thus, they were able to observe the effects of altering basolateral acid-base composition on J_V and $J_{\text{HCO}_3^-}$.

What they found was rather striking. When the investigators raised $[\text{CO}_2]_{\text{bl}}$ from 0 to 4.8 mM—at a fixed $[\text{HCO}_3^-]_{\text{bl}}$ of 22 mM and a fixed pH_{bl} of 7.40—they found that $J_{\text{HCO}_3^-}$ *increased* in a graded fashion. This result is what one might expect from what we learned about a metabolic compensation to a respiratory acidosis (see p. 641). That is, the kidney ought to respond to a rise in $[\text{CO}_2]_{\text{bl}}$ —the “respiratory” part of a respiratory acidosis—by reabsorbing more HCO_3^- and thereby tending to restore blood pH to a more alkaline value. However, the investigators were quite surprised to find that increases in $J_{\text{HCO}_3^-}$ were not accompanied by the expected increases in J_V (i.e., the extra NaHCO_3 reabsorbed by the proximal tubule should have been accompanied by osmotically obligated water, which should have raised J_V appreciably).

When the investigators raised $[\text{HCO}_3^-]_{\text{bl}}$ from 0 to 44 mM—at a fixed $[\text{CO}_2]_{\text{bl}}$ of 1.2 mM and a fixed pH_{bl} of 7.40—they found that $J_{\text{HCO}_3^-}$ *decreased* in a graded fashion. This result is what one might expect for the kidney's response to a metabolic alkalosis caused by an abnormality outside of the kidney. That is, the kidney ought to respond to a rise in $[\text{HCO}_3^-]_{\text{bl}}$ —the “metabolic” part of a metabolic alkalosis—by reabsorbing less HCO_3^- and thereby tending to restore blood pH to a more acidic value. However, the investigators were quite surprised to find that decreases in $J_{\text{HCO}_3^-}$ were not accompanied by the expected decreases in J_V (i.e., because the tubule reabsorbed less NaHCO_3 , it should also have reabsorbed less osmotically obligated water, so that J_V should have fallen appreciably).

Finally, when the investigators raised pH_{bl} from 6.8 to 8.0 mM—at a fixed $[\text{CO}_2]_{\text{bl}}$ of 1.2 mM and a fixed $[\text{HCO}_3^-]_{\text{bl}}$ of 22 mM—they found that $J_{\text{HCO}_3^-}$ *did not change!* One might have expected that a basolateral alkalosis (the “alkalosis” part of a respiratory or metabolic alkalosis) would have caused the tubule to reabsorb less HCO_3^- and thereby tend to restore blood pH to a more acidic value. In these experiments, the intracellular pH of the tubule cells changed appreciably, but neither change in pH, intracellular or basolateral, triggered a change in $J_{\text{HCO}_3^-}$ or J_V .

These experiments led the investigators to conclude that the proximal tubule cannot sense pH per se. Instead, they propose that the proximal-tubule cell has sensors for both basolateral CO_2 and basolateral HCO_3^- . In other words, the proximal tubule seems to regulate blood pH by sensing the body's two most important buffers. When activated, the CO_2 sensors would trigger an increase in NaHCO_3 reabsorption but a compensating decrease in the reabsorption of other solutes. When activated, the HCO_3^- sensors would trigger a decrease in NaHCO_3 reabsorption but a compensating increase in the reabsorption of other solutes. The compensating effects on the other solutes would serve to stabilize blood pressure.

Metabolic acidosis stimulates both proximal H^+ secretion and NH_3 production

The first compensatory response to metabolic acidosis is increased alveolar ventilation, which blows off CO_2 (see p. 710) and thus corrects the distorted $[\text{HCO}_3^-]/[\text{CO}_2]$ ratio in a primary metabolic acidosis. The kidneys can also participate in the compensatory response—assuming, of course, that the acidosis is not the consequence of renal disease. Proximal-tubule cells can directly sense an *acute* fall in basolateral $[\text{HCO}_3^-]$, which results in a stimulation of proximal H^+ secretion.  **N39-10** In intercalated cells in the distal nephron, metabolic acidosis stimulates apical membrane H pump insertion and activity. The mechanism may be proton-sensitive G protein–coupled receptors on the basolateral membrane of intercalated cells, and an HCO_3^- -sensitive soluble adenylyl cyclase (sAC) in the cytosol.

In *chronic* metabolic acidosis, the adaptive responses of the proximal tubule are probably similar to those outlined above for chronic respiratory acidosis. These include upregulation of apical NHE3 and electrogenic H pumps, as well as basolateral NBCe1 (Fig. 39-7), perhaps reflecting increases in the number of transporters on the surface membranes. The parallel activation of apical and basolateral transporters may minimize changes in pH_i , while increasing transepithelial HCO_3^- reabsorption. This upregulation appears to involve intracellular protein kinases, including the Src family of receptor-associated tyrosine kinases (see p. 70). Endothelin appears to be essential for the upregulation of NHE3 in chronic metabolic acidosis.

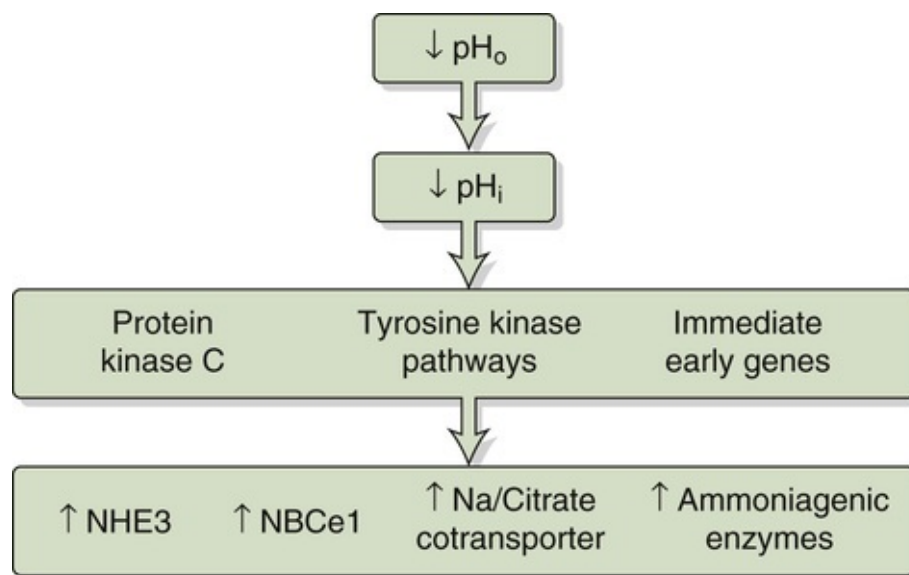

FIGURE 39-7 Effects of chronic acidosis on proximal-tubule function. Enhanced Na citrate reabsorption is a defense against acidosis by conversion of citrate to HCO_3^- . The price paid is enhanced stone formation because luminal citrate reduces stone formation by complexing with Ca^{2+} . Indeed, acidotic patients tend to get calcium-containing kidney stones.

In addition to increased H^+ secretion, the other ingredient needed to produce new HCO_3^- is enhanced NH_3 production. Together, the two increase NH_4^+ excretion. Indeed, the excretion of NH_4^+ into the urine increases markedly as a result of the adaptive response to chronic metabolic acidosis (Fig. 39-8). Thus, the ability to increase NH_3 synthesis is an important element in the kidney's defense against acidotic challenges. Indeed, as chronic metabolic acidosis develops, the kidneys progressively excrete a larger fraction of urinary H^+ as NH_4^+ . As a consequence, the excretion of titratable acid becomes a progressively smaller fraction of total acid excretion.

FIGURE 39-8 Effect of chronic metabolic acidosis on total NH_4^+ excretion into final urine. (Data from Pitts RF: Renal excretion of acid. Fed Proc 7:418–426, 1948.)

The adaptive stimulation of NH_3 synthesis, which occurs in response to a fall in pH_i , involves a stimulation of both glutaminase and phosphoenolpyruvate carboxykinase (PEPCK). The stimulation of mitochondrial glutaminase increases the conversion of glutamine to NH_4^+ and glutamate (see Fig. 39-5A). The stimulation of PEPCK enhances gluconeogenesis and thus the conversion of $\alpha\text{-KG}$ (the product of glutamate deamination) to glucose.

Metabolic alkalosis reduces proximal H^+ secretion and, in the CCT, may even provoke HCO_3^- secretion

Figure 39-9A illustrates the response of the proximal tubule to metabolic alkalosis. As shown in the upper curve, when the peritubular capillaries have a physiological $[\text{HCO}_3^-]$, increasing the *luminal* $[\text{HCO}_3^-]$ causes H^+ secretion to increase steeply up to a luminal $[\text{HCO}_3^-]$ of $\sim 45 \text{ mM}$. The reason is that the incremental luminal HCO_3^- is an additional buffer that minimizes the luminal acidification in the vicinity of the apical H^+ transporters.

A EFFECT OF BASOLATERAL ALKALOSIS ON H^+ SECRETION BY PROXIMAL TUBULES

**B CORTICAL COLLECTING TUBULE (CCT):
 β INTERCALATED CELL**

FIGURE 39-9 Effect of chronic metabolic alkalosis on renal acid-base transport. (Data from Alpern RJ, Cogan MG, Rector FC: Effects of extracellular fluid volume and plasma bicarbonate concentration on proximal acidification in the rat. *J Clin Invest* 71:736–746, 1983.)

As shown in the lower curve in [Figure 39-9A](#), when $[HCO_3^-]$ in the peritubular blood is higher than normal—that is, during metabolic alkalosis— H^+ secretion is lower for any luminal $[HCO_3^-]$. The likely explanation is that the proximal-tubule cell directly senses the increase in plasma $[HCO_3^-]$, depressing the rates at which NHE3 moves H^+ from cell to lumen and NBCe1 moves HCO_3^- from cell to blood.

So far, we have discussed the effect of metabolic alkalosis on H^+ secretion by the proximal tubule. In the ICT and CCT, metabolic alkalosis can cause the tubule to switch from secreting H^+ to secreting HCO_3^- .

into the lumen. The **α -intercalated cells** in the ICT and CCT secrete H^+ by using an apical H pump and a basolateral $Cl-HCO_3$ exchanger, which is AE1 (SLC4A1; see Fig. 39-4D). Metabolic alkalosis, over a period of days, shifts the intercalated-cell population, increasing the proportion of **β -intercalated cells** (see Fig. 39-9B)  **N39-5** at the expense of α cells. Because β cells have the opposite apical-versus-basolateral distribution of H pumps and $Cl-HCO_3$ exchangers, they secrete HCO_3^- into the lumen and tend to correct the metabolic alkalosis. The apical $Cl-HCO_3$ exchanger in β cells is **pendrin** (SLC26A4; see Table 5-4).

In contrast to chronic alkalosis, chronic *acidosis* alters the distribution of intercalated cell types in the distal nephron in favor of acid-secreting α cells (see Fig. 39-4D) over the base-secreting β -intercalated cells.

A rise in GFR increases HCO_3^- delivery to the tubules, enhancing HCO_3^- reabsorption (glomerulotubular balance for HCO_3^-)

Increasing either luminal flow or luminal $[HCO_3^-]$ significantly enhances HCO_3^- reabsorption,  **N39-11** probably by raising effective $[HCO_3^-]$ (and thus pH) in the microenvironment of H^+ transporters in the brush-border microvilli. Because a high luminal pH stimulates NHE3 and the H pumps located in the microvilli of the proximal tubule, increased flow translates to enhanced H^+ secretion. This flow dependence, an example of glomerulotubular (GT) balance (see p. 763), is important because it minimizes HCO_3^- loss, and thus the development of a metabolic acidosis, when GFR increases. Conversely, this GT balance of HCO_3^- reabsorption also prevents metabolic *alkalosis* when GFR decreases. The flow dependence of HCO_3^- reabsorption also accounts for the stimulation of H^+ transport that occurs after uninephrectomy (i.e., surgical removal of one kidney), when GFR in the remnant kidney rises in response to the loss of renal tissue.

N39-11

Flow Dependence of HCO_3^- Reabsorption

Contributed by Gerhard Giebisch, Erich Windhager

In the text, we point out that raising either luminal $[HCO_3^-]$ or luminal flow increases HCO_3^- reabsorption. One likely mechanism is mentioned in the text: The higher the flow or the higher the bulk luminal $[HCO_3^-]$, the higher the pH and $[HCO_3^-]$ in the unstirred layer that surrounds the microvilli on the apical membrane. In addition, increasing the flow also increases the shear force that acts on the central cilium present on every proximal-tubule cell. It is believed that the more the cilium bends with flow, the greater the signal to increase the reabsorption of solutes (including $NaHCO_3$) and water. This hypothesis would account for at least a portion of the glomerulotubular balance for both HCO_3^- reabsorption (see p. 834) and fractional Na^+ reabsorption (see p. 763).

Extracellular volume contraction—via ANG II, aldosterone, and sympathetic activity—stimulates renal H^+ secretion

A decrease in *effective circulating volume* stimulates Na^+ reabsorption by four parallel pathways (see pp. 838–840), including activation of the renin-angiotensin-aldosterone axis (and thus an increase in ANG II levels) and stimulation of renal sympathetic nerves (and thus the release of norepinephrine). Both ANG II and norepinephrine stimulate Na-H exchange in the proximal tubule. Because the proximal tubule couples Na^+ and H^+ transport, volume contraction increases not only Na^+ reabsorption but also H^+ secretion. Similarly, ANG II stimulates acid secretion by α -intercalated cells in the distal nephron. Volume expansion has the opposite effect. On a longer time scale, volume depletion also increases aldosterone levels, thereby enhancing H^+ secretion in cortical and medullary collecting ducts (see below). Thus, the regulation of effective circulating volume takes precedence over the regulation of plasma pH. 

N39-12

N39-12

Effect of Dietary Na^+ Intake on Proximal-Tubule NHE3 Activity

Contributed by Gerhard Giebisch, Erich Windhager

Decreased *dietary Na^+ intake* causes a decrease in effective circulating volume (i.e., volume contraction), resulting in increased activity of the apical NHE3. This effect is evident even if one assesses the activity in brush-border membrane vesicles removed from the animal. Consumption of a high- Na^+ diet has the opposite effect.

Hypokalemia increases renal H^+ secretion

As discussed on [page 803](#), acid-base disturbances can cause changes in K^+ homeostasis. The opposite is also true. Because a side effect of K^+ depletion is increased renal H^+ secretion, K^+ depletion is frequently associated with metabolic alkalosis. Several lines of evidence indicate that, in the proximal tubule, hypokalemia leads to a marked increase in apical Na-H exchange and basolateral Na/HCO_3 cotransport. As in other cells, in tubule cells the pH falls during K^+ depletion (see [p. 645](#)). The resulting chronic cell acidification may lead to adaptive responses that activate Na-H exchange and electrogenic Na/HCO_3 cotransport, presumably by the same mechanisms that stimulate H^+ secretion in chronic acidosis (see [Fig. 39-7](#)). In the proximal tubule, K^+ depletion also markedly increases NH_3 synthesis and NH_4^+ excretion, thus increasing urinary H^+ excretion as NH_4^+ . Finally, K^+ depletion stimulates apical K-H exchange in α -intercalated cells of the ICT and CCT (see [p. 799](#)) and enhances H^+ secretion as a side effect of K^+ retention.

Just as hypokalemia can maintain metabolic alkalosis, hyperkalemia is often associated with metabolic *acidosis*. A contributory factor may be reduced NH_4^+ excretion, perhaps because of lower synthesis in proximal-tubule cells, possibly due to a higher intracellular pH. In addition, with high luminal $[\text{K}^+]$ in the TAL, K^+ competes with NH_4^+ for uptake by apical Na/K/Cl cotransporters and K^+ channels, thereby reducing NH_4^+ reabsorption. As a result, the reduced NH_4^+ levels in the medullary interstitium provide less NH_3 for diffusion into the medullary collecting duct. Finally, with high $[\text{K}^+]$ in the medullary interstitium, K^+ competes with NH_4^+ for uptake by basolateral Na-K pumps in the medullary collecting

duct. The net effects are reduced NH_4^+ excretion and acidosis.

Both glucocorticoids and mineralocorticoids stimulate acid secretion

Chronic adrenal insufficiency (see [p. 1019](#)) leads to acid retention and, potentially, to life-threatening metabolic acidosis. Both glucocorticoids and mineralocorticoids stimulate H^+ secretion, but at different sites along the nephron.

Glucocorticoids (e.g., cortisol) enhance the activity of Na-H exchange in the proximal tubule and thus stimulate H^+ secretion. In addition, they inhibit phosphate reabsorption, raising the luminal availability of buffer anions for titration by secreted H^+ .

Mineralocorticoids (e.g., aldosterone) stimulate H^+ secretion by three coordinated mechanisms—one direct and two indirect. First, mineralocorticoids *directly* stimulate H^+ secretion in the collecting tubules and ducts by increasing the activity of the apical electrogenic H pump and basolateral Cl-HCO_3 exchanger (see [Fig. 39-4D](#)). Second, mineralocorticoids *indirectly* stimulate H^+ secretion by enhancing Na^+ reabsorption in the collecting ducts (see [p. 766](#)), which increases the lumen-negative voltage. This increased negativity may stimulate the apical electrogenic H pump in α -intercalated cells to secrete acid. Third, mineralocorticoids—particularly when administered for longer periods of time and accompanied by high Na^+ intake—cause K^+ depletion and *indirectly* increase H^+ secretion (see [pp. 834–835](#)).

Diuretics can change H^+ secretion, depending on how they affect transepithelial voltage, ECF volume, and plasma $[\text{K}^+]$

The effects of diuretics on renal H^+ secretion [N39-13](#) vary substantially from one diuretic to another, depending on both the site and the mechanism of action. From the point of view of acid-base balance, diuretics fall broadly into two groups: those that promote the excretion of a relatively alkaline urine and those that have the opposite effect.

N39-13

Effect of Diuretics on Renal H^+ Excretion

Contributed by Erich Windhager, Gerhard Giebisch

Box 40-3, as well as Table 40-3, summarizes some of the effects of various classes of diuretics and lists the protein targets of these diuretics in the kidney.

To the first group belong CA inhibitors and K^+ -sparing diuretics. The **CA inhibitors** lead to excretion of an alkaline urine by inhibiting H^+ secretion. Their greatest effect is in the proximal tubule, but they also inhibit H^+ secretion by the TAL and intercalated cells in the distal nephron. **K^+ -sparing diuretics**—including amiloride, triamterene, and the spironolactones—also reduce acid excretion. Both amiloride and triamterene inhibit the apical epithelial Na^+ channels (ENaCs; see [pp. 758–759](#)) in the collecting tubules and ducts, rendering the lumen more positive so that it is more difficult for the electrogenic H pump to secrete H^+ ions into the lumen. Spironolactones decrease H^+ secretion by interfering with the action of aldosterone.

The second group of diuretics—those that tend to *increase* urinary acid excretion and often induce alkalosis—includes **loop diuretics** such as furosemide (which inhibits the apical Na/K/Cl cotransporter in the TAL) and **thiazide diuretics** such as chlorothiazide (which inhibits the apical Na/Cl cotransporter in the DCT). These diuretics act by three mechanisms. First, all cause some degree of volume contraction, and thus lead to increased levels of ANG II and aldosterone (see [pp. 841–842](#)), both of which enhance H⁺ secretion. Second, these diuretics enhance Na⁺ delivery to the collecting tubules and ducts, thereby increasing the electrogenic uptake of Na⁺, raising lumen-negative voltage, and enhancing H⁺ secretion. Third, this group of diuretics causes *K⁺ wasting*; as discussed on [pages 834–835](#), K⁺ depletion enhances H⁺ secretion.

CHAPTER 40

Integration of Salt and Water Balance

Gerhard Giebisch, Erich E. Windhager, Peter S. Aronson

Two separate but closely interrelated control systems regulate the volume and osmolality of the extracellular fluid (ECF). It is important to regulate the **ECF volume** to maintain blood pressure, which is essential for adequate tissue perfusion and function. The body regulates ECF volume by adjusting the total-body content of NaCl. It is important to regulate the **extracellular osmolality** because hypotonic (see pp. 131–132) or hypertonic (see p. 131) osmolalities cause changes in cell volume that seriously compromise cell function, especially in the central nervous system (CNS). The body regulates extracellular osmolality by adjusting total-body water content. These two homeostatic mechanisms—for ECF volume and osmolality—use different sensors, different hormonal transducers, and different effectors (Table 40-1). However, they have one thing in common: some of their effectors, although different, are located in the kidney. In the case of the ECF volume, the control system modulates the urinary excretion of Na⁺. In the case of osmolality, the control system modulates the urinary excretion of solute-free water or simply free water (see pp. 806–807).

TABLE 40-1
Comparison of the Systems Controlling ECF Volume and Osmolality

	REGULATION OF ECF VOLUME AND BLOOD PRESSURE	REGULATION OF OSMOLALITY	
What is sensed?	Effective circulating volume	Plasma osmolality	
Sensors	Carotid sinus, aortic arch, renal afferent arteriole, atria	Hypothalamic osmoreceptors	
Efferent pathways	Renin-angiotensin-aldosterone axis, sympathetic nervous system, AVP, ANP	AVP	Thirst
Effector	Short term: Heart, blood vessels Long term: Kidney	Kidney	Brain: drinking behavior
What is affected?	Short term: Blood pressure Long term: Na ⁺ excretion	Renal water excretion	Water intake

Sodium Balance

The maintenance of the ECF volume, or Na⁺ balance, depends on signals that reflect the adequacy of the circulation—the so-called effective circulating volume, discussed below. Low- and high-pressure baroreceptors send afferent signals to the brain (see pp. 536–537), which translates this “volume signal” into several responses that can affect ECF volume or blood pressure over either the short or the long term. The short-term effects (over a period of seconds to minutes) occur as the autonomic nervous system and humoral mechanisms modulate the activity of the heart and blood vessels to control blood pressure. The long-term effects (over a period of hours to days) consist of nervous, humoral, and hemodynamic mechanisms that modulate renal Na⁺ excretion (see pp. 763–769). In the first part of this chapter, we discuss the entire feedback loop, of which Na⁺ excretion is the effector.

Why is the Na⁺ content of the body the main determinant of the ECF volume? Na⁺, with its associated anions, Cl[−] and HCO₃[−], is the main osmotic constituent of the ECF volume; when Na salts move, water must follow. Because the body generally maintains ECF osmolality within narrow limits (e.g., ~290

milliosmoles/kg, or 290 mOsm), it follows that whole-body Na^+ content—which the kidneys control—must be the major determinant of the ECF volume. A simple example illustrates the point. If the kidney were to enhance the excretion of Na^+ and its accompanying anions by 145 milliequivalents (meq) each—the amount of solute normally present in 1 L of ECF—the kidneys would have to excrete an additional liter of urine to prevent a serious fall in osmolality. Alternatively, the addition of 145 mmol of “dry” NaCl to the ECF obligates the addition of 1 L of water to the ECF; this addition can be accomplished by ingestion of water or reduction of renal excretion of free water. Relatively small changes in Na^+ excretion lead to marked alterations in the ECF volume. Thus, precise and sensitive control mechanisms are needed to safeguard and regulate the body's content of Na^+ .

Water Balance

The maintenance of osmolality, or water balance, depends on receptors in the hypothalamus that detect changes in the plasma osmolality. These receptors send signals to areas of the brain that (1) control thirst and thus regulate free-water intake and (2) control the production of arginine vasopressin (AVP)—also known as antidiuretic hormone (ADH)—and thus regulate free-water excretion by the kidneys. We discuss renal water excretion beginning on [page 806](#). In the second part of this chapter, we discuss the entire feedback loop, of which water excretion is merely the end point.

Why is the water content of the body the main determinant of osmolality? Total-body osmolality is defined as the ratio of total-body osmoles to total-body water (see [p. 102](#)). Although the ECF volume control system can regulate the amount of *extracellular* osmoles, it has little effect on *total-body* osmoles. Total-body osmoles are largely a function of the *intracellular* milieu because the intracellular compartment is larger than the ECF and its solute composition is highly regulated. Total-body osmoles do not change substantially except during growth or during certain disease states, such as diabetes mellitus (in which excess glucose increases total-body osmolality). Only by controlling water independent of Na^+ control can the body control osmolality.

Control of Extracellular Fluid Volume

In the steady state, Na^+ intake via the gastrointestinal tract equals Na^+ output from renal and extrarenal pathways

The two principal solutes in the ECF are Na^+ and Cl^- . **Sodium** is one of the most abundant ions in the body, totaling ~58 meq/kg body weight. Approximately 65% of the total Na^+ is located in the ECF, and an additional 5% to 10%, in the intracellular fluid (ICF). Extracellular and intracellular Na^+ , comprising 70% to 75% of the total-body pool, is readily exchangeable, as determined by its ability to equilibrate rapidly with injected radioactive Na^+ . The remaining 25% to 30% of the body's Na^+ pool is bound as Na^+ -apatites in bone. The concentration of Na^+ in the plasma and interstitial fluid typically ranges between 135 and 145 mM.

Chloride totals ~33 meq/kg body weight. Approximately 85% is extracellular, and the remaining 15% is intracellular. Thus, all Cl^- is readily exchangeable. The $[\text{Cl}^-]$ of plasma and interstitial fluid normally varies between 100 and 108 mM. Changes in total-body Cl^- are usually influenced by the same factors, and in the same direction, as changes in total-body Na^+ . Exceptions arise during acid-base disturbances, when Cl^- metabolism may change independently of Na^+ .

By definition, in the steady state, the total-body content of water and electrolytes is constant. For Na^+ , this concept can be expressed as

$$\text{Oral } \text{Na}^+ \text{ intake} = \text{Renal } \text{Na}^+ \text{ output} + \text{Extrarenal } \text{Na}^+ \text{ output}$$

(40-1)

Under normal circumstances, extrarenal Na^+ output is negligible. However, large fluid losses from the gastrointestinal tract (e.g., vomiting, diarrhea) or skin (e.g., excessive sweating, extensive burns) can represent substantial extrarenal Na^+ losses. The kidney responds to such deficits by reducing renal Na^+ excretion. Conversely, in conditions of excessive Na^+ intake, the kidneys excrete the surfeit of Na^+ .

The kidneys increase Na^+ excretion in response to an increase in ECF volume, not to an increase in extracellular Na^+ concentration

In contrast to many other renal mechanisms of electrolyte excretion, the renal excretion of Na^+ depends on the *amount* of Na^+ in the body and not on the Na^+ *concentration* in ECF. Because the amount of Na^+ is the product of ECF volume and the extracellular Na^+ concentration, and because the osmoregulatory system keeps plasma osmolality constant within very narrow limits, it is actually the *volume* of ECF that acts as the signal for Na^+ homeostasis.

Figure 40-1A demonstrates the renal response to an abrupt step increase and step decrease in Na^+ intake. A subject weighing 70 kg starts with an unusually low Na^+ intake of 10 mmol/day, matched by an

equally low urinary output. When the individual abruptly increases dietary Na^+ intake from 10 to 150 mmol/day—and maintains it at this level for several days—urinary Na^+ output also increases, but at first it lags behind intake. This initial period during which Na^+ intake exceeds Na^+ output is a state of **positive Na^+ balance**. After ~5 days, urinary Na^+ output rises to match dietary intake, after which total-body Na^+ does not increase further. In this example, we assume that the cumulative retention of Na^+ amounts to 140 mmol.

A EFFECT OF ABRUPT CHANGES IN Na^+ INTAKE

B EFFECT OF POSITIVE Na^+ BALANCE ON Na^+ EXCRETION

FIGURE 40-1 Na^+ balance. In **A**, the red curve shows the time course of dietary Na^+ intake, and the green curve shows Na^+ excretion. The gold area between the two curves at the beginning of the experiment corresponds to the accumulated total-body Na^+ of 140 mmol. This additional Na^+ , dissolved in ~1 L of ECF, accounts for the 1-kg gain in body weight (blue curve). (**B**, Data from Walser M: Phenomenological analysis of renal regulation of sodium and potassium balance. *Kidney Int* 27:837–841, 1985.)

The abrupt increase in dietary Na^+ initially elevates plasma osmolality, thus stimulating thirst and release of AVP. Because the subject has free access to water, and because the kidneys salvage water in response to AVP (see pp. 817–819), the volume of free water rises. This increase in free water not only prevents a rise in $[\text{Na}^+]$ and osmolality, but also produces a weight gain that, in this example, is 1 kg (see Fig. 40-1A). This weight gain corresponds, in our example, to the accumulation of 140 mmol of Na^+ and the accompanying free water, which makes 1 L of isotonic saline. In the new steady state, only the *extracellular* compartment has increased in volume. *Intracellular* volume does not change because, in the end, no driving force exists for water to cross cell membranes (i.e., extracellular osmolality is normal). Instead, the slight expansion of ECF volume signals the kidney to increase its rate of Na^+ excretion. The extracellular Na^+ *concentration* is unchanged during this period and thus cannot be the signal to increase Na^+ excretion.

When the subject in our example later reduces Na^+ intake to the initial level of 10 mmol/day (see Fig. 40-1A), Na^+ excretion diminishes until the initial balanced state (input = output) is established once again. Immediately after the reduction in Na^+ intake, Na^+ is temporarily out of balance. This time, we have a period of **negative Na^+ balance**, in which output exceeds input. During this period, the ECF volume falls

by 1 L, and body weight returns to normal. Again, the extracellular Na^+ concentration is unchanged during this transient period.

Ingestion of increasingly larger amounts of Na^+ results in *retention* of progressively larger amounts in the steady state and thus accumulation of progressively more ECF volume. Urinary Na^+ excretion increases linearly with this rise in retained Na^+ , as shown in [Figure 40-1B](#). The control system that so tightly links urinary Na^+ excretion to ECF volume is extremely sensitive. In our hypothetical example (see [Fig. 40-1A](#))—a 70-kg individual with an initial ECF volume of 17 L—expanding ECF volume by 1 L, or ~6%, triggers a 15-fold increase in steady-state urinary Na^+ excretion (i.e., from 10 mmol/day to 150 mmol/day in [Fig. 40-1A](#)). Physiologically normal individuals can be in Na^+ balance on a nearly Na^+ -free diet (1 to 2 mmol/day) without overt signs of ECF volume depletion. Conversely, even with consumption of a high- Na^+ diet (200 mmol/day versus the “normal” ~100 mmol/day for a Western diet), clinical signs of ECF volume excess, such as edema, are absent.

It is not the ECF volume as a whole, but the effective circulating volume, that regulates Na^+ excretion

Although we have referred to the overall expansion of the ECF volume as the signal for increased urinary Na^+ excretion, this is an oversimplification. Only certain regions of the ECF compartment are important for this signaling. For an expansion in ECF volume to stimulate Na^+ excretion—either acutely or chronically—the expansion must make itself evident in parts of the ECF compartment where the ECF volume sensors are located, namely, in blood-filled compartments. *ECF volume* per se is not the critical factor in regulating renal Na^+ excretion.

The critical parameter that the body recognizes is the **effective circulating volume** (see [pp. 554–555](#))—not something that we can identify anatomically. Rather, effective circulating volume is a *functional* blood volume that reflects the extent of tissue perfusion in specific regions, as evidenced by the fullness or pressure within their blood vessels. Normally, changes in effective circulating volume parallel those in total ECF volume. However, this relationship may be distorted in certain diseases, such as congestive heart failure, nephrotic syndrome, or liver cirrhosis. In all three cases, *total* ECF volume is grossly expanded (e.g., edema or ascites). In contrast, the *effective* circulating volume is low, resulting in Na^+ retention. For example, in congestive heart failure, particularly when edema is extensive, the total ECF volume is greatly increased. However, the low cardiac output fails to expand the key blood-filled compartments. As a result, Na^+ reabsorption by the renal tubules remains high (i.e., urinary Na^+ excretion is inappropriately low compared with Na^+ intake), which exacerbates the systemic congestion ([Box 40-1](#)).  [N40-1](#)

Box 40-1

Volume Expansion and Contraction

When Na^+ intake persists in the face of impaired renal Na^+ excretion (e.g., during renal failure), the body retains isosmotic fluid. The result is an expansion of plasma volume and of the interstitial fluid compartment. In the extreme, the interstitial volume increase can become so severe that the subepidermal tissues swell (e.g., around the ankles). When the physician presses with a finger against the skin and then removes the finger, the finger imprint remains in the tissue—**pitting edema**. Not all cases of lower-extremity edema reflect total-body Na^+ and fluid retention. For example, venous obstruction to return of

blood from the lower extremities can cause local edema in the lower legs. Patients with this condition should elevate their feet whenever possible and should wear compression stockings.

Fluid can also accumulate in certain transcellular spaces (see p. 102), such as the pleural cavity (pleural effusion) or the peritoneal cavity (ascites); such conditions reflect derangements of local Starling forces or an increase in protein permeability due to inflammation, which alters the fluid distribution between the plasma and the ECF (see Box 20-1). In cases of abnormal Na^+ retention, putting the subject on a low- Na^+ diet can partially correct the edema. Administration of diuretics **N40-2** can also reduce volume overload, as long as the kidney retains sufficient function to respond to them.

An excessive loss of Na^+ into the urine can be caused by disturbances of Na^+ reabsorption along the nephron and leads to a dramatic shrinkage of the ECF volume. Because the plasma volume is part of the ECF volume, significant reductions can severely affect the circulation, culminating in **hypovolemic shock** (see p. 583). Renal causes of reduced ECF volume include the prolonged use of powerful loop diuretics (see p. 757), osmotic diuresis (see Box 35-1) during poorly controlled diabetes mellitus, adrenal insufficiency with low aldosterone levels, and the recovery phase following acute renal failure or relief of urinary obstruction.

N40-1

Effect of Posture and Water Immersion on Na^+ Excretion

Contributed by Gerhard Giebisch, Erich Windhager

On page 838, we introduce congestive heart failure as an example of the nonparallel behavior of ECF volume on the one hand and effective circulating volume on the other. Two additional examples that depend upon gravity are posture and water immersion.

Urinary Na^+ excretion is lowest when one is standing (i.e., when thoracic perfusion is lowest), higher when one is lying down (recumbency), and highest when one is immersed up to the chin for several hours in warm water. During immersion, the hydrostatic pressure of the water compresses the tissues—and thus the vessels, particularly the veins—in the extremities and abdomen and consequently enhances venous return to the thorax. Recumbency—and, to a greater extent, water immersion—shifts blood into the thoracic vessels, increasing the so-called central blood volume (see p. 449). In contrast, the upright position depletes the intrathoracic blood volume. The thoracic vessels are immune to this compression because their extravascular pressure (i.e., intrapleural pressure; see p. 606) is unaffected by the water. Thus, it is the enhanced venous return alone that stimulates vascular sensors to increase Na^+ excretion. This example clearly demonstrates that only special portions within the ECF compartment play critical roles in the sensing of ECF volume.

N40-2

Sensitivity of the Natriuretic Response to Increased Extracellular Fluid Volume

Contributed by Erich Windhager, Gerhard Giebisch

Figure 40-1B shows a hypothetical example of how urinary Na^+ excretion (y-axis) changes in response to increases in isotonic extracellular water volume (upper x-axis) or amount of Na^+ retained by the body (lower x-axis). In the example in the figure, the urinary Na^+ excretion increases by 120 mmol/day for

every 100 mmol of cumulative Na^+ retention. This proportionality is indicated by the slope of the line. However, this slope need not be the same for every person.

In a patient with abnormal Na^+ retention, the natriuretic response must be less sensitive than normal (i.e., the slope of the line in Fig. 40-1B must be less steep). In other words, in response to an increase in Na^+ intake, the patient would have to accumulate more Na^+ and water (i.e., he or she would have to become more volume expanded than would a normal person) in order to sufficiently stimulate the kidneys to elicit the natriuretic response necessary for coming into Na^+ balance (i.e., achieving a steady state in which urinary excretion balances dietary intake).

Decreases in effective circulating volume trigger four parallel effector pathways to decrease renal Na^+ excretion

Figure 40-2 shows the elements of the feedback loop that controls the effective circulating volume. As summarized in Table 40-2, sensors that monitor changes in effective circulating volume are **baroreceptors** located in both high-pressure (see pp. 534–536) and low-pressure (see pp. 546–547) areas of the circulation. Although most are located within the vascular tree of the thorax, additional baroreceptors are present in the kidney—particularly in the afferent arterioles (see p. 730)—as well as in the CNS and liver. Of the pressures at these sites, it is renal perfusion pressure that is most important for long-term regulation of Na^+ excretion, and thus blood pressure, because increased resistance to renal blood flow (e.g., renal artery stenosis) causes sustained hypertension (Box 40-2). The sensors shown in Figure 40-2 generate four distinct hormonal or neural signals (pathways 1 to 4 in the figure).

Increased renal Na^+ retention counteracts decreased effective circulating volume.

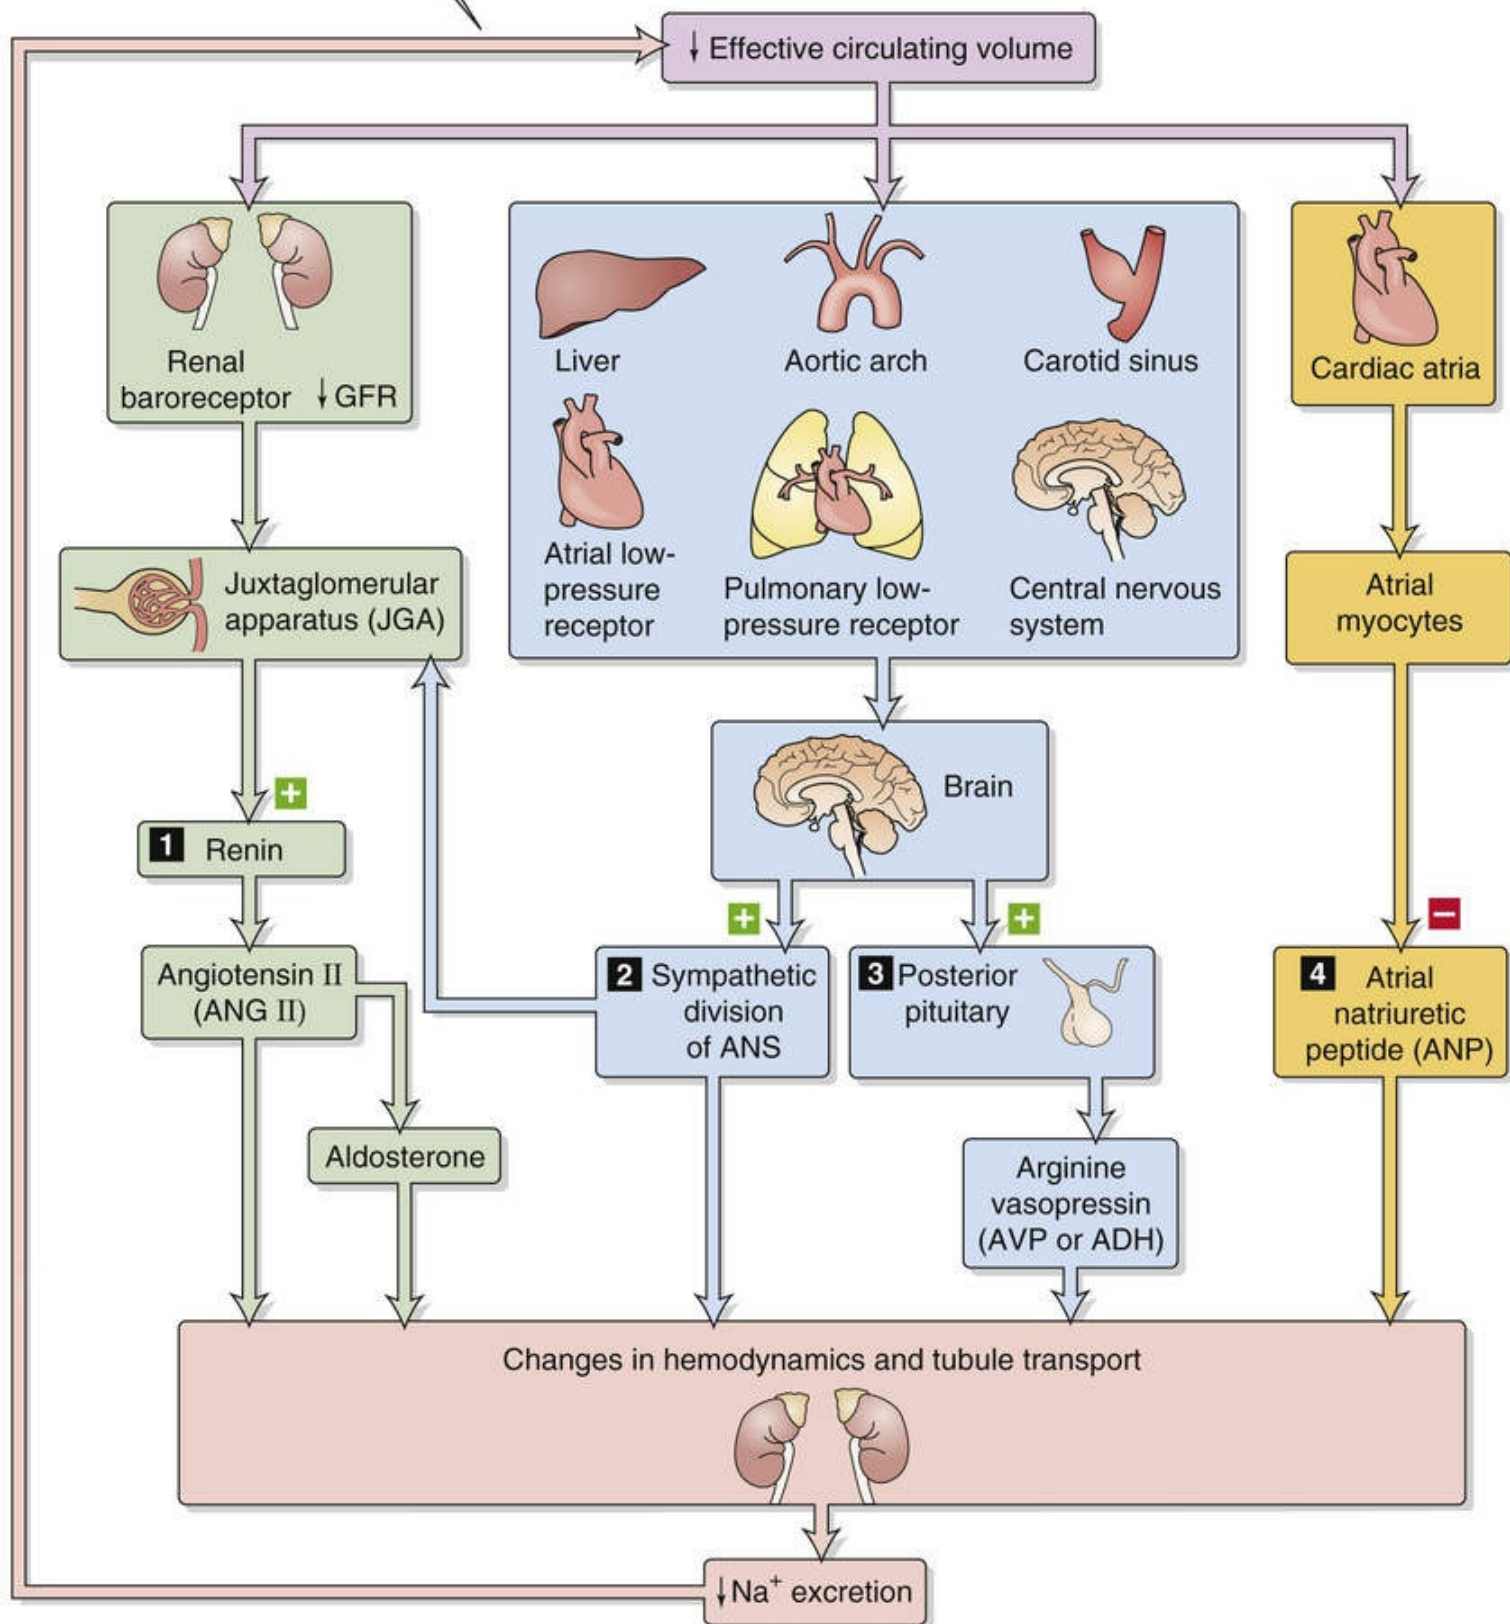

FIGURE 40-2 Feedback control of effective circulating volume. A low effective circulating volume triggers four parallel effector pathways (numbered 1 to 4) that act on the kidney, either by changing the hemodynamics or by changing Na^+ transport by the renal-tubule cells. ANS, autonomic nervous system.

Box 40-2

Renal Hypertension

In the 1930s, Goldblatt produced hypertension experimentally in unilaterally nephrectomized animals by placing a surgical clip around the renal artery of the remaining kidney (**one-kidney Goldblatt hypertension**). The constriction can be adjusted so that it results not in renal ischemia, but only in a reduction of the perfusion pressure distal to the clip. This maneuver stimulates the renal baroreceptors, leading to a rapid increase in synthesis and secretion of renin from the clipped kidney. The renin release reaches a peak after 1 hour. As renin cleaves ANG I from angiotensinogen, systemic ANG I levels rise quickly. ACE, present mainly in the lungs but also in the kidneys, then rapidly converts ANG I into ANG II. Thus, within minutes of clamping the renal artery, one observes a sustained rise in systemic arterial pressure. The newly established stable elevation in systemic pressure then normalizes the pressure in the renal artery downstream from the constriction. From this time onward, circulating renin and ANG II levels decline toward normal over 5 to 7 days, while the systemic arterial pressure remains abnormally high. The early rise in blood pressure is the result of the renin-angiotensin vasoconstrictor mechanism, which is activated by the experimentally induced reduction in pressure and flow in the renal artery distal to the constriction. The later phase of systemic hypertension is the result of aldosterone release and of the retention of salt and water.

Unilateral partial clamping of a renal artery in an otherwise healthy animal also produces hypertension (**two-kidney Goldblatt hypertension**). As in the one-kidney model, the clipped kidney increases its synthesis and secretion of renin. Renin then causes ANG II levels to increase systemically and will, in addition to the effect on the clamped kidney, cause the nonclamped contralateral kidney to retain salt and water. As in the one-kidney model, the resulting hypertension has an early vasoconstrictive phase and a delayed volume-dependent phase. These models of hypertension show that the kidney can be critical as a long-term baroreceptor. Thus, when increased resistance in a renal artery leads to reduced intrarenal perfusion pressure, the rest of the body, including central baroreceptors, experiences—and cannot counteract—the sustained hypertension.

In both types of Goldblatt hypertension, administration of ACE inhibitors can lower arterial blood pressure. In fact, inhibiting ACE is therapeutically effective even after circulating renin and ANG II levels have normalized. The reason is that maintained hypertension involves an increased *intrarenal* conversion of ANG I to ANG II (via renal ACE), with the ANG II enhancing proximal Na⁺ reabsorption. Indeed, direct measurements show that, even after *circulating* renin and ANG II levels have returned to normal, the *intrarenal* levels of ACE and ANG II are elevated. ACE inhibitors lower systemic and intrarenal ANG II levels.

These experimental models correspond to some forms of human hypertension, including hypertension produced by renin-secreting tumors of the JGA and by all types of pathological impairment of renal arterial blood supply. Thus, coarctation of the aorta, in which the aorta is constricted above the renal arteries but below the arteries to the head and upper extremities, invariably leads to hypertension. Renal hypertension also results from stenosis of a renal artery, caused, for example, by arteriosclerotic thickening of the vessel wall.

In the first pathway, the kidney itself senses a reduced effective circulating volume and directly stimulates a hormonal effector pathway, the **renin-angiotensin-aldosterone system**, discussed in the section beginning on [page 841](#). In addition, increased renal perfusion pressure itself can increase Na^+ excretion independent of the renin-angiotensin-aldosterone system, as we shall see beginning on [page 843](#).

The second and third effector pathways are neural. Baroreceptors detect decreases in effective circulating volume and communicate these via afferent neurons to the medulla of the brainstem. Emerging from the medulla are two types of efferent signals that ultimately act on the kidney. In one, increased activity of the **sympathetic division** of the autonomic nervous system reduces renal blood flow and directly stimulates Na^+ reabsorption, thereby reducing Na^+ excretion (discussed on [pp. 842–843](#)). In the other effector pathway, the **posterior pituitary** increases its secretion of AVP, which leads to conservation of water (discussed on [p. 843](#)). This AVP mechanism becomes active only after large declines in effective circulating volume.

The final pathway is hormonal. Reduced effective circulating volume decreases the release of **atrial natriuretic peptide (ANP)**, thus reducing Na^+ excretion (discussed on [p. 843](#)).

All four parallel effector pathways correct the primary change in effective circulating blood volume. An increase in effective circulating volume promotes Na^+ excretion (thus reducing ECF volume), whereas a decrease in effective circulating volume inhibits Na^+ excretion (thus raising ECF volume).

An important feature of renal Na^+ excretion is the two-way redundancy of control mechanisms. First, efferent pathways may act in concert on a single effector within the kidney. For instance, both sympathetic input and hemodynamic/physical factors often act on proximal tubules. Second, one efferent pathway may act at different effector sites. For example, angiotensin II (ANG II) enhances Na^+ retention *directly* by stimulating apical Na-H exchange in tubule cells (see [Fig. 35-4](#)) and *indirectly* by lowering renal plasma flow (see [p. 746](#)).

Increased activity of the renin-angiotensin-aldosterone axis is the first of four parallel pathways that correct a low effective circulating volume

The **renin-angiotensin-aldosterone** axis ([Fig. 40-3](#)) promotes Na^+ retention via the actions of both ANG II and aldosterone. For a consideration of this axis in the context of the physiology of the adrenal cortex, see [page 1029](#).

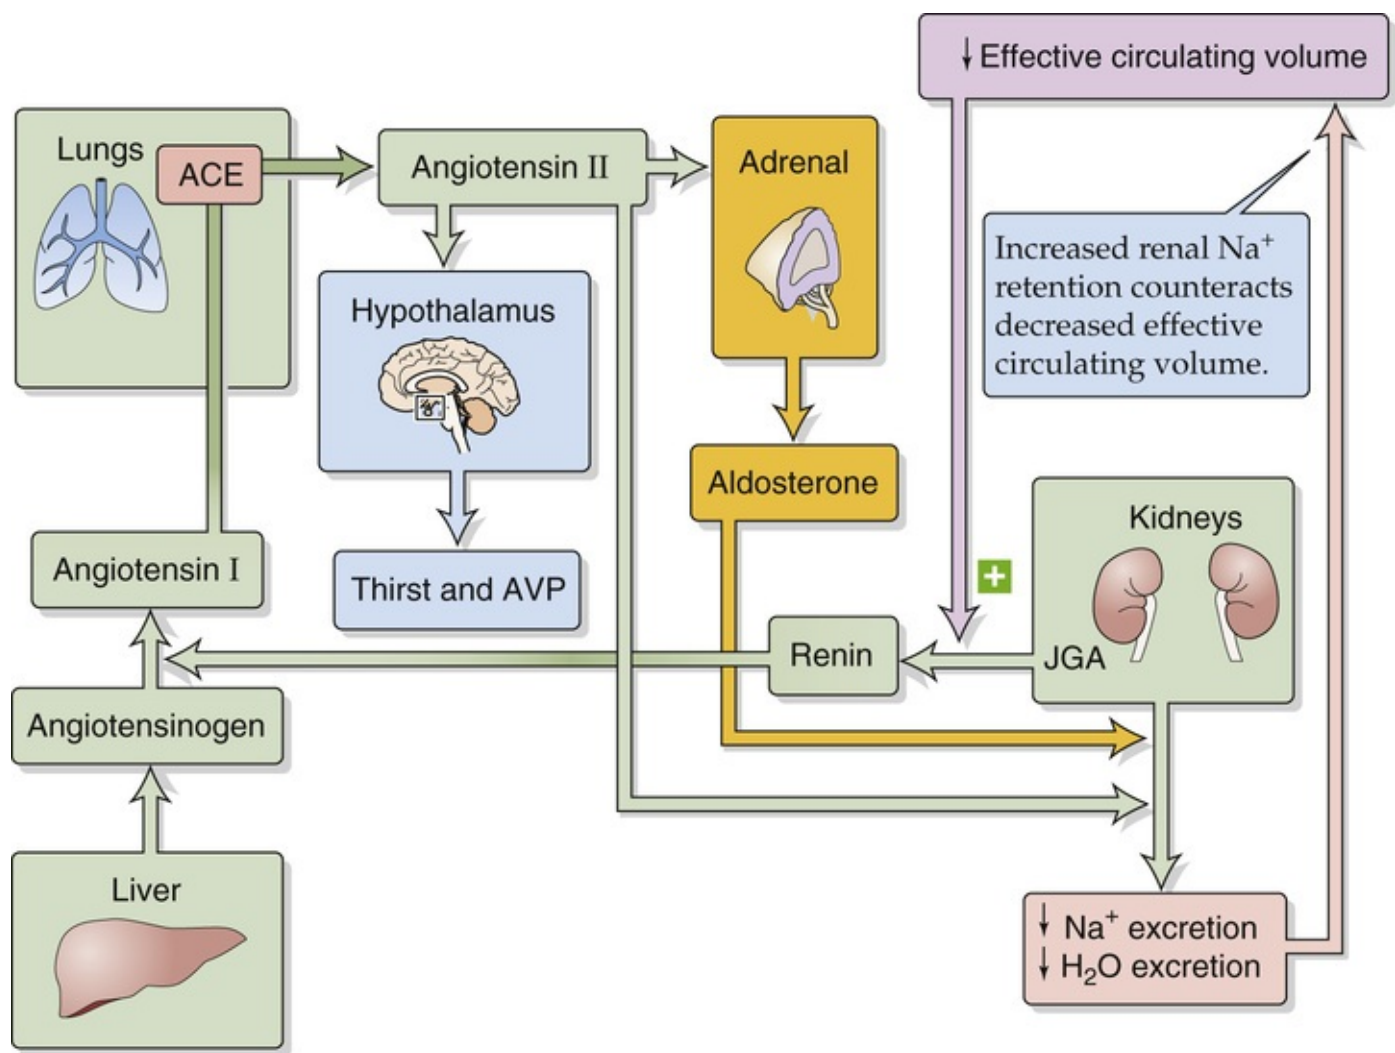

FIGURE 40-3 Renin-angiotensin-aldosterone axis.

Angiotensinogen, **N23-12** also known as renin substrate, is an α_2 -globulin that is synthesized by the liver and released into the systemic circulation. The liver contains only small stores of angiotensinogen. Another protein, **renin**, **N40-4** is produced and stored in distinctive granules by the **granular cells** of the renal **juxtaglomerular apparatus (JGA)**; see p. 727). As discussed below (see p. 841), decreases in effective circulating volume stimulate these cells to release renin, which is a protease that cleaves a peptide bond near the C terminus of angiotensinogen, releasing the decapeptide **angiotensin I (ANG I)**. **Angiotensin-converting enzyme (ACE)** rapidly removes the two C-terminal amino acids from the physiologically inactive ANG I to form the physiologically active octapeptide **ANG II**. ACE is present on the luminal surface of vascular endothelia throughout the body and is abundantly present in the endothelium-rich lungs. ACE in the kidney—particularly in the endothelial cells of the afferent and efferent arterioles, and also in the proximal tubule—can produce enough ANG II to exert *local* vascular effects. Thus, the kidney receives ANG II from three sources: (1) Systemic ANG II comes from the general circulation, originating largely from the pulmonary circulation. (2) Renal vessels generate ANG II from ANG I. (3) Proximal-tubule cells, which contain renin and ACE, secrete ANG II into its lumen. Both in the circulation and in the tubule lumen, aminopeptidases further cleave ANG II to the heptapeptides ANG III [ANG-(2-8)] and ANG-(1-7), which are biologically active.

N40-4

Renin Release from Granular Cells

As pointed out in the text, the granular cells are one of two cell types in which the exocytosis of a hormone *decreases* in response to a rise in $[Ca^{2+}]_i$. For example, if one raises $[K^+]_o$, the granular cell depolarizes. This depolarization probably opens voltage-gated Ca^{2+} channels (see p. 190) or decreases Ca^{2+} extrusion via an Na-Ca exchanger (see pp. 123–124). In either case, $[Ca^{2+}]_i$ rises and blocks renin release. Similarly, applying Ca^{2+} ionophores—compounds that increase the permeability of the cell membrane to Ca^{2+} —also raises $[Ca^{2+}]_i$ and reduces renin release.

Increases in intracellular levels of cAMP have the opposite effect of raising $[Ca^{2+}]_i$ —increases in $[cAMP]_i$ *stimulate* renin release from granular cells. Conversely, agents that inhibit adenylyl cyclase activity (e.g., β -adrenergic antagonists, α -adrenergic agonists, and A_1 adenosine receptor agonists) decrease $[cAMP]_i$ and thereby inhibit renin release.

Reference

Kurtz A. Cellular control of renin secretion. *Rev Physiol Biochem Pharmacol*. 1989;113:1–38.

The principal factor controlling plasma ANG II levels is renin release from JGA granular cells. A decrease in effective circulating volume manifests itself to the JGA—and thus stimulates renin release—in three ways (see [Fig. 40-2](#)):

- 1. Decreased systemic blood pressure (sympathetic effect on JGA).** A low effective circulating volume, sensed by baroreceptors located in the central arterial circulation (see [p. 534](#)), signals medullary control centers to increase sympathetic outflow to the JGA, which in turn increases renin release. Renal denervation or β -adrenergic blocking drugs (e.g., propranolol) inhibit renin release.
- 2. Decreased NaCl concentration at the macula densa (NaCl sensor).** Decreased effective circulating volume tends to increase filtration fraction (the inverse of the sequence shown in [Fig. 34-10](#)), thereby increasing Na^+ and fluid reabsorption by the proximal tubule (see [p. 842](#)) and reducing the flow of tubule fluid through the loop of Henle. Na^+ reabsorption in the thick ascending limb (TAL) then decreases luminal $[Na^+]$ more than if tubular flow were higher. The resulting decrease in luminal $[NaCl]$ at the macula densa stimulates renin release.
- 3. Decreased renal perfusion pressure (renal baroreceptor).** Stretch receptors in the granular cells (see [p. 727](#)) of the *afferent* arterioles sense the decreased distention associated with low effective circulating volume. This decreased stretch lowers $[Ca^{2+}]_i$, which increases renin release and initiates a cascade that tends to promote Na^+ reabsorption and thus increase blood pressure. Conversely, increased distention (high extracellular volume) inhibits renin release.

The above stimulation of renin release by a *decrease* in $[Ca^{2+}]_i$  **N40-4** stands in contrast to most Ca^{2+} -activated secretory processes, in which an *increase* in $[Ca^{2+}]_i$ stimulates secretion (see [p. 221](#)). Another exception is the chief cell of the parathyroid gland, in which an increase in $[Ca^{2+}]_i$ inhibits secretion of parathyroid hormone (see [pp. 1060–1061](#)).

Intracellular cAMP also appears to be a second messenger for renin release. Agents that activate

adenylyl cyclase **N40-5** enhance renin secretion, presumably via protein kinase A. The question whether the effects of $[cAMP]_i$ and $[Ca^{2+}]_i$ are independent or sequential remains open. **N40-3**

N40-3

Systemic versus Local Roles of the Juxtaglomerular Apparatus

Contributed by Emile Boulpaep, Walter Boron

The JGA performs two apparently opposite functions: maintaining a constant GFR (tubuloglomerular feedback, or TGF) and maintaining a constant whole-body blood pressure by modulating renin release. TGF (see pp. 750–751) is a local phenomenon, whereas the release of renin has systemic consequences (see pp. 841–842).

In the case of **tubuloglomerular feedback** (i.e., the *local* response), decreased renal perfusion pressure, reduced filtered load, or enhanced proximal fluid reabsorption all lead to a decrease in the flow of tubule fluid past the macula densa, as well as to a decrease in Na^+ delivery and Na^+ concentration. Within seconds after such a transient disturbance, and by an unknown mechanism, TGF dilates the afferent arteriole of the same nephron in an attempt to increase single-nephron glomerular filtration rate (SNGFR) and restore fluid and Na^+ to that particular macula densa.

In the case of **renin release** (i.e., the *systemic* response), by contrast, a sustained fall in arterial pressure or a contraction of the extracellular volume reduces fluid delivery to many maculae densae, leading to the release of renin. Renin, in turn, causes an increase in local and systemic concentrations of ANG II. Besides causing general vasoconstriction, ANG II *constricts* the afferent and efferent glomerular arterioles, thereby decreasing GFR. This effect is opposite to that of TGF: TGF dilates a single afferent arteriole, whereas renin release constricts many afferent and efferent arterioles.

TGF may be viewed as a mechanism designed to maintain a constant SNGFR, whereas renin release is aimed at maintaining blood pressure by both systemic and renal vasoconstriction (i.e., hemodynamic effects), as well as by reducing SNGFR and enhancing tubule Na^+ reabsorption (Na^+ -retaining effects). TGF is a minute-to-minute, fine control of SNGFR that can be superseded by the intermediate- to long-term effects of the powerful renin response, which comes into play whenever plasma volume and blood pressure are jeopardized. It must be emphasized that renin release is governed not only by the JGA but also by other mechanisms, in particular by changes in the activity of sympathetic nerves (see pp. 842–843).

N40-5

Other Factors that Activate Adenylyl Cyclase in Granular Cells

Contributed by Gerhard Giebisch, Erich Windhager

Agents that activate adenylyl cyclase in the granular cells of the JGA—and thus stimulate renin release—include forskolin, β -adrenergic agonists, A_2 adenosine receptor agonists, dopamine, and glucagon. In addition, exogenous cAMP and phosphodiesterase inhibitors enhance renin secretion. All of these agents presumably act through protein kinase A.

Additional factors also modulate renin release. Prostaglandins E_2 and I_2 and endothelin all activate renin release. Agents that blunt renin release include ANG II (which represents a short feedback loop), AVP, thromboxane A_2 , high plasma levels of K^+ , and nitric oxide.

ANG II has several important actions as follows:

1. **Stimulation of aldosterone release from glomerulosa cells in the adrenal cortex** (see p. 1028). In turn, aldosterone promotes Na^+ reabsorption in the distal tubule and collecting tubules and ducts (see p. 766).
2. **Vasoconstriction of renal and other systemic vessels.** ANG II increases Na^+ reabsorption by altering renal hemodynamics, probably in two ways (Fig. 40-4). First, at high concentrations, ANG II constricts the efferent more than the afferent arterioles, thus increasing filtration fraction and reducing the *hydrostatic pressure* in the downstream peritubular capillaries. The increased filtration fraction also increases the protein concentration in the downstream blood and hence raises the *colloid osmotic pressure* of the peritubular capillaries. The changes in each of these two Starling forces favor the uptake of reabsorbate from peritubular interstitium into peritubular capillaries (see pp. 763–765) and hence enhance the reabsorption of Na^+ and fluid by the proximal tubule. Second, ANG II decreases medullary blood flow through the vasa recta. Low blood flow decreases the medullary washout of $NaCl$ and urea (see pp. 813–815), thus raising $[urea]$ in the medullary interstitium and enhancing Na^+ reabsorption along the thin ascending limb of Henle's loop (see p. 811).

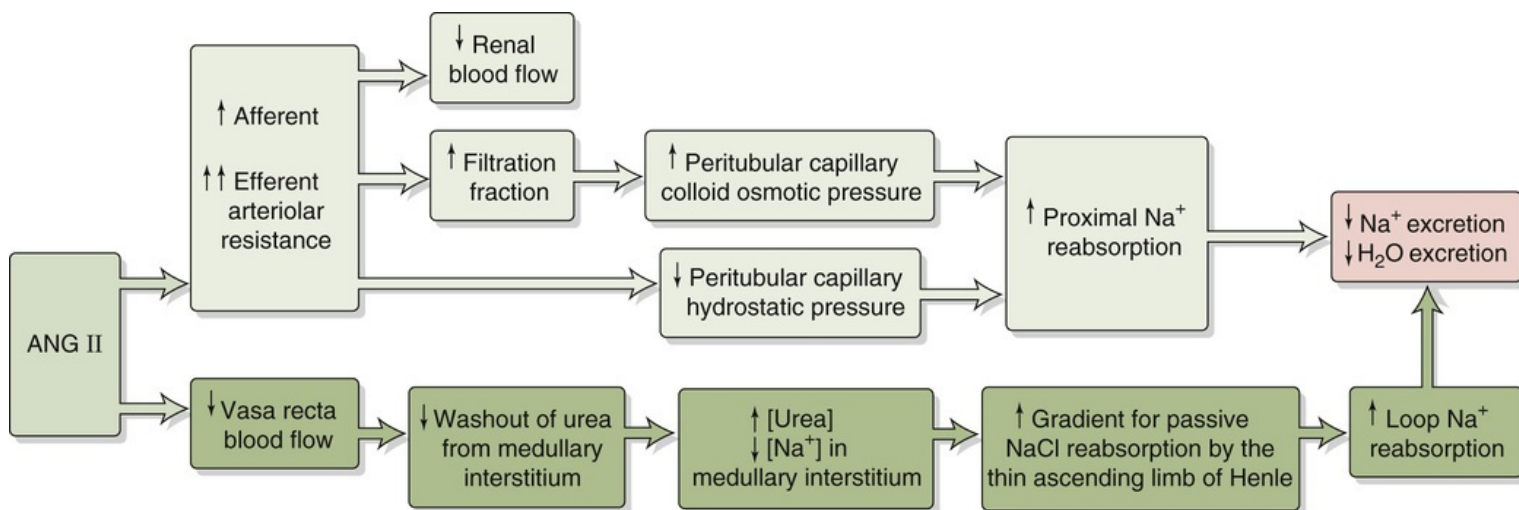

FIGURE 40-4 Hemodynamic actions of ANG II on Na^+ reabsorption.

3. **Enhanced tubuloglomerular feedback.** ANG II raises the sensitivity and lowers the set-point of the tubuloglomerular feedback mechanism (see pp. 750–751), so that an increase in Na^+ and fluid delivery to the macula densa elicits a more pronounced fall in the glomerular filtration rate (GFR).
4. **Enhanced Na-H exchange.** ANG II promotes Na^+ reabsorption in the proximal tubule, TAL, and initial collecting tubule (see pp. 765–766).
5. **Renal hypertrophy.** Over a prolonged time, ANG II induces hypertrophy of renal-tubule cells.

6. Stimulated thirst and AVP release. ANG II acts on the hypothalamus, where it increases the sensation of thirst and stimulates secretion of AVP from the posterior pituitary, both of which increase total-body free water. This ANG II effect represents an intersection between the systems for regulating effective circulating volume and osmolality.

Increased sympathetic nerve activity, increased AVP, and decreased ANP are the other three parallel pathways that correct a low effective circulating volume

Renal Sympathetic Nerve Activity

The second of the four parallel effector pathways for the control of effective circulating volume is the sympathetic nervous system. Enhanced activity of the renal sympathetic nerves has two *direct* effects on Na^+ reabsorption (see pp. 766–768): (1) increased renal vascular resistance, and (2) increased Na^+ reabsorption by tubule cells. In addition, increased sympathetic tone has an *indirect* effect—enhancing renin release from granular cells (see previous section). These multiple actions of sympathetic traffic to the kidney reduce GFR and enhance Na^+ reabsorption, thereby increasing Na^+ retention and increasing effective circulating volume.

In everyday life (i.e., the unstressed state), the role of sympathetic nerve activity in kidney function appears to be modest at best. However, sympathetic innervation may play a role during challenges to volume homeostasis. For example, low Na^+ intake triggers reduced renal Na^+ excretion; renal denervation blunts this response. Another example is hemorrhage, in which renal sympathetic nerves emerge as important participants in preserving ECF volume. Conversely, expansion of the intravascular volume increases renal Na^+ excretion; renal denervation sharply reduces this response as well.

Arginine Vasopressin (Antidiuretic Hormone)

As discussed below (see p. 844), the posterior pituitary releases AVP primarily in response to increases in extracellular *osmolality*. Indeed, AVP mainly increases distal-nephron water permeability, promoting water retention (see pp. 817–818). However, the posterior pituitary also releases AVP in response to large reductions in effective circulating volume (e.g., hemorrhage), and secondary actions of AVP—vasoconstriction (see p. 553) and promotion of renal Na^+ retention (see p. 768)—are appropriate for this stimulus.

Atrial Natriuretic Peptide

Of the four parallel effectors that correct a low effective circulating volume (see Fig. 40-2), ANP is the only one that does so by *decreasing* its activity. As its name implies, ANP promotes **natriuresis** (i.e., Na^+ excretion). Atrial myocytes synthesize and store ANP and release ANP in response to stretch (a low-pressure volume sensor; see p. 547). Thus, reduced effective circulating volume inhibits ANP release and reduces Na^+ excretion. ANP plays a role in the diuretic response to the redistribution of ECF and plasma volume into the thorax that occurs during water immersion and space flight (see p. 1233).

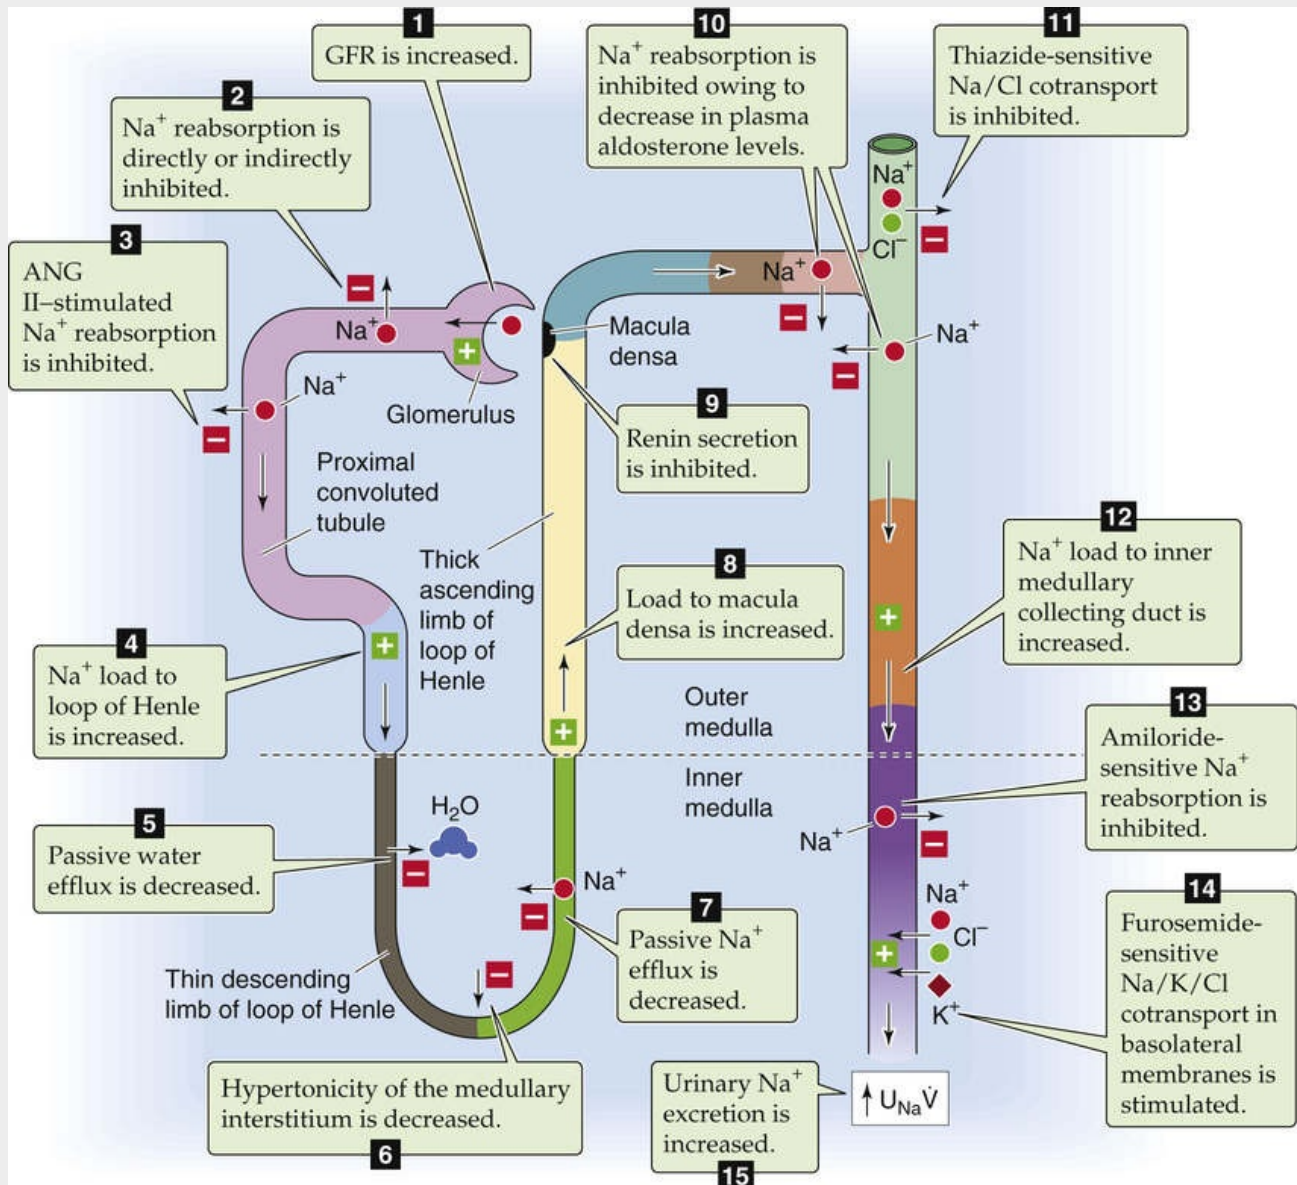

Acting through a receptor guanylyl cyclase (see pp. 66–67), ANP has many synergistic effects (see p. 768) on renal hemodynamics and on transport by renal tubules that promote renal Na^+ and water excretion.  **N40-6** Although ANP directly inhibits Na^+ transport in the inner medullary collecting duct, its major actions are **hemodynamic**—increased GFR and increased cortical and medullary blood flow.

ANP also decreases the release of renin, independently inhibits aldosterone secretion by the adrenal gland, and decreases release of AVP. In summary, a decrease in effective circulating volume leads to a fall in ANP release and a net decrease in Na^+ and water excretion.

Renal Sites of Action of Atrial Natriuretic Peptide

Contributed by Erich Windhager, Gerhard Giebisch

EFigure 40-1 Sites of action of ANP. $U_{\text{Na}} \dot{V}$, urinary sodium excretion rate. (Data from Atlas SA, Maack T: Atrial natriuretic factor. In Windhager E (ed): Handbook of Physiology, Section 8: Renal Physiology. New York, Oxford University Press [for American Physiological Society], 1992, pp 1577–1674.)

High arterial pressure raises Na^+ excretion by hemodynamic mechanisms, independent of changes in effective circulating

volume

We have seen that expanding the effective circulating volume stimulates sensors that increase Na^+ excretion via four parallel effector pathways (see [Fig. 40-2](#)). However, the kidney can also modulate Na^+ excretion in response to purely hemodynamic changes, as in the following two examples.

Large and Acute Decrease in Arterial Blood Pressure

If glomerulotubular (GT) balance (see [p. 763](#)) were perfect, decreasing the GFR would cause Na^+ excretion to fall linearly ([Fig. 40-5](#), blue line). However, acutely lowering GFR by partial clamping of the aorta causes a steep, nonlinear decrease in urinary Na^+ excretion (see [Fig. 40-5](#), red curve). When GFR falls sufficiently, the kidneys excrete only traces of Na^+ in a small volume of urine. This response primarily reflects the transport of the classical distal tubule (see [p. 765](#)), which continues to reabsorb Na^+ at a high rate despite the decreased Na^+ delivery.

FIGURE 40-5 Effect of changes in GFR on urinary Na^+ excretion. The blue line represents ideal glomerulotubular (GT) balance. The red curve summarizes data from dogs. The investigators reduced GFR by inflating a balloon in the aorta, above the level of the renal arteries. They increased GFR by compressing the carotid arteries and thus increased blood pressure. (Data from Thompson DD, Pitts RF: Effects of alterations of renal arterial pressure on sodium and water excretion. *Am J Physiol* 168:490–499, 1952.)

blood pressure rapidly reverses this effect. Finally, hypertension leads to increased pressure in the peritubular capillaries, thereby reducing proximal-tubule reabsorption (physical factors; see [p. 763](#)).

Control of Water Content (Extracellular Osmolality)

Water accounts for half or more of body weight (~60% in men and 50% in women; see [p. 102](#)) and is distributed between the ICF and ECF compartments. Changes in total-body water content in the absence of changes in total-body solute content lead to changes in osmolality, to which the CNS is extremely sensitive. Osmolality deviations of $\pm 15\%$ lead to severe disturbances of CNS function. Thus, osmoregulation is critical.

Two elements control water content and thus whole-body osmolality: (1) the kidneys, which control water excretion (see [pp. 806–807](#)); and (2) thirst mechanisms, which control the oral intake of water. These two effector mechanisms are part of negative-feedback loops that begin within the hypothalamus. An increase in osmolality stimulates separate osmoreceptors to secrete AVP (which reduces renal excretion of free water) and to trigger thirst (which, if fulfilled, increases intake of free water). As a result, the two complementary feedback loops stabilize osmolality and thus $[\text{Na}^+]$.

Increased plasma osmolality stimulates hypothalamic osmoreceptors that trigger the release of AVP, inhibiting water excretion

An increase in the osmolality of the ECF is the primary signal for the secretion of AVP from the posterior pituitary gland. An elegant series of animal studies by Verney in the 1940s established that infusing a hyperosmotic NaCl solution into the *carotid artery* abruptly terminates an established water diuresis ([Fig. 40-6A](#)). Infusing the same quantity of hyperosmotic NaCl into the *peripheral circulation* has little effect because the hyperosmolar solution becomes diluted by the time it reaches the cerebral vessels. Therefore, the osmosensitive site is intracranial. Surgically removing the posterior pituitary abolishes the effect of infusing hyperosmotic NaCl into the carotid artery (see [Fig. 40-6B](#)). However, injecting posterior-pituitary extracts into the animal inhibits the diuresis, regardless of whether the posterior pituitary is intact. Later work showed that Verney's posterior-pituitary extract contained an “antidiuretic hormone”—now known to be AVP—that the posterior pituitary secretes in response to increased plasma osmolality. Ingesting large volumes of water causes plasma osmolality to fall, thus leading to reduced AVP secretion.

A BEFORE REMOVAL OF POSTERIOR PITUITARY

B AFTER REMOVAL OF POSTERIOR PITUITARY

FIGURE 40-6 Sensing of blood osmolality in the dog brain. i.a., intra-arterial (carotid) injection; i.v., intravenous injection; p.o., per os (by mouth). (Data from Verney EG: The antidiuretic hormone and the factors which determine its release. *Proc Royal Soc Lond B* 135:25–106, 1947.)

In healthy individuals, plasma osmolality is ~290 mOsm. The **threshold** for AVP release is somewhat lower, ~280 mOsm (Fig. 40-7, red curve). Increasing the osmolality by only 1% higher than this level is sufficient to produce a detectable increase in plasma [AVP], which rises steeply with further increases in osmolality. Thus, hyperosmolality leads to increased levels of AVP, which completes the feedback loop by causing the kidneys to retain free water (see pp. 817–818).

FIGURE 40-7 Dependence of AVP release on plasma osmolality. (Data from Robertson GL, Aycinena P, Zerbe RL: Neurogenic disorders of osmoregulation. *Am J Med* 72:339–353, 1982.)

Although changes in plasma [NaCl] are usually responsible for changes in plasma osmolality, other solutes can do the same. For example, hypertonic mannitol resembles NaCl in stimulating AVP release. However, an equivalent increase in extracellular osmolality by urea has little effect on plasma AVP levels. The reason is that urea readily permeates cell membranes and hence exerts a low effective osmolality or tonicity (see pp. 132–133) and is thus poorly effective in shrinking cells.

Hypothalamic neurons synthesize AVP and transport it along their axons to the posterior pituitary, where they store it in nerve terminals prior to release

Osmoreceptors of the CNS appear to be located in two areas that breach the blood-brain barrier: the organum vasculosum of the lamina terminalis (OVLT) and the subfornical organ (SFO), two of the circumventricular organs (see pp. 284–285). Specific neurons in these regions (Fig. 40-8) are able to sense changes in *plasma* osmolality. Elevated osmolality increases the activity of mechanosensitive cation channels located in the neuronal membrane, which results in depolarization and thus an increased frequency of action potentials. Hypo-osmolality causes a striking decrease of frequency. The osmosensitive neurons project to large-diameter neurons in the supraoptic and paraventricular nuclei of the anterior hypothalamus (see Fig. 40-8). These neurons synthesize AVP, package it into granules, and transport the granules along their axons to nerve terminals in the posterior lobe of the pituitary, which is part of the brain (see pp. 979–981). When stimulated by the osmosensitive neurons, these **magnocellular neurons** release the stored AVP into the posterior pituitary—an area that also lacks a blood-brain barrier—and AVP enters the general circulation.

FIGURE 40-8 Control of AVP synthesis and release by osmoreceptors. Osmoreceptors are located in the OVLT and SFO, two areas that breach the blood-brain barrier. Signals from atrial low-pressure baroreceptors travel with the vagus nerve to the nucleus tractus solitarius (NTS); a second neuron carries the signal to the hypothalamus. aa, amino acids.

In humans and most mammals, the antidiuretic hormone is AVP, which is encoded by the messenger RNA for preproneurophysin II. After cleavage of the signal peptide, the resulting prohormone neurophysin II contains AVP, neurophysin II (NpII), and a glycopeptide (see Fig. 40-8). Cleavage of the prohormone within the secretory granule yields these three components. AVP has nine amino acids, with a disulfide bridge connecting two cysteine residues. Mutations of NpII impair AVP secretion, which suggests that NpII assists in the processing or secretion of AVP.

Levels of circulating AVP depend on both the rate of AVP release from the posterior pituitary and the rate of AVP degradation. The major factor controlling *AVP release* is plasma osmolality. However, as discussed below, other factors also can modulate AVP secretion.

Two organs, the liver and the kidney, contribute to the *breakdown of AVP* and the rapid decline of AVP levels when secretion has ceased. The half-life of AVP in the circulation is 18 minutes. Diseases of the liver and kidney may impair AVP degradation and may thereby contribute to water retention. For example, the congestion of the liver and impairment of renal function that accompany heart failure can compromise AVP breakdown, leading to inappropriately high circulating levels of AVP. Conversely, in pregnancy, placental vasopressinase activity can accelerate degradation of AVP.

Increased osmolality stimulates a second group of osmoreceptors that trigger thirst, which promotes water intake

The second efferent pathway of the osmoregulatory system is **thirst**, which regulates the oral intake of water. Like the osmoreceptors that trigger AVP release, the osmoreceptors that trigger thirst are located in two circumventricular organs, the OVLT and the SFO. Also like the osmoreceptors that trigger AVP release, those that trigger thirst respond to the cell shrinkage that is caused by hyperosmolar solutions. However, these thirst osmoreceptor neurons are distinct from the adjacent AVP osmoreceptor neurons in the OVLT and SFO.

Hyperosmolality triggers two parallel feedback-control mechanisms that have a common end point (Fig. 40-9): an increase in whole-body free water. In response to hyperosmolality, the AVP osmoreceptors in the hypothalamus trigger other neurons to release AVP. The result is the insertion of aquaporin 2 (AQP2) water channels in the collecting duct of the kidney, an increase in the reabsorption of water, and, therefore, a reduced *excretion* of free water. In response to hyperosmolality, the thirst osmoreceptors stimulate an appetite for water that leads to the increased *intake* of free water. The net effect is an increase in whole-body free water and, therefore, a reduction in osmolality.

accompanied by an increased slope, reflecting an increased sensitivity of the osmoreceptors to changes in osmolality.

Figure 40-9 summarizes the three pathways by which decreased effective circulating volume and low arterial pressure enhance AVP release: (1) A reduction in left atrial pressure—produced by volume depletion—via low-pressure receptors in the left atrium decreases the firing rate of vagal afferents (see [p. 547](#)). These afferents signal brainstem neurons in the nucleus tractus solitarius, causing magnocellular neurons in the hypothalamus to release AVP (see [Fig. 40-8](#)). Indeed, at constant osmolality, AVP secretion varies inversely with left atrial pressure. (2) Low effective circulating volume triggers granular cells in the JGA to release renin. This leads to the formation of ANG II, which acts on receptors in the OVLT and the SFO to stimulate AVP release. (3) More importantly, a fall in the arterial pressure similarly causes high-pressure carotid sinus baroreceptors to stimulate AVP release (see [pp. 534–536](#)).

Two clinical examples in which reduced effective circulating volume leads to increases in AVP are severe **hemorrhagic shock** and **hypovolemic shock** (e.g., shock resulting from excessive loss of ECF, as in cholera). In both cases, the water retention caused by AVP release accounts for the accompanying hyponatremia. In the first part of this chapter, we said that the appropriate renal response to decreased effective circulating volume is to retain Na^+ (i.e., isotonic saline). Why is it that, in response to shock, the body also retains free water? Compared with isotonic saline, free water is less effective as an expander of the ECF volume (see [p. 135](#)). Nevertheless, in times of profound need, the body uses free-water retention to help expand extracellular (and plasma) volume. Clearly, the body is willing to tolerate some hypo-osmolality of the body fluids as the price for maintaining an adequate blood volume.

A clinical example in which reduced effective circulating volume can lead to an *inappropriate* increase in AVP levels is **congestive heart failure** (see [p. 838](#)). In this situation, the water retention may be so severe that the patient develops **hyponatremia** (i.e., hypo-osmolality).

Volume Expansion

In contrast to volume contraction, chronic volume *expansion* reduces AVP secretion, as a consequence of the rightward shift of the threshold to higher osmolalities and of a decline in the slope (see [Fig. 40-7](#), blue curve). In other words, volume expansion decreases the sensitivity of the central osmoreceptors to changes in plasma osmolality. A clinical example is **hyperaldosteronism**. With normal thirst and water excretion, the chronic Na^+ retention resulting from the hyperaldosteronism would expand the ECF volume isotonicity, thus leaving plasma $[\text{Na}^+]$ unchanged. However, because chronic volume expansion downregulates AVP release, the kidneys do not retain adequate water, which results in slight **hypernatremia** (i.e., elevated plasma $[\text{Na}^+]$) and very modest hyperosmolality ([Box 40-3](#)).

Box 40-3

Diuretics

Diuretics reversibly inhibit Na^+ reabsorption at specific sites along the nephron, increasing the excretion of Na^+ and water, creating a state of negative Na^+ balance, and thereby contracting ECF volume. Properly speaking, these agents should be called **natriuretic** to emphasize this use to promote Na^+ excretion. This is in contrast to **aquaretic** agents (e.g., vasopressin receptor antagonists, or VRAs) that promote water excretion with little or no effect on Na^+ excretion. Nevertheless, it has been customary to refer to natriuretics as diuretics.

Clinicians use diuretics to treat hypertension as well as edema (see [Box 20-1](#)) caused by heart failure,

cirrhosis of the liver, or nephrotic syndrome. Common to these latter edematous diseases is an abnormal shift of ECF away from the *effective* circulating volume, which thereby activates the feedback pathways. The results are Na⁺ retention and expansion of *total* extracellular volume. However, this expansion, which results in edema formation, falls short of correcting the underlying decrease in the *effective* circulating volume. The reason that most of this added extracellular volume remains ineffective—and does not restore the effective circulating volume—is not intuitive but reflects the underlying pathologic condition that initiated the edema in the first place. Thus, treating these edematous diseases requires generating a negative Na⁺ balance, which can often be achieved by rigid dietary Na⁺ restriction or the use of diuretics. Diuretics are also useful in treating hypertension. Even though the primary cause of the hypertension may not always be an increase in the effective circulating volume, enhanced Na⁺ excretion is frequently effective in lowering blood pressure.

Classification

The site and mechanism of a diuretic's action determine the magnitude and nature of the response (Table 40-3). Both chemically and functionally, diuretics are very heterogeneous. For example, acetazolamide produces diuresis by inhibiting carbonic anhydrase and thus the component of proximal-tubule Na⁺ reabsorption that is coupled to HCO₃⁻ reabsorption. The diuretic effect of hydrochlorothiazide is largely the result of its ability to inhibit Na/Cl cotransport in the distal convoluted tubule. Spironolactone (which resembles aldosterone) competitively inhibits mineralocorticoid receptors in principal cells of the initial and cortical collecting tubule. Mannitol (reduced fructose) is a powerful osmotic diuretic (see Box 35-1) that reduces net Na⁺ transport in the proximal tubule and TAL by causing retention of water in the lumen and reduction in luminal [Na⁺].

TABLE 40-3
Action of Diuretics

SITE	DRUG	FINAL MOLECULAR “TARGET”	PHYSIOLOGICAL REGULATION OF “TARGET”		PAGE REFERENCE FOR TARGET
			STIMULATOR	INHIBITOR	
PCT	Acetazolamide	Carbonic anhydrase			pp. 828–829
PCT	Dopamine	Na-H exchanger (NHE3)	ANG II, sympathetic nerve activity, α-adrenergic agonists	Dopamine	p. 827
TAL	Loop diuretics: Furosemide Bumetanide Ethacrynic acid	Na/K/Cl cotransporter (NKCC2)	Aldosterone	PGE ₂	p. 757

Water-permeable segments	Osmotic diuretics (mannitol)				

CCT, cortical collecting tubule; DCT, distal convoluted tubule; IMCD, inner medullary collecting duct; PCT, proximal convoluted tubule; PGE₂, prostaglandin E₂.

An ideal diuretic should promote the excretion of urine whose composition resembles that of the ECF. Such diuretics do not exist. In reality, diuretics not only inhibit the reabsorption of Na⁺ and its osmotically obligated water, but also interfere with the renal handling of Cl⁻, H⁺, K⁺, and Ca²⁺, as well as with urinary concentrating ability. N40-7 Thus, many diuretics disturb the normal plasma electrolyte pattern. Table 40-4 summarizes the most frequent side effects of diuretic use on the electrolyte composition of the ECF. These electrolyte derangements are the predictable consequences of the

mechanism of action of individual diuretics at specific tubule sites.

TABLE 40-4
Complications of Diuretic Therapy

COMPLICATION	CAUSATIVE DIURETICS	SYMPTOMS	CAUSATIVE FACTORS
ECF volume depletion	Loop diuretics and thiazides	Lassitude, thirst, muscle cramps, hypotension	Rapid reduction of plasma volume
K ⁺ depletion	Acetazolamide, loop diuretics, thiazides	Muscle weakness, paralysis, cardiac arrhythmias	Flow and Na ⁺ -related stimulation of distal K ⁺ secretion
K ⁺ retention	Amiloride, triamterene, spironolactone	Cardiac arrhythmias, muscle cramps, paralysis	Block of ENaC in the collecting duct
Hyponatremia	Thiazides, furosemide	CNS symptoms, coma	Block of Na ⁺ transport in water-impermeable nephron segment
Metabolic alkalosis	Loop diuretics, thiazides	Cardiac arrhythmias, CNS symptoms	Excessive Cl ⁻ excretion, secondary volume contraction
Metabolic acidosis	Acetazolamide, amiloride, triamterene	Hyperventilation, muscular and neurological disturbances	Interference with H ⁺ secretion
Hypercalcemia	Thiazides	Abnormal tissue calcification, disturbances of nerve and muscle function	Increased Ca ²⁺ reabsorption in distal convoluted tubule
Hyperuricemia	Thiazides, loop diuretics	Gout	Decreased ECF volume, which activates proximal fluid and uric acid reabsorption

ENaC, epithelial Na⁺ channel.

Delivery of Diuretics to Their Sites of Action

Diuretics generally inhibit transporters or channels at the apical membranes of tubule cells. How do the diuretics get there? Plasma proteins bind many diuretics so that the free concentration of the diuretic in plasma water may be fairly low. Thus, glomerular filtration may deliver only a modest amount to the tubule fluid. However, organic anion or organic cation transporters in the S3 segment of the proximal tubule can secrete diuretics and can thereby produce high luminal concentrations. For example, the basolateral organic *anion* transporter system that carries para-aminohippurate (see pp. 779–781) also secretes thiazide diuretics, furosemide, and ethacrynic acid. Organic *cation* transporters (see pp. 783–784) secrete amiloride. The subsequent reabsorption of fluid along the nephron further concentrates diuretics in the tubule lumen. Not surprisingly, renal disease may compromise the delivery of diuretics and cause resistance to the actions of diuretics. N40-8

Response of Nephron Segments Downstream from a Diuretic's Site of Action

The proximal tubule reabsorbs the largest fraction of filtered Na⁺; the loop of Henle, the distal convoluted tubule, and the collecting ducts retrieve smaller fractions. Thus, intuition could suggest that the proximal tubule would be the best target for diuretics. However, secondary effects in downstream nephron segments can substantially mitigate the primary effect of a diuretic. Inhibiting Na⁺ transport by the proximal tubule raises Na⁺ delivery to downstream segments and almost always stimulates Na⁺ reabsorption there (see p. 765). As a result of this downstream Na⁺ reclamation, the overall diuretic action of proximally acting diuretics (e.g., acetazolamide) is relatively weak.

A diuretic is most potent if it acts downstream of the proximal tubule, a condition met by loop diuretics, which inhibit Na⁺ transport along the TAL. Although the TAL normally reabsorbs only 15% to 25% of the filtered load of Na⁺, the reabsorptive capacity of the more distal nephron segments is limited. Thus, the loop diuretics are currently the most powerful diuretic agents. Because nephron segments distal to the TAL have only modest rates of Na⁺ reabsorption, diuretics that target these segments are not as potent as loop diuretics. Nevertheless, distally acting diuretics are important because their effects are long lasting. Moreover, agents acting on the connecting and collecting tubules are **K⁺ sparing** (i.e., they tend to conserve body K⁺).

It is sometimes advantageous to use two diuretics that act at different sites along the nephron,

generating a synergistic effect. Thus, if a loop diuretic alone is providing inadequate diuresis, one could complement its action by adding a thiazide, which will block the compensating effect of the distal convoluted tubule to reabsorb Na^+ .

Blunting of Diuretic Action with Long-Term Use

The prolonged administration of a diuretic may lead to a sustained loss of body weight but only transient natriuresis. **N40-9** Most of the decline in Na^+ excretion occurs because the drug-induced fall in effective circulating volume triggers Na^+ retention mediated by increased sympathetic outflow to the kidneys (which lowers GFR), increased secretion of ANG II and aldosterone, and decreased secretion of ANP. Hypertrophy or increased activity of tubule segments downstream of the main site of action of the diuretic can also contribute to the diminished efficacy of the drug during long-term administration.

N40-7

Secondary Effects of Diuretic Drugs

Contributed by Erich Windhager, Gerhard Giebisch

As noted in the text, the perfect diuretic—which does not exist—would produce an increase in the urinary excretion of protein-free fluid with a composition otherwise identical to that of the ECF. However, diuretics not only inhibit the reabsorption of Na^+ and the osmotically obligated water, but also interfere with the renal handling of Cl^- , H^+ , K^+ , and Ca^{2+} , as well as with urinary concentrating ability.

1. **Urine $[\text{Cl}^-]$.** With the exception of carbonic anhydrase inhibitors, all diuretics promote the excretion of urine having a high $[\text{Cl}^-]$. The ratio $[\text{Cl}^-]/[\text{Na}^+]$ is greater in the urine than in the plasma.
2. **Urine pH.** Because of its inhibition of proximal-tubule HCO_3^- reabsorption, acetazolamide leads to excretion of a relatively alkaline urine. Thus, acetazolamide produces a mild metabolic acidosis. In contrast, the loop diuretics and thiazides cause the excretion of a Cl^- -rich, HCO_3^- -poor urine, which tends to induce a metabolic alkalosis.
3. **Urine $[\text{K}^+]$.** Some diuretics are called *K^+ -sparing* because they tend to conserve body K^+ . These diuretics—which include amiloride, triamterene, and spironolactone—block only a small fraction of Na^+ reabsorption, but reduce K^+ secretion through apical K^+ channels by hyperpolarizing the apical cell membrane. By inhibiting passive cation movement, they may induce hyperkalemia. This hyperkalemia may lead to metabolic acidosis (see p. 835).
4. **Urine $[\text{Ca}^{2+}]$.** With the exception of the chlorothiazides, most diuretics enhance Ca^{2+} excretion. They interfere with the passive reabsorption of Ca^{2+} through the paracellular pathway in both the proximal tubule and TAL (see p. 787). In the proximal tubule, the high luminal flow rate produced by the diuresis reduces the reabsorption of Ca^{2+} via solvent drag. In the TAL, loop diuretics diminish the lumen-positive potential that normally drives the passive reabsorption of Ca^{2+} .
5. **Urine osmolality.** Loop diuretics diminish the urinary concentrating ability by inhibiting Na^+ transport in the TAL (see p. 811).

Clinical side effects of diuretic therapy are summarized in Table 40-4.

N40-8

Reduced Delivery of Diuretics in Renal Disease

Contributed by Erich Windhager, Gerhard Giebisch

As noted in the text, diuretics cannot have their intended effects unless they have appropriate access to their protein targets in the tubule cells. The two access routes are filtration and secretion, of which secretion is usually the most important.

Not surprisingly, renal disease may compromise the net secretion of diuretics in three ways. First, the capability of the diseased cells to secrete diuretics may be impaired (i.e., decreased transport). Second, renal failure leads to a buildup in the blood of organic anions that would otherwise be secreted. These organic anions may competitively inhibit the transport of diuretics by the proximal tubule (i.e., competition). Third, in renal diseases in which breakdown of the glomerular filtration barrier leads to proteinuria, albumin and other proteins not normally present in the tubule lumen bind the diuretics and greatly reduce the concentration of unbound drug (i.e., binding).

N40-9

Blunting of Diuretic Action

Contributed by Erich Windhager, Gerhard Giebisch

Let us assume that a patient has a fixed daily intake of Na^+ . As noted in the text, the administration of a diuretic will cause an initial period of increased Na^+ excretion (negative Na^+ balance), peaking within a few days, that leads to a loss in weight. During prolonged administration of the diuretic, urinary Na^+ excretion will fall back toward normal over a period of many days, and the patient will reach a steady state (neutral Na^+ balance) in which Na^+ intake and excretion are equal, and in which the initial weight loss is maintained.

When the drug is discontinued, the patient will experience a transient period of diminished urinary Na^+ excretion, reaching a nadir after a few days. During this time he or she is in positive Na^+ balance. As a result, the patient will regain the weight that was lost during the initial phase of the diuretic treatment. However, over a period of many days, the Na^+ excretion eventually rises back to a normal level as the patient achieves a new steady state (neutral Na^+ balance) in which Na^+ intake and excretion are again equal, and the patient maintains a prediuretic weight.

Pregnancy

Leftward shifts in the threshold for AVP release and thirst often occur during pregnancy. These changes probably reflect the action of chorionic gonadotropin on the sensitivity of the osmoreceptors. Pregnancy is therefore often associated with a decrease of 8 to 10 mOsm in plasma osmolality. A similar but smaller change may also occur in the late phase of the menstrual cycle.

Other Factors

Pain, nausea, and several drugs (e.g., morphine, nicotine, and high doses of barbiturates) *stimulate* AVP secretion. In contrast, alcohol and drugs that block the effect of morphine (opiate antagonists) *inhibit* AVP secretion and thus promote diuresis. Of great clinical importance is the hypersecretion of AVP that may

occur postoperatively. In addition, some malignant tumors secrete large amounts of AVP. Such secretion of inappropriate amounts of “antidiuretic hormone” leads to pathological retention of water with dilution of the plasma electrolytes, particularly Na^+ . If progressive and uncorrected, this condition may lead to life-threatening deterioration of cerebral function (see [Box 38-3](#)).

Decreased effective circulating volume and low arterial pressure also trigger thirst

Large decreases in effective circulating volume and blood pressure not only stimulate the release of AVP, they also profoundly stimulate the sensation of thirst. In fact, hemorrhage is one of the most powerful stimuli of hypovolemic thirst: “Thirst among the wounded on the battlefield is legendary” (Fitzsimons). Therefore, three distinct stimuli—hyperosmolality, profound volume contraction, and large decreases in blood pressure—lead to the sensation of thirst. Low effective circulating volume and low blood pressure stimulate thirst centers in the hypothalamus via the same pathways by which they stimulate AVP release (see [Fig. 40-9](#)).

In addition to stimulating thirst, some of these hypothalamic areas are also involved in stimulating the desire to ingest salt (i.e., Na^+ appetite). We discuss the role of the hypothalamus in the control of appetite on [page 1001](#).

Defense of the effective circulating volume usually has priority over defense of osmolality

Under physiological conditions, the body regulates plasma *volume* and plasma *osmolality* independently. However, as discussed on [page 847](#), this clear separation of defense mechanisms against volume and osmotic challenges breaks down when more dramatic derangements of fluid or salt metabolism occur. In general, the body defends volume at the expense of osmolality. Examples include severe reductions in absolute blood volume (e.g., hemorrhage) and decreases in effective circulating volume even when absolute ECF volume may be expanded (e.g., congestive heart failure, nephrotic syndrome, and liver cirrhosis). All are conditions that strongly stimulate both Na^+ - and water-retaining mechanisms. However, hyponatremia can be the consequence. 🍷 [N40-10](#)

N40-10

Defense of Osmolality at the Expense of Effective Circulating Volume During Dehydration

Contributed by Gerhard Giebisch, Erich Windhager, Emile Boulpaep, Walter Boron

An exception to the rule of defending volume over osmolality occurs during severe water loss (i.e., dehydration; see p. 1215). In this case, the hyperosmolality that accompanies the dehydration maximally stimulates AVP secretion and thirst (see [Fig. 40-9](#)). Of course, severe dehydration also reduces total-body volume. However, this loss of free water occurs at the expense of both intracellular water (~60%) and extracellular water (~40%). Thus, dehydration does not put the effective circulating volume at as great a risk as the acute loss of an equivalent volume of blood. Because dehydration reduces effective circulating volume, one might think that the renin-angiotensin-aldosterone axis would lead to Na^+

retention during dehydration. However, the opposite effect may occur, possibly because hyperosmolality makes the glomerulosa cells of the adrenal medulla less sensitive to ANG II and thereby reduces the release of aldosterone. Thus, the kidneys fail to retain Na^+ appropriately. Accordingly, in severe dehydration, the net effect is an attempt to correct hyperosmolality by both water intake and retention, as well as by the loss of Na^+ (i.e., natriuresis) that occurs because aldosterone levels are inappropriately low for the effective circulating volume. Therefore, in severe dehydration, the body violates the principle of defending volume over osmolality.

If the dehydration occurs during exercise, the drive to preserve effective circulating volume will trump temperature regulation (see p. 1215), offsetting the earlier vasodilation of the skin and active muscle. We can infer that the exercise-induced dehydration, by triggering thirst and AVP secretion (see previous paragraph), leads to a correction of the hyperosmolality and an increase in effective circulating volume that, once again, allows the individual to sweat and effectively regulate whole-body temperature.

Organization of the Gastrointestinal System

Henry J. Binder

Overview of Digestive Processes

The gastrointestinal tract is a tube that is specialized along its length for the sequential processing of food

The gastrointestinal (GI) tract consists of both the series of hollow organs stretching from the mouth to the anus and the several accessory glands and organs that add secretions to these hollow organs ([Fig. 41-1](#)). Each of these hollow organs, which are separated from each other at key locations by sphincters, has evolved to serve a specialized function. The mouth and oropharynx are responsible for chopping food into small pieces, lubricating it, initiating carbohydrate and fat digestion, and propelling the food into the esophagus. The esophagus acts as a conduit to the stomach. The stomach (see [Chapter 42](#)) temporarily stores food and also initiates digestion by churning and by secreting proteases and acid. The small intestine (see [Chapters 44](#) and [45](#)) continues the work of digestion and is the primary site for the absorption of nutrients. The large intestine (see [Chapters 44](#) and [45](#)) reabsorbs fluids and electrolytes and also stores the fecal matter before expulsion from the body. The accessory glands and organs include the salivary glands, pancreas, and liver. The pancreas (see [Chapter 43](#)) secretes digestive enzymes into the duodenum, in addition to secreting HCO_3^- to neutralize gastric acid. The liver secretes bile (see [Chapter 46](#)), which the gallbladder stores for future delivery to the duodenum during a meal. Bile contains bile acids, which play a key role in the digestion of fats.

FIGURE 41-1 Major components of the human digestive system.

Although the anatomy of the wall of the GI tract varies along its length, certain organizational themes are common to all segments. [Figure 41-2](#), a cross section through a generic piece of stomach or intestine, shows the characteristic layered structure of mucosa, submucosa, muscle, and serosa.

A MACROSCOPIC VIEW OF THE WALL OF THE DUODENUM

B MICROSCOPIC VIEW OF THE WALL OF THE COLON

FIGURE 41-2 Wall of the GI tract. **A**, The wall of a segment of the duodenum consists of the following structures, from inside to outside: an epithelial layer with crypts, lamina propria, muscularis mucosae, submucosa, circular and then longitudinal layer of the muscularis externa, and serosa. **B**, The colon has the same basic structure as the small intestine. Some of the epithelial cells are on the surface and others are in the crypts that penetrate into the wall of the colon.

The **mucosa** consists of the epithelial layer, as well as an underlying layer of loose connective tissue

known as the **lamina propria**, which contains capillaries, enteric neurons, and immune cells (e.g., mast cells), as well as a thin layer of smooth muscle known as the *lamina muscularis mucosae* (literally, the muscle layer of the mucosa). The surface area of the epithelial layer is amplified by several mechanisms. Most cells have microvilli on their apical surfaces. In addition, the layer of epithelial cells can be evaginated to form **villi** or invaginated to form **crypts** (or glands). Finally, on a larger scale, the mucosa is organized into large folds.

The **submucosa** consists of loose connective tissue and larger blood vessels. The submucosa may also contain glands that secrete material into the GI lumen.

The **muscle layer**, the *muscularis externa*, includes two layers of smooth muscle. The inner layer is circular, whereas the outer layer is longitudinal. Enteric neurons are present between these two muscle layers.

The **serosa** is an enveloping layer of connective tissue that is covered with squamous epithelial cells.

Assimilation of dietary food substances requires digestion as well as absorption

The sedentary human body requires ~30 kcal/kg body weight each day (see [p. 1170](#)). This nutrient requirement is normally acquired by the oral intake of multiple food substances that the GI tract then assimilates. Although antigenic amounts of protein enter the body via the skin and across the pulmonary epithelium, caloric uptake by routes other than the GI tract is not thought to occur. Both the small and large intestines absorb water and electrolytes, but only the small intestine absorbs lipids, carbohydrates, and amino acids. However, even without effective GI function, parenteral (i.e., intravenous) alimentation can provide sufficient calories to sustain adults and to support growth in premature infants. Total parenteral nutrition has been used successfully on a long-term basis in many clinical settings in which oral intake is impossible or undesirable.

Food substances are not necessarily—and often are—consumed in a chemical form that the small intestine can directly absorb. To facilitate absorption, the GI tract digests the food by both mechanical and chemical processes.

Mechanical disruption of ingested food begins in the mouth with chewing (mastication). Individuals without teeth usually require their solid food to be cut into smaller pieces before eating. The mechanical processes that alter food composition to facilitate absorption continue in the stomach (see [p. 865](#)), both to initiate protein and lipid enzymatic digestion and to allow passage of gastric contents through the pylorus into the duodenum. This change in the size and consistency of gastric contents is necessary because solids that are >2 mm in diameter do not pass through the pylorus.

The chemical form in which different nutrients are ingested and absorbed varies according to the specific nutrient in question. For example, although most lipids are consumed in the form of triacylglycerols, it is fatty acids and monoacylglycerols, *not* triacylglycerols, that are absorbed by the small intestine. Thus, a complex series of chemical reactions (i.e., lipid digestion) are required to convert dietary triacylglycerols to these smaller lipid forms (see [pp. 927–928](#)). Similarly, amino acids are present in food as proteins and large peptides, but only amino acids and small peptides—primarily dipeptides and tripeptides—are absorbed by the small intestine. Carbohydrates are present in the diet as starch, disaccharides, and monosaccharides (e.g., glucose). However, because the small intestine absorbs all carbohydrates as monosaccharides, most dietary carbohydrates require chemical digestion before their absorption.

Digestion requires enzymes secreted in the mouth, stomach, pancreas, and small intestine

Digestion involves the conversion of dietary food nutrients to a form that the small intestine can absorb. For carbohydrates and lipids, these digestive processes are initiated in the mouth by salivary and lingual enzymes: amylase for carbohydrates and lipase for lipids. Protein digestion is initiated in the stomach by gastric proteases (i.e., pepsins), whereas additional lipid digestion in the stomach occurs primarily as a result of the lingual lipase that is swallowed, although some gastric lipase is also secreted. Carbohydrate digestion does not involve any secreted gastric enzymes.

Digestion is completed in the small intestine by the action of both pancreatic enzymes and enzymes at the brush border of the small intestine. Pancreatic enzymes, which include lipase, chymotrypsin, and amylase, are critical for the digestion of lipids, protein, and carbohydrates, respectively. The enzymes on the luminal surface of the small intestine (e.g., brush-border disaccharidases and dipeptidases) complete the digestion of carbohydrates and proteins. Digestion by these brush-border enzymes is referred to as *membrane digestion*.

The material presented to the small intestine includes both dietary intake and secretory products. The food material entering the small intestine differs considerably from the ingested material because of the mechanical and chemical changes just discussed. The load to the small intestine is also significantly greater than that of the ingested material. Dietary fluid intake is 1.5 to 2.5 L/day, whereas the fluid load presented to the small intestine is 8 to 9 L/day. The increased volume results from substantial quantities of salivary, gastric, biliary, pancreatic, and small-intestinal secretions. These secretions contain large amounts of protein, primarily in the form of the digestive enzymes discussed above.

Ingestion of food initiates multiple endocrine, neural, and paracrine responses

Digestion of food involves multiple secretory, enzymatic, and motor processes that are closely coordinated with one another. The necessary control is achieved by neural and hormonal processes that are initiated by dietary food substances; the result is a coordinated series of motor and secretory responses. For example, chemoreceptors, osmoreceptors, and mechanoreceptors in the mucosa in large part generate the afferent stimuli that induce gastric and pancreatic secretions. These receptors sense the luminal contents and initiate a neurohumoral response.

Endocrine, neural, and paracrine mechanisms all contribute to digestion. All three include sensor and transmitter processes. An **endocrine** mechanism (see p. 47) involves the release of a transmitter (e.g., peptide) into the blood.

For example, protein in the stomach stimulates the release of gastrin from antral G cells. Gastrin then enters the blood and stimulates H^+ release from parietal cells in the body of the stomach. A **neural** mechanism involves the activation of nerves and neurotransmitters that influence either secretory or motor activity. Neural transmission of these responses may involve the **enteric nervous system (ENS)** (see pp. 339–340) or the central nervous system (CNS). An example of neural control is activation of the vagus nerve in response to the smell of food. The resultant release of the neurotransmitter **acetylcholine (ACh)** also releases H^+ from parietal cells in the stomach.

The third mechanism of neurohumoral control is **paracrine** (see p. 47). In this mechanism, a transmitter is released from a sensor cell, and it affects adjacent cells without either entering the blood or activating neurons. For example, paracrine mechanisms help regulate gastric acid secretion by parietal cells: the

histamine released from so-called enterochromaffin-like (ECL) cells in the body of the stomach stimulates H^+ release from neighboring parietal cells.

In addition to the primary response that leads to the release of one or more digestive enzymes, other signals terminate these secretory responses. Enteric neurons are important throughout the initiation and termination of the responses.

Although the endocrine, neural, and paracrine responses are most often studied separately, with considerable effort made to isolate individual events, these responses do not occur as isolated events. Rather, each type is part of an integrated response to a meal that results in the digestion and absorption of food. This entire series of events that results from the ingestion of food can best be described as an integrated response that includes both afferent and efferent limbs.

In addition to its function in nutrition, the GI tract plays important roles in excretion, fluid and electrolyte balance, and immunity

Although its primary roles are digesting and absorbing nutrients, the GI tract also excretes **waste material**. Fecal material includes nondigested/nonabsorbed dietary food products, colonic bacteria and their metabolic products, and several excretory products. These excretory products include (1) heavy metals such as iron and copper, whose major route of excretion is in bile; and (2) several organic anions and cations, including drugs, that are excreted in bile but are reabsorbed either poorly or not at all by either the small or large intestine.

As noted above, the small intestine is presented with 8 to 9 L/day of fluid, an amount that includes ~ 1 L/day that the intestine itself secretes. Almost all this water is reabsorbed in the small and large intestine; therefore, stool has relatively small amounts of water (~ 0.1 L/day). Diarrhea (an increase in stool liquidity and weight, >200 g/day) results from either increased fluid secretion by the small or large intestine, or decreased fluid reabsorption by the intestines. An important clinical example of diarrhea is cholera, especially in developing countries. Cholera can be fatal because of the water and electrolyte imbalance that it creates. Thus, the GI tract plays a crucial role in maintaining overall **fluid and electrolyte balance** (see [Chapter 44](#)).

The GI tract also contributes to **immune function**. The mucosal immune system, or **gut-associated lymphoid tissue (GALT)**, consists of both organized aggregates of lymphoid tissue (e.g., Peyer's patches; see [Fig. 41-2B](#)) and diffuse populations of immune cells. These immune cells include lymphocytes that reside between the epithelial cells lining the gut, as well as lymphocytes and mast cells in the lamina propria. GALT has two primary functions: (1) to protect against potential microbial pathogens, including bacteria, protozoans, and viruses; and (2) to permit immunological *tolerance* to both the potentially immunogenic dietary substances and the bacteria that normally reside primarily in the lumen of the large intestine.

The mucosal immune system is important because the GI tract has the largest area of the body in potential direct contact with infectious, toxic, and immunogenic material. Approximately 80% of the immunoglobulin-producing cells are found in the small intestine. Although GALT has some interaction with the systemic immune system, GALT is operationally distinct. Finally, evidence indicates communication between the GALT and mucosal immune systems at other mucosal surfaces, such as the pulmonary epithelia.

Certain **nonimmunological defense** processes are also important in protecting against potential luminal

pathogens and in limiting the uptake of macromolecules from the GI tract. The nonimmunological mechanisms that are critical in maintaining the ecology of intestinal flora include gastric acid secretion, intestinal mucin, peristalsis, and the epithelial-cell permeability barrier. Thus, whereas relatively low levels of aerobic bacteria are present in the lumen of the small intestine of physiologically normal subjects, individuals with impaired small-intestinal peristalsis often have substantially higher levels of both aerobic and anaerobic bacteria in their small intestine. A consequence may be diarrhea or steatorrhea (i.e., increased fecal fat excretion). The clinical manifestation of impaired intestinal peristalsis is referred to as either *blind loop syndrome* or *stagnant bowel syndrome*.

Regulation of Gastrointestinal Function

The ENS is a “minibrain” with sensory neurons, interneurons, and motor neurons

The ENS (see [pp. 339–340](#)) is the primary neural mechanism that controls GI function and is one of the three divisions of the autonomic nervous system (ANS), along with the sympathetic and parasympathetic divisions. One indication of the importance of the ENS is the number of neurons consigned to it. The ENS consists of ~100 million neurons, roughly the number in the spinal cord or in the rest of the entire ANS. The ENS is located solely within GI tissue, but it can be modified by input from the brain. Neurons of the ENS are primarily, but not exclusively, clustered in one of two collections of neurons ([Fig. 41-3A](#)): the submucosal plexus and the myenteric plexus. The **submucosal** (or **Meissner's**) **plexus** is found in the submucosa only in the small and large intestine. The **myenteric** (or **Auerbach's**) **plexus** is located between the circular and longitudinal muscle layers throughout the GI tract from the proximal end of the esophagus to the rectum.

A LOCATION OF THE ENS

B CONNECTIONS OF ENS NEURONS

FIGURE 41-3 Schematic representation of the ENS. **A**, The submucosal (or Meissner's) plexus is located between the muscularis mucosae and the circular muscle of the muscularis externa. The myenteric (or Auerbach's) plexus is located between the circular and longitudinal layers of the muscularis externa. In addition to these two plexuses that have ganglia, three others—the mucosal, deep muscular, and tertiary plexuses—are present. **B**, The ENS consists of sensory neurons, interneurons, and motor neurons. Some sensory signals travel centrally from the ENS. Both the parasympathetic and the sympathetic divisions of the ANS modulate the ENS. This figure illustrates some of the typical circuitry of ENS neurons.

The ENS is a complete reflex circuit and can operate totally within the GI tract, without the participation of either the spinal cord or the cephalic brain. As with other neurons, the activity of the ENS is the result of the generation of action potentials by single neurons and the release of chemical neurotransmitters that affect either other neurons or effector cells (i.e., epithelial or muscle cells). The ENS consists of sensory circuits, interneuronal connections, and secretomotor neurons (see Fig. 41-3B). Sensory (or **afferent**) neurons monitor changes in luminal activity, including distention (i.e., smooth-muscle tension), chemistry (e.g., pH, osmolality, levels of specific nutrients), and mechanical stimulation. These sensory neurons activate **interneurons**, which relay signals that activate **efferent** secretomotor neurons that in turn stimulate or inhibit a wide range of effector cells: smooth-muscle cells, epithelial cells that secrete or absorb fluid and electrolytes, submucosal blood vessels, and enteric endocrine cells.

The largely independent function of the ENS has given rise to the concept of a GI “minibrain.” Because the efferent responses to several different stimuli are often quite similar, a generalized concept has developed that the ENS possesses multiple preprogrammed responses. For example, both mechanical distention of the jejunum and the presence of a bacterial enterotoxin in the jejunum can elicit identical responses: stimulation of profuse fluid and electrolyte secretion, together with propagated, propulsive, coordinated smooth-muscle contractions. Such preprogrammed efferent responses are probably initiated

by sensory input to the enteric interneuronal connections. However, efferent responses controlled by the ENS may also be modified by input from autonomic ganglia, which are in turn under the influence of the spinal cord and brain (see [p. 336](#)). 🧠 **N41-1** In addition, the ENS receives input directly from the brain via parasympathetic nerves (i.e., the vagus nerve).

N41-1

Hierarchical Reflex Loops in the ANS

Contributed by George Richerson

EFigure 41-1 At the lowest level, the ENS is an independent system consisting of afferent neurons, interneurons, and motor neurons. One level up, the autonomic ganglia control the autonomic end organs, including the ENS. One further level up, the spinal cord controls certain autonomic ganglia and integrates response among different levels of the spinal cord. The brainstem receives inputs from visceral afferents and coordinates the control of all viscera. Finally, forebrain CNS centers receive input from the brainstem and coordinate the activity of the ANS via input to the brainstem.

ACh, peptides, and bioactive amines are the ENS neurotransmitters that regulate epithelial and motor function

ACh is the primary preganglionic and postganglionic neurotransmitter regulating both secretory function and smooth-muscle activity in the GI tract. In addition, many other neurotransmitters are present in enteric neurons. Among the peptides, **vasoactive intestinal peptide (VIP)** has an important role in both inhibition of intestinal smooth muscle and stimulation of intestinal fluid and electrolyte secretion. Although VIP was first identified in the GI tract, it is now appreciated that VIP is also an important neurotransmitter in the brain (see [Table 13-1](#)). Also playing an important role in GI regulation are other peptides (e.g., enkephalins, somatostatin, and substance P), amines (e.g., serotonin), and nitric oxide (NO).

Our understanding of ENS neurotransmitters is evolving, and the list of identified agonists grows ever longer. In addition, substantial species differences exist. Frequently, chemical neurotransmitters are identified in neurons without a clear-cut demonstration of their physiological role in the regulation of organ function. More than one neurotransmitter has been identified within single neurons, a finding suggesting that regulation of some cell functions may require more than one neurotransmitter.

The brain-gut axis is a bidirectional system that controls GI function via the ANS, GI hormones, and the immune system

Well recognized, but poorly understood, is the modification of several different aspects of GI function by the brain. In other words, neural control of the GI tract is a function of not only intrinsic nerves (i.e., the ENS) but also nerves that are extrinsic to the GI tract. These extrinsic pathways are composed of elements of both the parasympathetic and, to a lesser extent, the sympathetic nervous system and are under the control of autonomic centers in the brainstem (see [p. 338](#)).

Parasympathetic innervation of the GI tract from the pharynx to the distal colon is through the vagus nerve; the distal third of the colon receives its parasympathetic innervation from the pelvic nerves (see [Fig. 14-4](#)). The preganglionic fibers of the parasympathetic nerves use ACh as their neurotransmitter and synapse on some neurons of the ENS (see [Fig. 41-3B](#)). These ENS neurons are thus postganglionic parasympathetic fibers, and their cell bodies are, in a sense, the parasympathetic ganglion. These postganglionic parasympathetic fibers use mainly ACh as their neurotransmitter; however, as noted in the previous section, many other neurotransmitters are also present. Parasympathetic stimulation—after one or more synapses in a very complex ENS network—increases secretion and motility. The parasympathetic nerves also contain afferent fibers (see [p. 339](#)) that carry information to autonomic centers in the medulla from chemoreceptors, osmoreceptors, and mechanoreceptors in the mucosa. The loop that is initiated by these afferents, integrated by central autonomic centers, and completed by the aforementioned parasympathetic efferents, is known as a **vagovagal reflex**.

The preganglionic **sympathetic** fibers to the GI tract synapse on postganglionic neurons in the

prevertebral ganglia (see Fig. 14-3); the neurotransmitter at this synapse is ACh (see p. 341). The postganglionic sympathetic fibers either synapse in the ENS or directly innervate effector cells (see Fig. 41-3B).

In addition to the control that is entirely within the ENS, as well as control via autonomic centers in the medulla, the GI tract is also under the control of higher CNS centers. Examples of cerebral function that affects GI behavior include the fight-or-flight response, which reduces blood flow to the GI tract, and the sight and smell of food, which increase gastric acid secretion.

Communication between the GI tract and higher CNS centers is bidirectional. For example, cholecystokinin from the GI tract mediates, in part, the development of food satiety in the brain. In addition, gastrin-releasing peptide, a neurotransmitter made in ENS cells (see p. 868), inhibits gastric acid secretion when experimentally injected into the ventricles of the brain. Table 41-1 summarizes peptide hormones made by the GI tract as well as their major actions.

TABLE 41-1
GI Peptide Hormones  N41-2

HORMONE	SOURCE	TARGET	ACTION
Cholecystokinin	I cells in duodenum and jejunum and neurons in ileum and colon	Pancreas	↑ Enzyme secretion
		Gall bladder	↑ Contraction
Gastric inhibitory peptide	K cells in duodenum and jejunum	Pancreas	Exocrine: ↓ fluid absorption Endocrine: ↑ insulin release
Gastrin	G cells, antrum of stomach	Parietal cells in body of stomach	↑ H ⁺ secretion
Gastrin-releasing peptide	Vagal nerve endings	G cells in antrum of stomach	↑ Gastrin release
Guanylin	Ileum and colon	Small and large intestine	↑ Fluid absorption
Motilin	Endocrine cells in upper GI tract	Esophageal sphincter Stomach Duodenum	↑ Smooth-muscle contraction
Neurotensin	Endocrine cells, widespread in GI tract	Intestinal smooth muscle	Vasoactive stimulation of histamine release
Peptide YY	Endocrine cells in ileum and colon	Stomach	↓ Vagally mediated acid secretion
		Pancreas	↓ Enzyme and fluid secretion
Secretin	S cells in small intestine	Pancreas	↑ HCO ₃ ⁻ and fluid secretion by pancreatic ducts
		Stomach	↓ Gastric acid secretion
Somatostatin	D cells of stomach and duodenum, δ cells of pancreatic islets	Stomach	↓ Gastrin release
		Intestine	↑ Fluid absorption/↓ secretion ↑ Smooth-muscle contraction
		Pancreas	↓ Endocrine/exocrine secretions
		Liver	↓ Bile flow
Substance P	Enteric neurons	Enteric neurons	Neurotransmitter
VIP	ENS neurons	Small intestine	↑ Smooth-muscle relaxation ↑ Secretion by small intestine
		Pancreas	↑ Secretion by pancreas

N41-2

GI Peptide Hormones

Contributed by Emile Boulpaep, and Walter Boron

The amino-acid sequences of several of the peptide hormones listed in Table 41-1 are presented elsewhere in the text or below:

- **Cholecystokinin (CCK):** The amino-acid sequence is presented in Figure 42-7C .
- **Cholecystokinin-like peptide (CCK-8):** The amino-acid sequence is presented in Figure 13-9. This is one of several cleavage products of CCK.

- **Gastric inhibitory peptide:** See Table 41-1. A peptide consisting of 42 amino acids. The single-letter code for these amino acids is YAEGTFISD YSIAMDKIHQ QDFVNWLLAQ KGKKNDWKHN ITQ.
- **Gastrin (“little” and “big”):** The amino-acid sequences are presented in Figure 42-7.
- **Gastrin-releasing peptide (GRP):** The amino-acid sequence is presented in Figure 13-9.
- **Guanylin (guanylyl cyclase activator 2A):** A peptide consisting of 15 amino acids. The single-letter code for these amino acids is PGTCEICAYA ACTGC.
- **Neurotensin:** The amino-acid sequence is presented in Figure 13-9.
- **Peptide YY:** Peptide YY (also known as PYY-I) consists of 36 amino acids. The single-letter code for these amino acids is YP IKPEAPGEDA SPEELNRYYA SLRHYLNLVT RQRY. Notice that the sequence starts and ends with a Y (i.e., tyrosine). PYY-II lacks the first two residues of PYY-I (i.e., YP) and thus is only 34 residues in length (see p. 1005).
- **Secretin:** This peptide (see p. 876) consists of 27 amino acids: HSD GTFTSELSRL REGARLQRL QGLV.
- **Somatostatin:** The amino-acid sequence is presented in Figure 13-9.
- **Substance P:** The amino-acid sequence is presented in Figure 13-9.
- **Vasoactive intestinal peptide (VIP):** The amino-acid sequence is presented in Figure 13-9.

In addition to the “hard-wired” communications involved in sensory input and motor output, communication via the gut-brain axis also requires significant participation of the **immune system**. Neuroimmune regulation of both epithelial and motor function in the small and large intestine primarily involves **mast cells** in the lamina propria of the intestine. Because the mast cells are sensitive to neurotransmitters, they can process information from the brain to the ENS and can also respond to signals from interneurons of the ENS. Mast cells also monitor sensory input from the intestinal lumen by participating in the immune response to foreign antigens. In turn, chemical mediators released by mast cells (e.g., histamine) directly affect both intestinal smooth-muscle cells and epithelial cells. Our understanding of how the immune system modulates the neural control of GI function is rapidly evolving.

In conclusion, three parallel components of the gut-brain axis—the ENS, GI hormones, and the immune system—control GI function, an arrangement that provides substantial redundancy. Such redundancy permits fine-tuning of the regulation of digestive processes and provides “backup” or “fail-safe” mechanisms that ensure the integrity of GI function, especially at times of impaired function (i.e., during disease).

Gastrointestinal Motility

Tonic and rhythmic contractions of smooth muscle are responsible for churning, peristalsis, and reservoir action

The motor activity of the GI tract performs three primary functions. First, it produces segmental contractions that are associated with nonpropulsive movement of the luminal contents. The result is the increased mixing—or **churning**—that enhances the digestion and absorption of dietary nutrients. Second, GI motor activity produces peristalsis, a progressive wave of relaxation followed by contraction. The result is **propulsion**, or the propagated movement of food and its digestive products in a caudal direction, ultimately eliminating nondigested, nonabsorbed material. Third, motor activity allows some hollow organs—particularly the stomach and large intestine—to hold the luminal content, exerting a **reservoir function**. This reservoir function is made possible by **sphincters** that separate the organs of the GI tract. All these functions are primarily accomplished by the coordinated activity of **smooth muscle** (see pp. 243–249).

The electrical and mechanical properties of intestinal smooth muscle needed for these functions include both tonic (i.e., sustained) contractions and rhythmic contractions (i.e., alternating contraction and relaxation) of individual muscle cells. The intrinsic rhythmic contractility is a function of the membrane voltage (V_m) of the smooth-muscle cell. V_m can either oscillate in a subthreshold range at a low frequency (several cycles per minute), referred to as **slow-wave activity**, or reach a threshold for initiating a true **action potential** (see Fig. 9-14). The integrated effect of the slow waves and action potentials determines the smooth-muscle activity of the GI tract. Slow-wave activity apparently occurs as voltage-gated Ca^{2+} channels depolarize the cell and increase $[Ca^{2+}]_i$, followed by the opening of Ca^{2+} -activated K^+ channels, which repolarize the cell (see p. 244).

These activities are regulated, in large part, by both neural and hormonal stimuli. Modulation of intestinal smooth-muscle contraction is largely a function of $[Ca^{2+}]_i$ (see pp. 246–247). Several agonists regulate $[Ca^{2+}]_i$ by one of two mechanisms: (1) activating G protein–linked receptors, which results in the formation of inositol 1,4,5-trisphosphate (IP_3) and the release of Ca^{2+} from intracellular stores; or (2) opening and closing of plasma-membrane Ca^{2+} channels. Both excitatory and inhibitory neurotransmitters can modulate smooth-muscle $[Ca^{2+}]_i$ and thus contractility. In general, ACh is the predominant neurotransmitter of *excitatory* motor neurons, whereas VIP and NO are the neurotransmitters of *inhibitory* motor neurons. Different neural or hormonal inputs probably increase (or decrease) the frequency with which V_m exceeds threshold and produces an action potential and thus increases (or decreases) muscle contractility.

An additional, unique factor in the aforementioned regulatory control is that luminal food and digestive products activate mucosal chemoreceptors and mechanoreceptors, as discussed above, thus inducing hormone release or stimulating the ENS and controlling smooth-muscle function. For example, gastric contents with elevated osmolality or a high lipid content entering the duodenum activate mucosal osmoreceptors and chemoreceptors that increase the release of cholecystikinin and thus delay gastric emptying (see p. 878).

Segments of the GI tract have both longitudinal and circular

arrays of muscles and are separated by sphincters that consist of specialized circular muscles

The muscle layers of the GI tract consist almost entirely of smooth muscle. Exceptions are the striated muscle of (1) the upper esophageal sphincter (UES), which separates the hypopharynx from the esophagus; (2) the upper third of the esophagus; and (3) the external anal sphincter. As shown above in [Figure 41-2](#), the two smooth-muscle layers are arranged as an inner circular layer and an outer longitudinal layer. The myenteric ganglia of the ENS are located between the two muscle layers.

The segments of the GI tract through which food products pass are hollow, low-pressure organs that are separated by specialized circular muscles or **sphincters**. These sphincters function as barriers to flow by maintaining a positive **resting pressure** that serves to separate the two adjacent organs, in which lower pressures prevail. Sphincters thus regulate both antegrade (forward) and retrograde (reverse) movement. For example, the resting pressure of the pyloric sphincter controls, in part, the emptying of gastric contents into the duodenum. On the opposite end of the stomach, the resting pressure of the lower esophageal sphincter (LES) prevents gastric contents from refluxing back into the esophagus and causing **gastroesophageal reflux disease (GERD)**. As a general rule, stimuli proximal to a sphincter cause sphincteric relaxation, whereas stimuli distal to a sphincter induce sphincteric contraction. Changes in sphincter pressure are coordinated with the smooth-muscle contractions in the organs on either side. This coordination depends on both the intrinsic properties of sphincteric smooth muscle and neurohumoral stimuli.

Sphincters effectively serve as one-way valves. Thus, the act of deglutition (or swallowing) induces relaxation of the UES, whereas the LES remains contracted. Only when the UES returns to its initial pressure does the LES begin to relax, ~3 seconds after the start of deglutition. Disturbances in sphincter activity are often associated with alterations in one or more of these regulatory processes.

Location of a sphincter determines its function

Six sphincters are present in the GI tract (see [Fig. 41-1](#)), each with a different resting pressure and different response to various stimuli. An additional sphincter, the sphincter of Oddi, regulates movement of the contents of the common bile duct into the duodenum.

Upper Esophageal Sphincter

Separating the pharynx and the upper part of the esophagus is the UES, which consists of striated muscle and has the highest resting pressure of all the GI sphincters. The swallowing mechanism, which involves the oropharynx and the UES, is largely under the control of the **swallowing center** in the medulla via cranial nerves V (trigeminal), IX (glossopharyngeal), X (vagus), and XII (hypoglossal). Respiration and deglutition are closely integrated (see [p. 720](#)).

The UES is closed during inspiration, thereby diverting atmospheric air to the glottis and away from the esophagus. During swallowing, the situation reverses, with closure of the glottis and inhibition of respiration, but with relaxation of the UES ([Fig. 41-4](#)). These changes permit the entry of food contents into the esophagus and not into the airways of the respiratory tract.

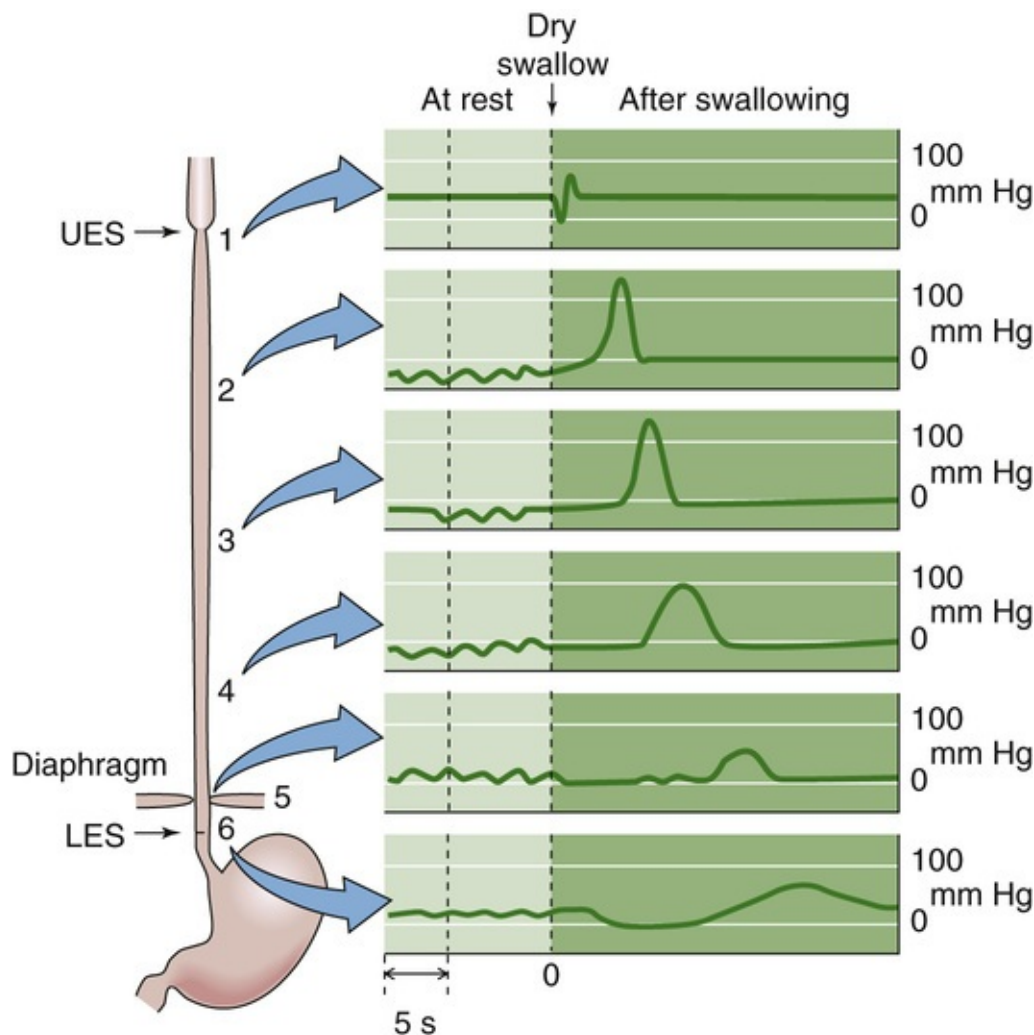

FIGURE 41-4 Esophageal pressures during swallowing. The swallowing center in the medulla that initiates deglutition includes the nucleus ambiguus (cranial nerves [CN] IX and X), the dorsal motor nucleus of the vagus (CN X), and others. Shown are recordings of intraluminal pressures at different sites along the esophagus, from the UES (*record 1*) to the LES (*record 6*). The left side of the graph shows the pressures at rest. As shown on the right side, after a dry swallow, the pressure wave of a “primary peristalsis” moves sequentially down the esophagus. (Data from Conklin JL, Christensen J: Motor functions of the pharynx and esophagus. In Johnson LR [ed]: *Physiology of the Gastrointestinal Tract*, 3rd ed. New York, Lippincott-Raven, 1994, pp 903–928.)

Lower Esophageal Sphincter

The esophagus is separated from the stomach by the LES, which is composed of specialized smooth muscle that is both anatomically and physiologically distinct from adjacent smooth muscle in the distal end of the esophagus and proximal portion of the stomach. The primary functions of the LES are (1) to permit coordinated movement of ingested food into the stomach from the esophagus after swallowing or deglutition, and (2) to prevent reflux of gastric contents into the esophagus. Either deglutition or distention of the esophagus results in a reduction in LES pressure (see Fig. 41-4), thereby permitting entry of food into the stomach. Relaxation of the LES occurs after the UES has already returned to its resting pressure. The LES maintains a resting tone that is the result of both intrinsic myogenic properties of the sphincteric muscle and cholinergic regulation. Relaxation of the LES is mediated both by the vagus nerve and by intrinsic properties of the smooth muscle, including important inhibitory effects by VIP and by NO.

Abnormalities of both resting LES pressure and its relaxation in response to deglutition are often associated with significant symptoms. Thus, a reduced resting LES pressure often results in gastroesophageal reflux, which may cause esophagitis (i.e., inflammation of the esophageal mucosa). A

defect in LES relaxation is a major component of a condition called **achalasia** ([Box 41-1](#)), which often results in dilation of the esophagus (megaesophagus) and is associated with difficulty in swallowing (dysphagia).

Box 41-1

Achalasia

Achalasia is a relatively uncommon condition associated with difficulty swallowing (dysphagia) and a dilated esophagus proximal to a narrowed, tapered area at the gastroesophageal junction. The term *achalasia* is derived from Greek words meaning “absence of relaxation.” The distal narrowed area of the esophagus suggests the presence of a stricture. However, it is easy to introduce an esophagoscope into the stomach through the narrowed area. Subsequent studies of esophageal motility in which investigators measured intraesophageal pressure demonstrated the presence of two defects in patients with achalasia: (1) failure of the LES to relax, and (2) impaired peristalsis in the distal two thirds of the body of the esophagus (i.e., the portion that consists of smooth muscle). Peristalsis is intact in the proximal third of the esophagus, which consists of striated muscle. In essence, the smooth-muscle portions of the esophagus behave as a denervated structure. The fundamental defect in achalasia is likely related to selective loss of intramural inhibitory neurons that regulate the LES, the neurotransmitters for which are VIP and NO. Treatment is either physical distention (or stretching) of the LES with a pneumatic-bag dilator or surgical cutting of the LES (i.e., an esophageal Heller myotomy via a laparoscopic approach).

Swallowing and the function of the UES and LES are closely integrated into the function of the esophagus. Under normal circumstances, esophageal muscle contractions are almost exclusively peristaltic and are initiated by swallowing. Deglutition initiates relaxation of the UES and propagated contractions, first of the UES and then of the muscles along the esophagus (see [Fig. 41-4](#)). In the meantime, the LES has already relaxed. The result of the advancing peristaltic wave is the caudad propulsion of a bolus toward the stomach.

Distention of the esophagus (in the absence of swallowing) also initiates propulsive esophageal contractions distal to the site of distention, as well as relaxation of the LES. Reflux of gastric contents into the lower part of the esophagus also produces such a local distention, without a swallow, and elicits the same response: peristaltic contractions that clear the esophagus of refluxed gastric material. Peristalsis that is initiated by swallowing is called **primary peristalsis**, whereas that elicited by distention of the esophagus is referred to as **secondary peristalsis**. Esophageal contractions after a swallow are regulated by the medullary swallowing center, intramural esophageal plexuses, the vagus nerve, and intrinsic myogenic processes.

Pyloric Sphincter

The pylorus is the sphincter that separates the stomach from the duodenum. The pressure of the pyloric sphincter regulates, in part, gastric emptying and prevents duodenal-gastric reflux. However, although a specific pyloric sphincter is present, it is quite short and is a relatively poor barrier (i.e., it can resist only a small pressure gradient). The stomach, duodenum, biliary tract, and pancreas—which are closely related embryologically—function as an integrated unit. Indeed, coordinated contraction and relaxation of the antrum, pylorus, and duodenum (which is sometimes referred to as the *antroduodenal cluster unit*)

are probably more important than simply the pressure produced by the pyloric smooth muscle per se. Regulation of gastric emptying is discussed further on [pp. 877–878](#).

Ileocecal Sphincter

The valve-like structure that separates the ileum and cecum is called the **ileocecal sphincter**. Similar to other GI sphincters, the ileocecal sphincter maintains a positive resting pressure and is under the control of the vagus nerve, sympathetic nerves, and the ENS. Distention of the ileum results in relaxation of the sphincter, whereas distention of the proximal (ascending) colon causes contraction of the ileocecal sphincter. As a consequence, ileal flow into the colon is regulated by luminal contents and pressure, both proximal and distal to the ileocecal sphincter.

Internal and External Anal Sphincters

The “anal sphincter” actually consists of both an internal and an external sphincter. The **internal sphincter** has both circular and longitudinal smooth muscle and is under involuntary control. The **external sphincter**, which encircles the rectum, contains only striated muscle but is controlled by both voluntary and involuntary mechanisms. The high resting pressure of the overall anal sphincter predominantly reflects the resting tone of the *internal* anal sphincter. Distention of the rectum ([Fig. 41-5A](#)), either by colonic contents (i.e., stool) or experimentally by balloon inflation, initiates the **rectosphincteric reflex** by relaxing the internal sphincter (see [Fig. 41-5B](#)). If defecation is not desired, continence is maintained by an involuntary reflex—orchestrated by the sacral spinal cord—that contracts the external anal sphincter (see [Fig. 41-5C](#)). If defecation is desired, a series of both voluntary and involuntary events occurs that includes relaxation of the external anal sphincter, contraction of abdominal wall muscles, and relaxation of pelvic wall muscles. Flexure of the hips and descent of the pelvic floor then facilitate defecation by minimizing the angle between the rectum and anus. In contrast, if a delay in defecation is needed or desired, voluntary contraction of the external anal sphincter is usually sufficient to override the series of reflexes initiated by rectal distention.

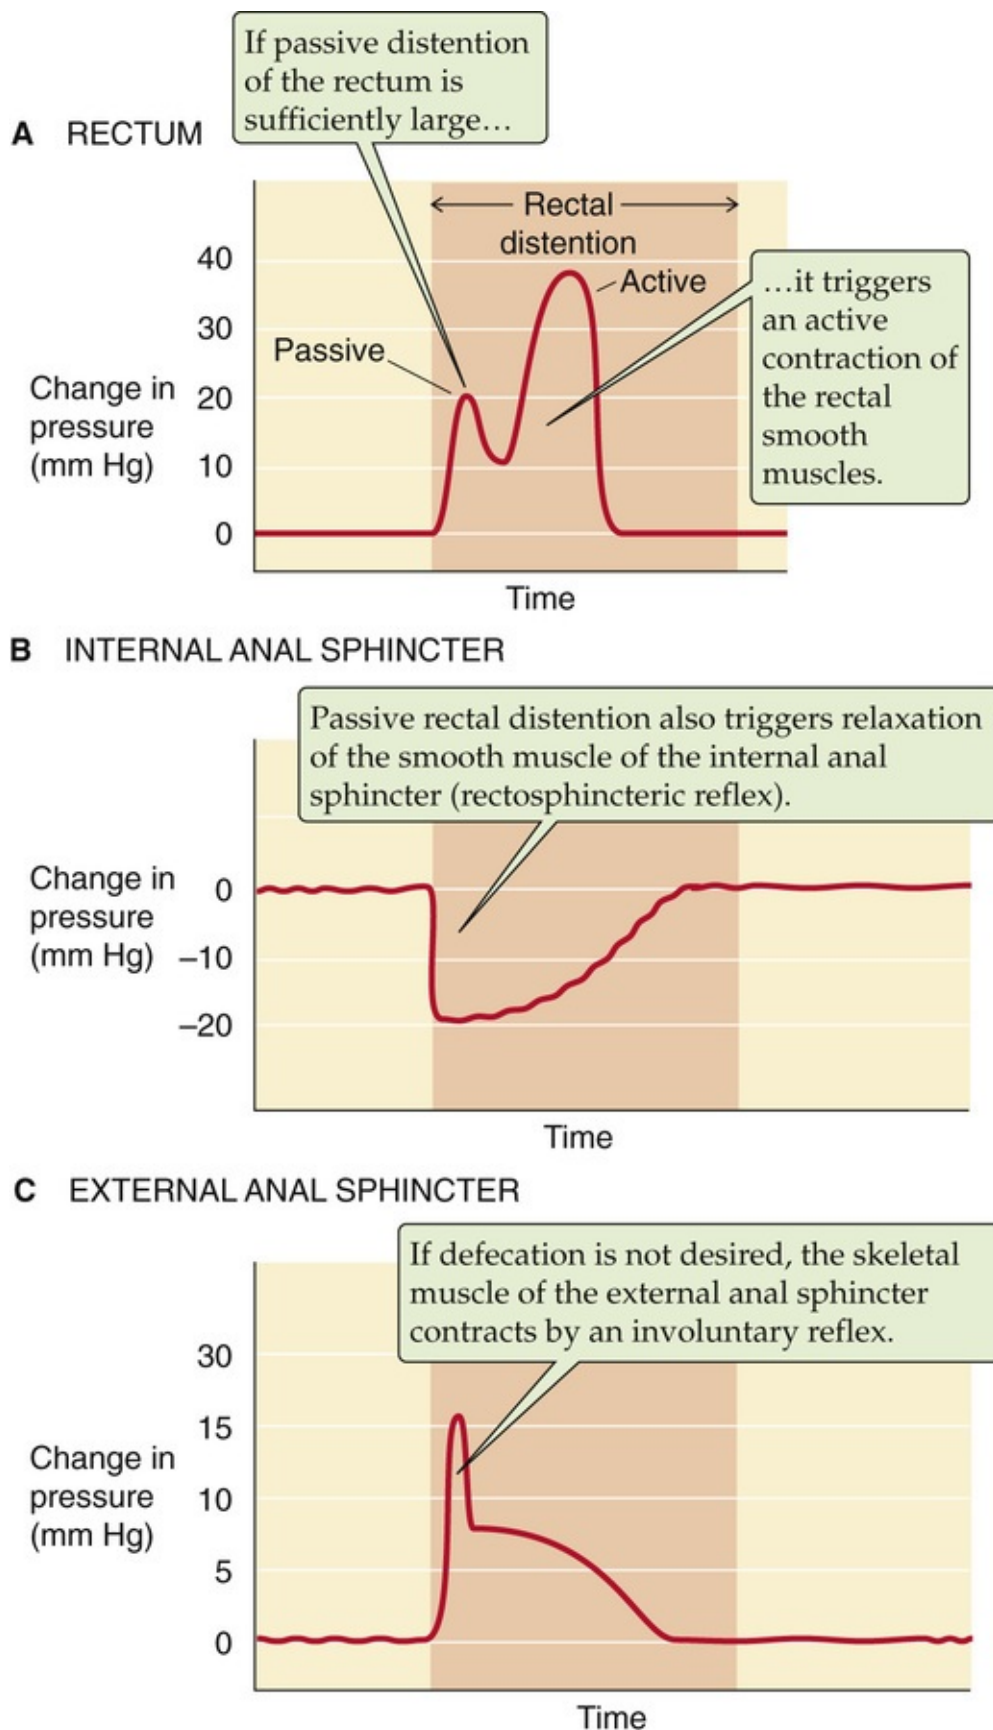

FIGURE 41-5 Pressure changes initiated by rectal distention. (Data from Schuster MM: Simultaneous manometric recording of internal and external anal sphincteric reflexes. Johns Hopkins Med J 116:70–88, 1965.)

Motility of the small intestine achieves both churning and propulsive movement, and its temporal pattern differs in the fed and fasted states

Digestion and absorption of dietary nutrients are the primary functions of the small intestine, and the motor activity of the small intestine is closely integrated with its digestive and absorptive roles. The two classes of small-intestinal motor activity are churning (or mixing) and propulsion of the bolus of luminal contents. **Churning**—which is accomplished by segmental, nonpropulsive contractions—mixes the luminal contents with pancreatic, biliary, and small-intestinal secretions, thus enhancing the digestion of dietary nutrients in the lumen. These segmental contractions also decrease the unstirred water layer that is adjacent to the apical membranes of the small-intestine cells, thus promoting absorption. Churning or mixing movements occur following eating and are the result of contractions of *circular* muscle in segments flanked at either end by receiving segments that relax. Churning, however, does not advance the luminal contents along the small intestine. In contrast, **propulsion**—which is accomplished by propagated, peristaltic contractions—results in caudad movement of the intestinal luminal contents, either for absorption at more distal sites of the small or large intestine or for elimination in stool. Peristaltic propulsion occurs as a result of contraction of the *circular* muscle and relaxation of the *longitudinal* muscle in the propulsive or upstream segment, together with relaxation of the *circular* muscle and contraction of the *longitudinal* muscle in the downstream receiving segment. Thus, circular smooth muscle in the small intestine participates in both churning and propulsion.

The V_m changes of intestinal smooth-muscle cells consist of both action potentials (see [p. 244](#)) and slow-wave activity (see [p. 244](#)). The patterns of electrical and mechanical activity differ in the fasting and fed states. In the **fasting state**, the small intestine is relatively quiescent but exhibits synchronized, rhythmic changes in both electrical and motor activity ([Fig. 41-6](#)). The interdigestive myoelectric or **migrating motor complex (MMC)** is the term used to describe these rhythmic contractions of the small intestine that are observed in the fasting state. MMCs in humans occur at intervals of 90 to 120 minutes and consist of four distinct phases: (1) a prolonged quiescent period, (2) a period of increasing action potential frequency and contractility, (3) a period of peak electrical and mechanical activity that lasts a few minutes, and (4) a period of declining activity that merges into the next quiescent period. During the interdigestive period, particles >2 mm in diameter can pass from the stomach into the duodenum, which permits emptying of ingested material from the stomach (e.g., bones, coins) that could not be reduced in size to <2 mm. The slow propulsive contractions that characterize phases 2 to 4 of the MMCs clear the small intestine of its residual content, including undigested food, bacteria, desquamated cells, and intestinal and pancreatic biliary secretions. MMCs usually originate in the stomach and often travel to the distal end of the ileum, but ~25% are initiated in the duodenum and proximal part of the jejunum.

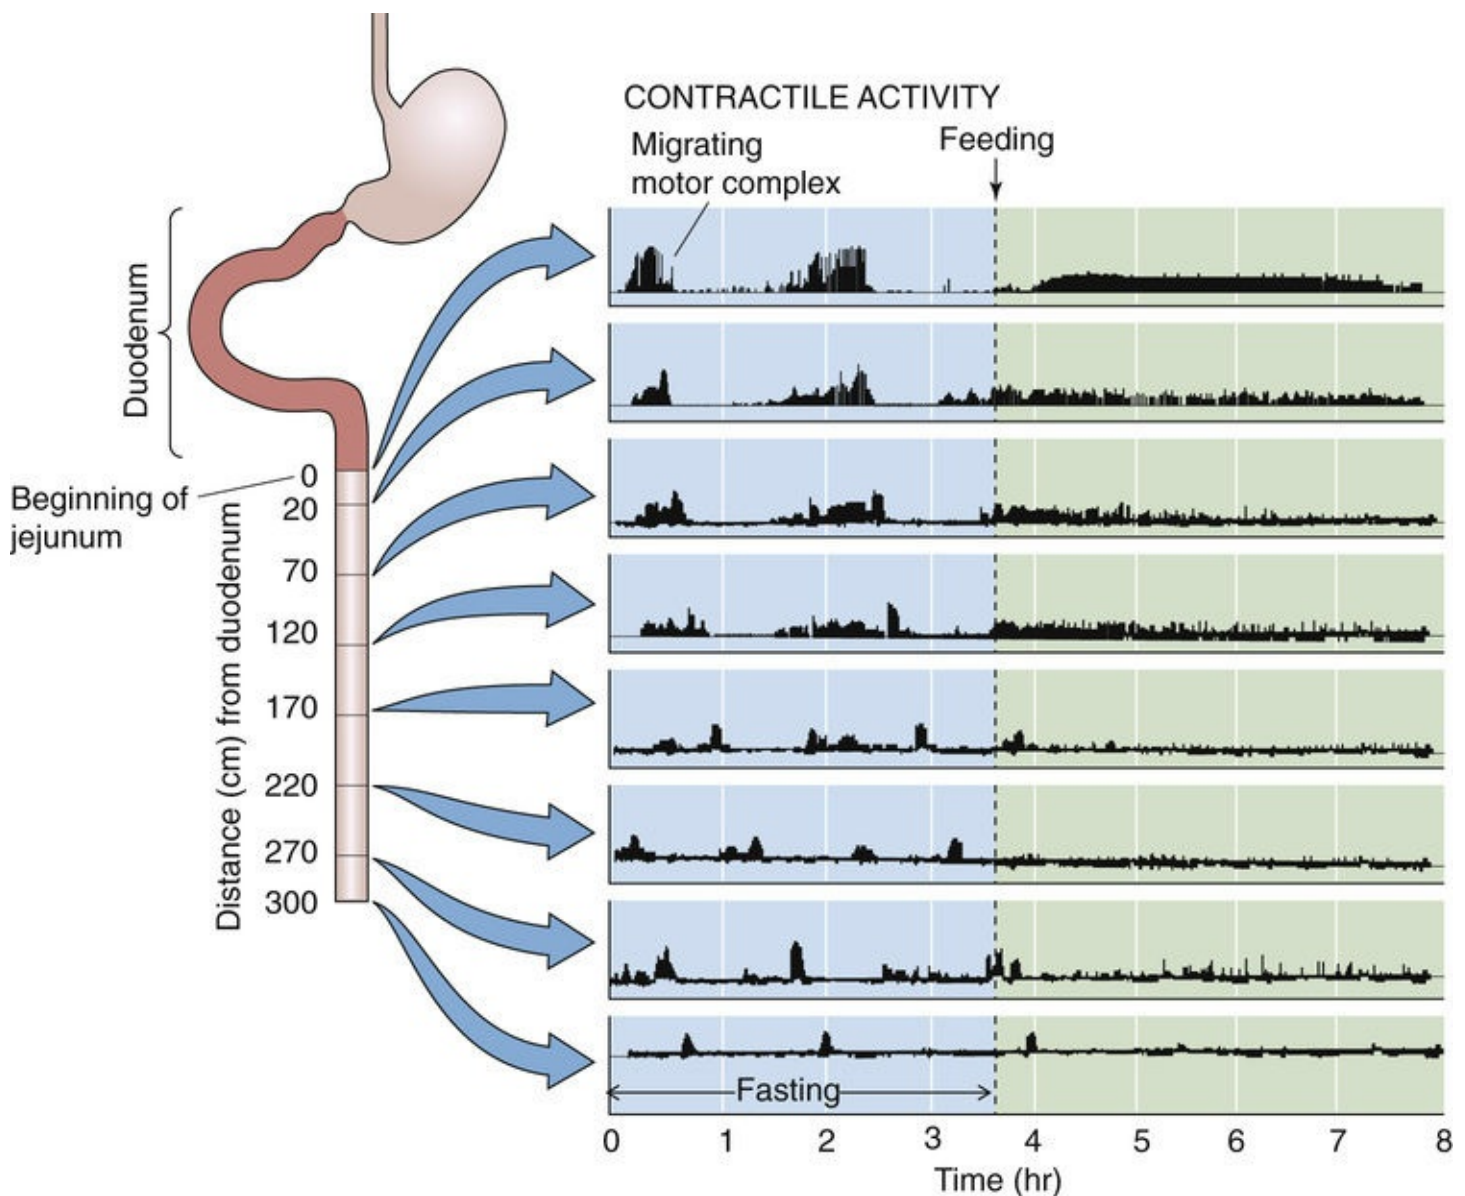

FIGURE 41-6 Mechanical activity in the fasting and fed states. Shown are records of intraluminal pressure along the small intestine of a conscious dog. Before feeding (*left side*), the pattern is one of MMCs. Feeding triggers a switch to a different pattern, characterized by both segmental contractions that churn the contents and peristaltic contractions that propel the contents along the small intestine. (Data from Itoh Z, Sekiguchi T: Interdigestive motor activity in health and disease. *Scand J Gastroenterol Suppl* 82:121–134, 1983.)

Feeding terminates MMCs and initiates the appearance of the fed motor pattern (see [Fig. 41-6](#)). The latter is less well characterized than MMCs but, as noted above, consists of both segmental contractions (churning), which enhance digestion and absorption, and peristaltic contractions (propulsion).

Determination of the primary factors that regulate both MMCs and transition to the fed pattern has been hampered by both species differences and complex interactions among the multiple probable mediators. Nonetheless, clear evidence has been presented for a role of the ENS, one or more humoral factors, and extrinsic innervation. A major determinant of the MMC pattern is the hormone **motilin**, a 22–amino-acid peptide that is synthesized in the duodenal mucosa and released just before the initiation of phase 3 of the MMC cycle. Motilin does not appear to have a role in the motor pattern that is observed in the fed state. Factors important in induction of the fed pattern include the activity of the vagus nerve (because sham feeding also both terminates MMCs and initiates a fed pattern) as well as the caloric content and type of food (e.g., fat more than protein) in the meal.

Motility of the large intestine achieves both propulsive

movement and a reservoir function

The human large intestine has four primary functions. First, the colon absorbs large quantities of fluid and electrolytes and converts the liquid content of ileocecal material to solid or semisolid stool. Second, the colon avidly absorbs the short-chain fatty acids formed by the catabolism (or fermentation) of dietary carbohydrates that are not absorbed in the small intestine. The abundant colonic microflora accomplish this fermentation. Third, the storage of colonic content represents a reservoir function of the large intestine. Fourth, the colon eliminates its contents in a regulated and controlled fashion, largely under voluntary control. To accomplish these important activities, the large intestine functionally acts as two distinct organs. The proximal (or ascending and transverse) part of the colon is the site where most of the fluid and electrolyte absorption occurs and where bacterial fermentation takes place. The distal (or descending and rectosigmoid) portion of the colon provides final desiccation, as well as reservoir function, and serves as a storage organ for colonic material before defecation.

In contrast to the motor pattern in the small intestine, no distinct fasting and fed patterns of contractions are seen in the colon. Similarly to small-intestinal motor activity, colonic contractions are regulated by myogenic, neurogenic, and hormonal factors. Parasympathetic control of the proximal two thirds of the colon is mediated by the vagus nerve, whereas parasympathetic control of the descending and rectosigmoid colon is mediated by pelvic nerves originating from the sacral spinal cord.

The **proximal colon** has two types of motor activity, nonpropulsive segmentation and mass peristalsis. **Nonpropulsive “segmentation”** is generated by slow-wave activity that produces circular-muscle contractions that churn the colonic contents and move them in an orad direction (i.e., toward the cecum). The segmental contractions that produce the churning give the colon its typical appearance of segments or haustra (see [Fig. 41-1](#)). During this mixing phase, material is retained in the proximal portion of the large intestine for relatively long periods, and fluid and electrolyte absorption continues. One to three times a day, a so-called **mass peristalsis** occurs in which a portion of the colonic contents is propelled distally 20 cm or more. Such mass peristaltic contractions are the primary form of propulsive motility in the colon and may be initiated by eating. During mass peristalsis, the haustra disappear; they reappear after the completion of mass peristalsis.

In the **distal colon**, the primary motor activity is nonpropulsive segmentation that is produced by annular or segmental contractions. It is in the distal part of the colon that the final desiccation of colonic contents occurs. It is also here that these contents are stored before an occasional mass peristalsis that propels them into the rectum. The **rectum** itself is kept nearly empty by nonpropulsive segmentation until it is filled by mass peristalsis of the distal end of the colon. As described in [Figure 41-5](#), filling of the rectum triggers a series of reflexes in the internal and external anal sphincters that lead to defecation ([Box 41-2](#)).

Box 41-2

Hirschsprung Disease

The anal sphincter controls defecation and consists of a smooth-muscle internal sphincter and a striated-muscle external sphincter. Distention of the rectum by inflation of a balloon—which simulates the effect of the presence of solid feces in the rectum—results in relaxation of the internal sphincter and contraction of the external sphincter (see [Fig. 41-5](#)). Voluntary control of the external sphincter regulates the timing of defecation.

Hirschsprung disease is a congenital polygenic disorder. At least 11 genes  **N41-3** have been

associated with Hirschsprung disease (<http://www.emedicine.com/radio/topic343.htm>. Accessed Sept 2014), including mutations in the RET receptor (a receptor tyrosine kinase) and its ligand. Variable penetrance leads to variable manifestations of the disease. At the cellular level, the fundamental defect is arrest of the caudad migration of neural crest cells, which are the precursors of ganglion cells. Symptoms include constipation, megacolon, and a narrowed segment of colon in the rectum. Histological examination of this narrowed segment reveals an absence of ganglion cells from both the submucosal and myenteric plexuses (see Fig. 41-3A). The patient's constipation and resulting megacolon are secondary to failure of this “aganglionic” segment to relax in response to proximal distention. Manometric assessment of the internal and external anal sphincters reveals that the smooth-muscle internal sphincter does not relax after rectal distention (see Fig. 41-5) but that the external anal sphincter functions normally. Treatment of this condition is usually surgical, with removal of the narrowed segment that is missing the ganglia that normally regulate relaxation of the smooth muscle of the internal anal sphincter.

N41-3

Mutations in Hirschsprung Disease

Contributed by Emile Boulpaep, and Walter Boron

At least 11 mutations are associated with Hirschsprung disease, including mutations in the following proteins:

- RET, an acronym for *rearranged during transfection*, is a receptor tyrosine kinase (RTK; see p. 66)
- Glial-cell derived neurotrophic factor (GDNF), which is the ligand for RET
- The endothelin-B receptor (EBNRB)
- Endothelin 3 (ET-3), which is the ligand for EBNRB

Gastric Function

Henry J. Binder

The stomach plays several important roles in human nutrition and has secretory, motor, and humoral functions. These activities are not separate and distinct, but rather represent integrated functions that are required to initiate the normal digestive process.

The stomach has several specific **secretory** products. In addition to the stomach's best-known product, acid, these products include pepsinogen, mucus, bicarbonate, intrinsic factor, and water. These substances continue the food digestion that was initiated by mastication and the action of salivary enzymes in the mouth. In addition, they help protect the stomach from injury. The stomach also has several important **motor** functions that regulate the intake of food, its mixing with gastric secretions and reduction in particle size, and the exit of partially digested material into the duodenum. Moreover, the stomach produces two important **humoral agents**—gastrin and somatostatin—that have both endocrine and paracrine actions. These peptides are primarily important in the regulation of gastric secretion.

Although these functions are important in the maintenance of good health, the stomach is nevertheless not required for survival. Individuals who have had their entire stomach removed (i.e., total gastrectomy) for non-neoplastic reasons can maintain adequate nutrition and achieve excellent longevity.

Functional Anatomy of the Stomach

The mucosa is composed of surface epithelial cells and glands

The basic structure of the stomach wall is similar to that of other regions of the gastrointestinal (GI) tract (see Fig. 41-2); therefore, the wall of the stomach consists of both mucosal and muscle layers. The stomach can be divided, based on its gross anatomy, into three major **segments** (Fig. 42-1): (1) A specialized portion of the stomach called the **cardia** is located just distal to the gastroesophageal junction and is devoid of the acid-secreting parietal cells. (2) The body or **corpus** is the largest portion of the stomach; its most proximal region is called the **fundus**. (3) The distal portion of the stomach is called the **antrum**. The surface area of the gastric mucosa is substantially increased by the presence of **gastric glands**, which consist of a pit, a neck, and a base. These glands contain several cell types, including mucous, parietal, chief, and endocrine cells; endocrine cells also are present in both corpus and antrum. The surface epithelial cells, which have their own distinct structure and function, secrete HCO_3^- and mucus.

FIGURE 42-1 Anatomy of the stomach. Shown are the macroscopic divisions of the stomach as well as two progressively magnified views of a section through the wall of the body of the stomach.

Marked cellular heterogeneity exists not only *within* segments (e.g., glands versus surface epithelial cells) but also between segments of the stomach. For instance, as discussed below, the structure and function of the mucosal epithelial cells in the antrum and body are quite distinct. Likewise, although the smooth muscle in the proximal and distal portions of the stomach appear structurally similar, their functions and pharmacological properties differ substantially.

With increasing rates of secretion of gastric juice, the H^+ concentration rises and the Na^+ concentration falls

The glands of the stomach typically secrete ~ 2 L/day of a fluid that is approximately isotonic with blood plasma. As a consequence of the heterogeneity of gastric mucosal function, early investigators recognized that gastric secretion consists of two distinct components: parietal-cell and nonparietal-cell secretion. Accordingly, gastric secretion consists of (1) an Na^+ -rich basal secretion that originates from nonparietal cells, and (2) a stimulated component that represents a pure parietal-cell secretion that is rich in H^+ . This model helps to explain the inverse relationship between the luminal concentrations of H^+ and Na^+ as a

function of the rate of gastric secretion (Fig. 42-2). Thus, at high rates of gastric secretion—for example, when gastrin or histamine stimulates parietal cells—intraluminal $[H^+]$ is high whereas intraluminal $[Na^+]$ is relatively low. At low rates of secretion or in clinical situations in which maximal acid secretion is reduced (e.g., pernicious anemia [N42-1](#)), intraluminal $[H^+]$ is low but intraluminal $[Na^+]$ is high.

FIGURE 42-2 Effect of the gastric secretion rate on the composition of the gastric juice.

N42-1

Pernicious Anemia

Contributed by Henry Binder

The close relationship between acid and gastrin release is clearly manifested in individuals with impaired acid secretion. In **pernicious anemia**, atrophy of the gastric mucosa in the corpus and an absence of parietal cells result in a lack in the secretion of both gastric acid and intrinsic factor (IF). Many patients with pernicious anemia exhibit antibody-mediated immunity against their parietal cells, and many of these patients also produce anti-IF autoantibodies.

Because IF is required for cobalamin absorption in the ileum, the result is impaired cobalamin absorption. In contrast, the antrum is normal. Moreover, plasma gastrin levels are markedly elevated as a result of the absence of intraluminal acid, which normally triggers gastric D cells to release somatostatin (see pp. 868–870); this, in turn, inhibits antral gastrin release (see Box 42-1). Because parietal cells are absent, the elevated plasma gastrin levels are not associated with enhanced gastric acid secretion.

The clinical complications of cobalamin deficiency evolve over a period of years. Patients develop **megaloblastic anemia** (in which the circulating red blood cells are enlarged), a distinctive form of glossitis, and a neuropathy. The earliest neurological findings are those of peripheral neuropathy, as manifested by paresthesias and slow reflexes, as well as impaired senses of touch, vibration, and temperature. If untreated, the disease will ultimately involve the spinal cord, particularly the dorsal

columns, thus producing weakness and ataxia. Memory impairment, depression, and dementia can also result. Parenteral administration of cobalamin reverses and prevents the manifestations of pernicious anemia, but it does not influence parietal cells or restore gastric secretion of either IF or intraluminal acid.

The proximal portion of the stomach secretes acid, pepsinogens, intrinsic factor, bicarbonate, and mucus, whereas the distal part releases gastrin and somatostatin

Corpus

The primary secretory products of the proximal part of the stomach—acid (protons), pepsinogens, and intrinsic factor—are made by distinct cells in glands of the corpus. The two primary cell types in the gastric glands of the body of the stomach are parietal cells and chief cells.

Parietal cells (or oxyntic cells) secrete both acid and intrinsic factor, a glycoprotein that is required for cobalamin (vitamin B₁₂) absorption in the ileum (see [pp. 935-937](#)). The parietal cell has a very distinctive morphology (see [Fig. 42-1](#)). It is a large triangular cell with a centrally located nucleus, an abundance of mitochondria, intracellular tubulovesicular membranes, and canalicular structures. We discuss H⁺ secretion in the next subchapter and intrinsic factor on [page 937](#).

Chief cells (or peptic cells) secrete pepsinogens, but not acid. These epithelial cells are substantially smaller than parietal cells. A close relationship exists among pH, pepsin secretion, and function. Pepsins are endopeptidases (i.e., they hydrolyze “interior” peptide bonds) and initiate protein digestion by hydrolyzing specific peptide linkages. The basal luminal pH of the stomach is 4 to 6; with stimulation, the pH of gastric secretions is usually reduced to <2. At pH values that are <3, pepsinogens are rapidly activated to pepsins. A low gastric pH also helps to prevent bacterial colonization of the small intestine.

Gastric pH and Pneumonia

Contributed by Henry Binder

Many patients hospitalized in the intensive care unit (ICU) receive prophylactic anti-ulcer treatments (e.g., proton pump inhibitors, such as omeprazole) that inhibit proton secretion and thereby raise gastric pH. Patients in the ICU who are mechanically ventilated or who have coagulopathies are highly susceptible to hemorrhage from gastric stress ulcers, a complication that can contribute significantly to overall morbidity and mortality. These different anti-ulcer regimens do effectively lessen the risk of developing stress ulcers. However, by raising gastric pH, these agents also lower the barrier to gram-negative bacterial colonization of the stomach. Esophageal reflux and subsequent aspiration of these organisms are common in these very sick patients, many of whom are already immunocompromised or even mechanically compromised by the presence of a ventilator tube. If these bacteria are aspirated into the airway, pneumonia can result. The higher the gastric pH, the greater the risk of pneumonia.

In addition to parietal and chief cells, glands from the corpus of the stomach also contain **mucus-secreting cells**, which are confined to the neck of the gland (see [Fig. 42-1](#)), and five or six **endocrine**

cells. Among these endocrine cells are **enterochromaffin-like (ECL) cells**, which release histamine.

Antrum

The glands in the antrum of the stomach do not contain parietal cells. Therefore, the antrum does not secrete either acid or intrinsic factor. Glands in the antral mucosa contain **chief cells** and **endocrine cells**; the endocrine cells include the so-called G cells and D cells, which secrete gastrin and somatostatin, respectively (see [Table 41-1](#)). These two peptide hormones function as both endocrine and paracrine regulators of acid secretion. As discussed in more detail below, **gastrin** stimulates gastric acid secretion by two mechanisms and is also a major trophic or growth factor for GI epithelial-cell proliferation. As discussed more fully below, **somatostatin** also has several important regulatory functions, but its primary role in gastric physiology is to inhibit both gastrin release and parietal-cell acid secretion.

In addition to the cells of the gastric glands, the stomach also contains superficial epithelial cells that cover the gastric pits as well as the surface in between the pits. These cells secrete HCO_3^- .

The stomach accommodates food, mixes it with gastric secretions, grinds it, and empties the chyme into the duodenum

In addition to its secretory properties, the stomach also has multiple motor functions. These functions are the result of gastric smooth-muscle activity, which is integrated by both neural and hormonal signals. Gastric motor functions include both propulsive and retrograde movement of food and liquid, as well as a nonpropulsive movement that increases intragastric pressure.

Similar to the heterogeneity of gastric epithelial cells, considerable diversity is seen in both the regulation and contractility of gastric smooth muscle. The stomach has at least two distinct areas of motor activity; the proximal and distal portions of the stomach behave as separate, but coordinated, entities. At least four events can be identified in the overall process of gastric filling and emptying: (1) receiving and providing temporary storage of dietary food and liquids; (2) mixing food and water with gastric secretory products, including pepsin and acid; (3) grinding food so that particle size is reduced to enhance digestion and to permit passage through the pylorus; and (4) regulating the exit of retained material from the stomach into the duodenum (i.e., gastric emptying of chyme) in response to various stimuli.

The mechanisms by which the stomach receives and empties liquids and solids are significantly different. Emptying of *liquids* is primarily a function of the smooth muscle of the *proximal* part of the stomach, whereas emptying of *solids* is regulated by *antral* smooth muscle.

Acid Secretion

The parietal cell has a specialized tubulovesicular structure that increases apical membrane area when the cell is stimulated to secrete acid

In the basal state, the rate of acid secretion is low. Tubulovesicular membranes are present in the apical portion of the resting, nonstimulated parietal cell and contain the H-K pump (or H,K-ATPase) that is responsible for acid secretion. Upon stimulation, cytoskeletal rearrangement causes the tubulovesicular membranes that contain the H-K pump to fuse into the canalicular membrane (Fig. 42-3). The result is a substantial increase (50- to 100-fold) in the surface area of the apical membrane of the parietal cell, as well as the appearance of microvilli. This fusion is accompanied by insertion of the H-K pumps, as well as K^+ and Cl^- channels, into the canalicular membrane. The large number of mitochondria in the parietal cell is consistent with the high rate of glucose oxidation and O_2 consumption that is needed to support acid secretion.

FIGURE 42-3 Parietal cell: resting and stimulated.

An H-K pump is responsible for gastric acid secretion by parietal cells

The parietal-cell H-K pump is a member of the gene family of P-type ATPases (see pp. 117-118) that includes the ubiquitous Na-K pump (Na,K-ATPase), which is present at the basolateral membrane of virtually all mammalian epithelial cells and at the plasma membrane of nonpolarized cells. Similar to other members of this ATPase family, the parietal-cell H-K pump requires both an α subunit and a β subunit for full activity. The catalytic function of the H-K pump resides in the α subunit; however, the β subunit is required for targeting to the apical membrane.  **N42-3** The two subunits form a heterodimer

with close interaction at the extracellular domain.

N42-3

Gastric H-K Pump

Contributed by Emile Boulpaep, and Walter Boron

The **α subunit** of the parietal-cell H-K pump has 1033 amino acids and 10 membrane-spanning segments. It is ~65% identical to the α subunit of the Na-K pump.

The **β subunit**, which consists of 290 amino acids, has only one membrane-spanning segment; it is 35% to 40% identical to the β subunit of the Na-K pump. The two subunits form a heterodimer with close interaction at the extracellular domain.

The activity of these P-type ATPases, including the gastric H-K pump, is affected by inhibitors that are clinically important in the control of gastric acid secretion. The two types of gastric H-K pump inhibitors are (1) substituted benzimidazoles (e.g., omeprazole), which act by binding covalently to cysteines on the extracytoplasmic surface; and (2) substances that act as competitive inhibitors of the K^+ -binding site (e.g., the experimental drug Schering 28080). **Omeprazole** is a potent inhibitor of parietal-cell H-K pump activity and is an extremely effective drug in the control of gastric acid secretion in both normal subjects and patients with hypersecretory states ([Box 42-1](#)). In addition, H-K pump inhibitors have been useful in furthering understanding of the function of these pumps. Thus, ouabain, a potent inhibitor of the Na-K pump, does not inhibit the gastric H-K pump, whereas omeprazole does not inhibit the Na-K pump. The *colonic* H-K pump, whose α subunit has an amino-acid sequence that is similar but not identical to that of both the Na-K pump and the parietal-cell H-K pump, is partially inhibited by ouabain but not by omeprazole.

Box 42-1

Gastrinoma or Zollinger-Ellison Syndrome

On rare occasions, patients with one or more ulcers have very high rates of gastric acid secretion. The increased acid secretion in these patients is most often a result of elevated levels of serum gastrin, released from a pancreatic islet cell adenoma or gastrinoma (Table 42-1). This clinical picture is also known as **Zollinger-Ellison (ZE) syndrome**. Because gastrin released from these islet cell adenomas is not under physiological control, but rather is continuously released, acid secretion is substantially increased under basal conditions. However, the intravenous administration of pentagastrin—a synthetic gastrin consisting of the last four amino acids of gastrin plus β -alanine—produces only a modest increase in gastric acid secretion. Omeprazole, a potent inhibitor of the parietal-cell H-K pump, is now an effective therapeutic agent to control the marked enhancement of gastric acid secretion in patients with gastrinoma and thus helps to heal their duodenal and gastric ulcers.

In contrast to patients with gastrinoma or ZE syndrome, other patients with **duodenal ulcer** have serum gastrin levels that are near normal. Their basal acid-secretion rates are modestly elevated but increase markedly in response to pentagastrin.

Patients with **pernicious anemia**  **N42-1** lack parietal cells and thus cannot secrete the H^+ necessary to stimulate the antral D cell (see Fig. 42-8). Consequently, the release of somatostatin from the D cell is

low, which results in minimal tonic inhibition of gastrin release from G cells. Thus, these patients have very high levels of serum gastrin, but virtually no H⁺ secretion (see Table 42-1).

TABLE 42-1
Serum Gastrin Levels and Gastric Acid Secretion Rates

SERUM GASTRIN (pg/mL)		H ⁺ SECRETION (meq/hr)	
		BASAL	AFTER PENTAGASTRIN
Normal	35	0.5–2.0	20–35
Duodenal ulcer	50	1.5–7.0	25–60
Gastrinoma	500	15–25	30–75
Pernicious anemia	350	0	0

The key step in gastric acid secretion is extrusion of H⁺ into the lumen of the gastric gland in exchange for K⁺ (Fig. 42-4). The K⁺ taken up into the parietal cells is recycled to the lumen through K⁺ channels. The final component of the process is passive movement of Cl[−] into the gland lumen. The net result is the secretion of HCl. Secretion of acid across the apical membrane by the H-K pump results in a rise in parietal-cell pH. The adaptive response to this rise in pH includes passive uptake of CO₂ and H₂O, which the enzyme **carbonic anhydrase** (see p. 630) converts to HCO_3^- and H⁺. The H⁺ is the substrate of the H-K pump. The HCO_3^- exits across the basolateral membrane via a Cl-HCO₃ exchanger (AE2 or SLC4A2), which also provides some of the Cl[−] required for net HCl movement across the apical/canalicular membrane. The basolateral Na-H exchanger may participate in intracellular pH regulation, especially in the basal state.

FIGURE 42-4 Acid secretion by parietal cells. When the parietal cell is stimulated, H-K pumps extrude H^+ into the lumen of the gastric gland in exchange for K^+ . The K^+ recycles back into the lumen via K^+ channels. Carbonic anhydrase (CA) provides the H^+ extruded by the H-K pump, as HCO_3^- exits via the basolateral anion exchanger (AE2). Cl^- enters across basolateral membrane via AE2, Na/K/Cl cotransporter NKCC1, and the electrogenic SLC26A7; Cl^- exits through apical CFTR (and perhaps ClC) channels.

Three secretagogues (acetylcholine, gastrin, and histamine) directly and indirectly induce acid secretion by parietal cells

The action of secretagogues on gastric acid secretion occurs via at least two parallel and perhaps redundant mechanisms (Fig. 42-5). In the first, acetylcholine (ACh), gastrin, and histamine bind **directly** to their respective receptors on the parietal-cell membrane and synergistically stimulate acid secretion. ACh (see Fig. 14-8) is released from endings of the vagus nerve (cranial nerve X), and as we will see below, gastrin is released from G cells. Histamine is synthesized from histidine in ECL cells of the lamina propria (see Fig. 13-8B). In the second mechanism, ACh and gastrin **indirectly** induce acid secretion as a result of their stimulation of histamine release from ECL cells.

FIGURE 42-5 Direct and indirect actions of the three acid secretagogues: ACh, gastrin, and histamine.

The three acid secretagogues act through either Ca^{2+} /diacylglycerol or cAMP

Stimulation of acid secretion by ACh, gastrin, and histamine is mediated by a series of intracellular signal-transduction processes similar to those responsible for the action of other agonists in other cell systems. All three secretagogues bind to specific G protein-coupled receptors on the parietal-cell membrane (Fig. 42-6).

FIGURE 42-6 Receptors and signal-transduction pathways in the parietal cell. The parietal cell has separate receptors for three acid secretagogues. ACh and gastrin each bind to specific receptors (M_3 and CCK_2 , respectively) coupled to the G protein G_{α_q} . The result is activation of PLC, which ultimately leads to the activation of PKC and the release of Ca^{2+} . The histamine binds to an H_2 receptor, coupled through G_{α_s} to adenylyl cyclase (AC). The result is production of cAMP and activation of PKA. Two inhibitors of acid secretion, somatostatin and prostaglandins, bind to separate receptors coupled to G_{α_i} . ER, endoplasmic reticulum.

ACh binds to an M_3 muscarinic receptor (see pp. 341–342) on the parietal-cell basolateral membrane. This ACh receptor couples to a GTP-binding protein (G_{α_q}) and activates phospholipase C (PLC), which converts phosphatidylinositol 4,5-bisphosphate (PIP_2) to inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG; see p. 58). IP_3 causes internal stores to release Ca^{2+} , which then probably acts via calmodulin-dependent protein kinase (see p. 60). DAG activates protein kinase C (PKC). The M_3 receptor also activates a Ca^{2+} channel.

Gastrin binds to a specific parietal-cell receptor that has been identified as the gastrin-cholecystokinin type 2 (CCK_2) receptor. Two related CCK receptors have been identified, CCK_1 and CCK_2 . Their amino-acid sequences are ~50% identical, and both are G protein coupled. The CCK_2 receptor has equal affinity for both gastrin and CCK. In contrast, the CCK_1 receptor's affinity for CCK is three orders of magnitude higher than its affinity for gastrin. These observations and the availability of receptor antagonists are beginning to clarify the parallel, but at times opposite, effects of gastrin and CCK on various aspects of GI function. The CCK_2 receptor couples to G_{α_q} and activates the same PLC pathway as does ACh; this process leads to both an increase in $[Ca^{2+}]_i$ and activation of PKC.

The **histamine** receptor on the parietal cell is an H_2 receptor that is coupled to the G_{α_s} GTP-binding protein. Histamine activation of the receptor complex stimulates the enzyme adenylyl cyclase, which, in

turn, generates cAMP. The resulting activation of protein kinase A leads to the phosphorylation of certain parietal-cell proteins, including the H-K pump.

Antral and duodenal G cells release gastrin, whereas ECL cells in the corpus release histamine

The presence of a gastric hormone that stimulates acid secretion was initially proposed in 1905. Direct evidence of such a factor was obtained in 1938, and in 1964 Gregory and Tracey isolated and purified gastrin and determined its amino-acid sequence. Gastrin has three major effects on GI cells: (1) stimulation of acid secretion by parietal cells (see Fig. 42-5), (2) release of histamine by ECL cells, and (3) regulation of mucosal growth in the corpus of the stomach, as well as in the small and large intestine.

Gastrin exists in several different forms, but the two major forms are G-17, or “little gastrin,” a 17–amino-acid linear peptide (Fig. 42-7A), and G-34, or “big gastrin,” a 34–amino-acid peptide (see Fig. 42-7B). A single gene encodes a peptide of 101 amino acids. Several cleavage steps and C-terminal amidation (i.e., addition of an -NH_2 to the C terminus) take place during gastrin's post-translational modification, a process that occurs in the endoplasmic reticulum, trans-Golgi apparatus, and both immature and mature secretory granules. The final product of this post-translational modification is either G-17 or G-34. The tyrosine residue may be either sulfated (so-called gastrin II) or nonsulfated (gastrin I); the two forms are equally active and are present in equal amounts. Gastrin and **CCK**, a related hormone, have identical C-terminal tetrapeptide sequences (see Fig. 42-7C) that possess all the biological activities of both gastrin and CCK. Both G-17 and G-34 are present in blood plasma, and their plasma levels primarily reflect their degradation rates. Thus, although G-17 is more active than G-34, the latter is degraded at a substantially lower rate than G-17. As a consequence, the infusion of an equal amount of G-17 or G-34 produces comparable increases in gastric acid secretion.

FIGURE 42-7 **A**, A single gene encodes a 101–amino-acid peptide that is processed to both G-17 (“little gastrin”) and G-34 (“big gastrin”). The N-terminal glutamine is modified to create a pyroglutamyl residue. The C-terminal phenylalanine is amidated. These modifications make the hormone resistant to carboxy- and aminopeptidases. **B**, The final 16 amino acids of G-34 are identical to the final 16 amino acids in G-17. Both G-17 and G-34 may be either *not sulfated* (gastrin I) or *sulfated* (gastrin II). **C**, The five final amino acids of CCK are identical to those of G-17 and G-34.

Specialized endocrine cells in both the antrum and duodenum make each of the two gastrins. **Antral G**

cells are the primary source of G-17, whereas **duodenal G cells** are the primary source of G-34. Antral G cells are unusual in that they respond to both luminal and basolateral stimuli ([Fig. 42-8](#)). Antral G cells have microvilli on their apical membrane surface and are referred to as an *open-type* endocrine cell. These G cells release gastrin in response to luminal peptides and amino acids, as well as in response to **gastrin-releasing peptide (GRP)**, a 27–amino-acid peptide that is released by vagal nerve endings. As discussed below, gastrin release is inhibited by somatostatin, which is released from adjacent D cells.

FIGURE 42-8 Regulation of gastric acid secretion. In the **corpus** of the stomach, the vagus nerve not only stimulates the parietal cell directly by releasing ACh, it also stimulates both ECL and D cells. Vagal stimulation of the ECL cells enhances gastric acid secretion via increased histamine release. Vagal stimulation of the D cells also promotes gastric acid secretion by inhibiting the release of somatostatin, which would otherwise inhibit—by paracrine mechanisms—the release of histamine from ECL cells and the secretion of acid by parietal cells. In the **antrum** of the stomach, the vagus nerve stimulates both G cells and D cells. The vagus stimulates the G cells via GRP, promoting gastrin release. This gastrin promotes gastric acid secretion by two endocrine mechanisms: directly via the parietal cell and indirectly via the ECL cell, which releases histamine. The vagal stimulation of D cells via ACh inhibits the release of somatostatin, which would otherwise inhibit—by paracrine mechanisms—the release of gastrin from G cells and—by an endocrine mechanism—acid secretion by parietal cells. Luminal H⁺ directly stimulates the D cells to release somatostatin, which inhibits gastrin release from the G cells, thereby reducing gastric acid secretion (negative feedback). In addition, products of protein digestion (i.e., peptides and amino acids) directly stimulate the G cells to release gastrin, which stimulates gastric acid secretion (positive feedback).

ECL cells in the **corpus** of the stomach synthesize histamine. The central role of histamine and ECL

cells is consistent with the observation that H_2 receptor antagonists (i.e., H_2 blockers), such as cimetidine and ranitidine, not only block the direct action of histamine on parietal cells but also substantially inhibit the acid secretion stimulated by ACh and gastrin (which activate ECL cells). The effectiveness of H_2 blockers in controlling acid secretion after stimulation by most agonists is well established in humans.

Gastric D cells release somatostatin, the central inhibitor of acid secretion

Gastric acid secretion is under close control of not only the stimulatory pathways discussed above but also the inhibitory pathways. The major inhibitory pathway involves the release of **somatostatin**, a polypeptide hormone made by D cells in the antrum and corpus of the stomach. Somatostatin is also made by the δ cells of the pancreatic islets (see [p. 1035](#)) and by neurons in the hypothalamus (see [pp. 993–994](#)). Somatostatin exists in two forms, SS-28 and SS-14, which have identical C termini. SS-28 is the predominant form in the GI tract.

Somatostatin inhibits gastric acid secretion by both direct and indirect mechanisms (see [Fig. 42-8](#)). In the **direct pathway**, somatostatin coming from two different sources binds to a $G\alpha_i$ -coupled receptor (SST) on the basolateral membrane of the parietal cell and inhibits adenylyl cyclase. The net effect is to antagonize the stimulatory effect of histamine and thus inhibit gastric acid secretion by parietal cells. The source of this somatostatin can be either *paracrine* (i.e., D cells present in the corpus of the stomach, near the parietal cells) or *endocrine* (i.e., D cells in the antrum). However, there is a major difference in what triggers the D cells in the corpus and in the antrum. Neural and hormonal mechanisms stimulate D cells in the *corpus* (which cannot sense intraluminal pH), whereas low intraluminal pH stimulates D cells in the *antrum*.

Somatostatin also acts via two **indirect pathways**, both of which are paracrine. In the corpus of the stomach, D cells release somatostatin, which inhibits the release of *histamine* from ECL cells (see [Fig. 42-8](#)). Because histamine is an acid secretagogue, somatostatin thus reduces gastric acid secretion. In the antrum of the stomach, D cells release somatostatin, which inhibits the release of *gastrin* from G cells. Because gastrin is another acid secretagogue, somatostatin also reduces gastric acid secretion by this route. The gastrin released by the G cell feeds back on itself by stimulating D cells to release the inhibitory somatostatin.

The presence of multiple mechanisms by which somatostatin inhibits acid secretion is another example of the *redundant regulatory pathways* that control acid secretion. An understanding of the regulation of somatostatin release from D cells is slowly evolving, but it appears that gastrin stimulates somatostatin release, whereas cholinergic agonists inhibit somatostatin release.

Several enteric hormones (“enterogastrone”) and prostaglandins inhibit gastric acid secretion

Multiple processes in the duodenum and jejunum participate in the negative-feedback mechanisms that inhibit gastric acid secretion. Fat, acid, and hyperosmolar solutions in the duodenum are potent inhibitors of gastric acid secretion. Of these inhibitors, lipids are the most potent, but acid is also quite important. Several candidate hormones have been suggested as mediators of this acid inhibition ([Table 42-2](#)). These include CCK, secretin (see [p. 889](#)), vasoactive intestinal peptide (VIP; see [Fig. 13-9](#)), gastric inhibitory peptide (GIP), neurotensin (see [Fig. 13-9](#)), and peptide YY (see [p. 892](#)). Although each inhibits acid

secretion after systemic administration, none has been *unequivocally* established as the sole physiological “enterogastrone.”

TABLE 42-2
Enteric Hormones that Inhibit Gastric H⁺ Secretion

HORMONE	SOURCE
CCK	I cells of duodenum and jejunum and neurons in ileum and colon
Secretin	S cells in small intestine
VIP	ENS neurons
GIP	K cells in duodenum and jejunum
Neurotensin	Endocrine cells in ileum
Peptide YY	Endocrine cells in ileum and colon
Somatostatin	D cells of stomach and duodenum, δ cells of pancreatic islets

Evidence suggests that **secretin**, which is released by duodenal S cells, may have a prime role in inhibiting gastric acid secretion after the entry of fat and acid into the duodenum. Secretin appears to reduce acid secretion by at least three mechanisms: (1) inhibition of antral gastrin release, (2) stimulation of somatostatin release, and (3) direct downregulation of the parietal-cell H⁺ secretory process.

The presence of luminal fatty acids causes enteroendocrine cells in the duodenum and the proximal part of the small intestine to release both GIP and CCK. **GIP** reduces acid secretion directly by inhibiting parietal-cell acid secretion and indirectly by inhibiting the antral release of gastrin. GIP also has the important function of stimulating insulin release from pancreatic islet cells in response to duodenal glucose and fatty acids and is therefore often referred to as glucose-dependent insulinotropic polypeptide (see [p. 1041](#)). CCK participates in feedback inhibition of acid secretion by directly reducing parietal-cell acid secretion. Finally, some evidence indicates that a neural reflex elicited in the duodenum in response to acid also inhibits gastric acid secretion.

Prostaglandin E₂ (PGE₂) inhibits parietal-cell acid secretion, probably by inhibiting histamine's activation of parietal-cell function at a site that is distal to the histamine receptor. PGE₂ appears to bind to an EP₃ receptor on the basolateral membrane of the parietal cell (see [Fig. 42-6](#)) and stimulates G α_i , which, in turn, inhibits adenylyl cyclase. In addition, prostaglandins also indirectly inhibit gastric acid secretion by reducing histamine release from ECL cells and gastrin release from antral G cells.

A meal triggers three phases of acid secretion

Basal State

Gastric acid secretion occurs throughout the day and night. Substantial increases in acid secretion occur after meals, whereas the rate of acid secretion between meals is low (i.e., the interdigestive phase). This interdigestive period follows a circadian rhythm; acid secretion is lowest in the morning before awakening and is highest in the evening. Acid secretion is a direct function of the number of parietal cells, which is also influenced, at least in part, by body weight. Thus, men have higher rates of basal acid secretion than do women. Considerable variability in basal acid secretion is also seen among normal individuals, and the resting intragastric pH can range from 3 to 7 (see [Box 42-1](#)).

In contrast to the low rate of acid secretion during the basal or interdigestive period, acid secretion is enhanced several-fold by eating ([Fig. 42-9](#)). Regulation of gastric acid secretion is most often studied in the fasting state, a state in which intragastric pH is relatively low because of the basal H⁺ secretory rate and the absence of food that would otherwise buffer the secreted gastric acid. Experimental administration of a secretagogue in the fasted state thus stimulates parietal cells and further lowers

intragastric pH. However, the time course of intragastric pH after a meal can vary considerably despite stimulation of acid secretion. The reason is that intragastric pH depends not only on gastric acid secretion but also on the buffering power (see p. 629) of food and the rate of gastric emptying of both acid and partially digested material into the duodenum.

FIGURE 42-9 Effect of eating on acid secretion. Ingesting food causes a marked fall in gastric $[H^+]$ because the food buffers the pre-existing H^+ . However, as the food leaves the stomach and as the rate of H^+ secretion increases, $[H^+]$ slowly rises to its “interdigestive” level.

Regulation of acid secretion during a meal can be best characterized as including three separate but interrelated phases: the *cephalic*, the *gastric*, and the *intestinal* phases. The cephalic and gastric phases are of primary importance. Regulation of acid secretion includes both the stimulatory and inhibitory mechanisms that we discussed above (see Fig. 42-8). ACh, gastrin, and histamine all promote acid secretion, whereas somatostatin inhibits gastric acid secretion.

Although dividing acid secretion during a meal into three phases has been used for decades, it is somewhat artificial because of considerable overlap in the regulation of acid secretion. For example, the vagus nerve is the central factor in the cephalic phase, but it is also important for the vagovagal reflex that is part of the gastric phase. Similarly, gastrin release is a major component of the gastric phase, but vagal stimulation during the cephalic phase also induces the release of antral gastrin. Finally, the development of a consensus model has long been hampered by considerable differences in regulation of the gastric phase of acid secretion in humans, dogs, and rodents.

Cephalic Phase

The smell, sight, taste, thought, and swallowing of food initiate the cephalic phase, which is primarily mediated by the vagus nerve (see Fig. 42-8). Although the cephalic phase has long been studied in experimental animals, especially in dogs by Pavlov, [N42-4](#) more recent studies of sham feeding have

confirmed and extended the understanding of the mechanism of the cephalic phase of acid secretion in humans. The aforementioned sensory stimuli activate the **dorsal motor nucleus of the vagus nerve** in the medulla (see [p. 339](#)) and thus excite parasympathetic preganglionic efferent nerves. Insulin-induced hypoglycemia also stimulates the vagus nerve and in so doing promotes acid secretion.

Stimulation of the vagus nerve results in four distinct physiological events (already introduced in [Fig. 42-8](#)) that together result in enhanced gastric acid secretion. First, in the body of the stomach, vagal postganglionic muscarinic nerves release ACh, which stimulates parietal-cell H^+ secretion directly. Second, in the lamina propria of the body of the stomach, the ACh released from vagal endings triggers histamine release from ECL cells, which stimulates acid secretion. Third, in the antrum, *peptidergic* postganglionic parasympathetic vagal neurons, as well as other enteric nervous system (ENS) neurons, release GRP, which induces gastrin release from antral G cells. This gastrin stimulates gastric acid secretion both directly by acting on parietal cells and indirectly by promoting histamine release from ECL cells. Fourth, in both the antrum and the corpus, the vagus nerve inhibits D cells, thereby reducing their release of somatostatin and reducing the background inhibition of gastrin release. Thus, the cephalic phase stimulates acid secretion directly and indirectly by acting on the parietal cell. The cephalic phase accounts for ~30% of total acid secretion and occurs before the entry of any food into the stomach.

One of the surgical approaches for the treatment of peptic ulcer disease is cutting the vagus nerves (vagotomy) to inhibit gastric acid secretion. Rarely performed, largely because of the many effective pharmacological agents available to treat peptic ulcer disease, the technique has nevertheless proved effective in selected cases. Because vagal stimulation affects several GI functions besides parietal-cell acid secretion, the side effects of vagotomy include a delay in gastric emptying and diarrhea. Selective vagotomies—severing *only those* vagal fibers leading to the parietal cell—minimize these untoward events.

Gastric Phase

Entry of food into the stomach initiates the two primary stimuli for the gastric phase of acid secretion ([Fig. 42-10](#)). First, the food distends the gastric mucosa, which activates a vagovagal reflex as well as

local ENS reflexes. Second, partially digested proteins stimulate antral G cells.

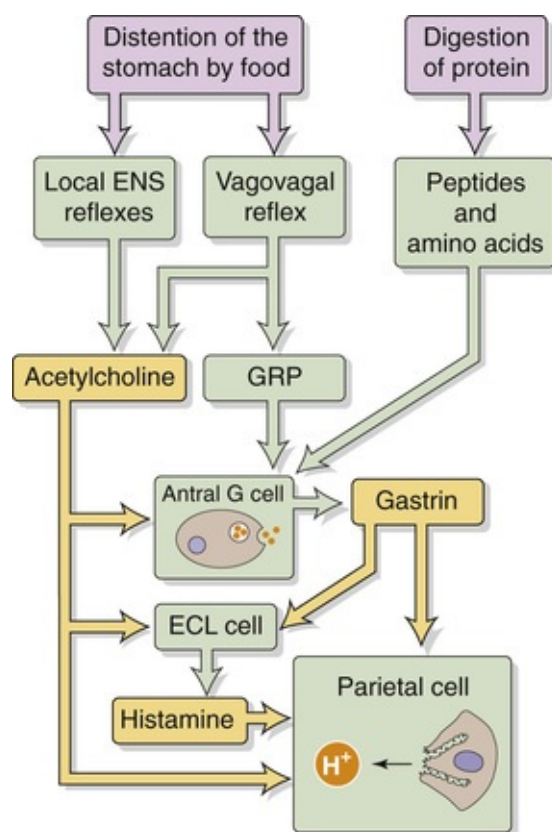

FIGURE 42-10 Gastric phase of gastric acid secretion. Food in the stomach stimulates gastric acid secretion by two major mechanisms: mechanical stretch and the presence of digested protein fragments (peptones).

Distention of the gastric wall—both in the corpus and antrum—secondary to entry of food into the stomach elicits two distinct neurally mediated pathways. The first is activation of a **vagovagal reflex** (see p. 857), in which gastric wall distention activates a vagal *afferent* pathway, resulting in a vagal *efferent* response in the dorsal nucleus of the vagus nerve. Stimulation of acid secretion in response to this vagal efferent stimulus occurs via the same four parallel pathways that are operative when the vagus nerve is activated during the cephalic phase (see Fig. 42-8). Second, gastric wall distention also activates a **local ENS pathway** that releases ACh, thereby activating parietal-cell acid secretion.

The presence of **partially digested proteins** (peptones) or amino acids in the antrum directly stimulates G cells to release gastrin (see Fig. 42-8). Intact proteins have no effect. Acid secretion and activation of pepsinogen are linked in a positive-feedback relationship. As discussed below, low pH enhances the conversion of pepsinogen to pepsin. Pepsin digests proteins to peptones, which promote gastrin release. Finally, gastrin promotes acid secretion, which closes the positive-feedback loop. Neither carbohydrate nor lipid participates in the regulation of gastric acid secretion. Components of wine, beer, and coffee stimulate acid secretion by this G-cell mechanism.

In addition to the two stimulatory pathways acting during the gastric phase, a third pathway *inhibits* gastric acid secretion by a classic negative-feedback mechanism, already noted above in our discussion of Figure 42-8. Low intragastric pH stimulates antral D cells to release somatostatin. Because somatostatin inhibits the release of gastrin by G cells, the net effect is a reduction in gastric acid secretion. The effectiveness of low pH in inhibiting gastrin release is emphasized by the following observation: Although peptones are normally a potent stimulus for gastrin release, they fail to stimulate

gastrin release either when the intraluminal pH of the antrum is maintained at 1.0 or when somatostatin is infused.

The gastric phase of acid secretion, which occurs primarily as a result of gastrin release, accounts for *50% to 60% of total gastric acid secretion*.

Intestinal Phase

The presence of amino acids and partially digested peptides in the proximal portion of the small intestine stimulates acid secretion by three mechanisms (Fig. 42-11). First, these peptones stimulate duodenal G cells to secrete gastrin, just as peptones stimulate antral G cells in the gastric phase. Second, peptones stimulate an unknown endocrine cell to release an additional humoral signal that has been referred to as entero-oxyntin. The chemical nature of this agent has not yet been identified. Third, amino acids absorbed by the proximal part of the small intestine stimulate acid secretion by mechanisms that require further definition.

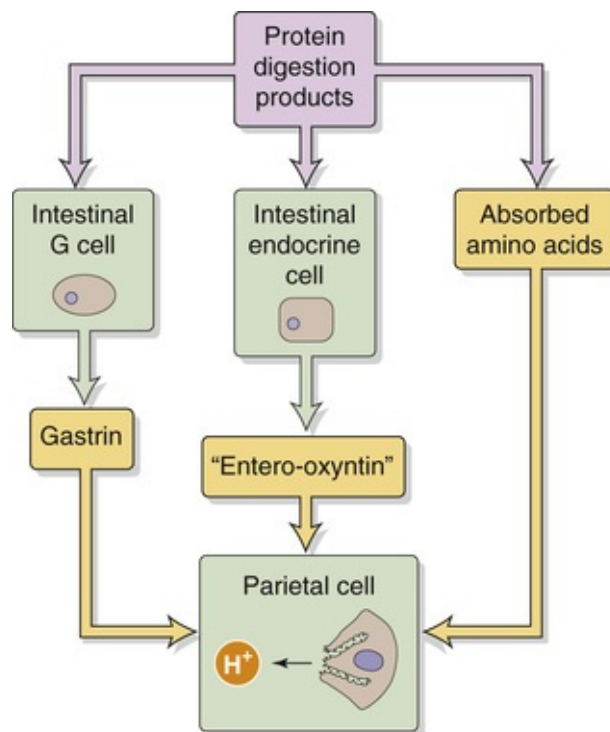

FIGURE 42-11 Intestinal phase of gastric acid secretion. Digested protein fragments (peptones) in the proximal small intestine stimulate gastric acid secretion by three major mechanisms.

Gastric acid secretion mediated by the intestinal phase is enhanced after a portacaval shunt. Such a shunt—used in the treatment of portal hypertension caused by chronic liver disease—diverts the portal blood that drains the small intestine around the liver on its return to the heart. Thus, the signal released from the small intestine during the intestinal phase is probably—in normal individuals—removed in part by the liver before reaching its target, the corpus of the stomach.

Approximately *5% to 10% of total gastric acid secretion* is a result of the intestinal phase.

Pepsinogen Secretion

Chief cells, triggered by both cAMP and Ca^{2+} pathways, secrete multiple pepsinogens that initiate protein digestion

The chief cells in gastric glands, as well as mucous cells, secrete **pepsinogens**, a group of proteolytic proenzymes (i.e., zymogens or inactive enzyme precursors) that belong to the general class of aspartic proteinases. They are activated to pepsins by cleavage of an N-terminal peptide. **Pepsins** are endopeptidases that initiate the hydrolysis of ingested protein in the stomach. Although eight pepsinogen isoforms were initially identified on electrophoresis, recent classifications are based on immunological identity, so pepsinogens are most often classified as group I pepsinogens, group II pepsinogens, and cathepsin E. Group I pepsinogens predominate. They are secreted from chief cells located at the base of glands in the corpus of the stomach. Group II pepsinogens are also secreted from chief cells but, in addition, are secreted from mucous neck cells in the cardiac, corpus, and antral regions.

Pepsinogen secretion in the basal state is ~20% of its maximal secretion after stimulation. Although pepsinogen secretion generally parallels the secretion of acid, the ratio of maximal to basal pepsinogen secretion is considerably less than that for acid secretion. Moreover, the cellular mechanism of pepsinogen release is quite distinct from that of H^+ secretion by parietal cells. Release of pepsinogen across the apical membrane is the result of a novel process called **compound exocytosis**, in which secretory granules fuse with both the plasma membrane and other secretory granules. This process permits rapid and sustained secretion of pepsinogen. After stimulation, the initial peak in pepsinogen secretion is followed by a persistent lower rate of secretion. This pattern of secretion has been interpreted as reflecting an initial secretion of *preformed* pepsinogen, followed by the secretion of *newly synthesized* pepsinogen. However, more recent in vitro studies suggested that a feedback mechanism may account for the subsequent reduced rate of pepsinogen secretion.

Two groups of agonists stimulate chief cells to secrete pepsinogen. One group acts through adenylyl cyclase and cAMP, and the other acts through increases in $[\text{Ca}^{2+}]_i$.

Agonists Acting via cAMP

Chief cells have receptors for **secretin/VIP**, **β_2 adrenergic** receptors, and **EP_2** receptors for **PGE_2** (see p. 64). All these receptors activate adenylyl cyclase. At lower concentrations than those required to stimulate pepsinogen secretion, PGE_2 can also inhibit pepsinogen secretion, probably by binding to another receptor subtype.

Agonists Acting via Ca^{2+}

Chief cells also have **M_3 muscarinic** receptors for **ACh**, as well as receptors for the **gastrin/CCK** family of peptides. Unlike gastric acid secretion, which is stimulated by the **CCK_2** receptor, pepsinogen secretion is stimulated by the **CCK_1** receptor, which has a much higher affinity for CCK than for gastrin. Activation of both the **M_3** and **CCK_1** receptors causes Ca^{2+} release from intracellular stores by **IP_3** and thereby raises $[\text{Ca}^{2+}]_i$. However, uncertainty exists about whether increased Ca^{2+} influx is also required and about

whether PKC also has a role.

Of the agonists just listed, the most important for pepsinogen secretion is ACh released in response to vagal stimulation. ACh not only stimulates chief cells to release pepsinogen, but also stimulates parietal cells to secrete acid. This gastric acid produces additional pepsinogen secretion by two different mechanisms. First, in the stomach, a fall in pH elicits a local cholinergic reflex that results in further stimulation of chief cells to release pepsinogen. Thus, the ACh that stimulates chief cells can come both from the vagus and from the local reflex. Second, in the duodenum, acid triggers the release of secretin from S cells. By an endocrine effect, this secretin stimulates the chief cells to release more pepsinogen. The exact role or roles of histamine and gastrin in pepsinogen secretion are unclear.

Low pH is required for both pepsinogen activation and pepsin activity

Pepsinogen is inactive and requires activation to a protease, pepsin, to initiate protein digestion. This activation occurs by spontaneous cleavage of a small N-terminal peptide fragment (the activation peptide), but only at a pH that is <5.0 (Fig. 42-12). Between pH 5.0 and 3.0, spontaneous activation of pepsinogen is slow, but it is extremely rapid at a pH that is <3.0 . In addition, pepsinogen is also autoactivated; that is, newly formed pepsin itself cleaves pepsinogen to pepsin.

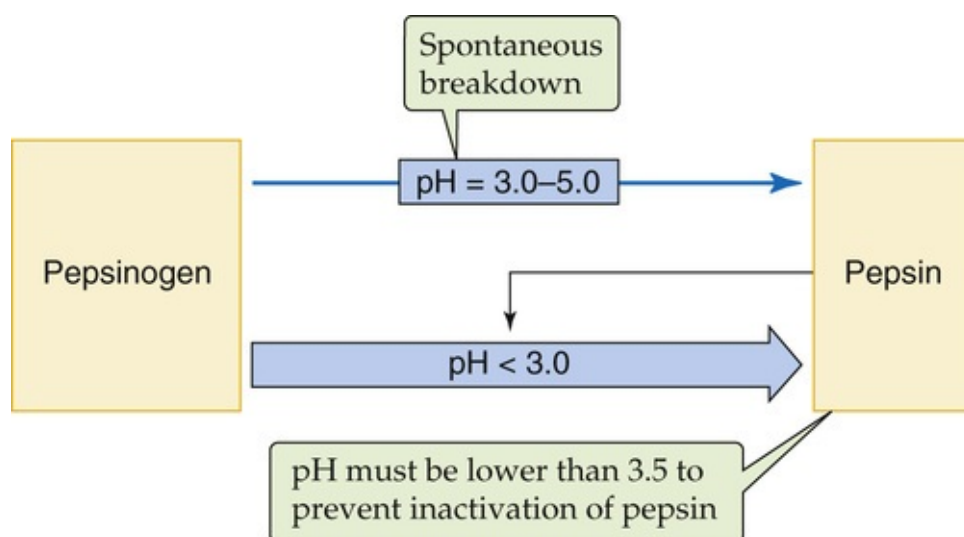

FIGURE 42-12 Activation of the pepsinogens to pepsins. At pH values from 5 to 3, pepsinogens spontaneously activate to pepsins by the removal of an N-terminal “activation peptide.” This spontaneous activation is even faster at pH values that are <3 . The newly formed pepsins themselves—which are active only at pH values <3.5 —also can catalyze the activation of pepsinogens.

Once pepsin is formed, its *activity* is also pH dependent. It has optimal activity at a pH between 1.8 and 3.5; the precise optimal pH depends on the specific pepsin, type and concentration of substrate, and osmolality of the solution. pH values >3.5 *reversibly* inactivate pepsin, and pH values >7.2 *irreversibly* inactivate the enzyme. These considerations are sometimes useful for establishing optimal antisecretory therapy in peptic ulcer disease.

Pepsin is an endopeptidase that initiates the process of protein digestion in the stomach. Pepsin action results in the release of small peptides and amino acids (peptones) that, as noted above, stimulate the release of gastrin from antral G cells; these peptones also stimulate CCK release from duodenal I cells. As previously mentioned, the peptones generated by pepsin stimulate the very acid secretion required for

pepsin activation and action. Thus, the peptides that pepsin releases are important in initiating a coordinated response to a meal. However, most protein entering the duodenum remains as large peptides, and nitrogen balance is not impaired after total gastrectomy.

Digestive products of both carbohydrates and lipids are also found in the stomach, although secretion of their respective digestive enzymes either does not occur or is not a major function of gastric epithelial cells. Carbohydrate digestion is initiated in the mouth by **salivary amylase**. However, after this enzyme is swallowed, the stomach becomes a more important site for starch hydrolysis than the mouth. The stomach itself does not secrete enzymes that hydrolyze starch or other saccharides. Lipid digestion also is initiated in the mouth by lingual lipase. However, significant lipid digestion occurs in the stomach as a result of both the **lingual lipase** that is swallowed and **gastric lipase**, both of which have an acid pH optimum (see [pp. 927–928](#)).

Protection of the Gastric Surface Epithelium and Neutralization of Acid in the Duodenum

At maximal rates of H^+ secretion, the parietal cell can drive the intraluminal pH of the stomach to 1 or less (i.e., $[\text{H}^+] > 100 \text{ mM}$) for long periods. The gastric epithelium must maintain an H^+ concentration gradient of more than a million-fold because the intracellular pH of gastric epithelial cells is ~ 7.2 (i.e., $[\text{H}^+] \cong 60 \text{ nM}$) and plasma pH is ~ 7.4 (i.e., $[\text{H}^+] \cong 40 \text{ nM}$). Simultaneously, the plasma-to-lumen Na^+ concentration ratio can approach ~ 30 because plasma $[\text{Na}^+]$ is 140 mM , whereas intragastric $[\text{Na}^+]$ can reach values as low as 5 mM , but only at high secretory rates (see Fig. 42-2). How is the stomach able to maintain these gradients? How is it that the epithelial cells are not destroyed by this acidity? Moreover, why do pepsins in the gastric lumen not digest the epithelial cells? The answer to all three questions is the so-called **gastric diffusion barrier**.

Although the nature of the gastric diffusion barrier had been controversial, it is now recognized that the diffusion barrier is both physiological and anatomical. Moreover, it is apparent that the diffusion barrier is characterized by at least three components: (1) relative impermeability to acid of the apical membrane and epithelial-cell tight junctions in the gastric glands, (2) a mucous gel layer varying in thickness between 50 and $200 \mu\text{m}$ overlying the surface epithelial cells, and (3) an HCO_3^- -containing microclimate adjacent to the surface epithelial cells that maintains a relatively high local pH.

Vagal stimulation and irritation stimulate gastric mucous cells to secrete mucins

The mucous layer is largely composed of mucins, phospholipids, electrolytes, and water. Gastric **mucins**—MUC1, MUC5, and MUC6—are the high-molecular-weight glycoproteins (see p. 38) that contribute to the formation of a protective layer over the gastric mucosa. These mucins are oligomers (di-, tri-, and tetramers) and higher-order multimers of peptides joined by disulfide bonds. Each peptide chain is linked to long polysaccharides, which are often sulfated and are thus mutually repulsive. The ensuing high carbohydrate content is responsible for the viscosity of mucus, which explains, in large part, its protective role in gastric mucosal physiology.

Mucus is secreted by three different mucous cells: surface mucous cells (i.e., on the surface of the stomach), mucous neck cells (i.e., at the point where a gastric pit joins a gastric gland), and glandular mucous cells (i.e., in the gastric glands in the antrum). The type of mucus secreted by these cells differs; mucus that is synthesized and secreted in the glandular cells is a neutral glycoprotein, whereas the mucous cells on the surface and in the gastric pits secrete both neutral and acidic glycoproteins. Mucin forms a **mucous gel layer** in combination with phospholipids, electrolytes, and water. This mucous gel layer provides protection against injury from noxious luminal substances, including acid, pepsins, bile acids, and ethanol. Mucin also lubricates the gastric mucosa to minimize the abrasive effects of intraluminal food.

The mucous barrier is not static. Abrasions can remove pieces of mucus. When mucus comes in contact with a solution with a very low pH, the mucus precipitates and sloughs off. Thus, the mucous cells must constantly secrete mucus. Regulation of mucus secretion by gastric mucosal cells is less well understood than is regulation of the secretion of acid, pepsinogens, and other substances by gastric cells. The two

primary stimuli for inducing mucus secretion are vagal stimulation and physical and chemical irritation of the gastric mucosa by ingested food. The current model of mucus secretion suggests that vagal stimulation induces the release of ACh, which leads to increases in $[Ca^{2+}]_i$ and thus stimulates mucus secretion. Unlike for acid and pepsinogen secretion, cAMP does not appear to be a second messenger for mucus secretion.

Gastric surface cells secrete HCO_3^- , stimulated by acetylcholine, acids, and prostaglandins

Surface epithelial cells both in the corpus and in the antrum of the stomach secrete HCO_3^- . Despite the relatively low rate of HCO_3^- secretion—in comparison with acid secretion— HCO_3^- is extremely important as part of the gastric mucosal protective mechanism. The mucous gel layer provides an unstirred layer under which the secreted HCO_3^- remains trapped and maintains a local pH of ~ 7.0 versus an intraluminal pH in the bulk phase of 1 to 3. As illustrated in [Figure 42-13A](#), an electrogenic Na/HCO_3 cotransporter (NBC) appears to mediate the uptake of HCO_3^- across the basolateral membrane of surface epithelial cells. The electrogenic $Cl-HCO_3$ exchanger SLC26A9 appears to mediate the exit of HCO_3^- into the apical mucous layer.

A NORMAL SURFACE EPITHELIUM

B DAMAGED MUCOSAL BARRIER

FIGURE 42-13 Diffusion barrier in the surface of the gastric mucosa. **A**, The mucus secreted by the surface cells acts as a diffusion barrier for H^+ and traps a relatively alkaline solution of HCO_3^- . This HCO_3^- titrates any H^+ that diffuses into the gel layer from the stomach lumen. The alkaline layer also inactivates any pepsin that penetrates into the mucus. **B**, If H^+ penetrates into the gastric epithelium, it damages mast cells, which release histamine and other agents, setting up an inflammatory response. If the insult is mild, the ensuing increase in blood flow can promote the secretion of both mucus and HCO_3^- . If the insult is more severe, the inflammatory response leads to a decrease in blood flow and thus to cell injury.

Similar to the situation for mucus secretion, relatively limited information is available about the regulation of HCO_3^- secretion. The present model suggests that *vagal stimulation* mediated by ACh leads to an increase in $[Ca^{2+}]_i$, which, in turn, stimulates HCO_3^- secretion. Sham feeding is a potent stimulus for HCO_3^- secretion via this pathway. A second powerful stimulus for gastric HCO_3^- secretion is *intraluminal acid*. The mechanism of stimulation by acid appears to be secondary to both activation of neural reflexes and local production of PGE_2 . Finally, evidence suggests that a humoral factor may also be involved in the induction of HCO_3^- secretion by acid.

Mucus protects the gastric surface epithelium by trapping an HCO_3^- -rich fluid near the apical border of these cells

Mucous cells on the surface of the stomach, as well as in the gastric pits and neck portions of the gastric glands, secrete both HCO_3^- and mucus. Why is this barrier so effective? First, the secreted mucus forms a mucous gel layer that is relatively impermeable to the *diffusion* of H^+ from the gastric lumen to the surface cells. Second, beneath this layer of mucus is a microclimate that contains fluid with a high pH and high $[HCO_3^-]$, the result of HCO_3^- secretion by gastric surface epithelial cells (see Fig. 42-13A). Thus, this HCO_3^- neutralizes most acid that diffuses through the mucous layer. Mucosal integrity, including that of the mucosal diffusion barrier, is also maintained by PGE_2 , which—as discussed in the previous section—stimulates mucosal HCO_3^- secretion.

Deep inside the gastric gland, where no obvious mucous layer protects the parietal, chief, and ECL cells, the impermeability of the cells' apical barrier appears to exclude H^+ even at pH values as low as 1. The paradox of how HCl secreted by the parietal cells emerges from the gland and into the gastric lumen may be explained by a process known as **viscous fingering**. Because the liquid emerging from the gastric gland is both extremely acidic and presumably under pressure, it can tunnel through the mucous layer covering the opening of the gastric gland onto the surface of the stomach. However, this stream of acid apparently does not spread laterally, but rather rises to the surface as a “finger” and thus does not neutralize the HCO_3^- in the microenvironment between the surface epithelial cells and the mucus.

The mucous gel layer and the trapped alkaline HCO_3^- solution protect the surface cells not only from H^+ but also from pepsin. The mucus per se acts as a pepsin-diffusion barrier. The relative alkalinity of the trapped HCO_3^- inactivates any pepsin that penetrates the mucus. Recall that pepsin is reversibly inactivated at pH values greater than ~ 3.5 and is irreversibly inactivated by pH values greater than ~ 7.2 . Thus, the mucus/ HCO_3^- layer plays an important role in preventing autodigestion of the gastric mucosa (Box 42-2).

Breakdown of the Gastric Barrier

The integrity of the gastric epithelial barrier can be conveniently judged by maintenance of a high lumen-negative transepithelial potential difference (PD) of approximately -60 mV. Several agents that cause mucosal injury, including mucosal ulceration, can alter the mucosal diffusion barrier. Salicylates, bile acids, and ethanol all impair the mucosal diffusion barrier and result in H^+ (acid) back-diffusion, an increase in intraluminal $[Na^+]$, a fall in PD, and mucosal damage (see Fig. 42-13B). Three decades ago, Davenport proposed an attractive model to explain how H^+ , after having breached the mucosal diffusion barrier, produces injury to the gastric mucosa. Although several details of this original model have been modified during the ensuing years, it is still believed that entry of acid into the mucosa damages mast cells, which release histamine and other mediators of **inflammation**. The histamine and other agents cause local vasodilation that increases blood flow. If the damage is not too severe, this response allows the surface cells to maintain their production of mucus and HCO_3^- . However, if the injury is more severe, inflammatory cells release a host of agents—including platelet-activating factor, leukotrienes, endothelins, thromboxanes, and oxidants—that reduce blood flow (ischemia) and result in tissue injury, including capillary damage.

Prostaglandins play a central role in maintaining mucosal integrity. For example, prostaglandins prevent or reverse mucosal injury secondary to salicylates, bile, and ethanol. This protective effect of prostaglandins is the result of several actions, including their ability to inhibit acid secretion, stimulate both HCO_3^- and mucus secretion, increase mucosal blood flow, and modify the local inflammatory response induced by acid.

Acid entry into the duodenum induces S cells to release secretin, triggering the pancreas and duodenum to secrete HCO_3^-

The overall process of regulating gastric acid secretion involves not only stimulation and inhibition of acid secretion (as discussed above), but also neutralization of the gastric acid that passes from the stomach into the duodenum. The amount of secreted gastric acid is reflected by a fall in intragastric pH. We have already seen that this fall in pH serves as the signal to antral D cells to release somatostatin and thus to inhibit further acid secretion, a classic negative-feedback process. Similarly, low pH in the duodenum serves as a signal for the secretion of alkali to neutralize gastric acid in the duodenum.

The key factor in this neutralization process is **secretin**, the same secretin that inhibits gastric acid secretion and promotes pepsinogen secretion by chief cells. A low duodenal pH, with a threshold of 4.5, triggers the release of secretin from **S cells** in the duodenum. However, the S cells are probably not pH sensitive themselves but, instead, may respond to a signal from other cells that are pH sensitive. Secretin stimulates the secretion of fluid and HCO_3^- by the pancreas (see pp. 886–887), thus leading to intraduodenal neutralization of the acid load from the stomach. Maximal HCO_3^- secretion is a function of the amount of acid entering the duodenum, as well as the length of duodenum exposed to acid. Thus, high rates of gastric acid secretion trigger the release of large amounts of secretin, which greatly stimulates pancreatic HCO_3^- secretion; the increased HCO_3^- , in turn, neutralizes the increased duodenal acid load.

In addition to *pancreatic* HCO_3^- secretion, the duodenal acid load resulting from gastric acid secretion

is partially neutralized by *duodenal* HCO_3^- secretion. This duodenal HCO_3^- secretion occurs in the proximal—but not the distal—part of the duodenum under the influence of prostaglandins. Attention has been focused on duodenal epithelial cells (villus or crypt cells) as the cellular source of HCO_3^- secretion, but the possibility that duodenal HCO_3^- originates, at least in part, from duodenal submucosal Brunner's glands has not been excluded. The mechanism of duodenal HCO_3^- secretion is similar to that in the pancreatic duct (see Fig. 43-6), and involves both Cl-HCO_3 exchange and cystic fibrosis transmembrane conductance regulator (CFTR) in the apical membrane. Patients with duodenal ulcer disease tend to have both increased gastric acid secretion and reduced duodenal HCO_3^- secretion (Box 42-3). Thus, the increased acid load in the duodenum is only partially neutralized, so the duodenal mucosa has increased exposure to a low-pH solution.

Box 42-3

Helicobacter pylori

During the past decade, our understanding of the etiology of duodenal and gastric ulcers has radically changed. Abundant evidence now indicates that most peptic ulcers are an infectious disease that in most (but not all) cases is caused by *Helicobacter pylori*, a gram-negative bacillus that colonizes the antral mucosa. Nonsteroidal anti-inflammatory drugs (NSAIDs) are responsible for ~20% of ulcers. Although almost all ulcers that are not associated with NSAID use are secondary to *H. pylori* infection, many, if not most, individuals with evidence of *H. pylori* infection do not have peptic ulcer disease. The factors responsible for *H. pylori*-induced inflammation or ulceration are not known. However, the increase in gastric acid secretion that is present in most patients with duodenal ulcers may occur because *H. pylori*-induced antral inflammation inhibits the release of somatostatin by antral D cells. Because somatostatin normally inhibits gastrin release by antral G cells, the result would be increased gastrin release and thus increased gastric acid secretion. Indeed, as noted in Table 42-1, serum gastrin levels are modestly elevated in patients with duodenal ulcers.

Inhibition of acid secretion heals, but does not cure, *H. pylori*-induced peptic ulcers. However, antibiotic therapy that eradicates *H. pylori* cures peptic ulcer disease. For their pioneering work on *H. pylori*, Barry J. Marshall and J. Robin Warren shared the 2005 Nobel Prize in Physiology or Medicine. N42-5.

Filling and Emptying of the Stomach

Gastric motor activity plays a role in filling, churning, and emptying

Gastric motor activity has three functions: (1) The receipt of ingested material represents the **reservoir function** of the stomach and occurs as smooth muscle relaxes. This response occurs primarily in the proximal portion of the stomach. (2) Ingested material is **churned** and is thereby altered to a form that rapidly empties from the stomach through the pylorus and facilitates normal jejunal digestion and absorption. Thus, in conjunction with gastric acid and enzymes, the motor function of the stomach helps to initiate digestion. (3) The pyloric antrum, pylorus, and proximal part of the duodenum function as a single unit for **emptying** into the duodenum the modified gastric contents (chyme), consisting of both partially digested food material and gastric secretions. Gastric filling and emptying are accomplished by the coordinated activity of smooth muscle in the esophagus, lower esophageal sphincter, and proximal and distal portions of the stomach, as well as the pylorus and duodenum ([Box 42-4](#)).

Box 42-4

Vomiting

Vomiting, a frequent sign and symptom in clinical medicine, represents a complex series of multiple afferent stimuli coordinated by one or more brain centers, leading to a coordinated neuromuscular response. **Nausea** is the sensation that vomiting may occur. The act of **emesis** involves several preprogrammed coordinated smooth- and striated-muscle responses. The initial event is the abolition of intestinal slow-wave activity that is linked to propulsive peristaltic contractions. As the normal peristaltic contractions of the stomach and small intestine wane, they are replaced by *retrograde* contractions, beginning in the ileum and progressing to the stomach. These retrograde contractions are accompanied by contraction of abdominal and inspiratory muscles (external intercostal muscles and diaphragm; see pp. 606–607) against a closed glottis, which results in an increase in intra-abdominal pressure. Relaxation of the diaphragmatic crural muscle and lower esophageal sphincter permits transmission of this increase in intra-abdominal pressure into the thorax, with expulsion of the gastric contents into the esophagus. Movement of the larynx upward and forward and relaxation of the upper esophageal sphincter are required for oral propulsion, whereas closure of the glottis prevents aspiration.

Three major categories of stimuli can potentially induce the foregoing series of events that leads to vomiting. First, gastric irritants and peritonitis, for example, probably act by vagal afferent pathways, presumably to rid the body of the irritant. Second, inner ear dysfunction or motion sickness acts through the vestibular nerve and vestibular nuclei. Third, drugs such as digitalis and certain cancer chemotherapeutic agents activate the *area postrema* in the brain (see p. 284). Pregnancy can also cause nausea and vomiting, by an unknown mechanism. Although several central loci receive these emetic stimuli, the primary locus is the *area postrema*, also called the *chemoreceptor trigger zone*. Although no single brainstem site coordinates vomiting, the nucleus tractus solitarius (NTS; see p. 348) plays an important role in the initiation of emesis. Neurotransmitter receptors that are important in various causes of vomiting include the NK₁ receptor (which binds substance P) in the NTS, 5-hydroxytryptamine type 3 (5-HT₃) receptors in vagal afferents, and dopamine D₂ receptors in the vestibular nucleus.

The pattern of gastric smooth-muscle activity is distinct during fasting and after eating. The pattern during fasting is referred to as the **migrating myoelectric (or motor) complex (MMC)**. This pattern is terminated by eating, at which point it is replaced by the so-called **fed pattern**. Just as the proximal and distal regions of the stomach differ in secretory function, they also differ in the motor function responsible for storing, processing, and emptying liquids and solids. The proximal part of the stomach is the primary location for storage of both liquids and solids. The distal portion of the stomach is primarily responsible for churning the solids and generating smaller liquid-like material, which then exits the stomach in a manner similar to that of ingested liquids. Thus, the gastric emptying of liquids and of solids is closely integrated.

Filling of the stomach is facilitated by both receptive relaxation and gastric accommodation

Even a dry swallow relaxes both the lower esophageal sphincter and the proximal part of the stomach. Of course, the same happens when we swallow food. These relaxations facilitate the entry of food into the stomach. Relaxation in the fundus is primarily regulated by a vagovagal reflex and has been called **receptive relaxation**. In a **vagovagal reflex**, afferent fibers running with the vagus nerve carry information to the central nervous system (CNS), and efferent vagal fibers carry the signal from the CNS to the stomach and cause relaxation by a mechanism that is neither cholinergic nor adrenergic. The result is that intragastric volume increases without an increase in intragastric pressure. If vagal innervation to the stomach is interrupted, gastric pressure rises much more rapidly.

Quite apart from the receptive relaxation of the stomach that anticipates the arrival of food after swallowing and esophageal distention, the stomach can also relax in response to gastric filling *per se*. Thus, increasing intragastric volume, as a result of either entry of food into the stomach or gastric secretion, does not produce a proportionate increase in intragastric pressure. Instead, small increases in volume do not cause increases in intragastric pressure until a threshold is reached, after which intragastric pressure rises steeply ([Fig. 42-14A](#)). This phenomenon is the result of *active* dilation of the fundus, called **gastric accommodation**. Vagotomy abolishes a major portion of gastric accommodation, so increases in intragastric volume produce greater increases in intragastric pressure. However, the role of the vagus nerve in gastric accommodation is one of modulation. It is generally believed that the **ENS** (see [pp. 855–856](#)) is the primary regulator permitting the storage of substantial amounts of solids and liquids in the proximal part of the stomach without major increases in intragastric pressure.

A GASTRIC ACCOMMODATION

B GASTRIC EMPTYING

FIGURE 42-14 Gastric filling and emptying. (B, Data from Dooley CP, Reznick JB, Valenzuela JE: Variations in gastric and duodenal motility during gastric emptying of liquid meals in humans. *Gastroenterology* 87:1114–1119, 1984.)

The stomach churns its contents until the particles are small enough to be gradually emptied into the duodenum

The substance most rapidly emptied by the stomach is isotonic saline or water. Emptying of these liquids occurs without delay and is faster the greater the volume of fluid. Acidic and caloric fluids leave the stomach more slowly, whereas fatty materials exit even more slowly (see Fig. 42-14B). Solids do not leave the stomach as such, but must first be reduced in size (i.e., trituration). Particles >2 mm do not leave the stomach during the immediate postprandial digestive period. The delay in gastric emptying of solids occurs because solids must be reduced in size to <2 mm; at that point, they are emptied by mechanisms similar to those for liquids.

Movement of solid particles toward the antrum is accomplished by the interaction of propulsive gastric

contractions and occlusion of the pylorus, a process termed **propulsion** (Fig. 42-15A). Gastric contractions are initiated by the gastric pacemaker, which is located on the greater curvature, approximately at the junction of the proximal and middle portions of the stomach. These contractions propel the luminal contents toward the pylorus, which is partially closed by contraction of the pyloric musculature before delivery of the bolus. This increase in pyloric resistance represents the coordinated response of antral, pyloric, and duodenal motor activity. Once a bolus of material is trapped near the antrum, it is churned to help reduce the size of the particles, a process termed **grinding** (see Fig. 42-15B). Only a small portion of gastric material—that containing particles <2 mm—is propelled through the pylorus to the duodenum. Thus, most gastric contents are returned to the body of the stomach for pulverization and shearing of solid particles, a process known as **retropulsion** (see Fig. 42-15C). These processes of propulsion, grinding, and retropulsion repeat multiple times until the gastric contents are emptied. Particles >2 mm are initially retained in the stomach but are eventually emptied into the duodenum by MMCs during the interdigestive period that begins ~ 2 hours or more after eating.

FIGURE 42-15 Mechanical actions of the stomach on its contents.

Modification of gastric contents is associated with the activation of multiple feedback mechanisms. This feedback usually arises from the duodenum (and beyond) and almost always results in a delay in gastric emptying. Thus, as small squirts of gastric fluid leave the stomach, chemoreceptors and mechanoreceptors—primarily in the proximal but also in the distal portion of the small intestine—sense

low pH, high caloric content, lipid, certain amino acids (i.e., tryptophan), or changes in osmolarity. These signals all decrease the rate of gastric emptying by a combination of neural and hormonal signals, including the vagus nerve, secretin, CCK, and GIP released from duodenal mucosa. Delayed gastric emptying involves (1) the coordinated function of fundic relaxation, (2) inhibition of antral motor activity, (3) stimulation of isolated, phasic contractions of the pyloric sphincter, (4) and altered intestinal motor activity.

Pancreatic and Salivary Glands

Christopher R. Marino, Fred S. Gorelick

Overview of Exocrine Gland Physiology

The pancreas and major salivary glands are compound exocrine glands

The exocrine pancreas and major salivary glands are compound exocrine glands—specialized secretory organs that contain a branching ductular system through which they release their secretory products. The principal function of these exocrine glands is to aid in the digestion of food. The saliva produced by the salivary glands lubricates ingested food and initiates the digestion of starch. Pancreatic juice, rich in HCO_3^- and digestive enzymes, neutralizes the acidic gastric contents that enter the small intestine and also completes the intraluminal digestion of ingested carbohydrate, protein, and fat. Each of these exocrine glands is under the control of neural and humoral signals that generate a sequential and coordinated secretory response to an ingested meal. We discuss the endocrine pancreas in [Chapter 51](#).

Morphologically, the pancreas and salivary glands are divided into small but visible **lobules**, each of which represents a subdivision of the parenchyma and is drained by a single **intralobular duct** ([Fig. 43-1A](#)). Groups of lobules separated by connective tissue septa are drained by larger **interlobular ducts**. These interlobular ducts empty into a **main duct** that connects the entire gland to the lumen of the gastrointestinal tract.

A ORGANIZATION OF THE PANCREAS

FIGURE 43-1 Pancreatic acinus and duct morphology. **A**, The fundamental secretory unit is composed of an acinus and an intercalated duct. Intercalated ducts merge to form intralobular ducts, which in turn merge to form interlobular ducts, and then the main pancreatic duct. **B**, The acinar cell is specialized for protein secretion. Large condensing vacuoles are gradually reduced in size and form mature zymogen granules that store digestive enzymes in the apical region of the acinar cell. **C**, The duct cell is a cuboidal cell with abundant mitochondria. Small microvilli project from its apical membrane.

Within the lobules reside the microscopic structural and functional secretory units of the gland. Each **secretory unit** is composed of an acinus and a small intercalated duct. The acinus represents a cluster of 15 to 100 acinar cells that synthesize and secrete proteins into the lumen of the epithelial structure. In the pancreas, acinar cells secrete ~20 different digestive zymogens (inactive enzyme precursors) and enzymes. In the salivary glands, the principal acinar cell protein products are α -amylase, mucins, and proline-rich proteins. Acinar cells from both the pancreas and salivary glands also secrete an isotonic, plasma-like fluid that accompanies the secretory proteins. In all, the final acinar secretion is a protein-rich product known as the primary secretion.

Each acinar lumen is connected to the proximal end of an **intercalated duct**. Distally, the intercalated ducts fuse with other small ducts to form progressively larger ducts that ultimately coalesce to form the intralobular duct that drains the lobule. Although the ducts provide a conduit for the transport of secretory proteins, the epithelial cells lining the ducts also play an important role in modifying the fluid and

electrolyte composition of the primary secretion. Thus, the final exocrine gland secretion represents the combined product of two distinct epithelial-cell populations, the acinar cell and the duct cell.

In addition to acini and ducts, exocrine glands contain a rich supply of nerves and blood vessels. Postganglionic **parasympathetic** and **sympathetic** fibers contribute to the autonomic regulation of secretion through the release of cholinergic, adrenergic, and peptide neurotransmitters that often bind to receptors on the acinar and duct cells. These *efferent* fibers also regulate blood flow. Both central and reflex pathways contribute to the neural regulation of exocrine secretion. The autonomic nerves also carry *afferent* pain fibers that are activated by glandular inflammation and trauma. The vasculature not only provides oxygen and nutrients for the gland but also carries the hormones that help to regulate secretion.

Acinar cells are specialized protein-synthesizing cells

Acinar cells—such as those in the pancreas (see [Fig. 43-1B](#)) and salivary glands (see [Fig. 43-10](#), below)—are polarized epithelial cells that are specialized for the production and export of large quantities of protein. Thus, the acinar cell is equipped with extensive rough endoplasmic reticulum. However, the most characteristic feature of the acinar cell is the abundance of electron-dense secretory granules at the apical pole of the cell. These granules are storage pools of secretory proteins, and they are poised to release their contents after stimulation of the cell by neurohumoral agents. The secretory granules of pancreatic acinar cells contain the mixture of zymogens and enzymes required for digestion. The secretory granules of salivary acinar cells contain either α -amylase (in the parotid gland) or mucins (in the sublingual glands). Secretory granules in the pancreas appear uniform, whereas those in the salivary glands often exhibit focal nodules of condensation within the granules known as *spherules*.

The pancreatic acinar cell has served as an important model for elucidating protein synthesis and export via the **secretory pathway** ([Fig. 43-2](#)). Synthesis of secretory proteins (see [pp. 34–35](#)) begins with the cellular uptake of amino acids and their incorporation into nascent proteins in the rough **endoplasmic reticulum (ER)**. Vesicular transport mechanisms then shuttle the newly synthesized proteins to the Golgi complex.

FIGURE 43-2 Movement of newly synthesized proteins through the secretory pathway. The four records in the graph show the time course of radiolabeled secretory proteins present in each compartment. (Data from Jamieson J, Palade G: *J Cell Biol* 34:597–615, 1967; and Jamieson J, Palade G: *J Cell Biol* 50:135–158, 1971.)

Within the **Golgi complex**, secretory proteins are segregated away from lysosomal enzymes. Most lysosomal enzymes require the mannose-6-phosphate receptor for sorting to the lysosome (see p. 40). However, the signals required to direct digestive enzymes into the secretory pathway remain unclear.

Secretory proteins exit the Golgi complex in **condensing vacuoles** or **immature secretory granules**. These large membrane-bound structures are acidic and maintain the lowest pH within the secretory pathway.

Maturation of the condensing vacuole to a secretory or zymogen granule is marked by condensation of the proteins within the vacuole and pinching off of membrane vesicles. The diameter of a **secretory (zymogen) granule** is about two thirds that of a condensing vacuole, and its content is more electron dense. Secretory proteins are stored in zymogen granules that are located in the apical region of the acinar cell. The bottom portion of Figure 43-2 shows the results of a pulse-chase experiment that follows the cellular itinerary of radiolabeled amino acids as they move sequentially through the four major compartments of the secretory pathway.

Exocytosis, the process by which secretory granules release their contents, is a complex series of

events that involves the movement of the granules to the apical membrane, fusion of these granules with the membrane, and release of their contents into the acinar lumen. Secretion is triggered by stimulation of cell-surface receptors by either hormones or neurotransmitters (neurohumoral stimulation). At the onset of secretion, the surface area of the apical plasma membrane transiently increases as much as 30-fold. Thereafter, activation of an apical endocytic pathway leads to retrieval of the secretory granule membrane for recycling and a decrease in the area of the apical plasma membrane back to its resting value. Thus, during the steady state of secretion, secretory granule membrane is simultaneously delivered to and retrieved from the apical membrane.

Before the exocytotic event, vacuolar-type H pumps (see pp. 118–119) in the vesicle membrane use the energy of ATP hydrolysis to transport H^+ from the cytosol to the lumen of the vesicle. This transport process sets up both a chemical gradient for H^+ (inside acid) and an electrical gradient (inside positive) across the vesicle membrane. Cl^- channels in the vesicle membrane can then allow Cl^- to flow into the vesicle lumen, in parallel with the H^+ , so that the overall process is HCl movement from cytosol to vesicle lumen. Water follows by osmosis. The above “secretion” of minute amounts of Cl^- into the secretory vesicle may contribute to the hydration of proteins within the granule before vesicle fusion. Furthermore, exocytosis of the vesicle contents may lead to a transient acidification of the acinar lumen and may modulate adjacent epithelial cells.

The cytoskeleton of the acinar cell plays an important role in the regulation of exocytosis. A component of the actin network appears to be required for delivery of the secretory granules to the apical region of the cell. A second actin network, located immediately below the apical membrane, acts as a barrier that blocks fusion of the granules with the apical plasma membrane. On stimulation, this second network reorganizes and then releases the blockade to permit the secretory granules to approach the apical plasma membrane. Fusion of the granules with the plasma membrane probably requires the interaction of SNAREs on secretory granules and the apical plasma membrane, as well as various other factors (see p. 37). After fusion, the granule contents enter the acinar lumen and move down the ducts into the gastrointestinal tract.

Duct cells are epithelial cells specialized for fluid and electrolyte transport

Pancreatic and salivary duct cells are polarized epithelial cells specialized for the transport of electrolytes across distinct apical and basolateral membrane domains. Duct epithelial cells contain specific membrane transporters and an abundance of mitochondria to provide energy for active transport, and they exhibit varying degrees of basolateral membrane infolding that increases the membrane surface area of pancreatic duct cells (see Fig. 43-1C) and salivary duct cells (see Fig. 43-10C). Although some duct cells contain prominent cytoplasmic vesicles, the synthetic machinery (i.e., ER and Golgi complex) of the duct cell is, in general, much less developed than that of the acinar cell.

Duct cells exhibit a considerable degree of morphological heterogeneity along the length of the ductal tree. At the junction between acinar and duct cells, and protruding into the pancreatic lumen, are small cuboidal epithelial cells known as centroacinar cells. These cells express very high levels of carbonic anhydrase (see p. 630) and presumably play a role in HCO_3^- secretion. The epithelial cells of the most proximal (intercalated) duct are squamous or low cuboidal, have an abundance of mitochondria, and tend to lack cytoplasmic vesicles. These features suggest that the primary function of these cells is fluid and electrolyte transport. Progressing distally, the cells become more cuboidal columnar and contain more

cytoplasmic vesicles and granules. These features suggest that these cells are capable of both transport of fluid and electrolytes and secretion of proteins. Functional studies indicate that the types of solute transport proteins within duct cells differ depending on the cell's location in the ductal tree.

Ion transport in duct cells is regulated by neurohumoral stimuli that act through specific receptors located on the basolateral membrane. As is the case for cells elsewhere in the body, duct cells can increase transcellular electrolyte movement either by activating individual transport proteins or by increasing the number of transport proteins in the plasma membrane.

Goblet cells contribute to mucin production in exocrine glands

In addition to acinar and duct cells, exocrine glands contain varying numbers of goblet cells. These cells secrete high-molecular-weight glycoproteins known as **mucins** (see [p. 874](#)). When hydrated, mucins form **mucus**. Mucus has several important functions, including lubrication, hydration, and mechanical protection of surface epithelial cells. Mucins also play an important immunological role by binding to pathogens and interacting with immune-competent cells. These properties may help to prevent infections. In the pancreas, mucin-secreting goblet cells are primarily found among the epithelial cells that line the large distal ducts. They can account for as many as 25% of the epithelial cells in the distal main pancreatic duct of some species. In the salivary gland, goblet cells are also seen in the large distal ducts, although in less abundance than in the pancreas. However, in many salivary glands, mucin is also secreted by acinar cells.

Pancreatic Acinar Cell

The acinar cell secretes digestive proteins in response to stimulation

To study secretion at the cellular level, investigators use enzymatically separated single acini (15 to 100 cells) or mechanically dissected single lobules (250 to 1000 cells). The measure of secretion is the release of digestive proteins into the incubation medium. The amount released over a fixed time interval is expressed as a percentage of the total content at the outset of the experiment. Because amylase is released in a fully active form, it is common to use the appearance of amylase activity as a marker for secretion by acinar cells.

When the acinar cells are in an unstimulated state, they secrete low levels of digestive proteins via a **constitutive secretory pathway**. Acinar cells stimulated by neurohumoral agents secrete proteins via a **regulated pathway**. Regulated secretion by isolated acinar cells in vitro is detected within 5 minutes of stimulation and is energy dependent. During a 30- to 60-minute stimulation period, acinar cells typically secrete 5 to 10 times more amylase than with constitutive release. However, during this period of regulated secretion, the cells typically secrete only 10% to 20% of the digestive proteins stored in their granules. Moreover, acinar cells are able to increase their rate of protein synthesis to replenish their stores.

The acinar cell exhibits two distinct patterns of regulated secretion: monophasic and biphasic ([Fig. 43-3A](#)). Increasing levels of an agonist that generates a *monophasic* dose-response relationship (e.g., gastrin-releasing peptide [GRP]) causes secretion to reach a maximal level that does not fall with higher concentrations of the agent. In contrast, increasing levels of a secretagogue that elicits a *biphasic* dose-response relationship (e.g., cholecystokinin and carbachol) causes secretion to reach a maximal level that subsequently diminishes. As discussed below, this biphasic response may reflect the presence of functionally separate high-affinity and low-affinity receptors, and is related to the pathogenesis of acute pancreatitis. [N43-1](#)

N43-1

Acute Pancreatitis

Contributed by Fred Gorelick

Acute pancreatitis is an inflammatory condition that may cause extensive local damage to the pancreas as well as compromise the function of other organs such as the lungs. The most common factors that initiate human acute pancreatitis are alcohol ingestion and gallstones. However, other insults may also precipitate acute pancreatitis. Hypertriglyceridemia, an inherited disorder of lipid metabolism, is one such culprit. Less commonly, toxins that increase ACh levels, such as cholinesterase inhibitors (some insecticides) or the sting of scorpions found in the Caribbean and South and Central America, may lead to pancreatitis. Supraphysiological levels of ACh probably cause pancreatitis by overstimulating the pancreatic acinar cell.

Experimental models of pancreatitis suggest a primary defect in protein processing and acinar cell secretory function. More than 100 years ago, it was found that treating animals with doses of ACh that are 10 to 100 times greater than those that elicit maximal enzyme secretion causes “hyperstimulation” pancreatitis. The same type of injury can be generated by CCK. The injury in this model appears to be linked to two events within the acinar cell: (1) Zymogens, in particular proteases, are pathologically processed within the acinar cell into active forms. In this model, the protective mechanisms outlined in Table 43-3 are overwhelmed, and active enzymes are generated within the acinar cell. (2) Acinar cell secretion is inhibited, and the active enzymes are retained within the cell. Although premature activation of zymogens is probably an important step in initiating pancreatitis, other events are important for perpetuating injury, including inflammation, induction of apoptosis, vascular injury, and occlusion that results in decreased blood flow and reduced tissue oxygenation (ischemia).

Knowledge of the mechanisms of acute pancreatitis may lead to effective therapies. In experimental models, administration of serine protease inhibitors that block the activation of pancreatic zymogens

improves the course of the acute pancreatitis. In some clinical forms of pancreatitis, prophylactic administration of the protease inhibitor gabexate appears to reduce the severity of the disease.

Acetylcholine and cholecystokinin mediate the regulated secretion of proteins by pancreatic acinar cells

Although at least a dozen different receptors are present on the plasma membrane of the pancreatic acinar cell, the most important in regulating protein secretion is the **M₃ muscarinic acetylcholine (ACh) receptor** (see [p. 341](#)), located on the basolateral membrane and also found in many glandular tissues.

Two closely related receptors for **cholecystokinin (CCK)** are distinguished by their structure, affinity for ligands, and tissue distribution (see [p. 867](#)). Although both CCK receptors may be activated by CCK or gastrin, the **CCK₁ receptor** (previously known as CCK_A, encoded by the *CCK1R* gene) has a much higher affinity for CCK than for gastrin, whereas the **CCK₂ receptor** (previously known as CCK_B, encoded by *CCK2R* gene) has approximately equal affinities for CCK and gastrin. In some species, both forms of the CCK receptor are present on the acinar cell. Although CCK₁ receptors are present in human acinar cells, their function is unknown. 🍷N43-2

N43-2

Affinity States of the Cholecystokinin Receptors

Contributed by Fred Suchy

An important feature of both CCK receptors is their ability to exist in both a high-affinity and a low-affinity state. Low (picomolar) concentrations of CCK activate the high-affinity forms of the CCK receptors and stimulate secretion. Conversely, supraphysiological (10- to 100-fold higher) concentrations of CCK activate the low-affinity forms of the receptors and inhibit secretion. These two affinity states (i.e., activated by different concentrations of CCK) of each of the two CCK receptors generate distinct second-messenger signaling patterns. It is likely that under physiological conditions, only the high-affinity states of the CCK or muscarinic receptor are activated. Stimulation of the lower-affinity states by supraphysiological concentrations of either CCK or ACh not only inhibits enzyme secretion but also may injure the acinar cell. 🍷N43-1

M₃ and CCK receptors have many similarities: both are basolateral, both are linked to the Gα_q heterotrimeric G protein, both use the phospholipase C (PLC)/Ca²⁺ signal-transduction pathway (see [pp. 58–60](#)), and both lead to increased enzyme secretion from the acinar cell.

Numerous other receptors—including those for gastrin-releasing peptide (GRP; see [p. 868](#)), calcitonin gene-related peptide (CGRP; see [p. 1067](#)), insulin (see [pp. 1035–1050](#)), secretin (see [pp. 886–887](#)), somatostatin (see [pp. 993–994](#)), and vasoactive intestinal peptide (VIP; see [Table 41-1](#))—are also found on the pancreatic acinar cell. Although these other receptors may also play a role in regulating secretion, protein synthesis, growth, and transformation, their precise physiological functions remain to be clearly defined.

Activation of receptors that stimulate different signal-transduction pathways may lead to an enhanced secretory response. For example, as shown in [Figure 43-3B](#), simultaneous stimulation of the high-affinity CCK receptor (which acts via [Ca²⁺]_i) and the VIP receptor (which acts via cAMP) generates an additive

effect on secretion. Alternatively, acinar cells that have previously been stimulated may become temporarily refractory to subsequent stimulation. This phenomenon is known as *desensitization*.

Ca²⁺ is the major second messenger for the secretion of proteins by pancreatic acinar cells

Ca²⁺

Much of the pioneering work on the role of intracellular Ca²⁺ in cell signaling has been performed on the pancreatic acinar cell (Fig. 43-4A). Generation of a cytosolic Ca²⁺ signal is a complex summation of cellular events (see p. 60). Even when the acinar cell is in the resting state, the cytosolic free Ca²⁺ level ([Ca²⁺]_i) oscillates slowly. Maximal stimulatory (i.e., physiological) concentrations of CCK or ACh increase the frequency of the oscillations (see Fig. 43-4B) but have less effect on the amplitude. This increase in the frequency of [Ca²⁺]_i oscillations is required for protein secretion by acinar cells. In contrast, a supramaximal (i.e., hyperstimulatory) concentration of CCK or ACh generates a sudden [Ca²⁺]_i spike that is 2 to 10 times greater than that seen with physiological stimulation and eliminates further [Ca²⁺]_i oscillations. This [Ca²⁺]_i spike and the subsequent absence of oscillations are associated with an inhibition of secretion that appears to be mediated by disruption of the cytoskeletal components that are required for secretion.

A SIGNAL-TRANSDUCTION PATHWAYS

B CHANGES IN INTRACELLULAR $[Ca^{2+}]_i$

FIGURE 43-4 Stimulation of protein secretion from the pancreatic acinar cell. **A**, The pancreatic acinar cell has at least two pathways for stimulating the insertion of zymogen granules and thus releasing digestive enzymes. **B**, Applying a physiological dose of CCK (i.e., 10 pM) triggers a series of $[Ca^{2+}]_i$ oscillations. However, applying a supraphysiological concentration of CCK (1 nM)—a dose that could initiate pancreatitis—elicits a single large $[Ca^{2+}]_i$ spike, halts the oscillations, and decreases amylase secretion. Recall from [Figure 43-3](#) that high levels of CCK also are less effective in causing amylase secretion. AC, adenylyl cyclase; CaM, calmodulin; PIP₂, phosphatidylinositol 4,5-bisphosphate; PK, protein kinases other than PKA and PKC; PP, phosphoprotein phosphatases. (**B**, Data from Tsunoda Y, Stuenkel EL, Williams JA: Characterization of sustained $[Ca^{2+}]_i$ increase in pancreatic acinar cells and its relation to amylase secretion. *Am J Physiol* 259:G792–G801, 1990.)

cAMP

Secretin, VIP, and CCK increase cAMP production and thus activate protein kinase A (PKA) in pancreatic acinar cells (see [Fig. 43-4A](#)). Low concentrations of CCK cause a transient stimulation of PKA, whereas supraphysiological concentrations of CCK cause a much more prominent and prolonged increase in $[cAMP]_i$ and PKA activity. One of the effects of cAMP is to enhance secretion that has been stimulated by activation of Ca^{2+} -dependent pathways (see [Fig. 43-3B](#)). **N43-3** ACh has little, if any, effect on the cAMP signaling pathway.

N43-3

Effect of cAMP on the EPAC/RAP1 Pathway

Contributed by Fred Gorelick, Emile Boulpaep, Walter Boron

cAMP can also activate the EPAC/RAP1 pathways, but the physiologic consequences of such activation have not been defined. **RAP1** is a small Ras-like GTPase. **EPAC** is the guanine nucleotide exchange factor (GEF) for RAP1 (see p. 56).

Effectors

As illustrated in [Figure 43-4A](#), the most important effectors of intracellular second messengers are the

protein kinases. Stimulation of CCK and muscarinic receptors on the acinar cell leads to the generation of similar Ca^{2+} signals and activation of calmodulin-dependent protein kinases (see p. 60) and members of the protein kinase C (PKC) family (see pp. 60–61). Activation of secretin or VIP receptors increases $[\text{cAMP}]_i$ and thus activates PKA. These second messengers probably also activate phosphoprotein phosphatases, as well as other protein kinases not depicted in Figure 43-4A. Some protein targets of activated kinases and phosphatases in the pancreatic acinar cell are involved in regulating secretion, whereas others mediate protein synthesis, growth, transformation, and cell death.

In addition to proteins, the pancreatic acinar cell secretes a plasma-like fluid

Besides secreting proteins, acinar cells in the pancreas secrete an isotonic, plasma-like fluid (Fig. 43-5). This NaCl-rich fluid hydrates the dense, protein-rich material that the acinar cells secrete. The fundamental transport event is the secretion of Cl^- across the apical membrane.  **N43-4** For transcellular (plasma-to-lumen) movement of Cl^- to occur, Cl^- must move into the cell across the basolateral membrane. As in many other Cl^- -secreting epithelial cells (see p. 139), in the acinar cell basolateral Cl^- uptake occurs via an Na/K/Cl cotransporter. The Na-K pump generates the Na^+ gradient that energizes the Na/K/Cl cotransporter. The K^+ entering through the Na-K pump and via the Na/K/Cl cotransporter exits through K^+ channels that are also located on the basolateral membrane. Thus, a pump, a cotransporter, and a channel are necessary to sustain the basolateral uptake of Cl^- into the acinar cell.

FIGURE 43-5 Stimulation of isotonic NaCl secretion by the pancreatic acinar cell. Both ACh and CCK stimulate NaCl secretion, probably through phosphorylation of basolateral and apical ion channels.

N43-4

Cl⁻ Secretion into Pancreatic Secretory Vesicles

Contributed by Fred Gorelick

As we have seen in the text (see p. 882), the secretory vesicles in the pancreatic acinar cell fuse with the apical membrane in the process of exocytosis. In the process, these cells release their protein into the lumen of the acinus.

Before the exocytotic event, these secretory vesicles, vacuolar-type H pumps in the vesicle membrane, use the energy of ATP hydrolysis to transport H^+ from the cytosol to the lumen of the vesicle. This transport process sets up both a chemical gradient for H^+ (inside acid) and an electrical gradient (inside positive) across the vesicle membrane. Cl^- channels in the vesicle membrane can then allow Cl^- to flow into the vesicle lumen, in parallel with the H^+ , so that the overall process is HCl movement from cytosol to vesicle lumen. Water follows by osmosis.

The above “secretion” of minute amounts of Cl^- into the secretory vesicle may contribute to the hydration of proteins within the granule before vesicle fusion.

The rise in $[\text{Cl}^-]_i$ produced by basolateral Cl^- uptake drives the secretion of Cl^- down its electrochemical gradient through channels in the apical membrane. As the transepithelial voltage becomes

more lumen negative, Na^+ moves through the cation-selective paracellular pathway (i.e., tight junctions) to join the Cl^- secreted into the lumen. Water also moves through this paracellular pathway, as well as via aquaporin water channels on the apical and basolateral membranes. Therefore, the net effect of these acinar cell transport processes is the production of an isotonic, NaCl -rich fluid that accounts for ~25% of total pancreatic fluid secretion.

Like the secretion of protein by acinar cells, secretion of fluid and electrolytes is stimulated by secretagogues that raise $[\text{Ca}^{2+}]_i$. In the pancreas, activation of muscarinic receptors by cholinergic neural pathways and activation of CCK receptors by humoral pathways increase the membrane conductance of the acinar cell. A similar effect is seen with GRP. Apical membrane Cl^- channels and basolateral membrane K^+ channels appear to be the effector targets of the activated Ca^{2+} signaling pathway. Phosphorylation of these channels by Ca^{2+} -dependent kinases is one likely mechanism that underlies the increase in open channel probability that accompanies stimulation.

Pancreatic Duct Cell

The pancreatic duct cell secretes isotonic NaHCO_3

The principal physiological function of the pancreatic duct cell is to secrete an HCO_3^- -rich fluid that alkalinizes and hydrates the protein-rich primary secretions of the acinar cell. The apical step of transepithelial HCO_3^- secretion (Fig. 43-6) is mediated in part by a **Cl-HCO_3 exchanger**, a member of the SLC26 family (see Table 5-4) that secretes intracellular HCO_3^- into the duct lumen. Luminal Cl^- must be available for this exchange process to occur. Although some luminal Cl^- is present in the primary secretions of the acinar cell, anion channels on the apical membrane of the duct cell provide additional Cl^- to the lumen in a process called *Cl^- recycling*. The most important of these anion channels is the **cystic fibrosis transmembrane conductance regulator (CFTR)**, a cAMP-activated Cl^- channel that is present on the apical membrane of pancreatic duct cells (see p. 120, Box 43-1). Cl^- recycling is facilitated by the coactivation of CFTR and SLC26 exchangers through direct protein-protein interactions. In some species, such as the rat and mouse, pancreatic duct cells also contain a Ca^{2+} -activated Cl^- channel on the apical membrane; this channel also provides Cl^- to the lumen for recycling. Apical Cl^- channels, including CFTR, may also directly serve as conduits for HCO_3^- movement from the duct cell to the lumen.

FIGURE 43-6 HCO_3^- secretion by the cells of the pancreatic duct. Secretin, via cAMP, phosphorylates and opens CFTR Cl^- channels. Exit of Cl^- through apical Cl^- channels depolarizes the basolateral membrane, generating the electrical gradient favoring electrogenic $\text{Na}^+/\text{HCO}_3^-$ cotransport. CaM, calmodulin.

Box 43-1

Cystic Fibrosis

Cystic fibrosis (CF) is the most common lethal genetic disease in people of European descent, in whom it affects ~1 in 2000. Approximately 1 in 20 white individuals carry the autosomal recessive genetic defect. Clinically, CF is characterized by progressive pancreatic and pulmonary insufficiency resulting from the complications of organ obstruction by thickened secretions. The disease results from mutations in the *CF* gene (located on chromosome 7) that alter the function of its product, CFTR (see Fig 5-10). **CFTR** is a cAMP-activated Cl^- channel that is present on the apical plasma membrane of many epithelial cells. In the pancreas, CFTR has been localized to the apical membrane of duct cells, where it functions to provide the luminal Cl^- for $\text{Cl}^-/\text{HCO}_3^-$ exchange (see Fig. 43-6).

Most *CF* gene mutations result in the production of a CFTR protein that is abnormally folded after its

synthesis in the ER. The ER quality-control system recognizes these molecules as defective, and most mutant CFTR molecules are prematurely degraded before they reach the plasma membrane. Subsequent loss of CFTR expression at the plasma membrane disrupts the apical transport processes of the duct cell and results in decreased secretion of HCO_3^- and water by the ducts. As a result, protein-rich primary (acinar) secretions thicken within the duct lumen and lead to ductal obstruction and eventual tissue destruction. Pathologically, the ducts appear dilated and obstructed, and fibrotic tissue and fat gradually replace the pancreatic parenchyma—hence the original designation of cystic fibrosis. The subsequent deficiency of pancreatic enzymes that occurs leads to the maldigestion of nutrients and thus the excretion of fat in the stool (steatorrhea) by patients with CF. Before the development of oral enzyme replacement therapy, many patients with CF died of complications of malnutrition.

Now, the major cause of morbidity and mortality in CF is progressive pulmonary disease. The pathophysiology of lung disease in CF is more complex than that of pancreatic disease. A major finding is that the airway mucus is thick and viscous as a result of insufficient fluid secretion into the airway lumen. The pulmonary epithelium probably both secretes fluid (in a mechanism that requires CFTR) and absorbs fluid (in a mechanism that requires apical ENaC Na^+ channels). In CF, the reduced activity of CFTR shifts the balance more toward absorption, and a thick mucous layer is generated that inhibits the ciliary clearance of foreign bodies (see p. 600). The results are an increased rate and severity of infections and thus inflammatory processes that contribute to the destructive process in the lung.

Pulmonary symptoms most commonly bring the patient to the physician's attention in early childhood. Cough and recurrent respiratory infections that are difficult to eradicate are usually the first indications of the illness. The child's sputum is particularly thick and viscous. Pulmonary function progressively declines over the ensuing years, and patients may also experience frequent and severe infections, atelectasis (collapse of lung parenchyma), bronchiectasis (chronic dilatation of the bronchi), and recurrent pneumothoraces (air in the intrapleural space). In addition to the pancreatic and pulmonary manifestations, CF also causes a characteristic increase in the $[\text{NaCl}]$ of sweat, which is intermediate in heterozygotes. Pharmacological approaches that bypass the Cl^- -transport defect in a lung with CF are currently being evaluated, and considerable effort is being directed toward the development of in vivo gene-transfer techniques to correct the underlying genetic defect.

The intracellular HCO_3^- that exits the duct cell across the apical membrane arises from two pathways. **N43-5** The first is direct uptake of HCO_3^- via an electrogenic Na/HCO_3 cotransporter (NBCe1-B or SLC4A4; see p. 122), which presumably operates with an $\text{Na}^+/\text{HCO}_3^-$ stoichiometry of 1 : 2. The second mechanism is the generation of intracellular HCO_3^- from CO_2 and OH^- , catalyzed by carbonic anhydrase (see p. 630). The OH^- in this reaction, along with H^+ , is derived from H_2O . Thus, the H^+ that accumulates in the cell must be extruded across the basolateral membrane. One mechanism of H^+ extrusion is Na-H exchange. The second mechanism for H^+ extrusion across the basolateral membrane, at least in some species, is an ATP-dependent H pump. Pancreatic duct cells contain acidic intracellular vesicles (presumably containing vacuolar-type H pumps) that are mobilized to the basolateral membrane of the cell after stimulation by secretin, a powerful secretagogue (see below). Indeed, H pumps are most active under conditions of neurohumoral stimulation. Thus, three basolateral transporters directly or indirectly provide the intracellular HCO_3^- that pancreatic duct cells need for secretion: (1) the electrogenic Na/HCO_3 cotransporter, (2) the Na-H exchanger, and (3) the H pump. The physiological importance of these three acid-base transporters in humans has yet to be fully established. The pancreatic duct cell

accounts for ~75% of total pancreatic fluid secretion.

N43-5

HCO_3^- Secretion by the Pancreatic Duct

Contributed by Emile Boulpaep, Walter Boron

The current model for HCO_3^- secretion by the pancreatic duct is very similar to that outlined in Figure 43-6. However, we can now add some important details about the apical step of HCO_3^- secretion. The Cl^- - HCO_3^- exchanger at the apical membrane is a member of the SLC26 family (Mount and Romero, 2004)—previously known as the SAT family—specifically, SLC26A6 (also known as CFEX). We now appreciate that SLC26A6, which is capable of exchanging several different anions (e.g., Cl^- , HCO_3^- , oxalate), is electrogenic (Jiang et al, 2002). When mediating Cl^- - HCO_3^- exchange, it appears that SLC26A6 exchanges two HCO_3^- ions for every Cl^- ion. This stoichiometry would strongly favor the efflux of HCO_3^- across the apical membrane of the pancreatic duct cell.

As noted in the text, the Cl^- that enters the cell via SLC26A exits the cell via apical Cl^- channels, principally CFTR. Interestingly, it appears that an interaction between the SLC26A6 protein and CFTR greatly increases the open probability of CFTR (Ko et al, 2004).

Another member of the SLC26 family—SLC26A3—also is present in the apical membrane of pancreatic duct cells. SLC26A3 is also electrogenic but has a stoichiometry opposite to that of SLC26A6, two Cl^- ions for every HCO_3^- . This transporter would extrude Cl^- (and take up HCO_3^-) from the duct cell across the apical membrane. Its physiological function might be to reabsorb HCO_3^- at times when the duct is not secreting HCO_3^- or to contribute to the recycling of Cl^- when the duct is secreting HCO_3^- .

Secretin (via cAMP) and ACh (via Ca^{2+}) stimulate HCO_3^- secretion by pancreatic ducts

When stimulated, the epithelial cells of the pancreatic duct secrete an isotonic NaHCO_3 solution. The duct cells have receptors for secretin, ACh, GRP (all of which stimulate HCO_3^- secretion), and substance P (which inhibits it). CCK may also modulate ductular secretory processes.

Secretin is the most important humoral regulator of ductal HCO_3^- secretion. Activation of the **secretin receptor** on the duct cell stimulates adenylyl cyclase, which raises $[\text{cAMP}]_i$. Because forskolin and cAMP analogs stimulate ductal HCO_3^- secretion, the secretin response has been attributed to its effect on

[cAMP]_i and activation of PKA. However, even low concentrations of secretin that do not measurably increase [cAMP]_i can stimulate HCO_3^- secretion. This observation suggests that the secretin response may be mediated by (1) unmeasurably small increases in total cellular cAMP, (2) cAMP increases that are localized to small intracellular compartments, or (3) activation of alternative second-messenger pathways. Secretin acts by stimulating the apical CFTR Cl^- channel and the basolateral Na/HCO_3 cotransporter without affecting the Na-H exchanger.

HCO_3^- secretion is also regulated by the parasympathetic division of the autonomic nervous system (see pp. 341–342). The postganglionic parasympathetic neurotransmitter **ACh**, acting through **muscarinic receptors** on the duct cell, increases $[\text{Ca}^{2+}]_i$ and activates Ca^{2+} -dependent protein kinases (PKC and the calmodulin-dependent protein kinases). The ACh effect is inhibited by atropine. Although ductular secretion in the rat is also stimulated by **GRP**, the second messenger mediating this effect is not known. In the duct cell, unlike in the acinar cell, GRP does not increase $[\text{Ca}^{2+}]_i$. GRP also does not raise $[\text{cAMP}]_i$.

In the rat, both basal and stimulated ductular HCO_3^- secretion is inhibited by **substance P**. The second messenger mediating this effect is also unknown. Because substance P inhibits HCO_3^- secretion regardless of whether the secretagogue is secretin, ACh, or GRP—which apparently act via three different signal-transduction mechanisms—substance P probably acts at a site that is distal to the generation of second messengers, such as by inhibiting the $\text{Cl}-\text{HCO}_3$ exchanger.

Apical membrane chloride channels are important sites of neurohumoral regulation

In the regulation of pancreatic duct cells by the neurohumoral mechanisms just discussed, the only effector proteins that have been identified as targets of the protein kinases and phosphatases are the apical Cl^- channels, basolateral K^+ channels, and Na/HCO_3 cotransporter. CFTR functions as a low-conductance apical Cl^- channel (see p. 120). CFTR has nucleotide-binding domains that control channel opening and closing as well as a regulatory domain with multiple potential PKA and PKC phosphorylation sites. Neurohumoral agents that control fluid and electrolyte secretion by the pancreatic duct cells act at this site. Agents that activate PKA are the most important regulators of CFTR function. PKC activation enhances the stimulatory effect of PKA on CFTR Cl^- transport, but alone it appears to have little direct effect on CFTR function. Thus, the CFTR Cl^- channel is regulated by ATP through two types of mechanisms: interaction with the nucleotide-binding domains and protein phosphorylation (see Fig. 5-10).  **N5-16**

In addition to CFTR, pancreatic duct cells in some species have Ca^{2+} -activated Cl^- channels (CaCCs) on the apical membrane. Not only does Ca^{2+} *directly* stimulate CaCCs, but cAMP may *indirectly* stimulate CaCCs by stimulating CFTR, which somehow promotes ATP efflux. Luminal ATP would then bind to an apical purinergic receptor, leading to the influx of Ca^{2+} and thus activation of CaCCs in an autocrine/paracrine fashion (see Fig. 43-6).

In rat pancreatic duct cells, Ca^{2+} -sensitive basolateral K^+ channels seem to be targets of neurohumoral stimulation. Activators of the cAMP pathway stimulate phosphorylation by PKA, thus enhancing the responsiveness of these channels to $[\text{Ca}^{2+}]_i$ and increasing their probability of being open.

Pancreatic duct cells may also secrete glycoproteins

Although the primary function of the pancreatic duct cells is to secrete HCO_3^- and water, these cells may also synthesize and secrete various high-molecular-weight proteoglycans. Some of these proteins are structurally distinct from the mucin that is produced by the specialized goblet cells in the duct. Unlike the proteins that are secreted by acinar cells, the glycoproteins synthesized in duct cells are not accumulated in large secretion granules. Rather, they appear to be continuously synthesized and secreted from small cytoplasmic vesicles. Secretin increases the secretion of glycoproteins from these cells, but this action appears to result from stimulation of glycoprotein synthesis, rather than from stimulation of vesicular transport or exocytosis itself. The role of these proteins may be to protect against protease-mediated injury to mucosal cells.

Composition, Function, and Control of Pancreatic Secretion

Pancreatic juice is a protein-rich, alkaline secretion

Humans produce ~1.5 L of pancreatic fluid each day. The pancreas has the highest rates of protein synthesis and secretion of any organ in the body. Each day the pancreas delivers between 15 and 100 g of protein into the small intestine. The level of pancreatic secretion is determined by a balance between factors that stimulate secretion and those that inhibit it.

The human pancreas secretes >20 proteins, some of which are listed in [Table 43-1](#). Most of these proteins are either inactive digestive enzyme precursors—**zymogens**—or active digestive enzymes. The secretory proteins responsible for digestion can be classified according to their substrates: **proteases** hydrolyze proteins, **amylases** digest carbohydrates, **lipases** and phospholipases break down lipids, and **nucleases** digest nucleic acids. The functions of other secretory proteins—such as glycoprotein II (GP2), lithostathine, and pancreatitis-associated protein—are less well defined.

TABLE 43-1
Secretory Products of the Pancreatic Acinar Cell

	FUNCTION
Zymogens	
Trypsinogens	Digestion
Chymotrypsinogen	Digestion
Proelastase	Digestion
Proprotease E	Digestion
Procarboxypeptidase A	Digestion
Procarboxypeptidase B	Digestion
Active Enzymes	
α-Amylase	Digestion
Carboxyl ester lipase	Digestion
Lipase	Digestion
RNAase	Digestion
DNAase	Digestion
Colipase	Digestion
Others	
Trypsin inhibitor	Block of trypsin activity
Lithostathine	Constituent of protein plugs
Glycoprotein 2 (GP2)	Formation of protein plugs
Pancreatitis-associated protein	Pancreatic growth, bacteriostasis
Na ⁺ , Cl ⁻ , H ₂ O	Hydration of secretions
Ca ²⁺	Stone formation in pancreatitis

GP2 is an unusual protein with an N-terminal glycosylphosphatidylinositol moiety that links it to the inner leaflet of the zymogen granule membrane. GP2 has been implicated in the regulation of endocytosis. After exocytosis, luminal cleavage of the GP2 linkage to the zymogen granule membrane seems to be necessary for proper trafficking of the zymogen granule membrane back into the cell from the plasma membrane. Under certain circumstances, the released GP2—and also **lithostathine**—may form protein aggregates in the pancreatic juice. This finding is not surprising inasmuch as GP2 is structurally related to the Tamm-Horsfall protein, which is secreted by the renal thick ascending limb (see [pp. 729–730](#)). The tendency of GP2 and lithostathine to form aggregates may have detrimental clinical consequences in that both proteins have been implicated in the pathological formation of protein plugs that can obstruct the lumen of acini in patients with cystic fibrosis (see [Box 43-1](#)) and chronic pancreatitis.

Pancreatitis-associated protein is a secretory protein that is present in low concentrations in the normal state. However, levels of this protein may increase up to several hundred-fold during the early phases of pancreatic injury. Pancreatitis-associated protein is a bacteriostatic agent that may help to prevent pancreatic infection during bouts of pancreatitis.

Pancreatic juice is also rich in Ca^{2+} and HCO_3^- . **Calcium** concentrations are in the millimolar range inside the organelles of the secretory pathway of the acinar cells, but lower in pancreatic secretions after dilution by Ca^{2+} -free duct secretions. These high levels of Ca^{2+} in the vesicles may be required to induce the aggregation of secretory proteins and to direct them into the secretory pathway. **Bicarbonate** secreted by duct cells neutralizes the acidic gastric secretions that enter the duodenum and allows digestive enzymes to function properly; HCO_3^- also facilitates the micellar solubilization of lipids and mucosal cell function. The $[\text{HCO}_3^-]$ in pancreatic juice increases with increases in the secretory flow rate (Fig. 43-7). In the unstimulated state, the flow is low, and the electrolyte composition of pancreatic juice closely resembles that of blood plasma. As the gland is stimulated and flow increases, exchange of Cl^- in the pancreatic juice for HCO_3^- across the apical membrane of the duct cells produces a secretory product that is more alkaline (pH of ~ 8.1) and has a lower $[\text{Cl}^-]$. Concentrations of Na^+ or K^+ , however, are not significantly altered by changes in flow.

FIGURE 43-7 Flow dependence of the electrolyte composition of pancreatic fluid. Increasing secretin levels not only increases the secretory rate, but also changes the composition of the fluid. (Data from Case RM, Harper AA, Scratcherd T: The secretion of electrolytes and enzymes by the pancreas of the anaesthetized cat. *J Physiol* 201:335–348, 1969.)

In the fasting state, levels of secreted pancreatic enzymes oscillate at low levels

Pancreatic secretion is regulated in both the fasted and fed states. Under basal conditions, the pancreas releases low levels of pancreatic enzymes (Fig. 43-8). However, during the digestive period (eating a meal), pancreatic secretion increases in sequential phases to levels that are 5- to 20-fold higher than basal levels. The systems that regulate secretion appear to be redundant; if one system fails, a second takes its place. These mechanisms ensure that the release of pancreatic enzymes corresponds to the amount of food in the small intestine.

FIGURE 43-8 Time course of pancreatic secretion during fasting and feeding. The interdigestive output of secretory products (e.g., trypsin) by the pancreas varies cyclically and in rough synchrony with the four phases of motor activity (migrating motor complexes) of the small intestine, shown by the colored vertical bands. Feeding causes a massive and sustained increase in trypsin release and switches small-intestinal motility to the fed state. (Data from DiMagno EP, Layer P: In Go VLW, DiMagno EP, Gardner JD, et al [eds]: *The Pancreas: Biology, Pathobiology and Disease*, 2nd ed. New York, Raven Press, pp 275–300, 1993.)

Like other organs in the upper gastrointestinal tract, the pancreas has a basal rate of secretion even when food is not being eaten or digested. During this **interdigestive (fasting) period**, pancreatic secretions vary cyclically and correspond to sequential changes in the motility of the small intestine (see p. 861). Pancreatic secretion is minimal when intestinal motility is in its quiescent phase (phase I); biliary and gastric secretions are also minimal at this time. As duodenal motility increases (phase II), so does pancreatic secretion. During the interdigestive period, enzyme secretion is maximal when intestinal motility—the migrating motor complexes (MMCs; see Fig 41-6)—is also maximal (phase III). However, even this maximal interdigestive secretory rate is only 10% to 20% of that stimulated by a meal. The peak phases of interdigestive intestinal motor activity and pancreatic secretory activity are followed by a declining period (phase IV). *Fluid and electrolyte secretion* rates during the interdigestive phase are usually <5% of maximum levels.

The cyclic pattern of interdigestive pancreatic secretion is mediated by intrinsic and extrinsic mechanisms. The predominant mechanism of pancreatic regulation is through **parasympathetic** pathways. Telenzepine, an antagonist of the M₁ muscarinic ACh receptor, reduces interdigestive enzyme secretion by >85% during phases II and III. Although cholinergic pathways are the major regulators of interdigestive pancreatic secretion, CCK and adrenergic pathways also play a role. CCK appears to stimulate pancreatic enzyme secretion during phases I and II. In contrast, basal **α-adrenergic** tone appears to suppress interdigestive pancreatic secretion. Although human and canine pancreas denervated during transplantation exhibits cyclic secretion, this secretion is no longer synchronous with duodenal motor activity. These observations support a role for the autonomic nervous system in regulating basal (resting) pancreatic secretion.

CCK from duodenal I cells stimulates acinar enzyme secretion, and secretin from S cells stimulates HCO_3^- and fluid secretion by ducts

CCK plays a central role in regulating pancreatic secretion. CCK is released from neuroendocrine cells (**I cells**; see Table 41-1) present in the duodenal mucosa (see Fig. 43-4). In response to a meal, plasma CCK levels increase 5- to 10-fold within 10 to 30 minutes.

The most potent stimulator of CCK release from I cells is **lipid** in the duodenal lumen. Protein digestive products (i.e., peptones, amino acids) also increase CCK release, but carbohydrate and acid have little effect. CCK secretion may also be stimulated by **CCK-releasing factors**, which are peptides released by mucosal cells of the duodenum or secreted by the pancreas. The level of these releasing factors may reflect a balance between the relative amounts of nutrients and digestive enzymes that are present in the gut lumen at any one time, so the level of the factors reflects the digestive milieu of the duodenum. In the fasting state, luminal CCK-releasing factors are degraded by digestive enzymes that accompany basal pancreatic secretion, so little releasing factor remains to stimulate the I cells. However, during a meal, the digestive enzymes are diverted to the digestion of ingested nutrients entering the gut lumen, and the CCK-releasing factors are spared degradation. Hence, the relative level of proteins to proteases in the small intestine determines the amount of CCK-releasing factor available to drive CCK release and thus pancreatic secretion.

Three lines of evidence show that CCK is a physiological mediator of pancreatic protein secretion: (1) CCK levels increase in the serum in response to a meal, (2) administration of exogenous CCK at the same levels produced by a meal stimulates pancreatic protein secretion to higher levels than those generated by a meal (the meal may also stimulate the release of inhibitory factors in addition to CCK), and (3) a specific CCK inhibitor reduces pancreatic protein secretion by >50%.

CCK may act on the acinar cell through both direct and indirect pathways: it can *directly* stimulate enzyme secretion through a CCK₁ receptor on the acinar cell (see Fig. 43-4), and it may *indirectly* stimulate enzyme secretion by activating the parasympathetic (cholinergic) nervous system. However, whether human acinar cells have CCK₁ receptors remains unclear. As we see below (see pp. 890–892), the parasympathetic pathway plays a major role in mediating the intestinal phase of pancreatic secretion. Vagal stimulation can drive pancreatic secretion to nearly maximum levels. Atropine, an antagonist of muscarinic ACh receptors (see pp. 341–342), reduces the secretion of enzymes and HCO_3^- during the intestinal phase of a meal. Atropine also inhibits secretion in response to stimulation by physiological levels of exogenous CCK. Together, these findings suggest that CCK somehow stimulates the

parasympathetic pathway, which in turn stimulates muscarinic receptors on the acinar cell but may have little direct effect on human acinar cells.

Like CCK, **GRP**—which is structurally related to bombesin—may also be a physiological regulator of pancreatic enzyme secretion. Stimulation of acinar cells with GRP leads to enzyme secretion. In contrast to the hormone CCK, the major source of GRP appears to be the vagal nerve terminals.

Secretin is the most potent humoral stimulator of fluid and HCO_3^- secretion by the pancreas (see [Fig. 43-6](#)). Secretin is released from neuroendocrine cells (S cells) in the mucosa of the small intestine in response to duodenal acidification and, to a lesser extent, bile acids and lipids. To stimulate secretin secretion, duodenal pH must fall to <4.5 . Like CCK levels, secretin levels increase after the ingestion of a meal. However, when these levels are reached experimentally by administration of exogenous secretin, pancreatic HCO_3^- secretion is less than that generated by a meal. These findings suggest that secretin is acting in concert with CCK, ACh, and other agents to stimulate HCO_3^- secretion.

In addition to hormones of intestinal origin, **insulin** and other hormones secreted by the islets of Langerhans within the pancreas (see [p. 1035](#)) may also influence pancreatic exocrine secretion. Blood flow from the pancreatic islets moves to the exocrine pancreas through a portal system. This organization allows high concentrations of islet hormones to interact with pancreatic acinar cells. One result of this arrangement may be that insulin modifies the composition of digestive enzymes within the acinar cell and increases the relative levels of amylase. Islet hormones may also have trophic effects on the exocrine pancreas and stimulate its growth. As a reflection of this function, the mass of the exocrine pancreas is substantially reduced in individuals with diabetes.

Regulation of exocrine pancreatic secretion is complex, and understanding this process has been made difficult by the following: (1) tissue levels of an exogenously infused hormone may not match those generated physiologically; (2) because several neurohumoral factors are released in response to a meal, the infusion of a single agent may not accurately reflect its physiological role; (3) specific neurohumoral inhibitors are often unavailable; and (4) pancreatic responses may differ depending on the species.

A meal triggers cephalic, gastric, and intestinal phases of pancreatic secretion

The digestive period has been divided into three phases ([Table 43-2](#)) based on the site at which food acts to stimulate pancreatic secretion, just as for gastric secretion (see [pp. 870–872](#)). These three phases (cephalic, gastric, and intestinal) are sequential and follow the progression of a meal from its initial smell and taste to its movement through the gastrointestinal tract ([Fig. 43-9](#)). These phases act in a coordinated fashion to maximize efficiency of the digestive process. For example, stimulation of secretion before the entry of food into the small intestine during the cephalic and gastric phases ensures that active enzymes are present when food arrives. Conversely, suppression of secretion during the late digestive phase suppresses the release of pancreatic enzymes when nutrients are no longer present in the proximal end of the small intestine.

TABLE 43-2
Three Phases of Pancreatic Secretion

PHASE	STIMULANT	REGULATORY PATHWAY	% OF MAXIMUM ENZYME SECRETION
Cephalic	Sight Smell Taste Mastication	Vagal pathways	25
Gastric	Distention Gastrin?	Vagal-cholinergic	10–20
Intestinal	Amino acids Fatty acids H ⁺	CCK Secretin Enteropancreatic reflexes	50–80

A CEPHALIC AND GASTRIC PHASES

B INTESTINAL PHASE

FIGURE 43-9 Three phases of pancreatic secretion.

During the cephalic phase, the sight, taste, and smell of food usually generates only a modest increase in fluid and electrolyte secretion (see [Fig. 43-9A](#)). However, these factors have prominent effects on enzyme secretion. In most animal species, enzyme secretion increases to 25% to 50% of the maximum rate evoked by exogenous CCK. In humans, the cephalic phase is short-lived and dissipates rapidly when food is removed. The cephalic phase is mediated by neural pathways. In the dog, stimulation of several regions of the hypothalamus (the dorsomedial and ventromedial nuclei and the mammillary body) enhances pancreatic secretion. The efferent signal travels along vagal pathways to stimulate pancreatic secretion via ACh, an effect blocked by atropine. The cephalic phase does not depend on gastrin or CCK release, but it is probably mediated by the stimulation of muscarinic receptors on the *acinar* cell.

Gastric Phase

During the gastric phase (see [Figure 43-9A](#)), the presence of food in the stomach modulates pancreatic secretion by (1) affecting the release of hormones, (2) stimulating neural pathways, and (3) modifying the pH and availability of nutrients in the proximal part of the small intestine. The presence of specific peptides or amino acids (peptones) stimulates gastrin release from G cells in the antrum of the stomach and, to a much lesser extent, G cells in the proximal part of the duodenum. The gastrin/CCK₂ receptor and the CCK₁ receptor are closely related (see [p. 867](#)). Although in some species the gastrin/CCK₂ receptor is not present on the pancreatic acinar cell, gastrin can still act—albeit not as well—through the CCK₁ receptor. Although physiological concentrations of gastrin can stimulate pancreatic secretion in some species, the importance of gastrin in regulating secretion in the human pancreas remains unclear. As far as local neural pathways are concerned, gastric distention stimulates low levels of pancreatic secretion, probably through a vagovagal gastropancreatic reflex. Although the presence of food in the stomach affects pancreatic secretion, the most important role for chyme in controlling pancreatic secretion occurs after the gastric contents enter the small intestine.

Intestinal Phase

During the intestinal phase, chyme entering the proximal region of the small intestine stimulates a major pancreatic secretory response by three major mechanisms (see [Fig. 43-9B](#)). First, gastric acid entering the duodenum—and to a lesser extent, bile acids and lipids—stimulate duodenal **S cells** to release secretin, which stimulates duct cells to secrete HCO_3^- and fluid. A threshold duodenal pH of <4.5 is needed to activate S-cell secretion. The acid stimulates fluid and electrolyte secretion to a greater extent than it stimulates protein secretion. Second, lipids and, to a lesser degree, peptones stimulate duodenal I cells to release CCK, which stimulates acinar cells to release digestive enzymes. Finally, the same stimuli that trigger I cells also activate a vagovagal enteropancreatic reflex that predominantly stimulates acinar cells.

The pattern of enzyme secretion—mediated by the CCK and vagovagal pathways—depends on the contents of the meal. For example, a *liquid meal* elicits a response that is only ~60% of maximal. In contrast, a solid meal, which contains larger particles and is slowly released from the stomach, elicits a prolonged response. Meals rich in *calories* cause the greatest response.

The *chemistry* of the ingested nutrients also affects pancreatic secretion via the CCK and vagovagal pathways. For example, perfusion of the duodenum with carbohydrates has little effect on secretion, whereas lipids are potent stimulators of pancreatic enzyme secretion. As far as *lipids* are concerned, triglycerides do not stimulate pancreatic secretion, but their hydrolytic products—monoglycerides and fatty acids—do. The longer the chain length of the fatty acid, the greater the secretory response; C-18 fatty acids generate protein secretion that is near the maximum produced by exogenous CCK. Some fatty acids

also stimulate pancreatic HCO_3^- secretion. Because fatty acids also reduce gastric acid secretion and delay gastric emptying, they may play an important role in modulating pH conditions in the proximal part of the small intestine. *Protein* breakdown products are intermediate in their stimulatory effect. Nonessential amino acids have little effect on protein secretion, whereas some essential amino acids (see [Table 58-2](#)) stimulate secretion. The most potent amino-acid stimulators are phenylalanine, valine, and methionine. Short peptides containing phenylalanine stimulate secretion to the same extent as the amino acid itself. Because gastric digestion generates more peptides than amino acids, it is likely that peptides provide the initial pancreatic stimulation during the intestinal phase.

The relative potency of the different nutrients in stimulating secretion is inversely related to the pancreatic reserves of digestive enzymes. Thus, the pancreas needs to release only a small portion of its amylase to digest the carbohydrate in a meal and to release only slightly greater portions of proteolytic enzymes to digest the proteins. However, a greater fraction of pancreatic lipase has to be released to efficiently digest the fat in most meals. The exocrine pancreas has the ability to respond to long-term changes in dietary composition by modulating the reserves of pancreatic enzymes. For example, a diet that is relatively high in carbohydrates may lead to a relative increase in pancreatic amylase content.

The pancreas has large reserves of digestive enzymes for carbohydrates and proteins, but not for lipids

The exocrine pancreas stores more enzymes than are required for digesting a meal. The greatest pancreatic reserves are those required for carbohydrate and protein digestion. The reserves of enzymes required for lipid digestion—particularly for triglyceride hydrolysis—are more limited. Even so, nutrient absorption studies after partial pancreatic resection show that maldigestion of dietary fat does not occur until 80% to 90% of the pancreas has been removed. Similar reserves exist for pancreatic endocrine function. These observations have important clinical implications because they indicate that individuals can tolerate large pancreatic resections for tumors without fear of developing maldigestion or diabetes postoperatively. When fat maldigestion or diabetes does develop because of pancreatic disease, the gland must have undergone extensive destruction. 🟡N43-6

N43-6

Chronic Pancreatitis and Pancreatic Insufficiency

Contributed by Fred Gorelick

Chronic pancreatitis is a localized and chronic inflammation of the pancreas. The most common causes are many years (10 to 20) of alcohol abuse or smoking. The clinical manifestations of chronic pancreatitis usually begin with chronic epigastric pain that radiates into the back, then progress to include calcification of the pancreas and progressive loss of the endocrine and exocrine tissues. The destruction of pancreatic tissues leads to diabetes and loss of nutrients (malabsorption). A distinct pattern of malabsorption is seen with chronic pancreatitis: individuals lose large amounts of dietary fat but have little loss of protein or carbohydrates. This type of malabsorption can cause fat droplets to appear in the patient's stool; this symptom is a strong clinical clue that a patient is not absorbing dietary lipids. An important reason for the selective loss of lipids is the shortage of lipase and its cofactors compared to other classes of digestive enzymes. This happens because the pancreatic reserves of lipase are very

limited and because lipase is very sensitive to an acid environment. Lipase is the only major pancreatic enzyme that become irreversibly inactive at $\text{pH} < 4.0$.

Although the pain of chronic pancreatitis can be difficult to treat, the malabsorption of lipids is very amenable to therapy. This involves giving exogenous pancreatic enzymes (usually extracted from porcine pancreas) by mouth with each meal. However, the critical lipase in these preparations must be protected from an acidic environment. This is done by either raising the pH of the stomach using inhibitors of acid secretion (see pp. 865–866) or encasing the enzyme in a coating that dissolves only when the preparation has reached the high-pH environment of the small intestine.

Fat in the distal part of the small intestine inhibits pancreatic secretion

Once maximally stimulated, pancreatic secretion begins to decrease after several hours. Nevertheless, the levels of secretion remain adequate for digestion. Regulatory systems only gradually return secretion to its basal (interdigestive) state. The regulatory mechanisms responsible for this feedback inhibition are less well characterized than those responsible for stimulating pancreatic secretion. The presence of fat in the distal end of the small intestine reduces pancreatic secretion in most animals, including humans. This inhibition may be mediated by **peptide YY (PYY)**, which is present in neuroendocrine cells in the ileum and colon. PYY may suppress pancreatic secretion by acting on inhibitory neural pathways as well as by decreasing pancreatic blood flow. **Somatostatin** (particularly SS-28; see pp. 993–994), released from intestinal D cells, and **glucagon**, released from pancreatic islet α cells, may also be factors in returning pancreatic secretion to the interdigestive state after a meal.

Several mechanisms protect the pancreas from autodigestion

Premature activation of pancreatic enzymes within acinar cells may lead to autodigestion and could play a role in initiating pancreatitis.  **N43-1** To avoid such injury, the acinar cell has mechanisms for preventing enzymatic activity ([Table 43-3](#)). First, many digestive proteins are stored in secretory granules as inactive precursors or zymogens. Under normal conditions, zymogens become activated only after entering the small intestine. There, the intestinal enzyme **enterokinase** converts trypsinogen to **trypsin** (see pp. 921–922), which initiates the conversion of all other zymogens to their active forms. Second, the secretory granule membrane is impermeable to proteins. Thus, the zymogens and active digestive enzymes are sequestered from proteins in the cytoplasm and other intracellular compartments. Third, enzyme inhibitors such as **pancreatic trypsin inhibitor**, co-packaged in the secretory granule, block the activity of trypsin aberrantly activated within the granule. However, sufficient pancreatic trypsin inhibitor is present in the secretory granules to block $<5\%$ of the potential trypsin activity. Fourth, the condensation of zymogens, the low pH, and the ionic conditions within the secretory pathway may further limit enzyme activity. Fifth, enzymes that become prematurely active within the acinar cell may themselves be degraded by other enzymes or be secreted before they can cause injury.

TABLE 43-3
Mechanisms that Protect the Acinar Cell from Autodigestion

PROTECTIVE FACTOR	MECHANISM
Packaging of many digestive proteins as zymogens	Precursor proteins lack enzymatic activity
Selective sorting of secretory proteins and storage in zymogen granules	Restricts the interaction of secretory proteins with other cellular compartments
Protease inhibitors in the zymogen granule	Block the action of prematurely activated enzymes
Condensation of secretory proteins at low pH	Limits the activity of active enzymes
Nondigestive proteases	Degrade active enzymes

Degradation of prematurely active enzymes may be mediated by other enzymes that are present within the secretory granule or by the mixing of secretory granule contents with lysosomal enzymes that can degrade active enzymes. Three mechanisms lead to the mixing of digestive proteases and lysosomal enzymes: (1) lysosomal enzymes may be co-packaged in the secretory granule; (2) secretory granules may selectively fuse with lysosomes (a process called *crinophagy*); and (3) secretory granules, as well as other organelles, may be engulfed by lysosomes (a process called *autophagy*). Failure of these protective mechanisms may result in the premature activation of digestive enzymes within the pancreatic acinar cell and may initiate pancreatitis (Box 43-2). 🟡N43-7

Box 43-2

Genetic Causes of Acute and Chronic Pancreatitis

Single genetic factors rarely cause pancreatitis but can work in combination with other genetic or environmental factors to increase disease risk. Most of the genetic factors associated with pancreatitis involve digestive enzymes. Of these, the majority are thought to lead to an increase in trypsin activity in the acinar cell. The first described was hereditary pancreatitis, in which mutations in a single gene are sufficient to cause the syndrome. 🟡N43-7 In hereditary pancreatitis, various mutations in cationic trypsinogen are thought to enhance either the sensitivity of the zymogen (cationic trypsinogen) to activation or the resistance of the active form (trypsin) to degradation.

Predisposing factors for pancreatitis include a high degree of trypsin activation, a low level of pancreatic trypsin inhibitor, and low activity of enzymes that degrade trypsin. All three factors determine the levels of active trypsin in the acinar cell, and mutations are known in proteins that regulate the latter two mechanisms. Mutations of a secretory pancreatic trypsin inhibitor—serine protease inhibitor Kazal-type 1, or SPINK1—which is co-packaged with trypsinogen in the secretory pathway, increase the risk of developing pancreatitis, but alone do not cause disease. Mutations in chymotrypsin C, a protease that degrades aberrantly activated trypsin in the pancreatic acinar cell, also predisposes to disease. It appears to particularly sensitize those who abuse alcohol.

Although classic cystic fibrosis generally results in pancreatic insufficiency at birth and not pancreatitis, mild mutations in CFTR that result in mild defects in Cl⁻ conductance (10% to 20% of normal) are a risk factor for developing pancreatitis. These can act in concert with alcohol abuse and SPINK mutations to increase disease risk further. One feature of alcohol-associated pancreatitis is the low risk of developing disease (5% to 10%) in abusers, which is consistent with the idea that other genetic or environmental factors must contribute to the disease risk.

N43-7
Hereditary Pancreatitis

A rare form of pancreatitis that provides insights into the mechanisms of disease is hereditary pancreatitis. This is an autosomal dominant disease with incomplete penetrance: only about 80% of those carrying disease mutations have clinical disease. Symptoms of pancreatitis often begin in childhood but may be delayed until early adulthood. Often individuals first experience bouts of pain and then develop the other features of chronic pancreatitis, especially pancreatic calcifications, early in the course of disease. There are no treatments that prevent disease progression. One of the unfortunate features of this disease is the increased risk of developing pancreatic cancer (35% to 55% lifetime risk versus 1.5% in the general population, or about a 30-fold increase). The genetic defect in hereditary pancreatitis is found in the gene encoding for cationic trypsinogen. Although a number of genetic defects, including those in CFTR and the pancreatic secretory trypsin inhibitor, can predispose to developing pancreatitis, the mutations in cationic trypsinogen found in hereditary pancreatitis are the only ones that alone cause disease. Although mutations at several sites within the gene have been described, the most common involve a mutation that exchanges a histidine for an arginine residue. This removes a potential cleavage site for serine proteases. Cleavage of cationic trypsin at this site would eliminate the catalytic activity of the enzyme. Such proteolysis of activated enzymes within the acinar cell likely represents a major protective mechanism. Indeed, inactivating mutations in several proteases that degrade trypsin, including chymotrypsin C, increase the risk of developing pancreatitis. Other mutations in cationic trypsinogen can also cause pancreatitis and may have this damaging effect by either increasing the efficiency of cationic trypsinogen activation or causing the enzyme to misfold and trigger an ER stress response.

Salivary Acinar Cell

Different salivary acinar cells secrete different proteins

The organizational structure of the salivary glands ([Fig. 43-10A](#)) is similar to that of the pancreas (see [Fig. 43-1A](#)), with secretory acinar units draining into progressively larger ducts. Unlike the pancreas, the salivary glands are heterogeneous in distribution and, in some species, contain two morphologically distinct acinar cell populations that synthesize and secrete different protein products. The **acinar cells** of the parotid glands in most species secrete a serous (i.e., watery) product that contains an abundance of **α -amylase**. Many acinar cells of the sublingual glands secrete a mucinous product that is composed primarily of **mucin glycoproteins**. [Figure 43-10B](#) shows an acinar cell that contains both serous and mucous granules. The submandibular gland of many species contains both mucous-type and serous-type acinar cells. In some species, these two distinct cell types are dispersed throughout the submandibular gland, whereas in other species such as humans, distinct mucous and serous acinar units are the rule. In addition to α -amylase and mucin glycoproteins, salivary acinar cells also secrete many proline-rich proteins. Like mucin proteins, proline-rich proteins are highly glycosylated, and like other secreted salivary proteins, they are present in the acinar secretory granules and are released by exocytosis.

A ORGANIZATION OF THE SALIVARY GLANDS

FIGURE 43-10 Salivary gland distribution and cellular morphology. **A**, Humans have three main bilateral salivary glands. The parotid glands are located in front of each ear, the submandibular glands are located laterally beneath each jaw bone, and the sublingual glands are located in the floor of the mouth, underneath both sides of the tongue.

Cholinergic and adrenergic neural pathways are the most important physiological activators of regulated secretion by salivary acinar cells

Unlike the pancreas, in which hormones have an important role in stimulating secretion, the salivary glands are mostly controlled by the autonomic nervous system (see [Chapter 14](#)). The major agonists of salivary acinar secretion are ACh and norepinephrine, which are released from postganglionic parasympathetic and sympathetic nerve terminals, respectively (see [Fig. 14-8](#) and [Table 43-4](#)). The cholinergic receptor on the salivary acinar cell is the muscarinic M_3 glandular subtype. The adrenergic receptors identified on these cells include both the α and β subtypes. Other receptors identified in salivary tissue include those for substance P (NK_1 receptors), VIP, purinergic agonists ($P2X_7$ receptors), neurotensin, prostaglandin, and epidermal growth factor (EGF). However, some of these other receptors are found only on specific salivary glands and may be present on duct cells rather than acinar cells. Significant species variation with regard to surface receptor expression is also seen. Thus, for the salivary glands, it is difficult to discuss the regulation of acinar cell secretion in general terms. It is fair to say, however, that both cholinergic and adrenergic neurotransmitters can stimulate exocytosis by salivary acinar cells.

TABLE 43-4
Autonomic Control of Salivary Secretion

AUTONOMIC PATHWAY	NEUROTRANSMITTER	RECEPTOR	SIGNALING PATHWAY	CELLULAR RESPONSE
Parasympathetic	ACh	Muscarinic (M ₃)	Ca ²⁺	Fluid > protein secretion
	Substance P	Tachykinin NK ₁	Ca ²⁺	Fluid > protein secretion
Sympathetic	Norepinephrine	α-adrenergic	Ca ²⁺	Fluid > protein secretion
	Norepinephrine	β-adrenergic	cAMP	Protein >> fluid secretion

Both cAMP and Ca²⁺ mediate salivary acinar secretion

Protein secretion by the salivary acinar cell, as by the pancreatic acinar cell, is associated with increases in both [cAMP]_i and [Ca²⁺]_i. Activation of cAMP via the β-adrenergic receptor is the most potent stimulator of amylase secretion in the rat parotid gland. Activation of Ca²⁺ signaling pathways via the α-adrenergic, muscarinic, and substance P receptors also stimulates amylase secretion by the parotid gland, but in general, these Ca²⁺ signaling pathways have a greater effect on fluid secretion. Increases in [Ca²⁺]_i cause G protein–dependent activation of PLC and thus lead to the formation of inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol (DAG). IP₃ releases Ca²⁺ from intracellular stores and stimulates Ca²⁺-dependent protein kinases such as PKC (see pp. 60–61) and calmodulin kinase (see p. 60), whereas DAG directly activates PKC (see pp. 60–61). The repetitive spikes in [Ca²⁺]_i in salivary acinar cells, as in pancreatic acinar cells, depend on Ca²⁺-induced Ca²⁺ release from intracellular stores (see p. 60) and on the influx of extracellular Ca²⁺. ATP co-released with norepinephrine (see pp. 345–346) activates a P2X7 receptor, which is a ligand-gated cation-selective channel that allows Ca²⁺ to enter across the plasma membrane and thus increase [Ca²⁺]_i.

Fluid and electrolyte secretion is the second major function of salivary acinar cells, accounting for ~90% of total salivary volume output under stimulatory conditions. The mechanisms in salivary acinar cells are similar to those in pancreatic acinar cells (see Fig. 43-5). The primary secretion of the salivary acinar cell is isotonic and results largely from the basolateral uptake of Cl[−] through Na/K/Cl cotransporters, working in conjunction with Na-K pumps and basolateral K⁺ channels. Secretion of Cl[−] and water into the lumen is mediated by apical Cl[−] and aquaporin water channels. Na⁺ and some water reach the lumen via paracellular routes. The salivary acinar cells in some glands and species express carbonic anhydrase as well as parallel basolateral Cl-HCO₃ exchangers (AE2) and Na-H exchangers (NHE1 and NHE4), as well as electrogenic Na/HCO₃ cotransporters (NBCe1-B or SLC4A4; see p. 122). These acid-base transporters probably also contribute to the primary secretion.

Stimulation of fluid and electrolyte secretion by salivary acinar cells is largely mediated by cholinergic and α-adrenergic input. Substance P, acting through its own receptor, also initiates conductance changes in the salivary acinar cell. All these effects seem to be mediated by rises in [Ca²⁺]_i. Apical Cl[−] channels and basolateral K⁺ channels appear to be the effector targets of the activated Ca²⁺ signaling pathway. Phosphorylation of these channels by Ca²⁺-dependent kinases may affect the probability that these channels will be open and may thus increase conductance.

Salivary Duct Cell

Salivary duct cells produce a hypotonic fluid that is poor in NaCl and rich in KHCO_3

In the salivary glands, as in the pancreas, the ducts modify the composition of the isotonic, plasma-like primary secretion of the acinar cells. As the fluid exits the salivary acinus, it passes through an intercalated duct (see Fig. 43-10A), with typical **intercalated duct cells** (see Fig. 43-10C). Later, abundant mitochondria and infoldings of the basolateral membrane give the basal portion of the duct cells a characteristic striated appearance—hence the term **striated duct cell** (see Fig. 43-10B). This morphology goes hand in hand with high rates of active transport. In general, salivary duct cells absorb Na^+ and Cl^- and, to a lesser extent, secrete K^+ and HCO_3^- . Because the epithelium is not very water permeable, the lumen thus becomes hypotonic. However, significant differences are seen in the various types of salivary glands.

Reabsorption of Na^+ by salivary duct cells is a two-step transcellular process (Fig. 43-11). First, Na^+ enters the cell from the lumen through apical epithelial Na^+ channels (ENaCs; see Table 6-2, family #14). Second, the basolateral Na-K pump extrudes this Na^+ . Elevated $[\text{Na}^+]_i$ provides feedback inhibition by downregulating ENaC activity, presumably via the ubiquitin-protein ligase Nedd4.

FIGURE 43-11 Salivary duct transporters.

Reabsorption of Cl⁻ is also a two-step transcellular process (see Fig. 43-11). Entry of Cl⁻ across the apical membrane occurs via a Cl-HCO₃ exchanger and CFTR. To a certain extent, apical CFTR also recycles Cl⁻ absorbed by the Cl-HCO₃ exchanger. Thus, CFTR may facilitate both HCO₃⁻ secretion and Cl⁻ reabsorption through bidirectional Cl⁻ movement across the apical membrane. Exit of Cl⁻ across the basolateral membrane of duct cells occurs via inwardly rectifying (ClC-2) Cl⁻ channels.

Secretion of HCO₃⁻ occurs via pathways (see Fig. 43-11) similar to those in pancreatic ducts and involves apical Cl-HCO₃ exchangers and CFTR, as well as basolateral Na/HCO₃ cotransporters (see p. 122). **N43-5**

Secretion of K⁺ occurs through the basolateral uptake of K⁺ via the Na-K pump (see Fig. 43-11). The mechanism of K⁺ exit across the apical membrane is not well established.

Parasympathetic stimulation decreases Na⁺ absorption, whereas aldosterone increases Na⁺ absorption by duct cells

Regulation of duct cell transport processes is less well understood in the salivary glands than in the pancreas. In the intact salivary gland (i.e., acini and ducts), secretion is stimulated primarily by *parasympathetic* input via ACh. In the duct cell, cholinergic agonists, acting through muscarinic receptors

(mostly M_3), increase $[Ca^{2+}]_i$ and presumably activate Ca^{2+} -dependent regulatory pathways. The effector targets of this Ca^{2+} signaling pathway are not known. The role played by duct cells in the increased saliva production that occurs in response to cholinergic stimulation is limited and may reflect decreased NaCl absorption more than increased $KHCO_3$ secretion.

The specific effects of *adrenergic* stimulation on the transport activity of duct cells are unclear. Nevertheless, activation of the β -adrenergic receptor increases $[cAMP]_i$ and activates the CFTR Cl^- channel.

Salivary duct cell function is also regulated by *circulating hormones*. The mineralocorticoid hormone **aldosterone** stimulates the absorption of NaCl and secretion of K^+ by salivary duct cells in several species. Although its role has not been well examined in salivary duct cells, aldosterone in other Na^+ -absorbing epithelia (e.g., kidney and colon) stimulates Na^+ transport by increasing both ENaC and Na-K pump activity (see [pp. 765–766](#)). Salivary duct cells may also have receptors for certain neuropeptides such as VIP, although their physiological significance remains unknown.

Salivary duct cells also secrete and take up proteins

Duct cells handle proteins in three ways. Some proteins that are synthesized by duct cells are secreted into the lumen, others are secreted into the blood, and still others are reabsorbed from the lumen to the cell.

Intralobular duct epithelial cells in rodent submandibular glands synthesize a variety of proteins that are stored in intracellular granules and are secreted in response to neurohumoral stimuli. EGF, nerve growth factor, and kallikrein are among the most abundant proteins that are packaged for secretion by these cells. Salivary duct cells may also synthesize, store, and secrete some digestive enzymes (α -amylase and ribonucleases). Degranulation of intralobular duct cells occurs primarily in response to α -adrenergic stimulation, which suggests that protein secretion by duct cells is regulated primarily by the sympathetic division.

Although regulatory peptides (i.e., glucagon and somatostatin) have also been detected in salivary duct cells, no evidence indicates that they are stored in granules or are secreted into the lumen (i.e., they may be basolaterally secreted as peptide hormones). In addition, duct cells synthesize polymeric immunoglobulin A (IgA) receptors that are responsible for the basolateral endocytosis of IgA, and they also synthesize a secretory component that facilitates the apical release of IgA.

Salivary duct cells can also remove organic substances from the duct lumen. Endocytosis of acinar proteins and other materials (e.g., ferritin) at the apical pole of the duct cell has been demonstrated immunocytochemically. In addition, salivary duct cells express the transferrin receptor (see [p. 42](#)) on the apical membrane, which indicates that some regulated endocytosis also occurs in these cells. The latter process may function to take up specific luminal substances or to traffic ion transporters to and from the apical plasma membrane.

Composition, Function, and Control of Salivary Secretion

Depending on protein composition, salivary secretions can be serous, seromucous, or mucous

Most saliva (~90%) is produced by the major salivary glands: the parotid, the sublingual, and the submandibular glands (see Fig. 43-10A). The remaining 10% of saliva comes from numerous minor salivary glands that are scattered throughout the submucosa of the oral cavity. Each salivary gland produces either a serous, a seromucous, or a mucous secretion; the definition of these three types of saliva is based on the glycoprotein content of the gland's final secretory product. In humans and most other mammals, the parotids produce a serous secretion (i.e., low glycoprotein content), the sublingual and submandibular glands produce a seromucous secretion, and the minor salivary glands produce a mucous secretion.

Serous secretions are enriched in α -amylase, and mucous secretions are enriched in mucin. However, the most abundant proteins in parotid and submandibular saliva are members of the group of **proline-rich proteins**, in which one third of all amino acids are proline. These proteins exist in acidic, basic, and glycosylated forms. They have antimicrobial properties and may play an important role in neutralizing dietary tannins, which can damage epithelial cells. In addition to serving these protective functions, proline-rich salivary proteins contribute to the lubrication of ingested foods and may enhance tooth integrity through their interactions with Ca^{2+} and hydroxyapatite. Saliva also contains smaller amounts of lipase, nucleases, lysozyme, peroxidases, lactoferrin, secretory IgA, growth factors, regulatory peptides, and vasoactive proteases such as kallikrein and renin (Table 43-5).

TABLE 43-5
Major Organic Components of Mammalian Saliva

COMPONENTS	CELL TYPE	GLANDS	POSSIBLE FUNCTION
Proline-rich proteins	Acinar	P, SM	Enamel formation Ca ²⁺ binding Antimicrobial Lubrication
Mucin glycoproteins	Acinar	SL, SM	Lubrication
Enzymes			
α -amylase	Acinar	P, SM	Starch digestion
Lipase	Acinar	SL	Fat digestion
Ribonuclease	Duct	SM	RNA digestion
Kallikrein	Duct	P, SM, SL	Unknown
Miscellaneous			
Lactoperoxidase	Acinar	SM	Antimicrobial
Lactoferrin	Acinar	Unknown	Antimicrobial
Lysozyme	Duct	SM	Antimicrobial
IgA receptor	Duct	Unknown	Antimicrobial
IgA secretory piece	Duct	Unknown	Antimicrobial
Growth factors	Duct	SM	Unknown

P, parotid; SL, sublingual; SM, submandibular..

Saliva functions primarily to prevent dehydration of the oral mucosa and to provide lubrication for the mastication and swallowing of ingested food. The senses of taste and, to a lesser extent, smell depend on an adequate supply of saliva. Saliva plays a very important role in maintaining proper oral hygiene. It

accomplishes this task by washing away food particles, killing bacteria (lysozyme and IgA activity), and contributing to overall dental integrity. Although α -amylase is a major constituent of saliva and digests a significant amount of the ingested starch, salivary amylase does not appear to be essential for effective carbohydrate digestion in the presence of a normally functioning pancreas. The same can be said for lingual lipase. However, in cases of pancreatic insufficiency, these salivary enzymes can partially compensate for the maldigestion that results from pancreatic dysfunction.

At low flow rates, the saliva is hypotonic and rich in K^+ , whereas at higher flow rates, its composition approaches that of plasma

The composition of saliva varies from gland to gland and from species to species. The primary secretion of the salivary acinar cell at rest is plasma-like in composition. Its osmolality, reflecting mainly Na^+ and Cl^- , is ~ 300 mOsm. The only significant difference from plasma is that the $[K^+]$ of the salivary primary secretion is always slightly higher than that of plasma. In some species, acinar cells may help to generate a Cl^- -poor, HCO_3^- -rich primary secretion after salivary gland stimulation. In most species, however, salivary gland stimulation does not significantly alter acinar cell transport function or the composition of the primary secretion. The leakiness of the tight junctions (see p. 137) between acinar cells contributes to the formation of a plasma-like primary secretory product.

The composition of the primary salivary secretion is subsequently modified by the transport processes of the duct cell (see Fig. 43-11). At low (basal) flow rates, Na^+ and Cl^- are absorbed from the lumen and K^+ is secreted into the lumen by the duct cells of most salivary glands (Table 43-6). These transport processes generate a K^+ -rich, hypotonic salivary secretion at rest. The tightness of the ductal epithelium inhibits paracellular water movement and therefore contributes to the formation of a hypotonic secretory product.

TABLE 43-6
Electrolyte Components of Human Parotid Saliva

COMPONENT	UNSTIMULATED OR BASAL STATE (mM)	STIMULATED (CHOLINERGIC AGONISTS) (mM)
Na^+	15	90
K^+	30	15
Cl^-	15	50
Total CO_2	15	60

From Thaysen JH, Thorn NA, Schwartz IL: Excretion of sodium, potassium, chloride and carbon dioxide in human parotid saliva. Am J Physiol 178:155–159, 1954.

At higher flow rates, the composition of the final secretory product begins to approach that of the plasma-like primary secretion (see Table 43-6). This observation suggests that, as in the case of the renal tubules, the ductular transport processes have limited capacity to handle the increased load that is presented to them as the flow rate accelerates. However, the extent to which the transporters are flow dependent varies from gland to gland and from species to species. Human saliva is always hypotonic, and salivary $[K^+]$ is always greater than plasma $[K^+]$. In humans, increased salivary flow alkalinizes the saliva and increases its $[HCO_3^-]$. This salivary alkalinization and net HCO_3^- secretion in humans neutralize the gastric acid that normally refluxes into the esophagus (Box 43-3).

Sjögren Syndrome

Sjögren syndrome is a chronic and progressive autoimmune disease that affects salivary secretion. Patients with Sjögren syndrome generate antibodies that react primarily with the salivary and lacrimal glands. Lymphocytes infiltrate the glands, and subsequent immunological injury to the acini leads to a decrease in net secretory function. Expression of the Cl-HCO_3 exchanger is lost in the striated duct cells of the salivary gland. Sjögren syndrome can occur as a primary disease (salivary and lacrimal gland dysfunction only) or as a secondary manifestation of a systemic autoimmune disease, such as rheumatoid arthritis. The disease primarily affects women; systemic disease usually does not develop.

Individuals with Sjögren syndrome have xerostomia (dry mouth) and *keratoconjunctivitis sicca* (dry eyes). Loss of salivary function causes these patients to have difficulty tasting, as well as chewing and swallowing dry food. They also have difficulty with continuous speech and complain of a chronic burning sensation in the mouth. On physical examination, patients with Sjögren syndrome have dry, erythematous oral mucosa with superficial ulceration and poor dentition (dental caries, dental fractures, and loss of dentition). Parotid gland enlargement is commonly present.

One of the proteins that is the target of the immunological attack in Sjögren syndrome is the water channel AQP5. No specific therapy for the disorder is available. Until the underlying cause of Sjögren syndrome is discovered, patients will have to rely on instillation of eyedrops and frequent ingestion of fluid to compensate for their deficiencies in lacrimal and salivary secretion. Various stimulants of salivary secretion (sialogogues), such as methylcellulose and sour candy, can also be helpful. Patients with severe involvement and functional disability are sometimes treated with corticosteroids and immunosuppressants.

Parasympathetic stimulation increases salivary secretion

Humans produce ~1.5 L of saliva each day. Under basal conditions, the salivary glands produce saliva at a rate of ~0.5 mL/min, with a much slower flow rate during sleep. After stimulation, flow increases 10-fold over the basal rate. Although the salivary glands respond to both cholinergic and adrenergic agonists *in vitro*, the parasympathetic nervous system is the most important physiological regulator of salivary secretion *in vivo*.

Parasympathetic Control

Parasympathetic innervation to the salivary glands originates in the salivatory nuclei of the brainstem (see Fig. 14-5). Both local input and central input to the salivatory nuclei can regulate the parasympathetic signals transmitted to the glands. Taste and tactile stimuli from the tongue are transmitted to the brainstem, where their signals can excite the salivatory nuclei and stimulate salivary gland secretion. Central impulses triggered by the sight and smell of food also excite the salivatory nuclei and can induce salivation before food is ingested. These central effects were best illustrated by the classic experiments of Ivan Pavlov, who conditioned dogs to salivate at the sound of a bell. For his work on the physiology of digestion, Pavlov received the 1904 Nobel Prize in Physiology or Medicine. 🧠N43-8

Ivan Petrovich Pavlov

Contributed by Emile Boulpaep, Walter Boron

The classical experiments demonstrating the cephalic phase of salivary and gastric secretion in dogs were the work of Ivan Petrovich Pavlov. For his contributions to digestive physiology, Pavlov received the 1904 Nobel Prize in Physiology or Medicine. For more information about Pavlov and the work that led to his Nobel Prize, visit <http://www.nobel.se/medicine/laureates/1904/index.html> (accessed September 2014).

Preganglionic parasympathetic fibers travel in cranial nerve (CN) VII to the submandibular ganglia, from which postganglionic fibers reach the sublingual and submandibular glands (see Fig. 14-4). Preganglionic parasympathetic fibers also travel in CN IX to the otic ganglia, from which postganglionic fibers reach the parotid glands. In addition, some parasympathetic fibers reach their final destination via the buccal branch of CN V to the parotid glands or via the lingual branches of CN V to the sublingual and submandibular glands. Postganglionic parasympathetic fibers from these ganglia directly stimulate the salivary glands through their release of ACh. The prominent role of the parasympathetic nervous system in salivary function can be readily appreciated by examining the consequences of cholinergic blockage. Disruption of the parasympathetic fibers to the salivary glands can lead to glandular atrophy. This observation suggests that parasympathetic innervation is necessary for maintaining the normal mass of salivary glands. Clinically, some medications (particularly psychiatric drugs) have “anticholinergic” properties that are most commonly manifested as “dry mouth.” For some medications, this effect is so uncomfortable for the patient that use of the medication must be discontinued. Conversely, excessive salivation is induced by some anticholinesterase agents that can be found in certain insecticides and nerve gases.

Sympathetic Control

The salivary glands are also innervated by postganglionic sympathetic fibers from the superior cervical ganglia that travel along blood vessels to the salivary glands (see Fig. 14-4). Although sympathetic (adrenergic) stimulation increases saliva flow, interruption of sympathetic nerves to the salivary glands has no major effect on salivary gland function in vivo. However, the sympathetic nervous system is the primary stimulator of the **myoepithelial cells** that are closely associated with cells of the acini and proximal (intercalated) ducts. These stellate cells have structural features of both epithelial and smooth-muscle cells. They support the acinar structures and decrease the flow resistance of the intercalated ducts during stimulated secretion. Thus, the net effect of myoepithelial-cell activation is to facilitate secretory flow in the proximal regions of the gland, thus minimizing the extravasation of secretory proteins that could otherwise occur during an acute increase in secretory flow.

The sympathetic division can also indirectly affect salivary gland function by modulating blood flow to the gland. However, the relative contribution of this vascular effect to the overall secretory function of the salivary glands is difficult to determine.

Not only is salivary secretion subject to cholinergic and adrenergic regulation, but some autonomic fibers that innervate the salivary glands contain VIP and substance P. Although acinar cells in vitro respond to stimulation by substance P, the physiological significance of these neurotransmitters in vivo has not been established. Salivary secretion is also regulated, in part, by mineralocorticoids. Stimulation by the adrenal hormone aldosterone produces saliva that contains relatively less Na^+ and more K^+ . The opposite effect on saliva is seen in patients with adrenal insufficiency caused by **Addison disease** (see [p. 1019](#)). The mineralocorticoid effect represents the only well-established example of regulation of salivary secretion by a hormone.

Intestinal Fluid and Electrolyte Movement

Henry J. Binder

Functional Anatomy

The small intestine and large intestine have many similarities in structure and function. In some cases, different regions of the intestinal tract carry out certain functions in much the same manner. In other cases, however, substantial heterogeneity exists between different intestinal segments (e.g., ileum versus jejunum) or between different mucosal areas (e.g., villus versus crypt) in one intestinal segment.

As discussed in [Chapter 41](#), the basic structure of the intestine is a hollow cylinder with columnar epithelial cells lining the lumen, with circular and longitudinal layers of smooth muscle in the wall, and with endocrine and neural elements (see [Fig. 41-2](#)). Enteric neurons, as well as endocrine and paracrine agonists, regulate both epithelial transport and motor activity during both the interdigestive and the postprandial periods. As a result, the intestines propel their contents in a caudad direction while either removing fluid and electrolytes from the intestinal lumen (i.e., absorption) or adding these substances to the lumen (i.e., secretion).

Both the small and large intestine absorb and secrete fluid and electrolytes, whereas only the small intestine absorbs nutrients

Among mammals, **absorption** of dietary nutrients is an exclusive function of the small intestine. Only during the neonatal period does significant nutrient absorption take place in the large intestine. The small intestine absorbs nonelectrolytes after extensive digestion of dietary nutrients by both luminal and brush-border enzymes, as discussed in [Chapter 45](#). In contrast, *both* the small intestine and the large intestine absorb fluid and electrolytes by several different cellular transport processes, which may differ between the small intestine and large intestine and are the subject of this chapter.

Another vitally important function of the intestinal epithelium is the **secretion** of intestinal fluid and electrolytes. Teleologically, fluid secretion may be considered an adaptive mechanism of the intestinal tract that protects from noxious agents, such as bacteria and bacterial toxins. In general, the cellular mechanisms of intestinal electrolyte secretion in the small intestine and colon are similar, if not identical. Frequently, the adaptive signal that induces the secretory response also induces a motor response from the intestinal muscle, resulting in a propagated propulsive response that promotes dilution and elimination of the offending toxin.

The small intestine has a villus-crypt organization, whereas the colon has surface epithelial cells with interspersed crypts

Both the small intestine and the large intestine have a specialized epithelial structure that correlates well with epithelial transport function.

The small intestine ([Fig. 44-1A](#)) consists of finger-like projections—**villi**—surrounded by the openings of glandular structures called **crypts of Lieberkühn**, or simply crypts. Both villi and crypts are covered by columnar epithelial cells. The cells lining the villi are considered to be the primary cells responsible for both nutrient and electrolyte *absorption*, whereas the crypt cells primarily participate in *secretion*.

A SMALL INTESTINE

B LARGE INTESTINE

FIGURE 44-1 Microscopic view of the anatomy of the small and large intestine. **A**, The surface area of the small intestine is amplified at three levels: (1) macroscopic folds of Kerckring, (2) microscopic villi and crypts of Lieberkühn, and (3) submicroscopic microvilli. **B**, The surface area of the colon is amplified at the same three levels as the small intestine: (1) macroscopic semilunar folds, (2) crypts (but not villi), and

The colon (see [Fig. 44-1B](#)) does not have villi. Instead, the cells lining the large intestine are surface epithelial cells, and interspersed over the colonic surface are numerous apertures of colonic crypts (or glands) that are similar in function and structure to the small-intestinal crypts. Not surprisingly, the surface epithelial cells of the colon are the primary cells responsible for colonic electrolyte *absorption*, whereas colonic gland cells are generally believed to mediate ion *secretion*.

The intestinal mucosa is a dynamic organ with continuous cell proliferation and migration. The zone of cell proliferation is at the base of the crypt in both the small and large intestine, and the program of events is similar in both organs. The **progenitor cell** is a stem cell that differentiates into several specialized cells (e.g., vacuolated, goblet, and Paneth cells) that line the villi and crypts in the small intestine and the surface and glands in the colon. The vacuolated cell migrates along the crypt-villus axis and becomes a villous absorptive cell after undergoing substantial changes in its morphological and functional characteristics. In the small intestine, these villous cells migrate until they reach the tips of the villi, undergo apoptosis (see [p. 1241](#)), and then slough into the lumen of the intestine. The overall period from the initiation of cell proliferation to sloughing is ~48 to 96 hours. The overall rate of cell migration may increase or decrease: decreased cell turnover occurs during starvation, whereas increased cell turnover occurs during feeding and lactation, as well as after intestinal resection. The compensatory response that follows intestinal resection involves both luminal and hormonal factors.

The surface area of the small intestine is amplified by folds, villi, and microvilli; amplification is less marked in the colon

An additional hallmark of both the small and large intestine is the presence of structures that amplify function by increasing the luminal surface area. These structures exist at three levels. In the small intestine, the first level consists of the macroscopic **folds of Kerckring** . The second level consists of the microscopic **villi** and **crypts** that we have already discussed. The third level is the submicroscopic **microvilli** on the apical surfaces of the epithelial cells. Thus, if the small intestine is thought of as a hollow cylinder, the net increase in total surface area of the small intestine (versus that of a smooth cylinder) is 600-fold. The total surface area of the human small intestine is ~200 m², or the surface area of a doubles tennis court ([Table 44-1](#)). The colonic surface area is also amplified, but to a more limited extent. Because the colon lacks villi, amplification is a result of only the presence of colonic folds, crypts, and microvilli. Amplification is an effective means of increasing the surface area that is available for intestinal absorption, the primary function of the small and large intestine.

TABLE 44-1

Structural and Functional Differences Between the Small and Large Intestine

	SMALL INTESTINE	LARGE INTESTINE
Length (m)	6	2.4
Area of apical plasma membrane (m ²)	~200	~25
Folds	Yes	Yes
Villi	Yes	No
Crypts or glands	Yes	Yes
Microvilli	Yes	Yes
Nutrient absorption	Yes	No
Active Na ⁺ absorption	Yes	Yes
Active K ⁺ secretion	No	Yes

Overview of Fluid and Electrolyte Movement in the Intestines

The small intestine absorbs ~6.5 L/day of an ~8.5-L fluid load that is presented to it, and the colon absorbs ~1.9 L/day

The fluid content of the average diet is typically 1.5 to 2.5 L/day. However, the fluid load to the small intestine is considerably greater—8 to 9 L/day. The difference between these two sets of figures is accounted for by salivary, gastric, pancreatic, and biliary secretions, as well as the secretions of the small intestine itself (Fig. 44-2). Similarly, the total quantity of electrolytes (Na^+ , K^+ , Cl^- , and HCO_3^-) that enters the lumen of the small intestine also comes from dietary sources in addition to endogenous secretions from the salivary glands, stomach, pancreas, liver, and small intestine.

FIGURE 44-2 Fluid balance in the gastrointestinal (GI) tract. For each segment of the GI tract, the figure shows substances flowing into the lumen on the left and substances flowing out of the lumen on the right. Of the ~8.5 L/day that are presented to the small intestine, the small intestine removes ~6.5 L/day, delivering ~2 L/day to the colon. The large intestine removes ~1.9 L/day, leaving ~0.1 L/day in the feces.

We can calculate the absorption of water and electrolytes from the small intestine by comparing the total load that is presented to the lumen of the small intestine (i.e., ~7.5 L/day entering from other organs + ~1.0 L/day secreted by the small intestine = ~8.5 L/day) with that leaving the small intestine (i.e., ileocecal flow). The latter is ~2.0 L/day in normal subjects. Thus, overall small-intestinal water absorption is about 8.5 – 2.0, or ~6.5 L/day. Na⁺ absorption is ~600 mmol/day. Maximal small-intestinal fluid absorption has not been directly determined but has been estimated to be as great as 15 to 20 L/day. Colonic fluid absorption is the difference between ileocecal flow (~2.0 L/day) and stool water, which is usually <0.2 L/day (~0.1 L/day). Thus, colonic water absorption is about 2.0 – 0.1, or ~1.9 L/day. In contrast, the maximal colonic water **absorptive capacity** is between 4 and 5 L/day. As a result, a significant increase in ileocecal flow (e.g., up to perhaps 5 L/day, as occurs with a decrease in small-intestinal fluid absorption) will not exceed the absorptive capacity of the large intestine. Thus, a compensatory increase in colonic fluid absorption can prevent an increase in stool water (i.e., diarrhea) despite substantial decreases in fluid absorption by the small intestine.

The small intestine absorbs net amounts of water, Na⁺, Cl⁻, and K⁺ and secretes HCO₃⁻, whereas the colon absorbs net amounts of water, Na⁺, and Cl⁻ and secretes both K⁺ and HCO₃⁻

Net ion movement represents the summation of several events. At the level of the entire small or large intestine, substantial movement of ions occurs from the intestinal lumen into the blood and from the blood into the lumen. The *net* ion movement across the entire epithelium is the difference between these two unidirectional fluxes.

Fluid and electrolyte transport in the intestine varies considerably in two different axes, both along the length of the intestines (*segmental heterogeneity*) and from the bottom of a crypt to the top of a villus or to the surface cells (*crypt-villus/surface heterogeneity*). A comparison of two different segments of intestine (e.g., duodenum versus ileum) shows that they differ substantially in function. These differences in function reflect **segmental heterogeneity** of ion transport processes along the longitudinal axis of the intestine in different macroscopic regions of both the small and the large intestine; these differences are both qualitative and quantitative. For example, HCO₃⁻ stimulation of Na⁺ absorption occurs only in the proximal part of the small intestine. In contrast, the so-called electrogenic Na⁺ absorption (i.e., absorption associated with the development of a transepithelial potential difference) is restricted to the rectosigmoid segment of the colon.

Within an intestinal segment (e.g., a piece of ileum), **crypt-villus/surface heterogeneity** leads to differences in transport function along the radial axis of the intestine wall. For example, it is generally believed that absorptive function is located in villous cells in the small intestine (and surface epithelial cells in the large intestine), whereas secretory processes reside in the crypt cells. Finally, at a certain level within a single villus or crypt—or within a very small area of the colonic surface epithelium—individual cells may demonstrate further heterogeneity (**cellular heterogeneity**), with specific transport mechanisms restricted to different cells.

Overall ion movement in any segment of the intestine represents the summation of these various

absorptive and secretory events. These events may be paracellular or transcellular, may occur in the villus or crypt, and may be mediated by a goblet cell or an absorptive cell.

Despite the segmental heterogeneity of small-intestinal electrolyte transport, overall water and ion movement in the proximal and distal portions of the small intestine is similar: in health, the small intestine is a net absorber of water, Na^+ , Cl^- , and K^+ , but is a net secretor of HCO_3^- (see Fig. 44-2). Fluid absorption is isosmotic in the small intestine, similar to that observed in the renal proximal tubule (see pp. 758–759). In general, absorptive processes in the small intestine are enhanced in the postprandial state. The human colon carries out net absorption of water, Na^+ , and Cl^- with few exceptions, but it carries out net secretion of K^+ and HCO_3^- .

The intestines absorb and secrete solutes by both active and passive mechanisms

As discussed on pages 136–140, intestinal epithelial cells are polar; that is, they have two very different membranes—an apical membrane and a basolateral membrane—separated from one another by tight junctions. The transport processes present in the small and large intestine are quite similar to those present in other epithelia, such as the renal tubules, with only some organ-specific specialization to distinguish them. The transepithelial movement of a solute across the entire epithelium can be either absorptive or secretory. In each case, the movement can be either transcellular or paracellular. In transcellular movement, the solute must cross the two cell membranes in series. In general, movement of the solute across at least one of these membranes must be active (i.e., against an electrochemical gradient). In paracellular movement, the solute moves passively between adjacent epithelial cells through the tight junctions.

All transcellular Na^+ absorption is mediated by the Na-K pump (i.e., Na,K-ATPase) located at the basolateral membrane. This enzyme is responsible for Na^+ extrusion across the basolateral membrane and results in a relatively low $[\text{Na}^+]_i$ (~15 mM) and an intracellular-negative membrane potential. This Na^+ gradient serves as the driving force, in large part, for Na^+ entry into the epithelial cell across the luminal (apical) membrane, a process mediated either by Na^+ channels or by Na^+ -coupled transporters (e.g., Na/glucose cotransport, Na-H exchange). The epithelial cell may also use this Na^+ gradient to energize other transport processes at the apical or basolateral membrane.

Intestinal fluid movement is always coupled to solute movement, and sometimes solute movement is coupled to fluid movement by solvent drag

Fluid movement is always coupled to active solute movement.  **N44-1** The model of the osmotic coupling of fluid movement to solute movement in the intestine is similar to that in all or most epithelial cells (see p. 139). It is likely that the water movement occurs predominantly by a paracellular route  **N44-2** rather than by a transcellular route.  **N44-3**

N44-1

Nonosmotic Coupling of Water and Solute Movement in the

Intestine

Contributed by Emile Boulpaep, Walter Boron

The classical view, presented in the text, is that water transport always osmotically follows solute transport—that is, there is no such thing as a water pump (see pp. 127–136). However, Loo, Wright, and Zeuthen have suggested that the Na/glucose cotransporter SGLT1 can transport >200 water molecules for every two Na⁺ ions and one glucose molecule that it transports. **N44-5** In the specific case of the small intestine, these authors propose that SGLT1 can cotransport enough water to account for ~50% of the total water absorption across the brush border of the human small intestine. On the other hand, Lapointe and colleagues have argued that the observed water movement is in fact secondary to local osmotic gradients that drive water movement via the classical pathway.

N44-5

The Water-Pump Controversy

Contributed by Emile Boulpaep, Walter Boron

Loo and colleagues have proposed that the Na/glucose cotransporter SGLT1 in the human small intestine cotransports not only Na⁺ and glucose, but water as well. In other words, with each cycle, SGLT1 would move 2 Na⁺ ions, 1 glucose molecule, and >200 water molecules. The authors envisage that the Na⁺ ions and glucose molecule—along with the water molecules—would diffuse from the extracellular fluid into a pore within the cotransporter protein. The cotransporter would then undergo a conformational change that would close an outer gate and thereby occlude these ions and molecules from the extracellular fluid. By opening an inner gate, the cotransporter would deocclude these particles and allow the 2 Na⁺ ions, the glucose molecule, and the 200+ water molecules to enter the cytoplasm of the intestinal cell (i.e., enterocyte). There is no controversy that this general model—minus the water—explains how SGLT1 works. The question is whether each cycle of the cotransporter *also* moves a fixed number of water molecules through the membrane protein along with the Na⁺ and glucose. Loo and colleagues suggest that the water pumped by SGLT1 would account for about half of the water taken up by the small intestine.

On the other hand, Lapointe and colleagues have challenged the conclusion of Loo and colleagues, suggesting that the data of Loo and colleagues can more easily be explained by the classical model. That is, as SGLT1 cotransports Na⁺ and glucose from the extracellular to the intracellular fluid, water would follow osmotically.

N44-2

Pathways of Intestinal Water Movement

Contributed by Emile Boulpaep, Walter Boron

Pappenheimer and Reiss have estimated that about 50% of the fluid absorption in the small intestine occurs by a paracellular route. Moreover, they concluded that solvent drag—the entrainment of solutes by the paracellular flow of water—is a major pathway for the absorption of glucose and amino acids in the small intestine.

In his 1988 review, Pappenheimer proposed the following model: Na⁺-coupled glucose uptake into the intestinal cell—followed by the deposition of solute in the lateral intercellular spaces between epithelial cells—provides the osmotic driving force for paracellular H₂O movement, and hence solvent drag. Moreover, he speculated that Na⁺-coupled glucose transport somehow causes contraction of a ring of actomyosin just beneath the apical membrane, which pulls the tight junction apart slightly and increases the paracellular conductance to H₂O.

As far as the transcellular component of H₂O movement is concerned, the aquaporins AQP7 and AQP8 are present in the apical membranes of the small intestine and may play a role in transcellular H₂O movement. Aquaporins are present in the colon, although their role there is not established.

Solute movement is the driving force for fluid movement. However, the converse may also be true: solute movement may be coupled to fluid movement by **solvent drag**, a phenomenon in which the dissolved solute is swept along by bulk movement of the solvent (i.e., water). Solvent drag accounts for a significant fraction of the Na^+ and urea absorbed in the human jejunum (but not in the more distal segments of the small intestine or the large intestine). For all intents and purposes, solvent drag occurs through the paracellular route, and it depends on the permeability properties of the tight junctions (reflection coefficient; see [p. 468](#)) and the magnitude of the convective water flow. Thus, solvent drag contributes primarily to the absorption of relatively small, water-soluble molecules, such as urea and Na^+ , and it does so mainly in epithelia with relatively high permeability. The transepithelial permeability of the jejunum is considerably greater than that of the ileum or colon, as evidenced by its lower spontaneous transepithelial voltage difference (V_{te}), higher passive movement of NaCl , and larger apparent pore size.

The resistance of the tight junctions primarily determines the transepithelial resistance of intestinal epithelia

Epithelial permeability is an inverse function of transepithelial resistance. In epithelial structures such as the small and large intestine, transepithelial resistance is determined by cellular resistance and paracellular resistance, which are arranged in parallel (see [pp. 136–137](#)). Paracellular resistance is considerably lower than transcellular resistance; therefore, overall mucosal resistance primarily reflects paracellular resistance, which in turn depends primarily on the properties of the tight junctions. Therefore, intestinal permeability is essentially a function of tight-junction structure. Just as transport function varies greatly throughout the intestine, major differences in transepithelial permeability and the properties of tight junctions are also present throughout the intestinal tract. In general, resistance increases in the aboral direction (i.e., moving away from the mouth). Thus, the resistance of the jejunum is considerably lower than that of the distal end of the colon. Evidence also indicates that the permeability of the tight junctions in the crypt is greater than that in the villus.

Cellular Mechanisms of Na⁺ Absorption

Both the small intestine and the large intestine absorb large amounts of Na⁺ and Cl⁻ daily, but different mechanisms are responsible for this extremely important physiological process in different segments of the intestine. The villous epithelial cells in the small intestine and the surface epithelial cells in the colon are responsible for absorbing most of the Na⁺. Absorption of Na⁺ is the result of a complex interplay of both apical and basolateral membrane transport processes. [Figure 44-3](#) summarizes the four fundamental mechanisms by which Na⁺ may enter the cell across the apical membrane. In each case, the Na-K pump is responsible, at least in part, for the movement of Na⁺ from cell to blood. Also in each case, the driving force for apical Na⁺ entry is provided by the large, inwardly directed electrochemical gradient for Na⁺, which in turn is provided by the Na-K pump.

A Na/GLUCOSE OR Na/AMINO ACID COTRANSPORTERS

B Na-H EXCHANGER

C PARALLEL Na-H AND Cl-HCO₃ EXCHANGERS

D EPITHELIAL Na⁺ CHANNEL

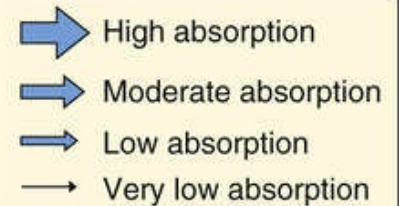

FIGURE 44-3 Modes of active Na⁺ absorption by the intestine. **A**, Nutrient-coupled Na⁺ absorption occurs in the villous cells of the jejunum and ileum and is the primary mechanism for postprandial Na⁺

absorption. **B**, Electroneutral Na-H exchange at the apical membrane, in the absence of Cl-HCO_3 exchange, is stimulated by the high pH of the HCO_3^- -rich luminal contents. **C**, Na-H and Cl-HCO_3 exchange may be coupled by an intracellular pH, resulting in electroneutral NaCl absorption, the primary mechanism for interdigestive Na^+ absorption. **D**, In electrogenic Na^+ absorption, the apical step of Na^+ movement occurs via ENaC channels. The thickness of the arrows in the insets indicates the relative magnitudes of Na^+ absorptive fluxes in different segments. CA, carbonic anhydrase.

The following four sections describe these four apical membrane transport processes.

Na/glucose and Na/amino-acid cotransport in the small intestine is a major mechanism for postprandial Na^+ absorption

“Nutrient-coupled” Na^+ absorption (see Fig. 44-3A) occurs throughout the small intestine. Although glucose- and amino acid-coupled Na^+ absorption also takes place in the colon of the newborn, it disappears during the neonatal period. Glucose- and amino acid-coupled Na^+ absorption occurs only in villous epithelial cells and not in crypt epithelial cells (see Fig. 44-1A). This process is the primary mechanism for Na^+ absorption after a meal, but it makes little contribution during the interdigestive period, when only limited amounts of glucose and amino acids are present in the intestinal lumen.

Glucose- and amino acid-coupled Na^+ absorption is mediated by specific apical membrane transport proteins. The Na/glucose cotransporter SGLT1 (see pp. 121–122) is responsible for glucose uptake across the apical membrane, as discussed in Chapter 45. Several distinct Na/amino-acid cotransporters, each specific for a different class of amino acids (see Table 36-1), are responsible for the Na^+ -coupled uptake of amino acids across the apical membrane. Because these transporters couple the energetically downhill movement of Na^+ to the uphill movement of glucose or an amino acid, the transporter processes are examples of **secondary active transport** (see p. 115). The glucose and amino acid-coupled uptake of Na^+ entry across the apical membrane increases $[\text{Na}^+]_i$, which in turn increases Na^+ extrusion across the basolateral membrane through the Na-K pump. Because the apical Na/glucose and Na/amino-acid cotransporters are electrogenic, as is the Na-K pump, the overall transport of Na^+ carries net charge and makes V_{te} more lumen negative. Thus, glucose- and amino acid-stimulated Na^+ absorption is an **electrogenic** process. As discussed below, the increase in the lumen-negative V_{te} provides the driving force for the parallel absorption of Cl^- .

Nutrient-coupled Na^+ transporters, unlike other Na^+ absorptive mechanisms in the small intestine, are not inhibited by either cAMP or $[\text{Ca}^{2+}]_i$. Thus, agonists that increase $[\text{cAMP}]_i$ (i.e., *Escherichia coli* or cholera enterotoxins) or $[\text{Ca}^{2+}]_i$ (i.e., serotonin) do not inhibit glucose- or amino acid-stimulated Na^+ absorption.

Electroneutral Na-H exchange in the duodenum and jejunum is responsible for Na^+ absorption that is stimulated by luminal alkalinity

Luminal HCO_3^- —the result of pancreatic, biliary, and duodenal secretion—increases Na^+ absorption in the proximal portion of the small intestine by stimulating apical membrane Na-H exchange (see Fig. 44-

3B). The Na-H exchanger couples Na^+ uptake across the apical membrane to proton extrusion into the intestinal lumen, a process that is enhanced by both decreases in intracellular pH (pH_i) and increases in luminal pH. The energy for Na-H exchange comes from the Na^+ gradient, a consequence of the ability of the Na-K pump to extrude Na^+ , thereby lowering $[\text{Na}^+]_i$. This process is characteristically inhibited by millimolar concentrations of the diuretic amiloride (Box 44-1).

Box 44-1

Oral Rehydration Solution

The therapeutic use of **oral rehydration solution (ORS)** provides an excellent demonstration of applied physiology. Many diarrheal illnesses (see Box 44-3) are caused by bacterial exotoxins that induce fluid and electrolyte secretion by the intestine. Hence such a toxin is referred to as an **enterotoxin**. Despite the massive toxin-induced fluid secretion, both intestinal morphology and nutrient-coupled Na^+ absorption are normal. Because nutrient-coupled (e.g., glucose- or amino acid-coupled) fluid absorption is intact, therapeutically increasing the concentration of glucose or amino acids in the intestinal lumen can enhance absorption. ORS contains varying concentrations of glucose, Na^+ , Cl^- , and HCO_3^- and is extremely effective in enhancing fluid and electrolyte absorption in secretory diarrhea when the intestine secretes massive amounts of fluid. Administration of ORS can reverse the dehydration and metabolic acidosis that may occur in severe diarrhea and that are often the primary cause of morbidity and mortality, especially in children younger than 5 years. ORS is the major advance of the past half century in the treatment of diarrheal disease, especially in developing countries. The development of ORS was a direct consequence of research on the physiology of glucose- and amino acid-stimulated Na^+ absorption.

Several isoforms of the Na-H exchanger exist (see p. 124), and different isoforms are present on the apical and basolateral membranes. Intestinal epithelial cells also have Na-H exchangers on their basolateral membranes. However, this NHE1 isoform, like its counterpart in nonepithelial cells, regulates pH_i (a “housekeeping” function) and does not contribute to the transepithelial movement of Na^+ . In contrast, both the NHE2 and NHE3 exchanger isoforms present on the apical membrane are responsible for transepithelial Na^+ movement and pH_i regulation. Although Na-H exchangers are present on the apical membrane of villous epithelial cells throughout the entire intestine, only in the duodenum and jejunum (i.e., the proximal part of the small intestine) is Na-H exchange present without the parallel presence of Cl-HCO_3 exchangers (see next section). Thus, in the proximal portion of the small intestine, the Na-H exchanger solely mediates the Na^+ absorption that is stimulated by the alkalinity of the HCO_3^- -rich intraluminal contents.

Parallel Na-H and Cl-HCO_3 exchange in the ileum and proximal part of the colon is the primary mechanism of Na^+ absorption during the interdigestive period

Electroneutral NaCl absorption occurs in portions of both the small and large intestine (see Fig. 44-3C). Electroneutral NaCl absorption is the result not of an Na/Cl cotransporter but rather of parallel apical membrane Na-H and Cl-HCO_3 exchangers that are closely linked by small changes in pH_i . In the human

colon, DRA (downregulated-in-adenoma, SLC26A3; see [Table 5-4](#)) mediates this Cl-HCO_3 exchange. This mechanism of NaCl absorption is the primary method of Na^+ absorption between meals (i.e., the interdigestive period), but it does not contribute greatly to postprandial Na^+ absorption, which is mediated primarily by the nutrient-coupled transporters described previously. Electroneutral NaCl absorption occurs in the ileum and throughout the large intestine, with the exception of the most distal segment. It is not affected by either luminal glucose or luminal HCO_3^- .

The overall electroneutral NaCl absorptive process is under the control of both cAMP and cGMP, as well as intracellular Ca^{2+} . Increases in each of these three intracellular messengers *reduce* NaCl absorption. Conversely, decreases in $[\text{Ca}^{2+}]_i$ and increases in aldosterone both *increase* electroneutral NaCl absorption.

Decreased NaCl absorption is important in the pathogenesis of most diarrheal disorders. For example, one of the common causes of traveler's diarrhea (see [Box 44-3](#)) is the heat-labile enterotoxin produced by the bacterium *E. coli*. This toxin activates adenylyl cyclase and increases $[\text{cAMP}]_i$, which in turn decreases NaCl absorption and stimulates active Cl^- secretion, as discussed below (see [pp. 905–908](#)). This toxin does not affect glucose-stimulated Na^+ absorption (see [pp. 903–904](#)).

Epithelial Na^+ channels are the primary mechanism of “electrogenic” Na^+ absorption in the distal part of the colon

In electrogenic Na^+ absorption (see [Fig. 44-3D](#)), Na^+ entry across the apical membrane occurs through epithelial Na^+ channels (ENaCs) that are highly specific for Na^+ (see [pp. 137–138](#)). Like the Na-H exchanger, these ENaCs are blocked by the diuretic amiloride, but at *micromolar* rather than *millimolar* concentrations. Na^+ absorption in the distal part of the colon is highly efficient. Because this segment of the colon is capable of absorbing Na^+ against large concentration gradients, it plays an important role in Na^+ conservation. Na^+ movement via electrogenic Na^+ absorption is not affected by luminal glucose or by HCO_3^- , nor is it regulated by cyclic nucleotides. However, it is markedly enhanced by mineralocorticoids (e.g., aldosterone).

Mineralocorticoids increase Na^+ absorption in the colon—as in other aldosterone-responsive epithelia, notably the renal collecting duct (see [pp. 765–766](#))—via multiple mechanisms. Aldosterone increases electrogenic Na^+ absorption by increasing Na^+ entry through the apical Na^+ channel and by stimulating activity of the Na-K pump. The increase in apical Na^+ uptake can occur (1) rapidly (i.e., within seconds) as a consequence of an increase in the opening of apical Na^+ channels, (2) more gradually (within minutes) because of the insertion of preformed Na^+ channels from subapical epithelial vesicle pools into the apical membrane, or (3) very slowly (within hours) as a result of an increase in the synthesis of both new apical Na^+ channels and Na-K pumps.

Cellular Mechanisms of Cl^- Absorption and Secretion

Cl^- absorption occurs throughout the small and large intestine and is often closely linked to Na^+ absorption. Cl^- and Na^+ absorption may be coupled through either an electrical potential difference or by pH_i . However, sometimes *no* coupling takes place, and the route of Cl^- movement may be either paracellular or transcellular.

Voltage-dependent Cl^- absorption represents coupling of Cl^- absorption to electrogenic Na^+ absorption in both the small intestine and the large intestine

Cl^- absorption can be a purely passive process ([Fig. 44-4A](#)), driven by the electrochemical gradient for Cl^- either across the tight junctions (paracellular route) or across the individual membranes of the epithelial cell (transcellular route). In either case, the driving force for Cl^- absorption derives from either of the two electrogenic mechanisms of Na^+ absorption: nutrient-coupled transport (see [pp. 903–904](#)) in the small intestine and ENaC channels in the distal end of the colon (see [p. 905](#)). This process is referred to as *voltage-dependent Cl^- absorption*; it is not an active transport process.

A PASSIVE Cl^- ABSORPTION

B Cl^- - HCO_3^- EXCHANGER

C PARALLEL Na^+ - H^+ AND Cl^- - HCO_3^- EXCHANGERS

FIGURE 44-4 Modes of Cl^- absorption by the intestine. **A**, In voltage-dependent Cl^- absorption, Cl^- may passively diffuse from lumen to blood across tight junctions, driven by a lumen-negative transepithelial voltage (paracellular route). Alternatively, Cl^- may diffuse through apical and basolateral Cl^- channels. **B**, In the absence of a parallel Na^+ - H^+ exchanger, electrogenic Cl^- - HCO_3^- exchange at the apical membrane results in Cl^- absorption and HCO_3^- secretion. **C**, Electroneutral NaCl absorption (see Fig. 44-3C) can mediate Cl^- absorption in the interdigestive period. Intracellular pH may couple the two exchangers. The thickness of the arrows in the insets indicates the relative magnitudes of Cl^- absorptive fluxes in different segments. CA, carbonic anhydrase.

Within the *small intestine*, induction of a lumen-negative potential difference by glucose- and amino acid-induced Na^+ absorption (see Fig. 44-3A) provides the driving force for Cl^- absorption that occurs following a meal. As noted above, nutrient-coupled Na^+ absorption primarily represents a villous cell process that occurs in the postprandial period and is insensitive to cyclic nucleotides and changes in $[\text{Ca}^{2+}]_i$. Voltage-dependent Cl^- absorption shares these properties. It is most likely that the route of voltage-dependent Cl^- absorption is paracellular.

In the *large intestine*, especially in the distal segment, electrogenic Na^+ absorption via ENaC channels (see Fig. 44-3D) also induces a lumen-negative potential difference that provides the driving force for colonic voltage-dependent Cl^- absorption. Factors that increase or decrease the voltage difference similarly affect Cl^- absorption (Box 44-2).

Box 44-2

Congenital Chloridorrhea

The congenital absence of an apical Cl-HCO_3 exchanger (which mediates the Cl-HCO_3 exchange involved in electroneutral NaCl absorption) is an autosomal recessive disorder known as **congenital chloridorrhea** or **congenital Cl^- diarrhea (CLD)**. Affected children have diarrhea with an extremely high stool $[\text{Cl}^-]$, a direct consequence of the absence of the apical membrane Cl-HCO_3 exchanger. In addition, because HCO_3^- secretion is reduced, patients are alkalotic (i.e., have an increased plasma $[\text{HCO}_3^-]$). The gene for congenital chloridorrhea is located on chromosome band 7q31. The gene product is the same as that of the *DRA* gene. *DRA* (SLC26A3; see Table 5-4) mediates electrogenic Cl-HCO_3 exchange. In addition, *DRA* transports sulfate and other anions. However, *DRA* is distinct from other electrogenic Cl-HCO_3 exchangers in the duodenum and pancreatic ducts (SLC26A6) as well as the anion exchanger (AE) subfamily that encodes electroneutral Cl-HCO_3 exchangers in erythrocytes and several other tissues. Indeed, Cl-HCO_3 exchange in these other tissues is unaffected in individuals with CLD, as are other intestinal transport processes.

Electroneutral Cl-HCO_3 exchange results in Cl^- absorption and HCO_3^- secretion in the ileum and colon

Electroneutral Cl-HCO_3 exchange, in the absence of parallel Na-H exchange, occurs in villous cells in the ileum and in surface epithelial cells in the large intestine (see Fig. 44-4B). It is not known whether this process occurs in the cells lining the crypts. A Cl-HCO_3 exchanger in the apical membrane is responsible for the 1 : 1 exchange of apical Cl^- for intracellular HCO_3^- . In humans, this Cl-HCO_3 exchanger is *DRA* (see Table 5-4). The details of Cl^- movement across the *basolateral* membrane are not well understood, but the process may involve a *ClC-2* Cl^- channel (see Table 6-2, family No. 16).

Parallel Na-H and Cl-HCO_3 exchange in the ileum and the proximal part of the colon mediates Cl^- absorption during the interdigestive period

Electroneutral NaCl absorption, discussed in connection with Na^+ absorption (see Fig. 44-3C), also

mediates Cl^- absorption in the ileum and proximal part of the colon (see Fig. 44-4C). The apical step of Cl^- absorption by this mechanism is mediated by parallel Na-H exchange (NHE3 or SLC9A3) and $\text{Cl}^-/\text{HCO}_3^-$ exchange (DRA or SLC26A3), which are coupled through pH_i .

Electrogenic Cl^- secretion occurs in crypts of both the small and the large intestine

In the previous three sections, we saw that intestinal Cl^- *absorption* occurs via three mechanisms. The small intestine and the large intestine are also capable of active Cl^- secretion, although Cl^- secretion is believed to occur mainly in the crypts rather than in either the villi or surface cells.  **N44-4**

N44-4

Spatial Distribution of Cl^- Secretion

Contributed by Emile Boulpaep, Walter Boron

We have already introduced the concept of a spatial distribution of absorptive and secretory processes in which secretory processes are restricted to crypt epithelial cells and absorptive processes to villous/surface epithelial cells in both the small and large intestine (see pp. 901–902). However, this model is an oversimplification. For example, active Cl^- secretion occurs in villous/surface epithelial cells as well as in crypt epithelial cells.

A small amount of Cl^- secretion probably occurs in the “basal” state but is masked by the higher rate of the three Cl^- absorptive processes that are discussed above in this subchapter. However, Cl^- secretion is markedly stimulated by secretagogues such as acetylcholine and other neurotransmitters. Moreover, Cl^- secretion is the major component of the ion transport events that occur during many clinical and experimental diarrheal disorders.

The cellular model of active Cl^- secretion is outlined in Figure 44-5 and includes three transport pathways on the basolateral membrane: (1) an Na-K pump, (2) an Na/K/Cl cotransporter (NKCC1 or SLC12A2), and (3) two types of K^+ channels (IK1 and BK). In addition, a Cl^- channel (cystic fibrosis transmembrane conductance regulator [CFTR]) is present on the apical membrane. This complex Cl^- secretory system is energized by the Na-K pump, which generates a low $[\text{Na}^+]_i$ and provides the driving force for Cl^- entry across the basolateral membrane through Na/K/Cl cotransport. As a result, $[\text{Cl}^-]_i$ is raised sufficiently that the Cl^- electrochemical gradient favors the passive efflux of Cl^- across the apical membrane. One consequence of these many transport processes is that the transepithelial voltage becomes more lumen negative, which promotes voltage-dependent Na^+ secretion. This Na^+ secretion that accompanies active Cl^- secretion presumably occurs through the tight junctions (paracellular pathway). Thus, the net result is stimulation of NaCl and fluid secretion.

FIGURE 44-5 Cellular mechanism of electrogenic Cl^- secretion by crypt cells. The basolateral Na/K/Cl cotransporter brings Cl^- into the crypt cell; the Cl^- exits across the apical Cl^- channel. Secretagogues may open pre-existing Cl^- channels or cause subapical vesicles to fuse with the apical membrane, thus delivering new Cl^- channels. The paracellular pathway allows Na^+ movement from blood to lumen, driven by the lumen-negative transepithelial voltage. The thickness of the arrows in the inset indicates the relative magnitudes of Cl^- secretory fluxes in different segments.

Normally (i.e., in the unstimulated state) the crypts secrete little Cl^- because the apical membrane Cl^- channels are either closed or not present. Cl^- secretion requires stimulation by any of several **secretagogues**, including (1) bacterial exotoxins (i.e., enterotoxins), (2) hormones and neurotransmitters, (3) products of cells of the immune system (e.g., histamine), and (4) laxatives ([Table 44-2](#)). These secretagogues act by increasing intracellular levels of cyclic nucleotides or Ca^{2+} . For example, vasoactive intestinal peptide (VIP) acts through adenylyl cyclase; the heat-stable toxin of *E. coli* acts through guanylyl cyclase; and acetylcholine acts through phospholipase C.

TABLE 44-2
Mode of Action of Secretagogues

CATEGORY	SECRETAGOGUE	SECOND MESSENGER
Bacterial enterotoxins	Cholera toxin	cAMP
	<i>Escherichia coli</i> toxins: heat labile	cAMP
	<i>E. coli</i> toxins: heat stable	cGMP
	<i>Yersinia</i> toxin	cGMP
	<i>Clostridium difficile</i> toxin	Ca ²⁺
Hormones and neurotransmitters	VIP	cAMP
	Guanylin	cGMP
	Acetylcholine	Ca ²⁺
	Bradykinin	Ca ²⁺
	Serotonin (5-HT)	Ca ²⁺
Immune cell products	Histamine	cAMP
	Prostaglandins	cAMP
Laxatives	Bile acids	Ca ²⁺
	Ricinoleic acid	?

The resulting activation of one or more protein kinases—by any of the aforementioned pathways—increases the Cl[−] conductance of the apical membrane either by activating pre-existing Cl[−] channels or by inserting into the apical membrane Cl[−] channels that—in the unstimulated state—are stored in subapical membrane vesicles. In either case, Cl[−] now exits the cell through apical Cl[−] channels; the result is a decrease in [Cl[−]]_i, which leads to increased uptake of Na⁺, Cl[−], and K⁺ across the basolateral membrane via NKCC1. The Na⁺ recycles out of the cell via the Na-K pump. The K⁺ recycles through basolateral K⁺ channels that open in response to the same protein kinases that increase Cl[−] conductance. The net result of all these changes is the initiation of active Cl[−] secretion across the epithelial cell.

The induction of apical membrane Cl[−] channels is extremely important in the pathophysiology of many diarrheal disorders. [Box 44-3](#) discusses the changes in ion transport that occur in secretory diarrheas such as that associated with cholera. A central role in **cystic fibrosis** has been posited for the CFTR Cl[−] channel in the apical membrane (see [p. 122](#)). However, other Cl[−] channels, including the Ca²⁺-activated CaCC (see [Table 6-2](#), family No. 17) are likely present in the intestine and may contribute to active Cl[−] secretion.

Box 44-3

Secretory Diarrhea

Diarrhea is a common medical problem and can be defined as a “symptom” (i.e., an increase in the number of bowel movements or a decrease in stool consistency) or as a sign (i.e., an increase in stool volume of >0.2 L/24 hr). Diarrhea has many causes and can be classified in various ways. One classification divides diarrheas by the causative factor. The causative factor can be failure to absorb a dietary nutrient, in which case the result is an **osmotic diarrhea**. An example of osmotic diarrhea is that caused by primary lactase deficiency. Alternatively, the causative factor may *not* be lack of absorption of a dietary nutrient, but rather endogenous secretion of fluid and electrolytes from the intestine, in which case the result is **secretory diarrhea**.

The leading causes of secretory diarrhea include infections with *E. coli* (the major cause of traveler's diarrhea) and cholera (a cause of substantial morbidity and mortality in developing countries). In these and other infectious diarrheas, an enterotoxin produced by one of many bacterial organisms raises intracellular concentrations of cAMP, cGMP, or Ca²⁺ (see [Table 44-2](#)).

A second group of secretory diarrheas includes those produced by different, relatively uncommon

hormone-producing tumors. Examples of such tumors include those that produce VIP (Verner-Morrison syndrome), glucagon (glucagonomas), and serotonin (carcinoid syndrome). These secretagogues act by raising either $[cAMP]_i$ or $[Ca^{2+}]_i$ (see Table 44-2). When tumors produce these secretagogues in abundance, the resulting diarrhea can be copious and explosive.

As we have seen, the secretory diarrheas have in common their ability to increase $[cAMP]_i$, $[cGMP]_i$, or $[Ca^{2+}]_i$. Table 44-4 summarizes the mechanisms by which these second messengers produce the secretory diarrhea. Because the second messengers do not alter the function of nutrient-coupled Na^+ absorption, administration of an oral rehydration solution containing glucose and Na^+ is effective in the treatment of enterotoxin-mediated diarrhea (see Box 44-1).

Cellular Mechanisms of K⁺ Absorption and Secretion

Overall net transepithelial K⁺ movement is absorptive in the small intestine and secretory in the colon

The gastrointestinal tract participates in overall K⁺ balance, although compared with the kidneys, the small intestine and large intestine play relatively modest roles, especially in healthy individuals.

The pattern of intestinal K⁺ movement parallels that of the kidney: (1) the intestines have the capacity for both K⁺ absorption and secretion, and (2) the intestines absorb K⁺ in the proximal segments but secrete it in the distal segments.

Dietary K⁺ furnishes 80 to 120 mmol/day, whereas stool K⁺ output is only ~10 mmol/day. The kidney is responsible for disposal of the remainder of the daily K⁺ intake (see [p. 795](#)). Substantial quantities of K⁺ are secreted in gastric, pancreatic, and biliary fluid. Therefore, the total K⁺ load presented to the small intestine is considerably greater than that represented by the diet. The concentration of K⁺ in stool is frequently >100 mM. This high stool [K⁺] is the result of several factors, including both colonic K⁺ secretion and water absorption, especially in the distal part of the colon.

K⁺ absorption in the small intestine probably occurs via solvent drag

Experiments in which a plasma-like solution perfused segments of the intestine have established that K⁺ is *absorbed* in the jejunum and ileum of the small intestine and is *secreted* in the large intestine. Although the small intestine absorbs substantial amounts of K⁺, no evidence has been presented to suggest that K⁺ absorption in the jejunum and ileum is an active transport process or even carrier mediated. Thus, K⁺ absorption in the small intestine is probably passive, most likely a result of **solvent drag** (i.e., pulled along by bulk water movement; see [p. 908](#)), as illustrated in [Figure 44-6A](#). Although changes in dietary Na⁺ and K⁺ and alterations in hydration influence K⁺ movement in the *colon*, similar physiological events do not appear to affect K⁺ absorption in the *small intestine*.

A PASSIVE K^+ ABSORPTION

B PASSIVE K^+ SECRETION

C ACTIVE K^+ SECRETION

D ACTIVE K^+ ABSORPTION

FIGURE 44-6 Cellular mechanisms of K^+ secretion and absorption. **A**, In the small intestine, K^+ absorption occurs via solvent drag. **B**, Throughout the colon, *passive* K^+ secretion occurs via tight junctions, driven by a lumen-negative transepithelial voltage. **C**, Throughout the colon, *active* K^+ secretion is transcellular. **D**, In the distal colon, *active* K^+ absorption is transcellular. The thickness of the arrows in the insets indicates the relative magnitude of K^+ flux in different segments.

Passive K^+ secretion is the primary mechanism for net colonic secretion

In contrast to the small intestine, the human colon is a net *secretor* of K^+ . This secretion occurs by two mechanisms: a passive transport process that is discussed in this section and an active process that is discussed in the next. Together, these two K^+ secretory pathways are greater than the modest component of active K^+ absorption in the distal part of the colon and thus account for the overall secretion of K^+ by the colon.

Passive K^+ secretion, which is the pathway that is primarily responsible for overall net colonic K^+ secretion, is driven by the lumen-negative V_{te} of 15 to 25 mV. The route of passive K^+ secretion is predominantly paracellular, not transcellular (see Fig. 44-6B). Because V_{te} is the primary determinant of passive K^+ secretion, it is not surprising that passive K^+ secretion is greatest in the distal end of the colon, where V_{te} difference is most negative. Similarly, increases in the lumen-negative V_{te} that occur as an adaptive response to dehydration—secondary to an elevation in aldosterone secretion (see the next section)—result in an enhanced rate of passive K^+ secretion. Information is not available regarding the distribution of passive K^+ secretion between surface epithelial and crypt cells.

Active K^+ secretion is also present throughout the large intestine and is induced both by aldosterone and by cAMP

In addition to *passive* K^+ secretion, *active* K^+ transport processes—both secretory and absorptive—are also present in the colon. However, active transport of K^+ is subject to considerable segmental variation in the colon. Whereas active K^+ *secretion* occurs throughout the colon, active K^+ *absorption* is present only in the distal segments of the large intestine. Thus, in the rectosigmoid colon, active K^+ absorption and active K^+ secretion are both operative and appear to contribute to total-body homeostasis.

The model of active K^+ secretion in the colon is quite similar to that of active Cl^- secretion (see Fig. 44-5) and is also parallel to that of active K^+ secretion in the renal distal nephron (see p. 799). The general paradigm of active K^+ transport in the colon is a “pump-leak” model (see Fig. 44-6C). Uptake of K^+ across the basolateral membrane is a result of both the Na-K pump and the Na/K/Cl cotransporter (NKCC1), which is energized by the low $[Na^+]_i$ that is created by the Na-K pump. Once K^+ enters the cell across the basolateral membrane, it may exit either across the apical membrane (K^+ secretion) or across the basolateral membrane (K^+ recycling). The cell controls the extent to which secretion occurs, in part by K^+ channels present in both the apical and the basolateral membranes. When apical K^+ channel activity is less than basolateral channel activity, K^+ recycling dominates. Indeed, in the basal state, the rate of active K^+ secretion is low because the apical K^+ channel activity is minimal in comparison with the K^+ channel activity in the basolateral membrane.

It is likely that aldosterone stimulates active K^+ secretion in surface epithelial cells of the large intestine, whereas cAMP enhances active K^+ secretion in crypt cells. In both cases, the rate-limiting step

is the apical BK K^+ channel, and both secretagogues act by increasing K^+ channel activity.

Aldosterone

The mineralocorticoid aldosterone enhances overall net K^+ secretion by two mechanisms. First, it increases **passive** K^+ secretion by increasing Na-K pump activity and thus increasing electrogenic Na^+ absorption (see Fig. 44-3D). The net effects are to increase the lumen-negative V_{te} and to enhance passive K^+ secretion (see Fig. 44-6B). Second, aldosterone stimulates **active** K^+ secretion by increasing the activity of both apical K^+ channels and basolateral Na-K pumps (see Fig. 44-6C).

cAMP and Ca^{2+}

VIP and cholera enterotoxin both increase $[cAMP]_i$ and thus stimulate K^+ secretion. Increases in $[Ca^{2+}]_i$ —induced, for example, by serotonin (or 5-hydroxytryptamine [5-HT])—also stimulate active K^+ secretion. In contrast to aldosterone, neither of these second messengers has an effect on the Na-K pump; rather, they increase the activity of both the apical and the basolateral K^+ channels. Because the stimulation of K^+ channels is greater at the apical than at the basolateral membrane, the result is an increase in K^+ exit from the epithelial cell across the apical membrane (i.e., secretion). Stimulation of K^+ secretion by cAMP and Ca^{2+} , both of which also induce active Cl^- secretion (see Fig. 44-5), contributes to the significant fecal K^+ losses that occur in many diarrheal diseases.

Active K^+ absorption takes place only in the distal portion of the colon and is energized by an apical H-K pump

As noted above, not only does the distal end of the colon actively secrete K^+ , it also actively absorbs K^+ . The balance between the two processes plays a role in overall K^+ homeostasis. Increases in dietary K^+ enhance both passive and active K^+ secretion (see Fig. 44-6B, C). However, dietary K^+ depletion enhances active K^+ absorption (see Fig. 44-6D). The mechanism of active K^+ absorption appears to be an exchange of luminal K^+ for intracellular H^+ across the apical membrane, mediated by an H-K pump (see pp. 117–118). The colonic H-K pump is ~60% identical at the amino-acid level to both the Na-K pump and the gastric parietal-cell H-K pump. Thus, active colonic K^+ absorption occurs via a *transcellular* route, in contrast to the *paracellular* route that characterizes K^+ absorption in the small intestine (see Fig. 44-6A). The mechanism of K^+ exit across the basolateral membrane may involve K/Cl cotransport. Not known is whether active K^+ secretion (see Fig. 44-6C) and active K^+ absorption (see Fig. 44-6D) occur in the same cell or in different cells.

Regulation of Intestinal Ion Transport

Chemical mediators from the enteric nervous system, endocrine cells, and immune cells in the lamina propria may be either secretagogues or absorptagogues

Numerous chemical mediators from several different sources regulate intestinal electrolyte transport. Some of these agonists are important both in health and in diarrheal disorders, and at times only quantitative differences separate normal regulatory control from the pathophysiology of diarrhea. These mediators may function in one or more modes: neural, endocrine, paracrine, and perhaps autocrine (see [p. 47](#)). Most of these agonists (i.e., secretagogues) promote secretion, whereas some others (i.e., absorptagogues) enhance absorption.

The **enteric nervous system (ENS)**, discussed on [pages 339–340 and 855–856](#), is important in the normal regulation of intestinal epithelial electrolyte transport. Activation of enteric secretomotor neurons results in the release of acetylcholine from mucosal neurons and in the induction of active Cl^- secretion (see [Fig. 44-5](#)). Additional neurotransmitters, including VIP, 5-HT, and histamine, mediate ENS regulation of epithelial ion transport.

An example of regulation mediated by the **endocrine system** is the release of aldosterone from the adrenal cortex and the subsequent formation of angiotensin II; both dehydration and volume contraction stimulate this renin-angiotensin-aldosterone axis (see [pp. 841–842](#)). Both angiotensin and aldosterone regulate total-body Na^+ homeostasis by stimulating Na^+ absorption, angiotensin in the small intestine, and aldosterone in the colon. Their effects on cellular Na^+ absorption differ. In the small intestine, angiotensin enhances electroneutral NaCl absorption (see [Fig. 44-3C](#)), probably by upregulating apical membrane Na-H exchange. In the colon, aldosterone stimulates electrogenic Na^+ absorption (see [Fig. 44-3D](#)).

The response of the intestine to angiotensin and aldosterone represents a classic endocrine feedback loop: dehydration results in increased levels of angiotensin and aldosterone, the primary effects of which are to stimulate fluid and Na^+ absorption by both the renal tubules (see [pp. 765–766](#)) and the intestines. The result is restoration of total-body fluid and Na^+ content.

Regulation of intestinal transport also occurs by **paracrine effects**. Endocrine cells constitute a small fraction of the total population of mucosal cells in the intestines. These endocrine cells contain several peptides and bioactive amines that are released in response to various stimuli. Relatively little is known about the biology of these cells, but gut distention can induce the release of one or more of these agonists (e.g., 5-HT). The effect of these agonists on adjacent surface epithelial cells represents a paracrine action.

Another example of paracrine regulation of intestinal fluid and electrolyte transport is the influence of **immune cells** in the *lamina propria* (see [Fig. 44-1](#)). [Table 44-3](#) lists these immune cells and some of the agonists that they release. The same agonist may be released from more than one cell, and individual cells produce multiple agonists. These agonists may activate epithelial cells directly or may activate other immune cells or enteric neurons. For example, reactive oxygen radicals released by mast cells affect epithelial-cell function by acting on enteric neurons and fibroblasts, and they also have direct action on surface and crypt epithelial cells.

TABLE 44-3

Products of Lamina Propria Cells that Affect Intestinal Ion Transport

CELL	PRODUCT
Macrophages	Prostaglandins O ₂ radicals
Mast cells	Histamine
Neutrophils	Eicosanoids Platelet-activating factor
Fibroblasts	Eicosanoids Bradykinin

A single agonist usually has multiple sites of action. For example, the histamine released from mast cells can induce fluid secretion as a result of its interaction with receptors on surface epithelial cells (Fig. 44-7). However, histamine can also activate ENS motor neurons, which can in turn alter epithelial-cell ion transport as well as intestinal smooth-muscle tone and blood flow. As a consequence, the effects of histamine on intestinal ion transport are multiple and amplified.

FIGURE 44-7 Mast cell activation. Activation of mast cells in the lamina propria triggers the release of histamine, which either directly affects epithelial cells or stimulates an enteric neuron and thus has an indirect effect. The neuron modulates the epithelium (secretion), intestinal smooth muscle (motility), or vascular smooth muscle (blood flow). ACh, acetylcholine; EP₂ receptor, prostaglandin E₂ receptor; IL-1, interleukin-1; PGE₂, prostaglandin E₂.

Secretagogues can be classified by their type and by the intracellular second-messenger system that they stimulate

Several agonists induce the accumulation of fluid and electrolytes in the intestinal lumen (i.e., net secretion). These secretagogues are a diverse, heterogeneous group of compounds, but they can be effectively classified in two different ways: by the type of secretagogue and by the intracellular second messenger that these agonists activate.

Grouped according to type, the secretagogues fall into four categories: (1) bacterial exotoxins (i.e., enterotoxins), (2) hormones and neurotransmitters, (3) products of cells of the immune system, and (4)

laxatives. [Table 44-2](#) provides a partial list of these secretagogues. A **bacterial exotoxin** is a peptide that is produced and excreted by bacteria that can produce effects independently of the bacteria. An **enterotoxin** is an exotoxin that induces changes in intestinal fluid and electrolyte movement. For example, *E. coli* produces two distinct enterotoxins (the so-called heat-labile and heat-stable toxins) that induce fluid and electrolyte secretion via two distinct receptors and second-messenger systems.

We can also classify secretagogues according to the signal-transduction system that they activate after binding to a specific membrane receptor. As summarized in [Table 44-2](#), the second messengers of these signal-transduction systems include cAMP, cGMP, and Ca^{2+} . For example, the **heat-labile** toxin of *E. coli* binds to apical membrane receptors, becomes internalized, and then activates basolateral adenylyl cyclase. The resulting increase in $[\text{cAMP}]_i$ activates protein kinase A. VIP also acts by this route ([Fig. 44-8](#)). The **heat-stable** toxin of *E. coli* binds to and activates an apical receptor guanylyl cyclase, similar to the atrial natriuretic peptide (ANP) receptor (see [p. 66](#)). The newly produced cGMP activates protein kinase G and may also activate protein kinase A. The natural agonist for this pathway is guanylin, a 15–amino-acid peptide secreted by mucosal cells of the small and large intestine. Still other secretory agonists (e.g., 5-HT) produce their effects by increasing $[\text{Ca}^{2+}]_i$ and thus activating protein kinase C or Ca^{2+} -calmodulin–dependent protein kinases. One way that secretagogues can increase $[\text{Ca}^{2+}]_i$ is by stimulating phospholipase C, which leads to the production of inositol 1,4,5-trisphosphate (IP_3) and the release of Ca^{2+} from intracellular stores (see [p. 60](#)). Secretagogues can also increase $[\text{Ca}^{2+}]_i$ by activating protein kinases, which may stimulate basolateral Ca^{2+} channels.

FIGURE 44-8 Action of secretagogues. Secretagogues (agents that stimulate the net secretion of fluid and electrolytes into the intestinal lumen) act by any of the mechanisms numbered 1, 2, or 3. AC, adenylyl cyclase; CaM, calmodulin; DAG, diacylglycerol; ER, endoplasmic reticulum; G_q and G_s , α -subunit types of G proteins; GPCRs, G protein–coupled receptors; PIP_2 , phosphatidylinositol 4,5-bisphosphate; PKA, protein kinase A; PKC, protein kinase C; PKG, cGMP-dependent protein kinase; PLC, phospholipase C.

Although the secretagogues listed in Table 44-2 stimulate fluid and electrolyte secretion via one of three distinct second messengers (i.e., cAMP, cGMP, and Ca^{2+}), the *end effects* are quite similar. As summarized in Table 44-4, all three second-messenger systems stimulate active Cl^- secretion (see Fig. 44-5) and inhibit electroneutral NaCl absorption (see Fig. 44-3C). The abilities of cAMP and Ca^{2+} to stimulate Cl^- secretion and inhibit electroneutral NaCl absorption are almost identical. In contrast,

cGMP's ability to stimulate Cl^- secretion is somewhat less, although its effects on electroneutral NaCl absorption are quantitatively similar to those of cAMP and Ca^{2+} . Both stimulation of Cl^- secretion and inhibition of electroneutral NaCl absorption have the same overall effect: *net secretion of fluid and electrolytes*. It is uncertain whether the observed decrease in electroneutral NaCl absorption is the result of inhibiting Na-H exchange, Cl-HCO_3 exchange, or both inasmuch as electroneutral NaCl absorption represents the coupling of separate Na-H and Cl-HCO_3 exchange processes via pH_i (see Fig. 44-3C).

TABLE 44-4
End Effects of Second Messengers on Intestinal Transport

SECOND MESSENGER	INCREASED ANION SECRETION	INHIBITED NaCl ABSORPTION
cAMP	+++	+++
cGMP	+	+++
Ca^{2+}	+++	+++

Mineralocorticoids, glucocorticoids, and somatostatin are absorptagogues

Although multiple secretagogues exist, relatively few agonists can be found that *enhance* fluid and electrolyte *absorption*. The cellular effects of these absorptagogues are less well understood than those of the secretagogues. Those few absorptagogues that have been identified increase intestinal fluid and electrolyte absorption by either a paracrine or an endocrine mechanism.

Corticosteroids are the primary hormones that enhance intestinal fluid and electrolyte absorption. **Mineralocorticoids** (e.g., aldosterone) stimulate Na^+ absorption and K^+ secretion in the distal end of the colon; they do not affect ion transport in the small intestine. Their cellular actions are outlined on [page 1027](#). Aldosterone induces both apical membrane Na^+ channels (a process that is inhibited by the diuretic amiloride) and basolateral Na-K pumps; this action results in substantial enhancement of colonic “electrogenic” Na^+ absorption. Although the effects of glucocorticoids on ion transport have most often been considered a result of crossover binding to the mineralocorticoid receptor (see [p. 766](#)), it is now evident that glucocorticoids also have potent actions on ion transport via their own receptor and that these changes in ion transport are distinct from those of the mineralocorticoids. **Glucocorticoids** stimulate electroneutral NaCl absorption (see Fig. 44-3C) throughout the large and small intestine without any effect on either K^+ secretion or electrogenic Na^+ absorption. Both corticosteroids act, at least in part, by genomic mechanisms (see [pp. 71–72](#)).

Other agonists appear to stimulate fluid and electrolyte absorption by stimulating electroneutral NaCl absorption and inhibiting electrogenic HCO_3^- secretion; both these changes *enhance fluid absorption*. Among these absorptagogues are **somatostatin**, which is released from endocrine cells in the intestinal mucosa (see [pp. 993–994](#)), and the enkephalins and norepinephrine, which are neurotransmitters of enteric neurons. The limited information available suggests that these agonists affect ion transport by *decreasing* $[\text{Ca}^{2+}]_i$, probably by blocking Ca^{2+} channels. Thus, it appears that fluctuations in $[\text{Ca}^{2+}]_i$ regulate Na^+ and Cl^- transport in both the absorptive (low $[\text{Ca}^{2+}]_i$) and secretory (high $[\text{Ca}^{2+}]_i$) directions. Therefore, Ca^{2+} is clearly a critical modulator of intestinal ion transport.

CHAPTER 45

Nutrient Digestion and Absorption

Henry J. Binder, Charles M. Mansbach II

In general, the digestive-absorptive processes for most of the constituents of our diet are highly efficient. For example, normal adult intestine absorbs ~95% of dietary lipid. However, we ingest most of the constituents of dietary food in a form that the intestine cannot readily absorb. Multiple digestive processes convert dietary food to a form that can be absorbed—primarily in the small intestine, but also, to a much smaller extent, in the colon.

The **digestive process**—the enzymatic conversion of complex dietary substances to a form that can be absorbed—is initiated by the sight, smell, and taste of food. Although some digestion (that of carbohydrates) begins in the mouth and additional digestion may occur within the lumen of the stomach, most digestive processes occur in the small intestine. Digestion within the small intestine occurs either in the *lumen*, mediated by pancreatic enzymes, or at the small-intestinal *brush-border membrane* (membrane digestion), mediated by brush-border enzymes. Several different patterns of luminal, brush-border, and cytosolic digestion exist ([Fig. 45-1](#)). Some of the dietary carbohydrate and protein that escape digestion and absorption in the small intestine are altered in the large intestine by bacterial enzymes to short-chain fatty acids (SCFAs)  **N45-1** that are absorbed by the colon.

FIGURE 45-1 General mechanisms of digestion and absorption. Digestion-absorption can follow any of five patterns. First, the substance (e.g., glucose) may not require digestion; the intestinal cells may absorb the nutrient as ingested. Second, a polymer (e.g., protein) may be digested in the lumen to its constituent monomers (e.g., amino acids) by pancreatic enzymes prior to absorption. Third, an oligomer (e.g., sucrose) is digested into its constituent monomers (e.g., monosaccharides) by brush-border enzymes prior to absorption. When in free solution, fructose is present primarily as the pyranose (6-membered ring) form and less so as the furanose (5-membered ring) form. Fourth, an oligomer (e.g., oligopeptide) may be directly absorbed by the cell and then broken down into monomers (e.g., amino acids) inside the cell. Finally, a substance (e.g., TAG) may be broken down into its constituent components prior to absorption; the cell may then resynthesize the original molecule.

N45-1

Fatty Acids

Chain Length

Contributed by Emile Boulpaep, Walter Boron

Name	Abbreviation	Number of Carbon Atoms
Short-chain fatty acid	SCFA	<6
Medium-chain fatty acid	MCFA	6–12
Long-chain fatty acid	LCFA	13–21
Very-long-chain fatty acid	VLCFA	>21

The digestive processes for carbohydrates, proteins, and lipids result in the conversion of dietary

nutrients to chemical forms for which intestinal **absorptive processes** exist. As a consequence, the digestive-absorptive processes for the several dietary constituents are closely integrated and regulated biological events that ensure survival. Multiple diseases can alter these digestive-absorptive processes and can thereby impair nutrient **assimilation** (i.e., the overall process of digestion and absorption). Because of the substantial segmental distribution of nutrient absorption along the gastrointestinal tract ([Fig. 45-2](#)), the clinical manifestations of disease ([Table 45-1](#)) often reflect these segmental differences.

FIGURE 45-2 Sites of nutrient absorption. **A**, The entire small intestine absorbs carbohydrates, proteins, and lipids. However, the absorption is greatest in the duodenum, somewhat less in the jejunum, and much less in the ileum. The thickness of the arrows indicates the relative magnitude of total absorption at the indicated site *in vivo* (see *inset*). The maximal absorptive capacity of a specific segment under *optimized* experimental conditions (e.g., substrate concentrations) may be greater. **B**, Some substances are actively absorbed only in the duodenum. **C**, Bile acids are absorbed along the entire small intestine, but active absorption occurs only in the ileum. **D**, The vitamin cobalamin is absorbed only in the ileum.

TABLE 45-1
Major Gastrointestinal Diseases and Nutritional Deficiencies

DISEASE	ORGAN SITE OF PREDOMINANT PATHOLOGY	DEFECTIVE Process
Celiac disease (see Box 45-5)	Duodenum and jejunum	Fat absorption, lactose hydrolysis
Chronic pancreatitis	Exocrine pancreas	Fat digestion
Surgical resection of ileum; Crohn disease of ileum	Ileum	Cobalamin and bile-acid absorption
Primary lactase deficiency	Small intestine	Lactose hydrolysis

Carbohydrate Digestion

Carbohydrates, providing ~45% of total energy needs of Western diets, require hydrolysis to monosaccharides before absorption

We can classify dietary carbohydrates into two major groups: (1) the **monosaccharides** (monomers), and (2) the **oligosaccharides** (short polymers) and **polysaccharides** (long polymers). The small intestine can directly absorb the monomers but not the polymers. Some polymers are **digestible**, that is, the body can digest them to form the monomers that the small intestine can absorb. Other polymers are **nondigestible**, or “fiber.” The composition of dietary carbohydrate is quite varied and is a function of culture. The diet of individuals in so-called developed countries contains considerable amounts of “refined” sugar and, compared with individuals in most developing countries, less fiber. Such differences in the fiber content of the Western diet may account for several diseases that are more prevalent in these societies (e.g., colon carcinoma and atherosclerosis). As a consequence, the consumption of fiber by the health-conscious public in the United States has increased during the past 3 decades. In general, increased amounts of fiber in the diet are associated with increased stool weight and frequency.

Approximately 45% to 60% of dietary carbohydrate is in the form of **starch**, which is a polysaccharide. Starch is a storage form for carbohydrates that is primarily found in plants, and it consists of both amylose and amylopectin. In contrast, the storage form of carbohydrates in animal tissues is glycogen, which is consumed in much smaller amounts. **Amylose** is a straight-chain glucose polymer that typically contains multiple glucose residues, connected by α -1,4 linkages. In contrast, **amylopectin** is a massive branched glucose polymer that may contain 1 million glucose residues. In addition to the α -1,4 linkages, amylopectin has frequent α -1,6 linkages at the branch points. Amylopectins are usually present in much greater quantities (perhaps 4-fold higher) than amylose. Glycogen—the “animal starch”—has α -1,4 and α -1,6 linkages like amylopectin. However, glycogen is more highly branched (i.e., more α -1,6 linkages).

Most dietary oligosaccharides are the disaccharides sucrose and lactose, which represent 30% to 40% of dietary carbohydrates. **Sucrose** is table sugar, derived from sugar cane and sugar beets, whereas **lactose** is the sugar found in milk. The remaining carbohydrates are the monosaccharides **fructose** and **glucose**, which make up 5% to 10% of total carbohydrate intake. There is no evidence of any intestinal absorption of either starches or disaccharides. Because the small intestine can absorb only *monosaccharides*, all dietary carbohydrate must be digested to monosaccharides before absorption. The colon cannot absorb monosaccharides.

Dietary fiber consists of both soluble and insoluble forms and includes lignins, pectins, and cellulose. These fibers are primarily present in fruits, vegetables, and cereals. Cellulose is a glucose polymer connected by β -1,4 linkages, which cannot be digested by mammalian enzymes. However, enzymes from colonic bacteria may degrade fiber. This process is carried out with varying efficiency; pectins, gum, and mucilages are metabolized to a much greater degree than either cellulose or hemicellulose. In contrast, lignins, which are aromatic polymers and not carbohydrates, are not altered by microbial enzymes in the colonic lumen and are excreted unaltered in stool.

As we discuss below, the digestive process for dietary carbohydrates has two steps: (1) **intraluminal hydrolysis** of starch to oligosaccharides by salivary and pancreatic amylases (Fig. 45-3), and (2) so-

called **membrane digestion** of oligosaccharides to monosaccharides by brush-border disaccharidases. The resulting carbohydrates are absorbed by transport processes that are specific for certain monosaccharides. These transport pathways are located in the apical membrane of the small-intestinal villous epithelial cells.

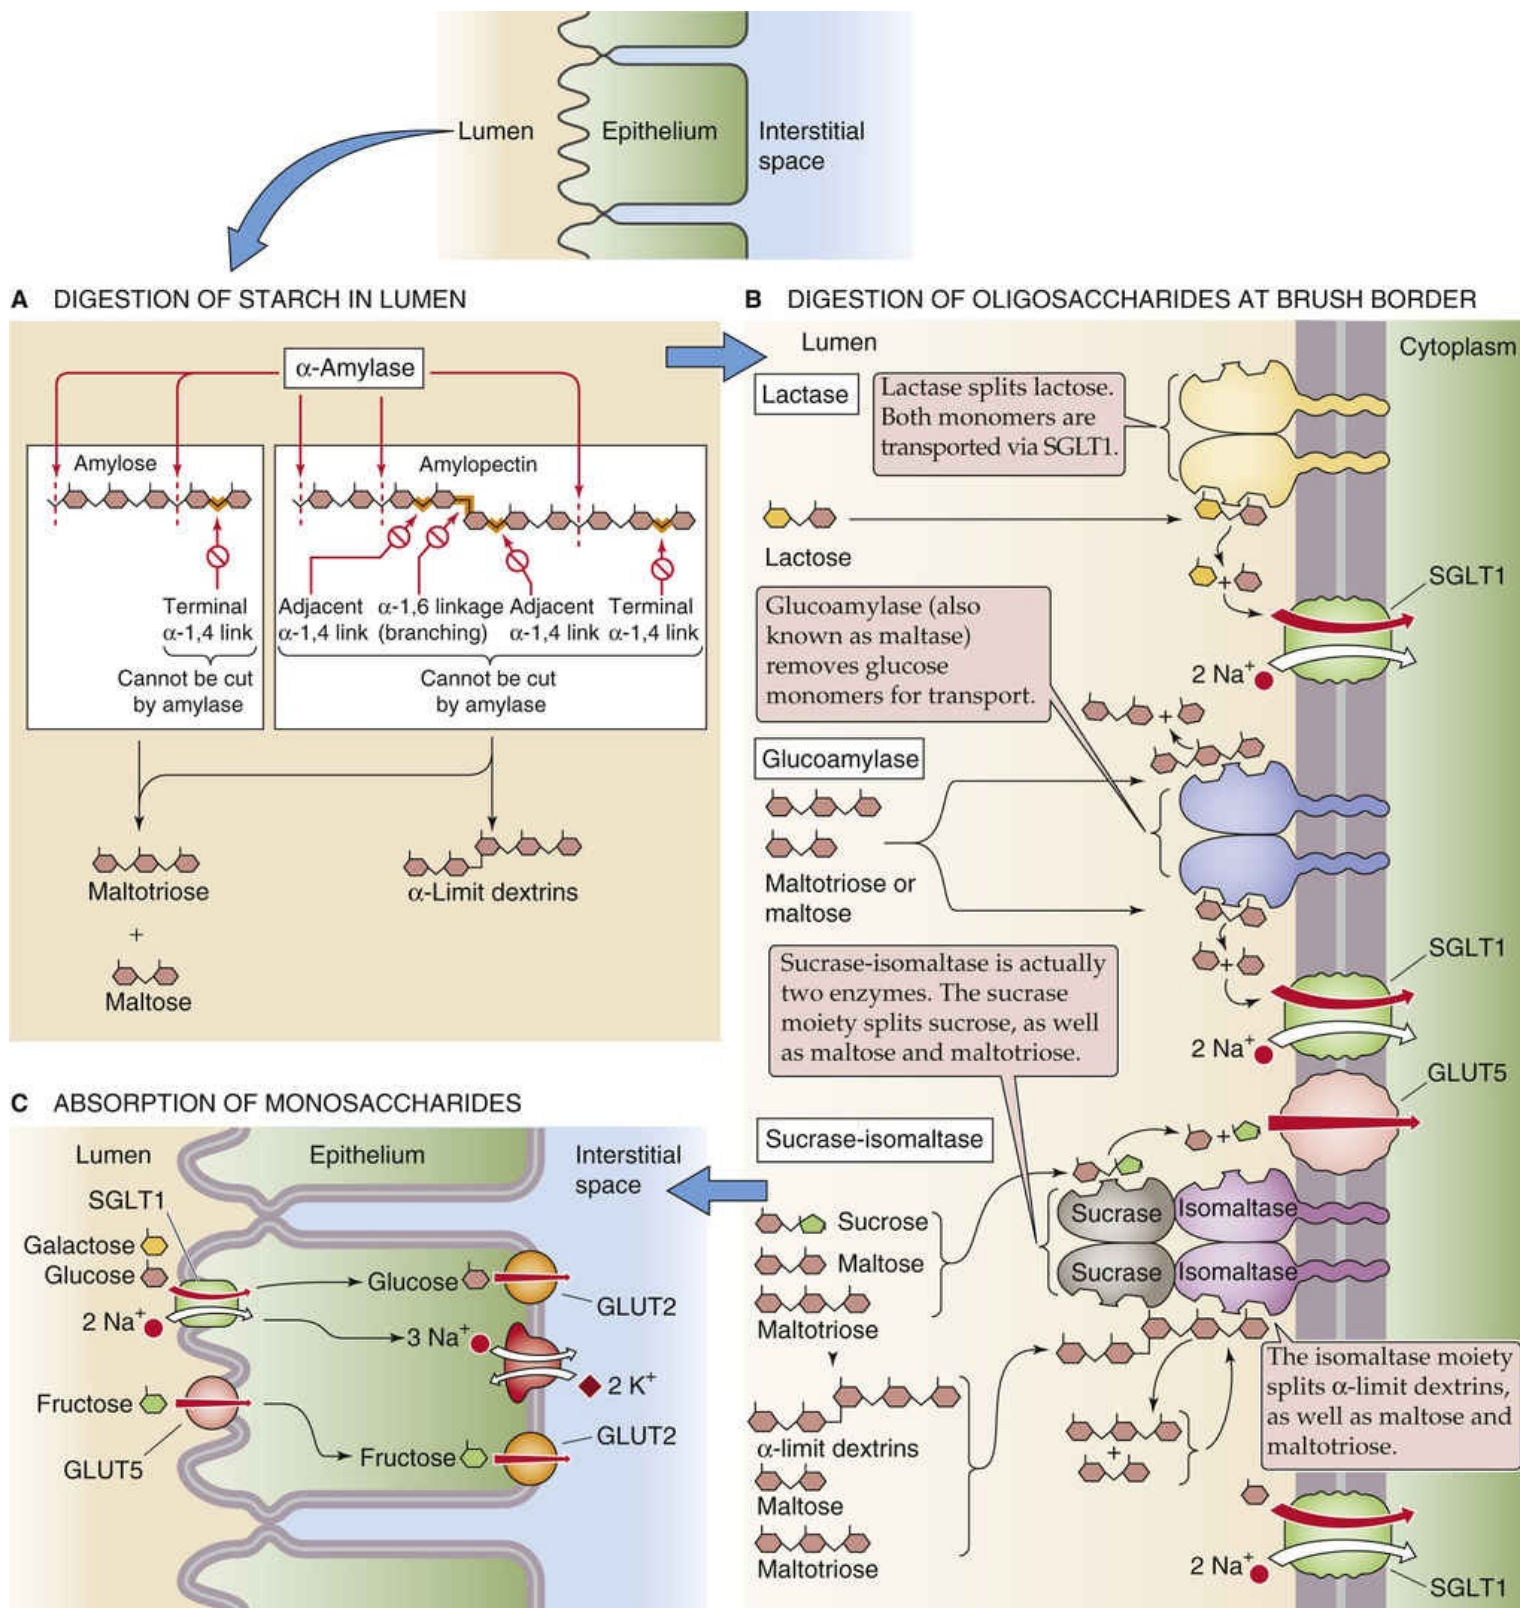

FIGURE 45-3 Digestion of carbohydrates to monosaccharides. **A**, Salivary and pancreatic α -amylase are endoenzymes. They can digest the linear “internal” α -1,4 linkages between glucose residues but cannot break “terminal” α -1,4 linkages between the last two sugars in the chain. They also cannot split the α -1,6 linkages at the branch points of amylopectin or the adjacent α -1,4 linkages. As a result, the products of α -amylase action are linear glucose oligomers, maltotriose (a linear glucose trimer), maltose (a linear

glucose dimer), and α -limit dextrins (which contain an α -1,6 branching linkage). **B**, The brush-border oligosaccharidases are intrinsic membrane proteins with their catalytic domains facing the lumen. Sucrase-isomaltase is actually two enzymes, and therefore, there are a total of four oligosaccharidases that split the oligosaccharides produced by α -amylase into monosaccharides. **C**, SGLT1 is the Na^+ -coupled transporter that mediates the uptake of glucose or galactose from the lumen of the small intestine into the enterocyte. GLUT5 mediates the facilitated diffusion of fructose into the enterocyte. Once the monosaccharides are inside the enterocyte, GLUT2 mediates their efflux across the basolateral membrane into the interstitial space.

Luminal digestion begins with the action of salivary amylase and finishes with pancreatic amylase

Acinar cells from both the salivary glands (see pp. 893–894) and pancreas (see p. 882) synthesize and secrete α -amylases. Salivary and pancreatic amylases, unlike most of the pancreatic proteases that we discuss below, are secreted not in an inactive proenzyme form, but rather in an active form. Salivary and pancreatic α -amylases have similar enzymatic function, and their amino-acid sequences are 94% identical.

Salivary α -amylase in the mouth initiates starch digestion; in healthy adults, this step is of relatively limited importance. Salivary amylase is inactivated by gastric acid but can be partially protected by complexing with oligosaccharides.

Pancreatic α -amylase completes starch digestion in the lumen of the small intestine. Although amylase binds to the apical membrane of enterocytes, this localization does not provide any kinetic advantage for starch hydrolysis. Cholecystokinin (CCK; see pp. 882–883) stimulates the secretion of pancreatic α -amylase by pancreatic acinar cells.

α -amylase is an **endoenzyme** that hydrolyzes *internal* α -1,4 linkages (see Fig. 45-3A). α -amylase does not cleave terminal α -1,4 linkages, α -1,6 linkages (i.e., branch points), or α -1,4 linkages that are immediately adjacent to α -1,6 linkages. As a result, starch hydrolysis products are maltose, maltotriose, and α -limit dextrins. Because α -amylase has no activity against terminal α -1,4 linkages, glucose is *not* a product of starch digestion. The intestine cannot absorb these products of amylase digestion of starch, and thus further digestion is required to produce substrates (i.e., monosaccharides) that the small intestine can absorb by specific transport mechanisms.

“Membrane digestion” involves hydrolysis of oligosaccharides to monosaccharides by brush-border disaccharidases

The human small intestine has three brush-border proteins with oligosaccharidase activity: lactase, glucoamylase (most often called maltase), and sucrase-isomaltase. These are all integral membrane proteins whose catalytic domains face the intestinal lumen (see Fig. 45-3B). Sucrase-isomaltase is actually two enzymes—sucrase and isomaltase (also known as α -dextrinase or debranching enzyme)—bound together. Thus, four oligosaccharidase entities are present at the brush border. **Lactase** has only one substrate; it breaks lactose into glucose and galactose. The other three enzymes have more complicated substrate spectra. All will cleave the terminal α -1,4 linkages of maltose, maltotriose, and α -limit dextrins. In addition, each of these three enzymes has at least one other activity. **Maltase** can also degrade the α -1,4 linkages in straight-chain oligosaccharides up to nine monomers in length. However,

maltase cannot split either sucrose or lactose. The **sucrase** moiety of sucrase-isomaltase is required to split sucrose into glucose and fructose. The **isomaltase** moiety of sucrase-isomaltase is critical; it is the only enzyme that can split the branching α -1,6 linkages of α -limit dextrins. 🍷N45-2

N45-2

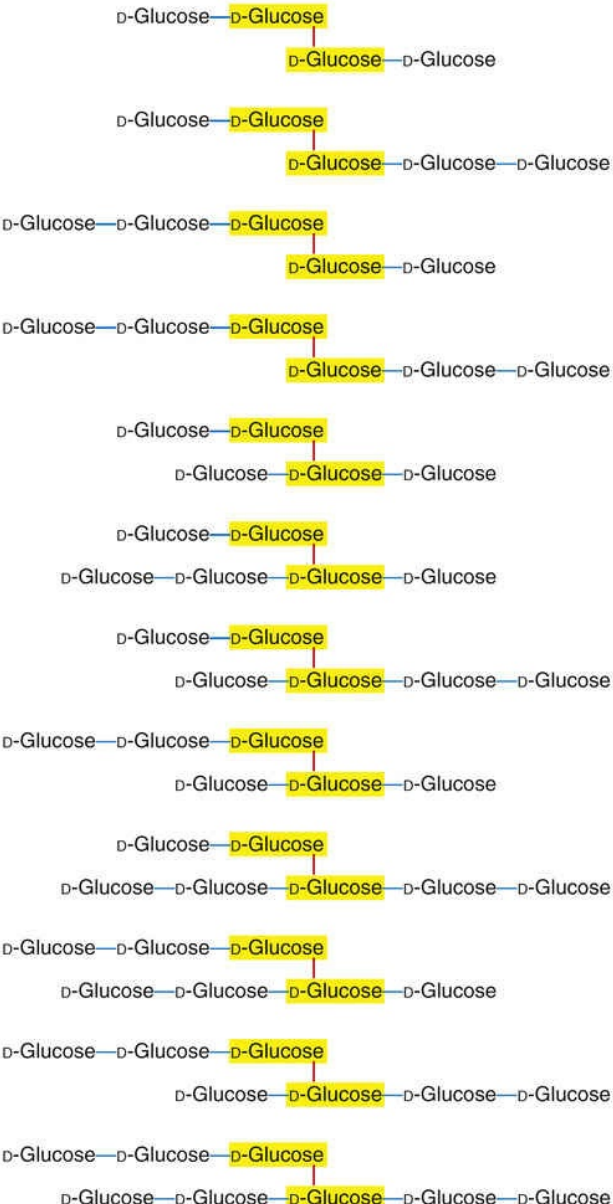

Oligosaccharidases

Contributed by Emile Boulpaep, Walter Boron

The oligosaccharidases are large integral membrane proteins that are anchored to the apical membrane by a transmembrane stalk; >90% of the protein is extracellular. Villous epithelial cells synthesize the disaccharidases via the secretory pathway (see pp. 34–35). The proteins undergo extensive N-linked and O-linked glycosylation in the Golgi and then traffic to the apical membrane.

Sucrase-isomaltase is a special case. After the insertion of the single sucrase-isomaltase peptide (including its transmembrane stalk) into the brush-border membrane, pancreatic proteases cleave the peptide between the sucrase and isomaltase moieties. After this cleavage, the isomaltase moiety remains continuous with the transmembrane stalk, and the sucrase moiety remains attached to the isomaltase moiety by van der Waals forces. Thus, sucrase-isomaltase differs from the other two oligosaccharidases in that the mature protein consists of two peptide chains (encoded by the same mRNA nonetheless), each with a distinct catalytic site and distinct substrate specificities.

See eFigure 45-1 for a summary of the composition of sugars and oligosaccharides. As we saw in the text, sucrase is unique in splitting sucrose, and the isomaltase is unique in splitting the α -1,6 linkage of α -limit dextrins. The table lists the enzymatic specificities for each of the brush-border oligosaccharidases.

SUGAR	COMPONENTS	LINKAGE
Lactose	D-Galactose—D-Glucose	β -1,4*
Sucrose	D-Glucose—D-Fructose	α -1,2
Maltose	D-Glucose—D-Glucose	α -1,4
Isomaltose	D-Glucose D-Glucose	α -1,6
Maltotriose	D-Glucose—D-Glucose—D-Glucose	Both α -1,4
α -limit dextrins	<p>By definition, these are small D-glucose polymers that have been exhaustively digested by enzymes (e.g., amylase) that cannot attack α-1,6 branch points, α-1,4 linkages that are adjacent to α-1,6 branch points, or terminal α-1,4 linkages. According to the rules summarized in the text, these are all the possibilities:</p> 	<p>Coupled mainly by 1,4 linkages, but containing one internal 1,6 linkage (highlighted in yellow) from a former branch point. Note: "internal" means that at least one 1,4 linkage separates the 1,6 linkage from an end.</p>

*For a 1,4 linkage, the linkage is between the number 1 carbon atom of the leftmost sugar in the "Components" column and the number 4 carbon atom of the rightmost sugar.

FIGURE 45-1 Composition of common oligosaccharide.

Specificities of Oligosaccharidases

	SUBSTRATES				
ENZYME	LACTOSE (SPLITTING THE β -1,4 LINKAGE BETWEEN D-GALACTOSE AND D-GLUCOSE)	TERMINAL α -1,4 LINKAGES	INTERNAL α -1,4 LINKAGES IN OLIGOSACCHARIDES UP TO 9 MONOMERS IN LENGTH	SUCRASE (SPLITTING α -1,2 LINKAGES BETWEEN D-GLUCOSE AND D-GALACTOSE)	α -1,6 (BRANCHING) LINKAGES OF α -LIMIT DEXTRINS
Lactase	✓				
Maltase		✓	✓		
Sucrase*		✓		✓	
Isomaltase*		✓			✓

*Sucrase and isomaltase are separate peptides, held together by van der Waals forces and anchored to the membrane via the transmembrane stalk of the isomaltase.

The action of the four oligosaccharidases generates several monosaccharides. Whereas the hydrolysis products of maltose are two glucose residues, those of sucrose are glucose and fructose. The hydrolysis of lactose by lactase yields glucose and galactose. The activities of the hydrolysis reactions of sucrase-isomaltase and maltase are considerably greater than the rates at which the various transporters can absorb the resulting monosaccharides. Thus, uptake, not hydrolysis, is the rate-limiting step. In contrast, lactase activity is considerably less than that of the other oligosaccharidases and is rate limiting for overall lactose digestion-absorption.

The oligosaccharidases have a varying spatial distribution throughout the small intestine. In general, the abundance and activity of oligosaccharidases peak in the proximal jejunum (i.e., at the ligament of Treitz) and are considerably less in the duodenum and distal ileum. Oligosaccharidases are absent in the large intestine. The distribution of oligosaccharidase activity parallels that of active glucose transport.

These oligosaccharidases are affected by developmental and dietary factors in different ways. In many nonwhite ethnic groups, as well as in almost all other mammals, lactase activity markedly decreases after weaning in the postnatal period. The regulation of this decreased lactase activity is genetically determined.  **N45-3** The other oligosaccharidases do not decrease in the postnatal period. In addition, long-term feeding of sucrose upregulates sucrase activity. In contrast, fasting reduces sucrase activity much more than it reduces lactase activity. In general, lactase activity is both more susceptible to enterocyte injury (e.g., following viral enteritis) and slower to recover from damage than is other oligosaccharidase activity. Thus, reduced lactase activity (as a consequence of both genetic regulation and environmental effects) has substantial clinical significance in that lactose ingestion may result in a range of symptoms in affected individuals ([Fig. 45-4A](#), [Box 45-1](#)).

A PRESENCE OF LACTASE ACTIVITY

B LACTASE DEFICIENCY

FIGURE 45-4 Effects of lactase deficiency on levels of glucose in the plasma and H_2 in the breath. **A**, In an individual with normal lactase activity, blood glucose levels rise after the ingestion of either glucose or lactose. Thus, the small intestine can split the lactose into glucose and galactose, and absorb the two monosaccharides. At the same time, H_2 in the breath is low. **B**, In an adult with low lactase activity, the rise in blood levels is less pronounced after ingesting lactose. Because the rise is normal after ingesting glucose, we can conclude that the difference is due to lactase activity. Conversely, the individual with lactase deficiency excretes large amounts of H_2 into the breath. This H_2 is the product of lactose catabolism by colonic bacteria.

Box 45-1

Lactase Deficiency

Primary lactase deficiency is most prevalent in nonwhites, and it also occurs in some whites. Primary lactase deficiency represents an isolated deficiency of lactase, with all other brush-border enzymes being at normal levels and without any histological abnormalities. Lactase activity decreases after weaning; the time course of its reduction is determined by hereditary factors. Ingestion of lactose in the form of milk and milk products by individuals with decreased amounts of small-intestinal lactase activity may be associated with a range of gastrointestinal symptoms, including diarrhea, cramps, and flatus, or with no discernible symptoms. Several factors determine whether individuals with lactase deficiency experience symptoms after ingestion of lactose, including rate of gastric emptying, transit time through the small intestine, and, most importantly, the ability of colonic bacteria to metabolize lactose to SCFAs, CO_2 , and H_2 . Figure 45-4A shows the rise of plasma [glucose] following the ingestion of either lactose or glucose in adults *with* normal lactase levels. This figure also shows that the [H_2] in the breath rises only slightly following the ingestion of either lactose or glucose in individuals with normal lactase levels.

Figure 45-4B shows that in individuals with primary lactase deficiency, the ingestion of lactose leads to a much smaller rise in plasma [glucose], although the ingestion of glucose itself leads to a normal rise in plasma [glucose]. Thus, no defect in glucose absorption per se is present, but simply a markedly reduced capacity to hydrolyze lactose to glucose and galactose. In lactase-deficient individuals, breath H_2 is markedly increased after lactose ingestion because nonabsorbed lactose is metabolized by colonic bacteria to H_2 , which is absorbed into the blood and is subsequently excreted by the lungs. In contrast, the rise in breath H_2 after the ingestion of glucose is normal in these individuals.

Treatment for symptomatic individuals with primary lactase deficiency is reduction or elimination of consumption of milk and milk products or the use of milk products treated with a commercial lactase preparation.

N45-3

Lactose Intolerance

Contributed by Henry Binder

Some authors object to the statement that lactose intolerance in adults is a lactase “deficiency” and instead propose that the normal course of events is for lactase activity to decline after weaning. According to one view, lactase “persistence” evolved in certain human populations after the domestication of herd animals allowed the consumption of nonhuman milk. This hypothesis could account for the geographical distribution of lactose intolerance in humans.

Carbohydrate Absorption

The three monosaccharide products of carbohydrate digestion—**glucose**, **galactose**, and **fructose**—are absorbed by the small intestine in a two-step process involving their uptake across the apical membrane into the epithelial cell and their coordinated exit across the basolateral membrane (see [Fig. 45-3C](#)). Na/glucose transporter 1 (SGLT1) is the membrane protein responsible for glucose and galactose uptake at the *apical membrane*. The exit of all three monosaccharides across the *basolateral membrane* uses a facilitated sugar transporter (GLUT2). Because SGLT1 cannot carry fructose, the apical step of fructose absorption occurs by the facilitated diffusion of fructose via GLUT5. Thus, although two different apical membrane transport mechanisms exist for glucose and fructose uptake, a single transporter (GLUT2) is responsible for the movement of both monosaccharides across the basolateral membrane.

SGLT1 is responsible for the Na⁺-coupled uptake of glucose and galactose across the apical membrane

The uptake of glucose across the apical membrane via SGLT1 ([Fig. 45-5A](#)) represents active transport, because the glucose influx occurs against the glucose concentration gradient (see [pp. 121–122](#)). Glucose uptake across the apical membrane is energized by the electrochemical Na⁺ gradient, which in turn is maintained by the extrusion of Na⁺ across the basolateral membrane by the Na-K pump. This type of Na⁺-driven glucose transport is an example of *secondary active transport* (see [p. 115](#)). Inhibition of the Na-K pump reduces active glucose absorption by decreasing the apical membrane Na⁺ gradient and thus decreasing the driving force for glucose entry.

A STRUCTURE OF SGLT1

B STRUCTURAL REQUIREMENTS OF SUGAR

FIGURE 45-5 Na^+ -coupled hexose transporter. **A**, The SGLT family of proteins has 14 membrane-spanning segments. This diagram represents the structure of the vSGLT Na/galactose cotransporter from the bacterium *Vibrio parahaemolyticus*. **B**, SGLT1 transports only hexoses in a D configuration and with a pyranose ring. This figure shows D-glucose; D-galactose is identical, except that the H and OH on carbon 4 are inverted. (A, Data from Faham S, Watanabe A, Besserer GM, et al: The crystal structure of a sodium galactose transporter reveals mechanistic insights into Na^+ /sugar symport. *Science* 321:810–814, 2008.)

The affinity of SGLT1 for glucose is markedly reduced in the absence of Na^+ . The varied affinity of SGLT1 for different monosaccharides reflects its preference for specific molecular configurations. SGLT1 has two structural requirements for monosaccharides: (1) a hexose in a D configuration, and (2) a hexose that can form a six-membered pyranose ring (see Fig. 45-5B). SGLT1 does not absorb L-glucose, which has the wrong stereochemistry, and it does not absorb D-fructose, which forms a five-membered ring (Box 45-2). **ON45-4**

Box 45-2

Glucose-Galactose Malabsorption

Molecular studies have been performed on jejunal mucosa from patients with so-called glucose-galactose malabsorption (or monosaccharide malabsorption). These individuals have diarrhea when they ingest dietary sugars that are normally absorbed by SGLT1. This diarrhea results from both reduced small-intestinal Na^+ and fluid absorption (as a consequence of the defect in Na^+ -coupled monosaccharide absorption) and fluid secretion secondary to the osmotic effects of nonabsorbed monosaccharide. Eliminating the monosaccharides glucose and galactose, as well as the disaccharide lactose (i.e., glucose + galactose), from the diet eliminates the diarrhea. The monosaccharide fructose, which crosses the apical membrane via GLUT5, does not induce diarrhea. Early studies identified the abnormality in this hereditary disorder as a defect at the apical membrane that is presumably related to defective or absent SGLT1. Molecular studies of SGLT1 have revealed multiple mutations that result in single amino-acid substitutions in SGLT1, each of which prevents the transport of glucose by SGLT1 in affected individuals. Patients with glucose-galactose malabsorption do not have glycosuria (i.e., glucose in the urine), because glucose reabsorption by the proximal tubule normally occurs via both SGLT1 and SGLT2 (see p. 772).

N45-4

Na/Glucose Cotransporters

Contributed by Emile Boulpaep, Walter Boron

Because the membrane potential across the luminal membrane is 40 to 50 mV (cell interior negative), and intracellular $[\text{Na}^+]$ is far less than luminal $[\text{Na}^+]$, a “downhill” electrochemical Na^+ gradient exists across the apical membrane that is the primary driving force for the uptake of glucose (and other actively transported monosaccharides) by **SGLT1** (see pp. 121–122).

Glucose uptake at the apical membrane has other characteristics of a carrier-mediated active transport process, including saturation kinetics, competitive inhibition, and energy dependence.

SGLT1 belongs to the SLC5 family of transporters that couple Na^+ to monosaccharides and other small molecules. These membrane proteins have 14 predicted membrane-spanning segments. The gene for SGLT1 has been localized to human chromosome 22. Kinetic studies of the SGLT1 expressed in host cells have confirmed many of the characteristics of the Na/glucose cotransport system that had been identified in native tissue. Expression studies have established that the Na^+ :sugar stoichiometry of SGLT1 is a 2 : 1 ratio. Its cousins SGLT2 and SGLT3 both have an Na^+ :sugar stoichiometry of 1 : 1.

For a discussion of the **stereospecificity** of sugars, see the biochemistry text by Voet and Voet, page 254 (Fig. 10–4).

The GLUT transporters mediate the facilitated diffusion of fructose at the apical membrane and of all three

monosaccharides at the basolateral membrane

Early work showed that fructose absorption is independent of Na^+ but has characteristics of both a carrier-mediated and a passive process. These observations show that the small intestine has separate transport systems for glucose and fructose. Subsequent studies established that *facilitated diffusion* is responsible for fructose absorption. Fructose uptake across the *apical membrane* is mediated by **GLUT5**, a member of the GLUT family of transport proteins (see [p. 114](#)). GLUT5 is present mainly in the jejunum. 🍌N45-5

N45-5

Facilitated Diffusion of Monosaccharides by the GLUT transporters

Contributed by Emile Boulpaep, Walter Boron

The GLUT transporters are part of the SLC2 family of hexose and polyol transporters. Based on hydropathy analysis and other data, these proteins are believed to have 12 transmembrane segments. Note that the GLUT transporters (see [p. 114](#)) have no homology to Na/glucose cotransporters—or SGLTs (see [pp. 121–122](#)).

GLUT2 is a basolateral membrane transport protein that carries glucose, galactose, and fructose. It consists of 524 amino acids.

GLUT5 is an apical membrane protein that carries fructose. It consists of 501 amino acids, and its mRNA has been primarily identified in the jejunum. GLUT5 has 41% homology to GLUT2.

Reference

Uldry M, Thorens B. The SLC2 family of facilitated hexose and polyol transporters. *Pflugers Arch.* 2004;447:480–489.

The efflux of glucose, fructose, and galactose across the *basolateral membrane* also occurs by facilitated diffusion. The characteristics of the basolateral sugar transporter, identified as **GLUT2**, are similar to those of other sugar transport systems in erythrocytes, fibroblasts, and adipocytes. GLUT2 has no homology to SGLT1 but is 41% identical to GLUT5, which is responsible for the uptake of fructose from the lumen.

Protein Digestion

Proteins require hydrolysis to oligopeptides or amino acids before absorption in the small intestine

With the exception of antigenic amounts of dietary protein that are absorbed intact, proteins must first be digested into their constituent oligopeptides and amino acids before being taken up by the enterocytes. Digestion-absorption occurs through four major pathways. First, several *luminal* enzymes (i.e., proteases) from the stomach and pancreas may hydrolyze proteins to peptides and then to amino acids, which are then absorbed (Fig. 45-6). Second, *luminal* enzymes may digest proteins to peptides, but enzymes present at the *brush border* digest the peptides to amino acids, which are then absorbed. Third, *luminal* enzymes may digest proteins to peptides, which are themselves taken up as oligopeptides by the enterocytes. Further digestion of the oligopeptides by cytosolic enzymes yields intracellular amino acids, which are moved by transporters across the basolateral membrane into the blood. Fourth, luminal enzymes may digest dietary proteins to oligopeptides, which are taken up by enterocytes via an endocytotic process (Fig. 45-7) and moved directly into the blood. Overall, protein digestion-absorption is very efficient; <4% of ingested nitrogen is excreted in the stool.

FIGURE 45-6 Action of luminal, brush-border, and cytosolic peptidases. Pepsin from the stomach and the five pancreatic proteases hydrolyze proteins—both dietary and endogenous—to single amino acids, AA, or to oligopeptides, $(AA)_n$. These reactions occur in the lumen of the stomach or small intestine. A variety of peptidases at the brush borders of enterocytes then progressively hydrolyze oligopeptides to amino acids. The enterocyte directly absorbs some of the small oligopeptides via the action of the H/oligopeptide cotransporter PepT1. These small peptides are digested to amino acids by peptidases in the cytoplasm of the enterocyte.

FIGURE 45-7 Absorption of whole proteins. Both enterocytes and specialized M cells can take up intact proteins. The more abundant enterocytes can endocytose far more total protein than can the M cells. However, the lysosomal proteases in the enterocytes degrade ~90% of this endocytosed protein. The less abundant M cells take up relatively little intact protein, but about half of this emerges intact at the basolateral membrane. There, immunocompetent cells process the target antigens and then transfer them to lymphocytes, initiating an immune response.

The protein that is digested and absorbed in the small intestine comes from both dietary and endogenous sources. Dietary protein in developed countries amounts to 70 to 100 g/day. This amount is far in excess of minimum daily requirements and represents 10% to 15% of energy intake. In contrast, dietary protein content in developing countries in Africa is often 50 g/day. Deficiency states are rare unless intake is markedly reduced.

Proteins are encoded by messenger RNA (mRNA) and consist of 20 different amino acids. Nine of these amino acids are essential (see [Table 58-2](#)); that is, they are not synthesized in adequate amounts by the body and thus must be derived from either animal or plant protein sources. In addition, cells synthesize some other amino acids by post-translational modifications: γ -carboxyglutamic acid, hydroxylysine, 4-hydroxyproline, and 3-hydroxyproline. Protein digestion is influenced by the amino-acid composition of the protein, by the source of protein, and by food processing. Thus, proteins rich in proline and hydroxyproline are digested relatively less completely. Cooking, storage, and dehydration also reduce the completeness of digestion. In general, protein derived from animal sources is digested more completely than plant protein.

In addition to protein from dietary sources, significant amounts of endogenous protein are secreted into the gastrointestinal tract, then conserved by protein digestion and absorption. Such endogenous sources represent ~50% of the total protein entering the small intestine and include enzymes, hormones, and immunoglobulins present in salivary, gastric, pancreatic, biliary, and jejunal secretions. A second large source of endogenous protein is desquamated intestinal epithelial cells as well as plasma proteins that the small intestine secretes.

Neonates can absorb substantial amounts of *intact protein* from colostrum (see [p. 1146](#)) through the process of endocytosis. This mechanism is developmentally regulated and in humans remains active only until ~6 months of age. In adults, proteins are almost exclusively digested to their constituent amino acids and dipeptides, tripeptides, or tetrapeptides before absorption. However, even adults absorb small amounts of intact proteins. These absorbed proteins can be important in inducing immune responses to dietary proteins.

Luminal digestion of protein involves both gastric and pancreatic proteases, and yields amino acids and oligopeptides

Both gastric and pancreatic proteases, unlike the digestive enzymes for carbohydrates and lipids, are secreted as **proenzymes** that require conversion to their active form for protein hydrolysis to occur. The gastric chief cells secrete **pepsinogen**. We discuss the pH-dependent activation of pepsinogen on [pages 873–874](#). **Pepsin** has a maximal hydrolytic activity between pH 1.8 and 3.5, and becomes irreversibly inactivated at above pH 7.2. Pepsin is an endopeptidase with primary specificity for peptide linkages of aromatic and larger neutral amino acids. Although pepsin in the stomach partially digests 10% to 15% of dietary protein, pepsin hydrolysis is not absolutely necessary; patients with either total gastrectomies or pernicious anemia [N45-6](#) (who do not secrete acid and thus whose intragastric pH is always >7) do not have increased fecal nitrogen excretion.

N45-6

Pernicious Anemia

Contributed by Henry Binder

The close relationship between acid and gastrin release is clearly manifested in individuals with impaired acid secretion. In **pernicious anemia**, atrophy of the gastric mucosa in the corpus and an absence of parietal cells result in a lack in the secretion of both gastric acid and intrinsic factor (IF). Many patients with pernicious anemia exhibit antibody-mediated immunity against their parietal cells, and many of these patients also produce anti-IF autoantibodies.

Because IF is required for cobalamin absorption in the ileum, the result is impaired cobalamin absorption. In contrast, the antrum is normal. Moreover, plasma gastrin levels are markedly elevated as a result of the absence of intraluminal acid, which normally triggers gastric D cells to release somatostatin (see pp. 868–870); this, in turn, inhibits antral gastrin release (see Box 42-1). Because parietal cells are absent, the elevated plasma gastrin levels are not associated with enhanced gastric acid secretion.

The clinical complications of cobalamin deficiency evolve over a period of years. Patients develop **megaloblastic anemia** (in which the circulating red blood cells are enlarged), a distinctive form of glossitis, and a neuropathy. The earliest neurological findings are those of peripheral neuropathy, as manifested by paresthesias and slow reflexes, as well as impaired senses of touch, vibration, and temperature. If untreated, the disease will ultimately involve the spinal cord, particularly the dorsal columns, thus producing weakness and ataxia. Memory impairment, depression, and dementia can also result. Parenteral administration of cobalamin reverses and prevents the manifestations of pernicious anemia, but it does not influence parietal cells or restore gastric secretion of either IF or intraluminal

acid.

Five pancreatic enzymes ([Table 45-2](#)) participate in protein digestion and are secreted as inactive proenzymes. Trypsinogen is initially activated by a jejunal brush-border enzyme, enterokinase (enteropeptidase), by the cleavage of a hexapeptide, thereby yielding trypsin. **Trypsin** not only autoactivates trypsinogen but also activates the other pancreatic proteolytic proenzymes. The secretion of proteolytic enzymes as proenzymes, with subsequent luminal activation, prevents pancreatic **autodigestion** before enzyme secretion into the intestine.

TABLE 45-2
Pancreatic Peptidases

PRO ENZYME	ACTIVATING AGENT	ACTIVE ENZYME	ACTION	PRODUCTS
Trypsinogen	Enteropeptidase (i.e., enterokinase from jejunum) and trypsin	Trypsin	Endopeptidase	Oligopeptides (2–6 amino acids)
Chymotrypsinogen	Trypsin	Chymotrypsin	Endopeptidase	Oligopeptides (2–6 amino acids)
Proelastase	Trypsin	Elastase	Endopeptidase	Oligopeptides (2–6 amino acids)
Procarboxypeptidase A	Trypsin	Carboxypeptidase A	Exopeptidase	Single amino acids
Procarboxypeptidase B	Trypsin	Carboxypeptidase B	Exopeptidase	Single amino acids

Pancreatic proteolytic enzymes are either exopeptidases or endopeptidases and function in an integrated manner. Trypsin, chymotrypsin, and elastase are **endopeptidases** with affinity for peptide bonds adjacent to specific amino acids, so that their action results in the production of oligopeptides with two to six amino acids. In contrast, the **exopeptidases**—carboxypeptidase A and carboxypeptidase B—hydrolyze peptide bonds adjacent to the carboxyl (C) terminus, which results in the release of individual amino acids. The coordinated action of these pancreatic proteases converts ~70% of luminal amino nitrogen to oligopeptides and ~30% to free amino acids.

Brush-border peptidases fully digest some oligopeptides to amino acids, whereas cytosolic peptidases digest oligopeptides that directly enter the enterocyte

Small peptides present in the small-intestinal lumen after digestion by gastric and pancreatic proteases undergo further hydrolysis by peptidases at the brush border (see [Fig. 45-6](#)). Multiple peptidases are present both on the brush border and in the cytoplasm of villous epithelial cells. This distribution of cell-associated peptidases stands in contrast to that of the oligosaccharidases, which are found only at the brush border. Because each peptidase recognizes only a limited repertoire of peptide bonds, and because the oligopeptides to be digested contain 24 different amino acids, large numbers of peptidases are required to ensure the hydrolysis of peptides.

As we discuss below, a transporter on the apical membrane of enterocytes can take up small oligopeptides, primarily dipeptides and tripeptides. Once inside the cell, these oligopeptides may be further digested by *cytoplasmic* peptidases. The brush-border and cytoplasmic peptidases have substantially different characteristics. For example, the brush-border peptidases have affinity for relatively larger oligopeptides (three to eight amino acids), whereas the cytoplasmic peptidases primarily hydrolyze dipeptides and tripeptides. Because the brush-border and cytoplasmic enzymes often have different biochemical properties (e.g., heat lability and electrophoretic mobility), it is evident that the peptidases in the brush border and cytoplasm are distinct, independently regulated molecules.

Like the pancreatic proteases, each of the several brush-border peptidases is an endopeptidase, an

exopeptidase, or a dipeptidase with affinity for specific peptide bonds. The exopeptidases are either carboxypeptidases, which release C-terminal amino acids, or aminopeptidases, which hydrolyze the amino acids at the amino (N)–terminal end. **Cytoplasmic peptidases** are relatively less numerous.

Protein, Peptide, and Amino-Acid Absorption

Absorption of whole protein by apical endocytosis occurs primarily during the neonatal period

During the postnatal period, intestinal epithelial cells absorb protein by endocytosis, a process that provides a mechanism for transfer of passive immunity from mother to child. The uptake of intact protein by the epithelial cell ceases by the sixth month; the cessation of this protein uptake, called *closure*, is hormonally mediated. For example, administration of corticosteroids during the postnatal period induces closure and reduces the time that the intestine can absorb significant amounts of whole protein.

The adult intestine can absorb finite amounts of intact protein and polypeptides. Uncertainty exists regarding the cellular route of absorption, as well as the relationship of the mechanism of protein uptake in adults to that in neonates. Enterocytes can take up by endocytosis a small amount of intact protein, most of which is degraded in lysosomes (see Fig. 45-7). A small amount of intact protein appears in the interstitial space. The uptake of intact protein also occurs through a second, more specialized route. In the small intestine, immediately overlying **Peyer's patches** (follicles of lymphoid tissue in the lamina propria), **M cells** replace the usual enterocytes on the surface of the gut. M cells have few microvilli and are specialized for protein uptake. They have limited ability for lysosomal protein degradation; rather, they package ingested proteins (i.e., antigens) in clathrin-coated vesicles, which they secrete at their basolateral membranes into the lamina propria. There, immunocompetent cells process the target antigens and transfer them to lymphocytes to initiate an immune response. Although protein uptake in adults may not have nutritional value, such uptake is clearly important in mucosal immunity and probably is involved in one or more disease processes.

The apical absorption of dipeptides, tripeptides, and tetrapeptides occurs via an H⁺-driven cotransporter

Virtually all absorbed protein products exit the villous epithelial cell and enter the blood as individual amino acids. Substantial portions of these amino acids are released in the lumen of the small intestine by luminal proteases and brush-border peptidases and, as we discuss below, move across the apical membranes of enterocytes via several amino-acid transport systems (see Fig. 45-6). However, substantial amounts of protein are absorbed from the intestinal lumen as dipeptides, tripeptides, or tetrapeptides and then hydrolyzed to amino acids by intracellular peptidases.

The transporter responsible for the uptake of luminal oligopeptides (Fig. 45-8A) is distinct from the various amino-acid transporters. Furthermore, administering an amino acid as a peptide (e.g., the dipeptide glycylglycine) results in a higher blood level of the amino acid than administering an equivalent amount of the same amino acid as a monomer (e.g., glycine; see Fig. 45-8B). One possible explanation for this effect is that the oligopeptide cotransporter, which carries multiple amino acids rather than a single amino acid into the cell, may simply be more effective than amino-acid transporters in transferring amino-acid monomers into the cell. This accelerated peptide absorption has been referred to as a *kinetic advantage* and raises the question of the usefulness of the enteral administration of crystalline amino acids to patients with impaired intestinal function or catabolic deficiencies. The evidence for a specific transport process for dipeptides, tripeptides, and tetrapeptides comes from direct measurements of

oligopeptide transport, molecular identification of the transporter, and studies of the hereditary disorders of amino-acid transport, cystinuria, and Hartnup disease.

FIGURE 45-8 Absorption of oligopeptides. **A**, The H^+ /oligopeptide cotransporter PepT1 moves dipeptides, tripeptides, and tetrapeptides into the enterocyte, across the apical membrane. Peptidases in the cytoplasm hydrolyze the oligopeptides into their constituent amino acids, which then exit across the basolateral membrane via one of three Na^+ -independent amino-acid transporters. **B**, If glycine is present in the lumen only as a free amino acid, then the enterocyte absorbs it only via apical amino-acid transporters. However, if the same amount of glycine is present in the lumen in the form of the dipeptide glycylglycine, the rate of appearance of glycine in the blood is about twice as high. Thus, PepT1, which moves several amino-acid monomers for each turnover of the transporter, is an effective mechanism for absorbing "amino acids."

Oligopeptide uptake is an active process driven not by an Na^+ gradient, but by a proton gradient. Oligopeptide uptake occurs via an **H^+ /oligopeptide cotransporter** known as PepT1 (SLC15A1; see p. 123), which is also present in the renal proximal tubule. PepT1 also appears to be responsible for the intestinal uptake of certain dipeptide-like antibiotics (e.g., oral amino-substituted cephalosporins). As noted above, after their uptake, dipeptides, tripeptides, and tetrapeptides are usually hydrolyzed by cytoplasmic peptidases to their constituent amino acids, the forms in which they are transported out of the cell across the basolateral membrane. Because peptides are almost completely hydrolyzed to amino acids intracellularly, few peptides appear in the portal vein. Proline-containing dipeptides, which are relatively resistant to hydrolysis, are the primary peptides present in the circulation.

Amino acids enter enterocytes via one or more group-specific apical transporters

Multiple amino-acid transport systems have been identified and characterized in various nonepithelial cells. The absorption of amino acids across the small intestine requires sequential movement across both the apical and basolateral membranes of the villous epithelial cell. Although the amino-acid transport systems have overlapping affinities for various amino acids, the consensus is that at least seven distinct

transport systems are present at the apical membrane (see [Table 36-1](#)); we discuss the basolateral amino-acid transporters in the next section. Whereas many apical amino-acid transporters are probably unique to epithelial cells, some of those at the basolateral membrane are probably the same as in nonepithelial cells.

The predominant apical amino-acid transport system is **system B⁰** (SLC6A19, SLC6A15; see [Table 36-1](#)) and results in Na⁺-dependent uptake of neutral amino acids. As is the case for glucose uptake (see [p. 919](#)), uphill movement of neutral amino acids is driven by an inwardly directed Na⁺ gradient that is maintained by the basolateral Na-K pump. The uptake of amino acids by system B⁰ is an electrogenic process and represents another example of *secondary active transport*. It transports amino acids with an L-stereo configuration and an amino group in the α position. System B⁰⁺ (SLC6A14) is similar to system B⁰ but has broader substrate specificity. System b⁰⁺ (SLC7A9/SLC3A1 dimer) differs from B⁰⁺ mainly in being independent of Na⁺.

Other apical carrier-mediated transport mechanisms exist for anionic (i.e., acidic) α amino acids, cationic (i.e., basic) α amino acids, β amino acids, and imino acids (see [Table 36-1](#)). Because these transporters have overlapping affinities for amino acids, and because of species differences as well as segmental and developmental differences among the transporters, it has been difficult to establish a comprehensive model of apical membrane amino-acid transport in the mammalian small intestine ([Box 45-3](#)).

Box 45-3

Defects in Apical Amino-Acid Transport

Hartnup Disease and Cystinuria

Hartnup disease and cystinuria are hereditary disorders of amino-acid transport across the apical membrane. These autosomal recessive disorders are associated with both small-intestine and renal-tubule abnormalities (see [Box 36-1](#)) in the absorption of neutral amino acids in the case of Hartnup disease and of cationic (i.e., basic) amino acids and cystine in the case of cystinuria.

The clinical signs of **Hartnup disease** are most evident in children and include the skin changes of pellagra, cerebellar ataxia, and psychiatric abnormalities. In Hartnup disease, the absorption of neutral amino acids by system B⁰ (SLC6A19) in the small intestine is markedly reduced, whereas that of cationic amino acids is intact ([Fig. 45-9](#)).

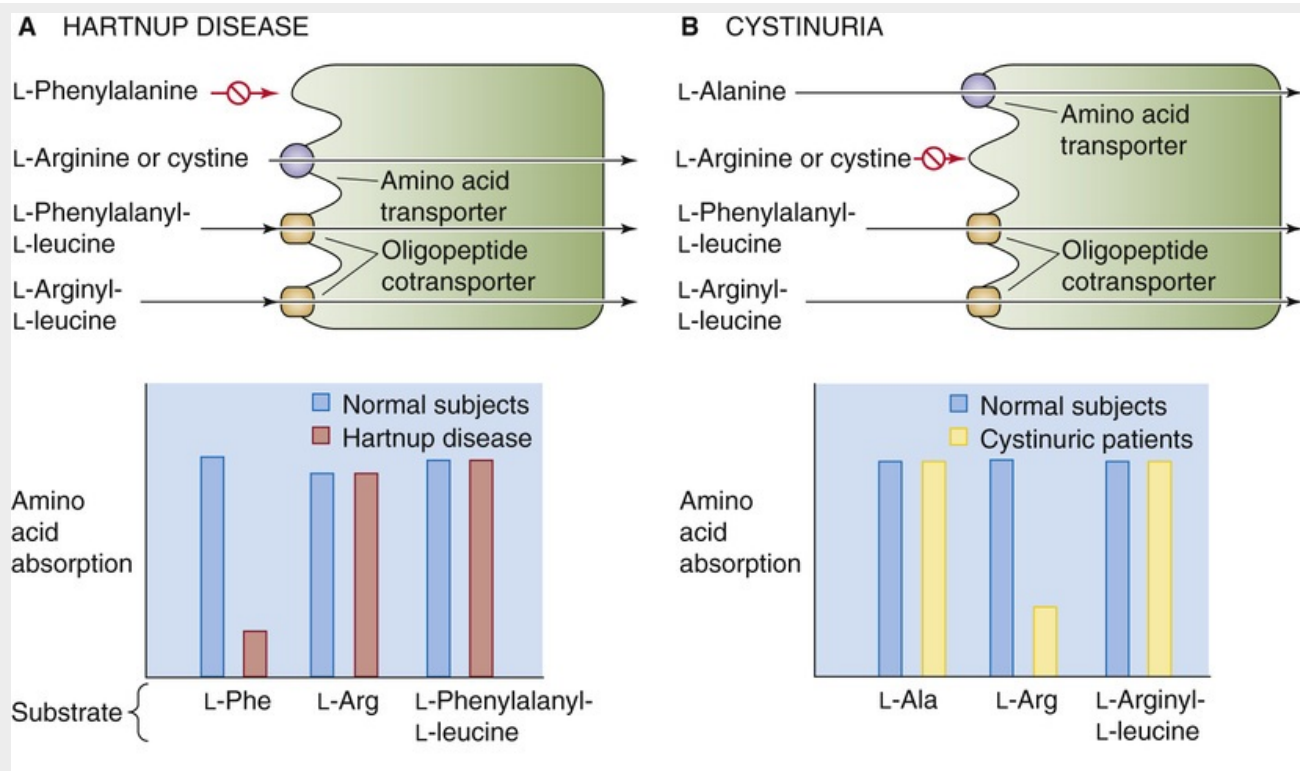

FIGURE 45-9 Genetic disorders of apical amino-acid transport. **A**, In Hartnup disease, an autosomal recessive disorder, the apical system B^0 (SLC6A19) is defective. As a result, the absorption of neutral amino acids, such as L-phenylalanine, is reduced. However, the absorption of L-cystine (i.e., Cys-S-S-Cys) and cationic (i.e., basic) amino acids (e.g., L-arginine) remains intact. The enterocyte can absorb L-phenylalanine normally if the amino acid is present in the form of the dipeptide L-phenylalanyl-L-leucine, inasmuch as the oligopeptide cotransporter PepT1 is normal. **B**, In cystinuria, an autosomal recessive disorder, the apical system b^{0+} (SLC7A9/SLC3A1 dimer) is defective. As a result, the absorption of L-cystine and cationic amino acids (e.g., L-arginine) is reduced. However, the absorption of amino acids that use System B^0 (e.g., L-alanine) is normal. The enterocyte can absorb L-arginine normally if the amino acid is present in the form of the dipeptide L-arginyl-L-leucine.

The principal manifestation of **cystinuria** is the formation of kidney stones. In cystinuria, the absorption of cationic amino acids by system b^{0+} (SLC7A9/SLC3A1 dimer) is abnormal as a result of mutations in SLC7A9 or SLC3A1, but absorption of neutral amino acids is normal.

Because neither of these diseases involves the oligopeptide cotransporter, the absorption of oligopeptides containing either neutral or cationic amino acids is normal in both diseases. Only 10% of patients with Hartnup disease have clinical evidence of protein deficiency (e.g., pellagra) commonly associated with defects in protein or amino-acid absorption. The lack of evidence of protein deficiency is a consequence of the presence of more than one transport system for different amino acids, as well as a separate transporter for oligopeptides. Thus, oligopeptides containing neutral amino acids are absorbed normally in Hartnup disease, and oligopeptides with cationic amino acids are absorbed normally in cystinuria.

These two genetic diseases also emphasize the existence of amino-acid transport mechanisms on the basolateral membrane that are distinct and separate from the apical amino-acid transporters. Thus, in both Hartnup disease and cystinuria, oligopeptides are transported normally across the apical membrane and are hydrolyzed to amino acids in the cytosol, and the resulting neutral and cationic amino acids are readily transported out of the cell across the basolateral membrane.

At the basolateral membrane, amino acids exit enterocytes

via Na⁺-independent transporters and enter via Na⁺-dependent transporters

Amino acids appear in the cytosol of intestinal **villous cells** as the result either of their uptake across the apical membrane or of the hydrolysis of oligopeptides that had entered the apical membrane (see [Fig. 45-6](#)). The enterocyte subsequently uses ~10% of the absorbed amino acids for intracellular protein synthesis.

Movement of amino acids across the basolateral membrane is bidirectional; the movement of any one amino acid can occur via one or more amino-acid transporters. At least six amino-acid transport systems are present in the basolateral membrane (see [Table 36-1](#)). Three amino-acid transport processes on the basolateral membrane mediate amino-acid *exit* from the cell into the blood and thus complete the process of protein assimilation. Two other amino-acid transporters mediate *uptake* from the blood for the purposes of cell nutrition. The three Na⁺-independent amino-acid transport systems appear to mediate amino-acid movement *out* of the epithelial cell into blood. The two Na⁺-dependent processes facilitate their movement *into* the epithelial cell. Indeed, these two Na⁺-dependent transporters resemble those that are also present in nonpolar cells.

In general, the amino acids incorporated into protein within villous cells are derived more from those that enter across the apical membrane than from those that enter across the basolateral membrane. In contrast, **epithelial cells in the intestinal crypt** derive almost all their amino acids for protein synthesis from the circulation; crypt cells do not take up amino acids across their apical membrane ([Box 45-4](#)).

Box 45-4

Defect in Basolateral Amino-Acid Transport

Lysinuric Protein Intolerance

Lysinuric protein intolerance is a rare autosomal recessive disorder of amino-acid transport across the basolateral membrane ([Fig. 45-10](#)). Evidence indicates impaired cationic amino-acid transport, and symptoms of malnutrition are seen. It appears that the defect is in system y⁺L, which is located solely on the basolateral membrane. System y⁺L has two subtypes, y⁺LAT1 (SLC7A7/SLC3A2 dimer) and y⁺LAT2 (SLC7A6/SLC3A2 dimer). Mutations in the *SLC7A7* gene (subtype y⁺LAT1) cause the disease lysinuric protein intolerance. These patients exhibit normal absorption of cationic amino acids across the apical membrane. Unlike in Hartnup disease or cystinuria, in which the enterocytes can absorb the amino acid normally if it is presented as an oligopeptide, in lysinuric protein intolerance the enterocytes cannot absorb the amino acid regardless of whether the amino acid is “free” or is part of an oligopeptide. These observations are best explained by hypothesizing that the patients hydrolyze intracellular oligopeptides properly but have a defect in the transport of cationic amino acids across the basolateral membrane. This defect is present not only in the small intestine but also in hepatocytes and kidney cells, and perhaps in nonepithelial cells as well.

FIGURE 45-10 Genetic disorder of basolateral amino-acid transport. Lysinuric protein intolerance is an autosomal recessive defect in which the Na⁺-independent y⁺L amino-acid transporter on the apical and basolateral membranes is defective. However, the absence of apical y⁺L (SLC7A6/SLC3A2 or SLC7A7/SLC3A2 dimers) does not present a problem because Na⁺-dependent amino-acid transporters can take up lysine, and PepT1 can take up lysine-containing oligopeptides (Lys-XX). However, there is no other mechanism for moving lysine out of the enterocyte across the basolateral membrane.

Lipid Digestion

Natural lipids of biological origin are sparingly soluble in water

Lipids in the diet are derived from animals or plants and are composed of carbon, hydrogen, and a smaller amount of oxygen. Some lipids also contain small but functionally important amounts of nitrogen and phosphorus ([Fig. 45-11](#)). Lipids are typified by their preferential solubility in organic solvents compared with water. A widely used indicator of the lipidic nature of a compound is its octanol-water partition coefficient, which for most lipids is between 10^4 and 10^7 .

FIGURE 45-11 Chemical formulas of some common lipids. The example in **A** is stearic acid, a fully saturated fatty acid with 18 carbon atoms. **B** shows glycerol, a trihydroxy alcohol, with hydroxyl groups in positions *sn1*, *sn2*, and *sn3*. In **C**, the left *sn1*- and center *sn2*-fatty acids are palmitic acid, a fully saturated fatty acid with 16 carbon atoms. The rightmost *sn3*-fatty acid is palmitoleic acid, which is also a 16-carbon structure, but with a double bond between carbons 9 and 10. In **F**, the left *sn1*-fatty acid is palmitic acid, and the right *sn2*-fatty acid is palmitoleic acid. In **I**, the example is the result of esterifying cholesterol and palmitic acid.

The biological fate of lipids depends critically on their chemical structure as well as on their interactions with water and other lipids in aqueous body fluids (e.g., intestinal contents and bile). Thus, lipids have been classified according to their physicochemical interactions with water. Lipids may be either **nonpolar** and thus very insoluble in water (e.g., cholesteryl esters and carotene) or polar and thus interacting with water to some degree. Even polar lipids are only amphiphilic; that is, they have both

polar (hydrophilic) and nonpolar (hydrophobic) groups. Polar lipids range from the insoluble, nonswelling amphiphiles (e.g., triacylglycerols) to the soluble amphiphiles (e.g., bile acids). Added in small amounts, insoluble polar lipids form stable monolayers on the surface of water (see [Fig. 2-1C](#)), whereas the soluble amphiphiles do not. The physicochemical behavior in bulk solution varies from insolubility—as is the case with **triacylglycerols (TAGs)** and cholesterol—to the formation of various macroaggregates, such as liquid crystals and micelles. Less-soluble lipids may be incorporated into the macroaggregates of the more polar lipids and are thus stably maintained in aqueous solutions.

Dietary lipids are predominantly TAGs

The term **fat** is generally used to refer to TAGs—formerly called triglycerides—but it is also used loosely to refer to lipids in general. Of the fat in an adult diet, >90% is **TAGs**, which are commonly long-chain fatty acyl esters of glycerol, a trihydroxyl alcohol. The three esterification (i.e., acylation) positions on the glycerol backbone that are occupied by hydroxyl groups are designated **sn1**, **sn2**, and **sn3**, according to a stereochemical numbering system adopted by an international committee on biochemical nomenclature (see [Fig. 45-11C–E](#)). At body temperature, fats are usually liquid droplets. Dietary fat is the body's only source of essential fatty acids, and its hydrolytic products promote the absorption of fat-soluble vitamins (the handling of which is discussed on [p. 933](#)). Fat is also the major nutrient responsible for postprandial satiety.

Typical adult Western diets contain ~140 g of fat per day (providing ~60% of the energy), which is more than the recommended intake of less than ~70 g of fat per day (<30% of total dietary calories). The ratio of **saturated** to **unsaturated** fatty acids in TAGs is high in animal fats and low in plant fats. Current guidelines suggest that only one third of lipid intake should be saturated fats. Cholesterol intake should be limited to <300 mg/day, and *trans* fatty acids avoided. Of the fats ingested, those that are liquid at room temperature should be emphasized, especially those that contain omega-3 (or n-3) fatty acids [N45-7](#) found especially in fish. Because of the high fat content of milk, newborn infants consume three to five times more lipid than adults, relative to body weight.

Omega-3 Fatty Acids

Contributed by Emile Boulpaep, Walter Boron

eFigure 45-2 shows the structure of α -linolenic acid (ALA), which is an 18-carbon fatty acid with three double bonds.

If we use the numbering system of chemists—which, as indicated by the blue numerals in the figure, assigns the carboxyl carbon as the No. 1 position—the three double bonds begin at positions 9, 12, and 15. Thus, this fatty acid can be referred to as 18 : 3 Δ ^{9c,12c,15c}.

Alternatively, physiologists count from the opposite or methyl (–CH₃) end of the carbon chain—also known as the **n end**—starting with the terminal or **omega (ω) carbon**. In eFigure 45-2, we indicate this numbering system by the red numerals. The rationale for the *n* numbering system is that the methyl end of the molecule is less susceptible to biochemical modification. In this nomenclature, the double bond closest to the methyl carbon is termed the omega-3 or n-3 double bond, and fatty acids containing such a double bond are termed **omega-3** or **n-3 fatty acids**. We would refer to α -linolenic acid as 18 : 3(n-3). Here the first double bond starts at the n-3 position and the other two double bonds each begin 3 carbons

further down the chain (i.e., at n-6 and n-9).

Approximately 5% (4 to 6 g/day) of dietary lipids come from cell membranes and are **phospholipids**. Most phospholipids are *glycerophospholipids*. They consist of a glycerol backbone that is esterified at the first two positions to fatty acids and at the third position to a phosphate that in turn is esterified to a head group (see Fig. 2-2A–C). One of the *glycerophospholipids*, phosphatidylcholine (lecithin), is the predominant phospholipid (see Fig. 45-11F). The *sphingolipids* (see Fig. 2-2D, E), which have a serine rather than a glycerol backbone, form the other major class of membrane phospholipids.

The typical Western diet contains ~0.5 g of unesterified **cholesterol** (also derived from animal cell membranes; see Fig. 45-11H), whereas esterified cholesterol (see Fig. 45-11I) is usually found only in liver or food made from blood products. Traces of **lipovitamins** and **provitamins** (e.g., carotene) are present in dietary fat, which may also contain lipid-soluble toxins and carcinogens from the environment. These **undesirable lipid-soluble chemicals**—which include nitrosamines, aflatoxins, and polycyclic hydrocarbons such as benzo(a)pyrene—are all found in small amounts in margarine, vegetable oils, and other dietary fats. The diet also may contain skin lipids, which are chemically diverse and complex and are difficult to digest.

Endogenous lipids are phospholipids and cholesterol from bile and membrane lipids from desquamated intestinal epithelial cells

The bile secreted into the intestine (see p. 957) plays a key role in the assimilation of dietary lipids, as we explain below. This bile contains phospholipid (10 to 15 g/day)—also predominantly phosphatidylcholine—and unesterified cholesterol (1 to 2 g/day). Quantitatively, these biliary lipids exceed those present in the diet by 2- to 4-fold. Membrane lipids from desquamated intestinal cells account for a further 2 to 6 g of lipid for digestion. Dead bacteria contribute ~10 g/day of lipids, mainly in the colon.

The mechanical disruption of dietary lipids in the mouth and stomach produces an emulsion of lipid particles

The central process in the digestion of lipids is their hydrolysis in the aqueous milieu of the intestinal lumen. Lipid hydrolysis is catalyzed by **lipases** secreted by the glands and cells of the upper gastrointestinal tract. The products of lipolysis diffuse through the aqueous content of the intestinal lumen, traverse the so-called unstirred water layer and mucus barrier that line the intestinal epithelial surface, and enter the enterocyte for further processing. Because dietary lipids are insoluble in water, digestive lipases have evolved to act more efficiently at oil-water interfaces than on water-soluble substrates.

A key step preliminary to lipid digestion is the transformation of ingested solid fat and oil masses into an emulsion of fine oil droplets in water. The **emulsification** of dietary fats begins with food preparation (grinding, marinating, blending, and cooking), followed by chewing and gastric churning (see [pp. 876–877](#)) caused by antral peristalsis against a closed pylorus. Emulsification of ingested lipids is enhanced when muscular movements of the stomach intermittently squirt the gastric contents into the duodenum and, conversely, when peristalsis of the duodenum propels the duodenal contents in retrograde fashion into the stomach through the narrow orifice of a contracted pylorus. The grinding action of the antrum also mixes food with the various digestive enzymes derived from the mouth and stomach. Intestinal peristalsis mixes luminal contents with pancreatic and biliary secretions. Together, these mechanical processes that reduce the size of the lipid droplets also dramatically increase their ratio of surface area to volume, thereby increasing the area of the oil-water interface.

The fine emulsion produced by the mechanical processes just outlined is stabilized by coating the emulsion droplets with membrane lipids, denatured protein, dietary polysaccharides, certain products of digestion—including fatty acids released by gastric lipase as well as fatty acids and **monoacylglycerols (MAGs)** from intestinal and pancreatic digestion—and biliary phospholipids and cholesterol. This coating prevents the lipid droplets from coalescing. Phospholipids and cholesterol are well suited as emulsion stabilizers because they are attracted to oil-water interfaces by virtue of their amphiphilic properties. Thus, they form a surface monomolecular layer on emulsion particles. The polar groups of the phospholipids and hydroxyl groups of cholesterol project into the water; the charges on the polar groups and their high degree of hydration prevent coalescence of the emulsion particles. The core of the emulsion particle is composed of TAG, which also contains cholesteryl esters and other nonpolar or weakly polar lipids. A very small fraction of the TAG in the lipid particle localizes to the particle surface. The fat in breast milk is already emulsified by proteins and phospholipids incorporated into the surface of fat droplets during lactation. Foods such as sauces, ice cream, and puddings are stably emulsified during their preparation.

Lingual and gastric (acid) lipase initiate lipid digestion

In some species, but not in humans, a small amount of lipid digestion begins in the mouth, mediated by lingual lipase. In the stomach, both **lingual lipase** that is swallowed and a gastric lipase secreted by gastric chief cells digest substantial amounts of lipid. Human **gastric lipase** is a 42-kDa glycoprotein whose secretion is stimulated by gastrin. Gastric lipase secretion is already well established in the neonatal period (unlike pancreatic lipase secretion), and thus gastric lipolysis is important for fat digestion in newborn infants. Gastric lipase is also important in the digestion of dietary fat in patients with pancreatic insufficiency, where it hydrolyzes approximately one third of the fat due to its preference for fatty acids at the *sn*3 position, leaving behind intact *sn*1,2-**diacylglycerols (DAGs)** (see [Fig. 45-11D](#)). Gastric and lingual—as well as pharyngeal—lipases belong to a family of serine hydrolases that have acidic pH optima (pH 4), are stable in the acidic environment of the stomach, are resistant to digestion by pepsin, and are not inhibited by the surface layer of membrane lipids (emulsifiers) that envelopes TAG

droplets. However, acid lipases are inactive at neutral pH and also are readily inactivated by pancreatic proteases (especially in the presence of bile salts) once they reach the small intestine. 🍌N45-8

N45-8

Gastric Lipase

Contributed by Henry Binder

In healthy adult humans, ~15% of fat digestion occurs in the stomach. In patients with pancreatic insufficiency, however, the lack of pancreatic proteases and HCO_3^- in the duodenal lumen may permit the continued action of gastric lipase after the gastric contents leave the stomach and enter the duodenum. Extended gastric lipase activity partly alleviates fat malabsorption resulting from pancreatic disease and pancreatic lipase deficiency.

The carboxyl groups of **long-chain fatty acids (LCFAs)**, 🍌N45-1 released from TAGs in the stomach, are protonated and insoluble at the acidic pH prevailing in the stomach. LCFAs are not absorbed in the stomach, but rather they remain in the core of the TAG droplets. In the more alkaline environment of the small intestine, the fatty acids become ionized and participate in emulsification of the lipid droplets. Medium-chain fatty acids (MCFAs), 🍌N45-1 and SCFAs are mainly protonated in gastric juice during feeding and passively move across the gastric mucosa into portal blood. 🍌N45-9

N45-9

Gastric Absorption of Medium- and Short-Chain Fatty Acids

Contributed by Emile Boulpaep, Walter Boron

In aqueous solutions, fatty acids exist in both anionic (A^-) and neutral/protonated (HA) forms, according to the following equilibrium:

All of the fatty acids, regardless of the length of the alkyl chain, are relatively water soluble when the fatty acids are in their anionic form. However, the solubility of the protonated forms of the fatty acids depends markedly on the length of the alkyl chain. Thus, as stated in the text, the protonated forms of the LCFAs are relatively water insoluble. On the other hand, the protonated forms of the MCFAs and SCFAs become progressively more water soluble.

The pK values for the equilibrium in Equation NE 45-1 are rather independent of the length of the alkyl chain. Indeed, all saturated fatty acids of physiological importance have pK values between those of the 2-carbon acetic acid ($\text{pK} = 4.76$) and the 3-carbon propionic acid ($\text{pK} = 4.87$). Only the 1-carbon formic acid has an appreciably lower pK value (~3.75). Thus, at the lowest gastric pH values, all fatty acids—long-chain, medium-chain, and short-chain—exist almost exclusively in the neutral/protonated (HA) forms. The major difference, as noted in the text, is that the protonated forms of the LCFAs, which are

insoluble in water and thus largely partitioned into triacylglycerol droplets, are unavailable for uptake in the stomach. The protonated forms of the MCFAs and SCFAs are more water soluble and thus more available for passive absorption by nonionic diffusion (see p. 784) in the stomach.

Pancreatic (alkaline) lipase, colipase, milk lipase, and other esterases—aided by bile salts—complete lipid hydrolysis in the duodenum and jejunum

The process of fat digestion that begins in the stomach is completed in the proximal small intestine, predominantly by enzymes synthesized and secreted by pancreatic acinar cells (see p. 882) and carried into the duodenum in the pancreatic juice. In humans, a lipase found in human milk—the so-called **bile salt**—stimulated milk lipase—also digests fat. A similar lipase is found in the milk of relatively few other animal species. Milk lipase is stable during passage through the acid environment of the stomach, yet it is active at the alkaline pH of the duodenum and jejunum, where it hydrolyzes DAGs, MAGs, cholesteryl esters, and fat-soluble vitamin esters, as well as TAGs. Bile salts not only stimulate milk lipase activity but also protect the enzyme from proteolysis in the small intestine. Like gastric lipase, milk lipase is important for fat digestion in breast-fed infants.

Once the fatty acids generated in the stomach reach the duodenum, they trigger the release of **CCK** and gastric inhibitory polypeptide (GIP) from the duodenal mucosa. CCK stimulates the *flow of bile* into the duodenum by causing the gallbladder to contract and the sphincter of Oddi to relax (see pp. 961–962). CCK also stimulates the *secretion of pancreatic enzymes*, including lipases and esterases (see pp. 882–883). As we discuss below, LCFAs also facilitate the lipolytic action of pancreatic lipase.

The major lipolytic enzyme of pancreatic juice is a 48-kDa carboxylic esterase known as **pancreatic (TAG) lipase**, sometimes referred to as colipase-dependent pancreatic lipase. In adults but not in infants, the active form of this enzyme is secreted into the duodenum at a level 1000-fold higher than that necessary to digest all dietary TAGs not hydrolyzed in the stomach.  **N45-10** Full lipolytic activity of pancreatic lipase requires the presence of the small (10-kDa) protein cofactor called **colipase**, as well as an alkaline pH, Ca^{2+} , bile salts, and fatty acids. The pancreas secretes colipase in the pro form (i.e., procolipase), which has no intrinsic lipolytic activity. Trypsin cleaves procolipase into colipase and an N-terminal pentapeptide, enterostatin. This cleavage is important because the newly formed colipase is a cofactor of pancreatic lipase, as we discuss below. In addition, the N-terminal pentapeptide may partially control satiety.

N45-10

Pancreatic Lipase

Contributed by Emile Boulpaep, Walter Boron

The crystal structure of human pancreatic lipase, a 48-kDa protein, has been elucidated, and models of enzyme action have been devised.

Pancreatic lipase is active only at the oil-water interface of a TAG droplet. However, surface emulsifier components (e.g., phospholipids, proteins, fatty acids) present at that interface inhibit lipase action. Bile-salt micelles also inhibit lipolysis by displacing the lipase from the oil-droplet surface. Colipase reverses this inhibition through interfacial binding, either by attaching first to the interface and serving as an anchor for the binding of the lipase, or by first forming a colipase–pancreatic lipase complex that then binds to the lipid interface. Colipase also can penetrate the phospholipid coating of the TAG emulsion. Bile-salt micelles bring the colipase closer to the interface. Because bile salts are nearby, they can participate in the solubilization and removal of the products of lipolysis released from the emulsion droplet. Fatty acids have a biphasic effect. Increasing levels at first enhance emulsification and augment lipolysis (probably by enhancing the binding of the colipase-lipase complex to the lipid interface). Further increases in fatty-acid levels cause product inhibition of lipase.

Studies of the crystal structure of pancreatic lipase have shown that when the enzyme is free in solution, the catalytic site of the lipase—located in a cleft in the molecule—is partly covered by a lid formed by a loop of its peptide chain. The interaction of the colipase and lipase with the interface causes a conformational change in the lipase molecule that opens the lid, thereby allowing lipid substrate to diffuse to the now-exposed catalytic site of the enzyme.

Pancreatic lipase mainly hydrolyzes the ester bonds of TAGs at the first and third positions of the glycerol backbone. The end products of such reactions are two fatty acids and a single *sn*2-MAG (2-MAG) (see [Fig. 45-11E](#)).

The pancreas secretes other enzymes that hydrolyze lipid esters. **Carboxyl ester hydrolase** is a pancreatic enzyme that is the same protein as bile salt–stimulated milk lipase. Like milk lipase, carboxyl ester hydrolase lacks substrate specificity and is active against a wide range of esters. Carboxyl ester hydrolase is probably the same enzyme as “pancreatic esterase,” “cholesterol esterase,” “lysophospholipase,” and others. Among the many products of reactions catalyzed by this enzyme are free cholesterol and free glycerol.

The pancreas also secretes **phospholipase A₂ (PLA₂)**, which is active against glycerophospholipids (but not sphingolipids), releasing a single *sn*2–fatty acid, which is usually an unsaturated fatty acid, to yield *sn*1-lysophospholipids (see [Fig. 45-11G](#)). Pancreatic PLA₂, secreted as a trypsin-activatable proenzyme, is effective at alkaline pH and requires bile salts and Ca²⁺ for activity. A separate PLA₂ in the small intestine, with a preference for phosphatidylglycerol, a common phospholipid in bacteria, is derived from Paneth cells, whereas phospholipase found in the colon probably comes from anaerobic flora there. In contrast to the human intestinal lipases, bacterial lipases are nonspecific with respect to substrates, have neutral or slightly acidic pH optima, are not inhibited by bile acids, and do not require cofactors. In the human colon, both TAGs and phospholipids are totally hydrolyzed by bacteria. Fecal fat is thus generally present as **fatty-acid soaps** and sterols. Even in cases of severe fat malabsorption, intact acylglycerols are rarely found in the stools unless the patient has exocrine pancreatic insufficiency. The chemical test for stool fat, Sudan III staining, must be done in an acid environment because it depends on the property of Sudan III dye to partition into “oils” that contain protonated fatty acids.

Lipid Absorption

Products of lipolysis enter the bulk water phase of the intestinal lumen as vesicles, mixed micelles, and monomers

After their secretion in pancreatic juice and bile, respectively, the various activated pancreatic lipases and biliary bile salts, phosphatidylcholine, and cholesterol adsorb to the surface of the **emulsion droplets** arriving from the stomach ([Fig. 45-12A](#)). The lipolytic products—MAGs, fatty acids (including long-chain species from gastric lipolysis) that are now ionized at duodenal pH 5.5 to 6.5, lysophosphatidylcholine, and cholesterol—act as additional emulsifiers. As surface TAGs are hydrolyzed, they are replaced by TAGs from the core of the emulsion particle. As the emulsion droplets become progressively smaller, their surface area increases, so that the rate of hydrolysis increases. Initially, a crystalline calcium–fatty-acid soap phase forms near the surface of the TAG droplet, until the local free Ca^{2+} is depleted. At the same time, a multilamellar liquid crystalline layer of fatty acids, MAGs, lysophosphatidylcholine, cholesterol, and possibly bile salts builds up on the surface of the emulsion particle. This liquid crystalline layer buds off as a **multilamellar liquid crystal vesicle** (see [Fig. 45-12B](#)), which consists of several lipid bilayers. Bile-salt micelles transform these multilamellar vesicles into **unilamellar vesicles** (see [Fig. 45-12C](#)), which are single-lipid bilayers, and then into **mixed micelles** (see [Fig. 45-12D](#)) composed of bile salts and mixed lipids (i.e., fatty acids, MAG, lysophospholipids, and cholesterol).

FIGURE 45-12 Breakdown of emulsion droplets to mixed micelles. **A**, The core of the emulsion droplet contains TAGs, DAGs, and cholesteryl esters. On the surface are fatty acids, MAGs, lysolecithins, and cholesterol. Adsorbed to the surface are pancreatic lipase and possibly bile salts. As the lipases hydrolyze the TAGs at the surface, the TAGs from the core replace them, causing the droplet to shrink. **B**, A multilamellar liquid-crystalline layer of fatty acids, MAGs, lysolecithins, cholesterol, and bile salts builds up on the surface of the emulsion droplet, causing a small piece to bud off as a multilamellar vesicle. **C**, The addition of more bile salts to the multilamellar vesicle thins out the lipid coating and converts the multilamellar vesicle to a unilamellar vesicle. **D**, Further addition of bile salts leads to formation of a mixed micelle, in which hydrophobic lipid tails face inward and polar head groups face outward.

Continued digestion by PLA_2 and other esterases can still occur on the mixture of aggregates now present. If intestinal contents taken from humans during fat digestion are centrifuged, three phases separate. An oily layer floats on top and contains fat droplets and lipolytic products that have not been solubilized by bile salts. A middle layer contains lipid vesicles, mixed lipid–bile-salt micelles, simple bile-salt micelles, and lipid monomers. Finally, a pellet contains debris, liquid crystals, and precipitated calcium soaps of fatty acids. Whereas most fat absorption in health is from the micellar phase of digested lipid, in situations in which intraluminal bile-salt concentrations are low (e.g., in newborns and patients with obstructive jaundice), lipid absorption can occur from vesicles.

Lipids diffuse as mixed micelles and monomers through unstirred layers before crossing the jejunal enterocyte brush border

To reach the interior of the enterocyte, lipolytic products must cross several barriers. These include (1) the mucous gel layer that lines the intestinal epithelial surface, (2) the unstirred water layer (disequilibrium zone) contiguous with the enterocyte's apical membrane, and (3) the apical membrane itself. Although the mucous gel that lines the intestine is 95% water, its interstices provide a barrier to the free diffusion—from the bulk phase to the unstirred water layer—of lipid macroaggregates, particularly the various vesicles that exist in equilibrium with the mixed micelles and monomers. Because of this diffusion barrier, the unstirred water lying adjacent to the enterocyte's apical membrane is not in equilibrium with the bulk phase of water in the lumen. According to calculations based on the diffusion of various probes under different experimental conditions and luminal fluid flow rates, it was originally estimated that the unstirred water layer was several hundred micrometers thick and posed a significant barrier to the diffusion of lipid nutrients to the enterocyte brush border. It is now thought that the unstirred water layer is likely only ~40 μm thick and does not constitute a major absorptive barrier.

For SCFAs and MCFAs,  **N45-1** which are readily soluble in water, diffusion of these monomers through the unstirred water layer to the enterocyte is efficient. As fatty-acid chain length increases, the monomer's solubility in water decreases, whereas its partitioning into micelles increases. It is true that the diffusion of a single monomer through the aqueous barriers is speedier than that of a single micelle or vesicle. However, mixed-lipid micelles act as a reservoir to give the aqueous solution such a high *effective concentration* of fatty acids and other lipid products that the diffusion of these micelles is the most efficient mechanism for bringing lipolytic products to the enterocytes. Calculations suggest that, compared with monomers dissolved in water, vesicular solubilization increases the “concentration” of LCFAs  **N45-1** near the enterocyte's brush-border membrane by a factor of 100,000 and micellar solubilization by a factor of 1,000,000.

When the fatty-acid/bile-salt mixed micelles reach the enterocyte surface, they encounter an acidic microclimate generated by Na-H exchange at the brush-border membrane. It is postulated that fatty acids now become protonated and leave the mixed micelle to enter the enterocyte. The uptake of fatty acids could occur by nonionic diffusion (see [pp. 784–785](#)) of the uncharged fatty acid or by collision and incorporation of the fatty acid into the cell membrane. However, it is clear that at least three integral membrane proteins promote the uptake of fatty acids ([Fig. 45-13](#)): **fatty-acid translocase (FAT** or **CD36**), the plasma-membrane **fatty acid-binding protein (FABPpm)**, and **fatty-acid transport proteins (FATPs, members of the SLC27 family; see [p. 967](#))**. Similarly, unesterified cholesterol and lysophospholipids must leave the micelle carrier to enter the enterocyte as monomers. Investigators have suggested that cholesterol derived from bile is better absorbed than dietary cholesterol. Most of the bile salts do not enter the enterocyte with the dietary lipids, but any that do are pumped back out into the lumen via ABCG5/ABCG8 transporters (see [p. 957](#)). The bile salts are absorbed via active transport by the apical, Na^+ -dependent bile-acid transporter (ASBT) in the distal ileum (see [pp. 962–963](#)). As with fatty acids, 2-MAGs, lysophospholipids, and cholesterol traditionally were assumed to enter the enterocyte by simple diffusion across the apical plasma membrane of the brush-border villi. More recently, however, in addition to carriers for fatty acids, membrane proteins have been identified in both enterocytes and hepatocytes that may be responsible for the transfer of fatty acids, phospholipids, and cholesterol across their respective cell membranes. As well as providing a mechanism for facilitated or active absorption of

the various products of lipid digestion, such carriers may yet be therapeutic targets for inhibiting lipid absorption. The drug ezetimibe, which lowers plasma cholesterol, impedes cholesterol uptake by inhibiting the internalization, at the enterocyte apical membrane, of a complex consisting of cholesterol and the **Niemann-Pick C-1 like 1 (NPC1L1) protein**.

FIGURE 45-13 Micellar transport of lipid breakdown products to the surface of the enterocyte. Mixed micelles carry lipids through the acidic unstirred layer to the surface of the enterocyte. 2-MAG, fatty acids, lysophospholipids, and cholesterol leave the mixed micelle and enter an acidic microenvironment created by an apical Na-H exchanger. The acidity favors the protonation of the fatty acids. The lipids enter the enterocyte by (1) nonionic diffusion, (2) incorporation into the enterocyte membrane ("collision"), or (3) carrier-mediated transport.

The enterocyte re-esterifies lipid components and assembles them into chylomicrons

The assimilation of fats, as described thus far, has been a process of disassembly of energy-dense, water-insoluble lipid macromolecular aggregates into monomers for intestinal absorption. The enterocyte elegantly reverses this process (Fig. 45-14). After absorbing LCFAs, MAGs, lysophospholipids, and cholesterol, the enterocyte re-esterifies them and assembles the products with specific apolipoproteins (or simply "apoproteins") into emulsion-like particles called chylomicrons. The enterocyte then exports the chylomicrons to the lymph (chyle) for ultimate delivery to other organs via the bloodstream. This process enables the delivery of dietary lipids to their intended target tissues (muscle and adipose tissue) while preventing the disruptive effects on cell membranes, were fatty acids to remain unesterified.

FIGURE 45-14 Re-esterification of digested lipids by the enterocyte and the formation and secretion of chylomicrons. The enterocyte takes up SCFAs, MCFAs, and glycerol and passes them unchanged into the blood capillaries. The enterocyte also takes up LCFAs and 2-MAG and resynthesizes them into TAG in the SER. The enterocyte also processes cholesterol into cholesteryl esters and lysolecithin into lecithin (phosphatidylcholine). The fate of these substances, and the formation of chylomicrons, is illustrated by steps 1 to 7.

Chylomicrons are the largest of the five lipoprotein particles in the bloodstream. We discuss the other lipoprotein particles—very-low-density lipoproteins (VLDLs), intermediate-density lipoproteins (IDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs)—on [pages 969–970](#) (see also [Table 46-4](#)). With an average diameter of ~250 nm (range, 75 to 1200 nm), chylomicrons consist primarily of TAGs, with smaller amounts of phospholipids, cholesteryl esters, cholesterol, and various apolipoproteins.

The first step in the enterocyte's re-formation of TAGs is the binding of **LCFAs** to a 14-kDa cytosolic protein called the intestinal-type **fatty acid-binding protein (FABP)**, or FABP2. The intestinal concentration of FABP2 is highest in regions that absorb fats, namely, the villi of the proximal jejunal enterocytes. FABP2 preferentially binds long-chain (rather than medium- or short-chain) fatty acids, thus minimizing both reflux back into the intestinal lumen and toxic damage to the enterocyte. FABP2 also ensures transfer of fatty acids to the enterocyte's smooth endoplasmic reticulum (SER) for re-esterification to form TAGs. After a meal, enterocytes mainly use the **MAG pathway** [N45-11](#) to re-esterify absorbed fatty acids to absorbed 2-MAG. During fasting, enterocytes mainly use the phosphatidic-acid pathway [N45-11](#) to esterify fatty acids that enter from the bloodstream and those derived from biliary phosphatidylcholine. The necessary phosphatidic acid may arise either from glycerol-3-phosphate—itself derived from the metabolism of glucose or amino acids—or from the

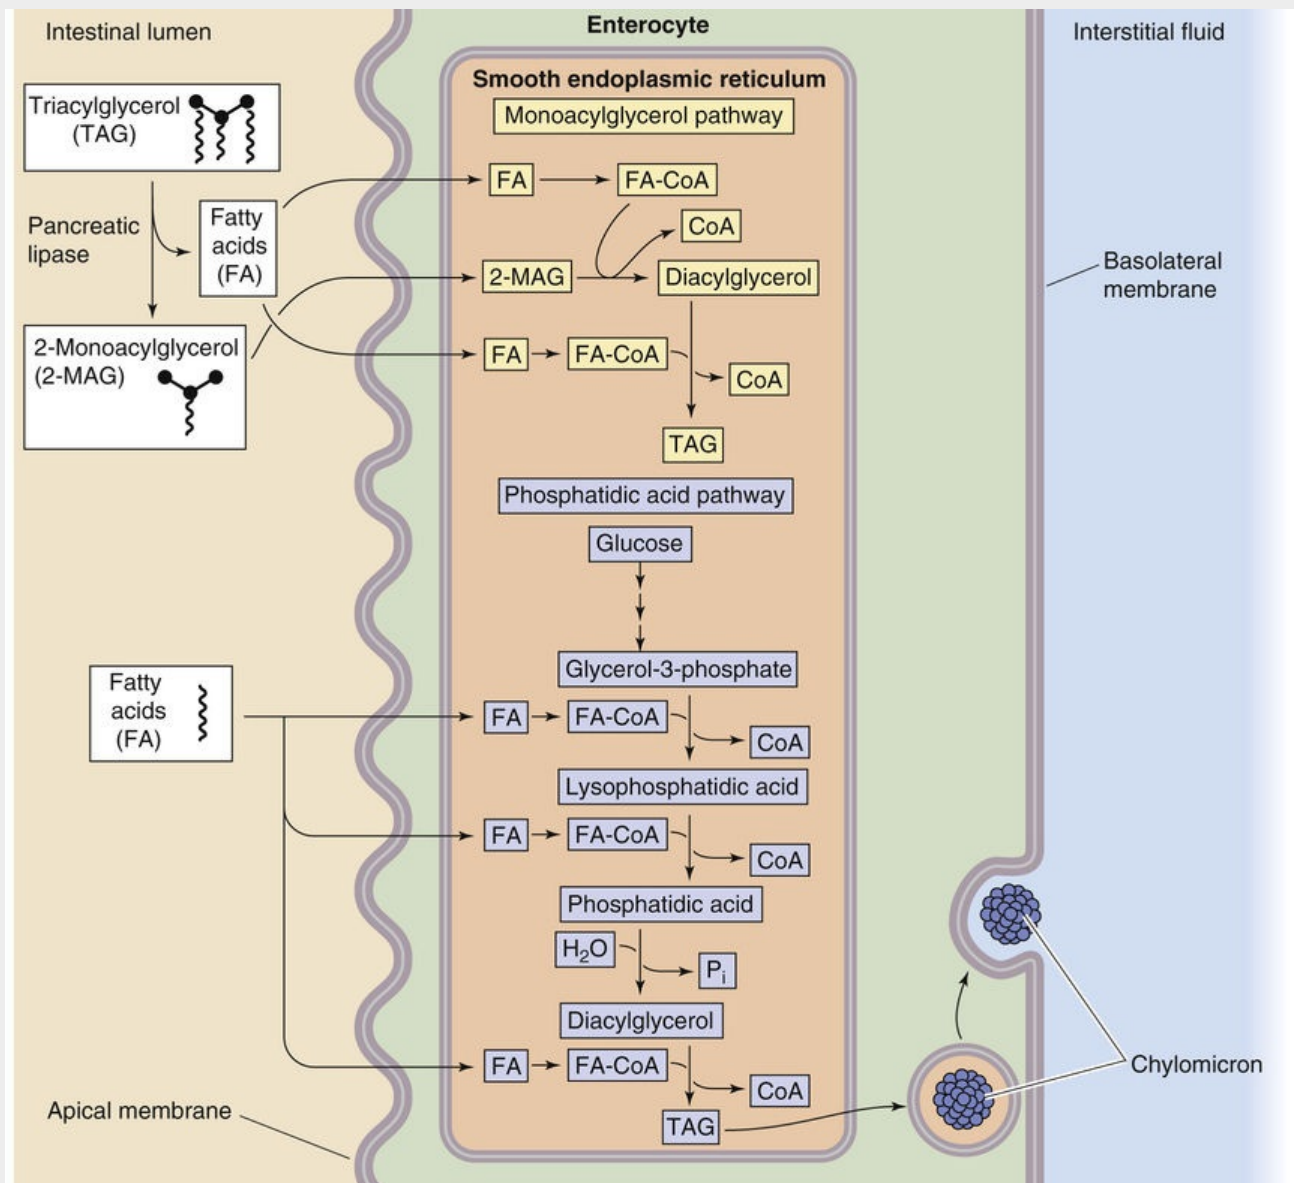

breakdown of bile phosphatidylcholine that enters from the intestinal lumen. Both the MAG and the phosphatidic-acid pathways depend on the activation of the fatty acid to acyl coenzyme A (acyl CoA), catalyzed by long-chain acyl CoA synthetase. 🍷**N45-12** LCFAs are the preferred substrate for this enzyme. The net effect of this series of reactions is the very rapid formation of TAGs in the SER, which maintains low fatty-acid concentrations in the enterocyte. TAGs and fat droplets may be seen in the cisternae of the SER on electron microscopy. The enterocyte also esterifies both **cholesterol** and **lysophosphatidylcholine**. 🍷**N45-13**

Regeneration of Triacylglycerols Inside of Enterocytes

Contributed by Adrian Reuben

As summarized in eFig. 45-3, pancreatic lipase breaks down **TAGs** into **fatty acids** and **2-MAGs** in the lumen of the small intestine. These products enter the enterocyte, which uses either the MAG or the phosphatidic-acid pathways to re-esterify them. The resulting TAGs are packaged into chylomicrons, which enter the lymph and, ultimately, the blood.

N45-13

Intestinal Esterification of Cholesterol and Synthesis of Phosphatidylcholine

Contributed by Adrian Reuben

Esterification of cholesterol by enterocytes may involve several enzymes, such as cholesterol esterase and acyl CoA: cholesterol acyltransferase.

The enterocyte may produce phosphatidylcholine (i.e., lecithin) intracellularly by using lysolecithin

acyltransferase to esterify absorbed lysolecithin or by de novo synthesis from phosphatidic acid.

Besides the lipids, the other components of the chylomicron are the various apolipoproteins (see [Table 46-4](#)), which the enterocyte synthesizes in the rough endoplasmic reticulum (RER). These apolipoproteins, with the exception of apolipoprotein A-I, move to the lumen of the SER, where they associate with newly synthesized TAGs (see [Fig. 45-14](#)). Apolipoprotein A-I associates with chylomicrons in the Golgi apparatus. Besides incorporating apolipoproteins, the packaging of nascent chylomicrons involves adding esterified cholesterol and a surface coating of phosphatidylcholine and other phospholipids. It is thought that vesicles (the prechylomicron transport vesicle) derived from the SER carry nascent chylomicrons to the *cis* face of the Golgi apparatus, where they fuse and deliver their contents internally. Enzymes in the Golgi apparatus glycosylate the apolipoproteins. Vesicles carrying processed chylomicrons bud off from the *trans* face of the Golgi and move toward the basolateral plasma membrane of the enterocyte. This process is the rate-limiting step in the transit of dietary fat across the enterocyte. There the vesicles fuse with the basolateral membrane and leave the enterocyte.

The foregoing discussion focused on the digestion and absorption of *long-chain* TAGs. The handling of TAGs with **MCFAs** is very different, inasmuch as (1) they are water soluble, and (2) the fatty-acid re-esterification enzymes prefer longer-chain fatty acids. Because of their water solubility, fatty acids and MAGs derived from medium-chain TAGs do not require either mixed micelles or bile salts for transport. Further, because the enterocyte does not re-esterify MCFAs, they move from the cell directly into the portal blood. As a result, medium-chain TAGs are suitable fat (caloric) substitutes for feeding patients with fat malabsorption.

The enterocyte secretes chylomicrons into the lymphatics during feeding and secretes VLDLs during fasting

As we have described, vesicles carrying mature chylomicrons discharge their contents from the enterocyte into the lamina propria via exocytosis at the basolateral membrane. Chylomicrons are too large to pass through the fenestrae of blood capillaries, and thus they enter **lymph** through the larger interendothelial channels of the lymphatic capillaries. In both the fed and fasted states, the intestine also secretes into the lymph **VLDLs**, which are smaller (30 to 80 nm) than chylomicrons. VLDLs have a protein and lipid composition similar to that of chylomicrons (see [Table 46-4](#)) but are synthesized independently and carry mainly endogenous (as opposed to dietary) lipids. The lymph lacteals originate in the tips of the villi and discharge their contents into the cisternae chyli. Lymph flows from the cisternae chyli to the thoracic duct, to enter the blood circulation via the left subclavian vein. The protein and lipid composition of both chylomicrons and VLDLs are modified during their passage through lymph and on entry into the blood.

The process of lipid digestion and absorption has great reserve capacity and many redundancies. For example, the mechanical disruption of food is accomplished in several ways by the mouth, stomach, and proximal intestine. Many of the digestive lipases have overlapping functions, and pancreatic lipase, in particular, is secreted in great excess. Much of the small intestine is not used for fat absorption in healthy individuals because most of the dietary lipid is absorbed within 60 cm from the pylorus. Nonetheless, fat malabsorption does occur in many disease states ([Box 45-5](#)). A logical classification for these disorders can be devised based on knowledge of the normal physiology. Thus, fat malabsorption may occur because of impairments in intraluminal digestion, intraluminal dispersion, mucosal penetration, chylomicron

assembly, or transport from enterocyte to the blood circulation. Within each major category are subdivisions. Frequently, the pathophysiology of these disorders is mixed (i.e., more than one step in the digestive or absorptive process is deranged), but nonetheless the defective components can be identified, and appropriate therapy given.

Box 45-5

Celiac Disease

Celiac disease (CD) is a not-uncommon disease that over the years has had a variety of names, including celiac sprue, gluten enteropathy, and nontropical sprue. CD was thought to affect primarily children with clinical manifestations of diarrhea and fat malabsorption, the latter leading to excess fecal fat (steatorrhea), and abnormal results on small-intestinal biopsy, all of which respond to a gluten-free diet. However, we now recognize that CD affects a much larger number of children and adults (perhaps nearly 1% of Americans), with a wide spectrum of symptoms or even no symptoms at all. These patients may have diarrhea, steatorrhea, growth retardation, bone disease, or anemia. Duodenal biopsy reveals atrophy of the epithelial villi (see p. 901)—often referred to as a *flat biopsy*—but with elongated crypts.

CD represents an autoimmune response to a peptide component of gluten called gliadin that is found in wheat, rye, and barley. The development of serological tests—including the detection in the serum of antibodies to tissue transglutaminase (anti-tTG)—has resulted in an increase in the number of individuals diagnosed with CD.

The abnormalities found on biopsy correlate with the symptoms. The absence of villous surface epithelial cells results in decreased nutrient absorption (often accompanied by steatorrhea). The elongation of crypts, which are responsible for electrogenic Cl^- secretion (see pp. 907–908), accounts for the small-intestinal fluid secretion that occurs in untreated CD.

The need to maintain a gluten-free diet is lifelong. Considerable research focuses on the development both of enzymes that will detoxify gliadin peptides (in vivo or in vitro) and of drugs that will prevent these peptides from being absorbed by the small intestine. Success with either approach would permit patients with CD to consume gluten-containing products with impunity.

Digestion and Absorption of Vitamins and Minerals

Intestinal absorption of fat-soluble vitamins follows the pathways of lipid absorption and transport

Table 45-3 summarizes characteristics of the fat-soluble vitamins A (see pp. 367–368), D (see pp. 1063–1067), E, and K (see pp. 440–442). As a class, these vitamins rely on the lipid-absorption process discussed in the preceding subchapter. Although individual fat-soluble vitamins, once digested and absorbed, have somewhat specific fates according to their chemical nature, they have numerous overlapping physical properties that determine their similar handling in the intestinal lumen as well as uptake and processing by enterocytes. In contrast to their water-soluble counterparts (discussed below), fat-soluble vitamins do not form classical coenzyme structures or prosthetic groups with soluble apolipoproteins. Fat-soluble vitamins can also be stored in fat depots in the body. Each of the fat-soluble vitamins is really a family of related compounds, some of which are esters.

TABLE 45-3
Vitamins

VITAMIN	ROLE	RDA	EFFECT OF DEFICIENCY
A (retinol)	Retinal pigment	Male: 1000 µg Female: 800 µg	Follicular hyperkeratosis, night blindness
B ₁ (thiamine)	Coenzyme in decarboxylation of pyruvate and α-keto acids	Male: 1.5 mg Female: 1.1 mg	Beriberi
B ₂ (riboflavin)	Component of coenzymes FAD and FMN, H carriers in mitochondria	Male: 1.7 mg Female: 1.3 mg	Hyperemia of nasopharyngeal mucosa, normocytic anemia
B ₃ (niacin, nicotinic acid)	Component of coenzymes NAD and NADP, H carriers in mitochondria	Male: 19 mg Female: 15 mg	Pellagra
B ₆ (pyridoxine)	Coenzyme in transamination for synthesis of amino acids	Male: 2 mg Female: 1.6 mg	Stomatitis, glossitis, normocytic anemia
B ₁₂ (cobalamin; see pp. 935–937)	Coenzyme in reduction of ribonucleotides to deoxyribonucleotides. Promotes formation of erythrocytes, myelin	2 µg	Pernicious anemia (a megaloblastic anemia)
C (ascorbic acid)	Coenzyme in formation of hydroxyproline used in collagen	60 mg	Scurvy
D (1,25-dihydroxy-cholecalciferol; see pp. 1063–1067)	Ca ²⁺ absorption	5–10 µg	Rickets
E (α-tocopherol)	Antioxidant: thought to prevent oxidation of unsaturated fatty acids	Male: 10 mg Female: 8 mg	Peripheral neuropathy
K (K ₁ = phylloquinone, K ₂ = various menaquinones)	Clotting: necessary for synthesis by liver of prothrombin and factors VII, IX, and X	Male: 70–80 µg Female: 60–65 µg	Hemorrhagic disease
Folate (see pp. 933–935)	Backbone used to synthesize purines and thymine	Male: 200 µg Female: 180 µg Pregnancy: 400 µg	Megaloblastic anemia
Biotin	Coenzyme in carboxylation reactions	30–100 µg*	Neurological changes
Pantothenic acid	Component of CoA; necessary for carbohydrate and fat metabolism involving acetyl CoA; amino-acid synthesis	4–7 mg*	Abdominal pain, vomiting, neurological signs

*Safe and allowable range.

FAD, flavin adenine dinucleotide; FMN, flavin mononucleotide; NAD, nicotinamide adenine dinucleotide; NADP, nicotinamide adenine dinucleotide phosphate.

After ingestion, fat-soluble vitamins are released from their association with proteins by the acidity of

gastric juice or by proteolysis. In addition, carboxyl ester hydrolases (found in pancreatic juice and in the mucosal brush border) liberate free vitamins from their esters. In the proximal small intestine, fat-soluble vitamins incorporate with other lipid products into emulsion droplets, vesicles, and mixed micelles, which ferry them to the enterocyte surface for uptake. The absorption efficiency of fat-soluble vitamins varies from 50% to 80% for A, D, and K to only 20% to 30% for vitamin E. Other ingestants—including dietary components and drugs and their carrier vehicles—can modify the absorption of fat-soluble vitamins. For example, high doses of vitamin A impair the absorption of vitamins E and K, whereas high doses of vitamin E enhance the absorption of vitamin A.

Enterocytes take up fat-soluble vitamins by simple diffusion or via transporters. After entry into the enterocyte, fat-soluble vitamins diffuse to the SER attached to carrier proteins—such as a **cellular retinol-binding protein** in the case of vitamin A, or retinol—or by other mechanisms. In the SER, the vitamins associate with lipid droplets that form nascent chylomicrons and VLDLs, which then translocate through the Golgi and secretory vesicles for exocytosis into lymph. During passage through the enterocyte, vitamin A and tiny amounts of vitamin D are esterified with LCFAs, but vitamin E and K are not.

Once in the systemic blood circulation, the fat-soluble vitamins A, D, E, and K enter the liver by receptor-mediated endocytosis of chylomicrons or remnant chylomicrons, as discussed on [pages 966–968](#).

Fat-soluble vitamin deficiency occurs in various fat-malabsorption states, including those induced by malabsorptive bariatric surgery, [N45-14](#) drugs that impair TAG hydrolysis (e.g., orlistat), drugs that bind bile acids (e.g., cholestyramine), and reduction of bile acids by impaired hepatobiliary function or by unabsorbable dietary fat substitutes. Fat-soluble vitamin deficiency can also result from impaired hepatic function. The consequences can include blindness and other irreversible eye disorders (deficiency of vitamin A); bone demineralization and resorption (deficiency of vitamin D); neurological, neuromuscular, and erythrocyte aberrations (deficiency of vitamin E); and both hemorrhagic and hypercoagulable states (disorders of vitamin K).

N45-14

Bariatric Surgery

Contributed by Emile Boulpaep, Walter Boron

Bariatrics (from Greek *baros* [weight] + *iater* [physician]) is a branch of medicine that focuses on treating obesity. Bariatric surgery—or weight-loss surgery—includes a variety of procedures for treating morbid obesity but does not include procedures for removing body fat per se (e.g., liposuction).

Bariatric surgery is sometimes classified into three groups depending on whether the surgical procedure predominantly produces malabsorption, restriction (or reduction) of stomach size, or a mixed malabsorption/restriction. To the extent that the surgery results in malabsorption of fats, a consequence can be a deficiency of the fat-soluble vitamins. In patients who have undergone such surgery, vitamin D deficiency is common.

In addition, bariatric surgery patients are also commonly deficient in several water-soluble vitamins (e.g., cobalamin, thiamine, folate) and minerals (e.g., iron, zinc, magnesium). In the case of cobalamin or vitamin B₁₂, the stomach contributes the **IF** that binds the cobalamin (see Fig. 45-16). Vitamin B₁₂ must be given parenterally to avoid pernicious anemia (see [N45-6](#)).

Treatment of fat-soluble vitamin deficiency includes administration of water-miscible emulsions of vitamins A and E, which can enter enterocytes without special handling in the intestinal lumen. These compounds then move into portal blood together with small amounts of the more polar forms of some of the vitamins, such as retinoic acid in the case of vitamin A and menadione in the case of vitamin K.

Dietary folate (PteGlu7) must be deconjugated by a brush-border enzyme before absorption by an anion exchanger at the apical membrane

Folate is also referred to as folic acid, or pteroylmonoglutamate (PteGlu1). As we discuss below, the reduced form of folate—tetrahydrofolate (THF)—is a cofactor in biochemical reactions involving the transfer of 1-carbon fragments. The recommended dietary allowance (RDA) for folate is 200 µg for men and 180 µg for women (see [Table 45-3](#)), but it is more than doubled in pregnant women (see [p. 1143](#)). THF is essential for the synthesis of thymine and purines, which are critical components of DNA. Thus, folate deficiency compromises DNA synthesis and cell division, an effect that is most clinically noticeable in the bone marrow, where the turnover of cells is rapid. Because RNA and protein synthesis are not impaired, large red blood cells called megaloblasts are produced. The resultant *megaloblastic anemia* can become quite severe if untreated. Megaloblastic cells also may be seen in other organs with rapid cell turnover, such as the small intestine. Folic acid supplementation during pregnancy also reduces the risk of neural tube defects.

The medicinal form of folate is PteGlu1, a **monoglutamate**. [Fig. 45-15A](#) shows the structure of PteGlu1 and also illustrates how folate can act as a methyl acceptor or donor in the interconversion of serine to glycine. Dietary folate exists in several forms, much of it as **folate polyglutamate**, or PteGlu7 (see [Fig. 45-15B](#)), which is widely available in the diet, particularly in spinach, beans, and liver. The intestinal absorption of PteGlu7 requires deconjugation by a brush-border peptidase to PteGlu1, which then enters the enterocyte via a transporter (see [Fig. 45-15C](#)). This deconjugation is catalyzed by folate conjugase, a zinc-activated exopeptidase present in the brush border. This enzyme removes glutamate residues from PteGlu7 in a stepwise fashion before absorption of PteGlu1. This stepwise hydrolysis of the polyglutamate chain of PteGlu7 is the rate-limiting step in folate digestion-absorption. Both folate deconjugation and folate absorption occur only in the proximal small intestine and are maximally active at a pH of 5.

A MEDICINAL FOLATE (PteGlu1)

B FOOD FOLATE (PteGlu7)

C FOLATE ABSORPTION

D METHYLATION OF REDUCED FOLATE

FIGURE 45-15 Folate deconjugation and absorption. **A**, THF has three parts: the biologically active pteridine moiety, a *p*-aminobenzoate, and a glutamate. PteGlu1 is the oxidized form of folate and is biologically inactive. **B**, Dietary folate is similar to medicinal folate but has several glutamate residues. PteGlu7 is also oxidized and inactive. **C**, In the proximal small intestine, a brush-border peptidase sequentially removes all but the last of the glutamate residues from dietary folate. The enterocyte then absorbs the resulting PteGlu1 using a folate-OH exchanger. Once inside the enterocyte, the PteGlu1 exists across the basolateral membrane via an unknown transporter. The enterocyte may reduce some of the PteGlu1 to DHF and then to THF, the biologically active form of folate. The enterocyte may then methylate some of the THF to form N⁵-methyl-THF, as summarized in **D**. **D**, After the cell has reduced PteGlu1 to THF by adding the four highlighted hydrogens, it first converts THF to 5,10-methylene-THF, breaking down serine to glycine in the process. This 5,10-methylene-THF is the methyl donor in the conversion of the nucleotide dUMP to dTMP in the synthesis of DNA. A second reaction converts this 5,10-methylene-THF to N⁵-methyl-THF, which can then act as a methyl donor in the synthesis of methionine (see [Fig. 45-16B](#)). NAD, nicotinamide adenine dinucleotide; NADH, nicotinamide adenine dinucleotide (reduced form).  **N45-15**

N45-15

NADH/NAD⁺ versus NADPH/NADP⁺

Contributed by Alisha Bouzaher

NADH and NAD⁺ are, respectively, the reduced and oxidized forms of nicotinamide adenine dinucleotide (NAD) and their close analogs are NADPH and NADP⁺, the reduced and oxidized forms of nicotinamide adenine dinucleotide phosphate (NADP). The coenzymes NADH and NADPH each consist of two nucleotides joined at their phosphate groups by a phosphoanhydride bond. NADPH is structurally distinguishable from NADH by the additional phosphate group residing on the ribose ring of the nucleotide, which allows enzymes to preferentially interact with either molecule.

Total concentrations of NAD⁺/NADH (10⁻⁵ M) are higher in the cell by ~10-fold compared to NADP⁺/NADPH (10⁻⁶ M). Ratios of the oxidized and reduced forms of these coenzymes offer perspective into the metabolic activity of the cell. The high NAD⁺/NADH ratio favors the transfer of a hydride from a substrate to NAD⁺ to form NADH, the reduced form of the molecule and oxidizing agent. Therefore, NAD⁺ is highly prevalent within catabolic reaction pathways where reducing equivalents (carbohydrate, fats, and proteins) transfer protons and electrons to NAD⁺. NADH acts as an energy carrier, transferring electrons from one reaction to another. Conversely, the NADP⁺/NADPH ratio is low, favoring the transfer of a hydride to a substrate oxidizing NADPH to NADP⁺. Thus, NADPH is utilized as a reducing agent within anabolic reactions, particularly the biosynthesis of fatty acids.

PteGlu1 absorption is saturable, shows substrate specificity, and is markedly enhanced at an acid pH. Folate absorption represents an apical membrane anion-exchange process in which folate uptake is linked

to the efflux of OH^- across the apical membrane (i.e., folate- OH exchange). The mechanism of folate movement out of the epithelial cell across the basolateral membrane is not understood.

The PteGlu1 taken up by the enterocyte is not biologically active. The enzyme difolate reductase acts on PteGlu1 to form first dihydrofolate (DHF) and then the biologically active derivative THF. The cell then converts THF to 5,10-methylene-THF (see [Fig. 45-15D](#)), the form of folate needed for DNA synthesis. The cell also can transform this 5,10-methylene-THF to N^5 -methyl-THF, which—as we discuss in the next section—can act as a methyl donor in the synthesis of methionine. The circulating, storage, and active forms of folate constitute various reduced (DHF and THF) and methylated derivatives of folate. The liver is the primary site at which dietary pteroylglutamates are reduced and methylated, although the intestinal epithelium may make a small contribution to these reactions.

Vitamin B₁₂ (cobalamin) binds to haptocorrin in the stomach and then to intrinsic factor in the small intestine before endocytosis by enterocytes in the ileum

Cobalamin, or **vitamin B₁₂** ([Fig. 45-16A](#)), is synthesized only by microorganisms, not by mammalian cells. The primary source of cobalamin in humans is the ingestion of animal products—meat, fish, shellfish, eggs, and (to a limited extent) milk. Cobalamin is not present in vegetables or fruit. Therefore, strict vegetarians are at risk of developing dietary cobalamin deficiency.

A CYANOCOBALAMIN

B METHYLATION CYCLE

C COBALAMIN HANDLING BY THE STOMACH AND PROXIMAL SMALL INTESTINE

D COBALAMIN ABSORPTION BY ILEAL ENTEROCYTE

FIGURE 45-16 Cobalamin and the role of intrinsic factor (IF) in the absorption of cobalamin. **A**,

Cyanocobalamin. **B**, Methylation cycle. Cobalamin is the coenzyme for the enzyme homocysteine : methionine methyltransferase, which transfers a methyl group from N⁵-methyltetrahydrofolate to homocysteine, thereby forming methionine and THF. **C**, Steps 1 to 8 show the fate of dietary cobalamin (CBL). Steps 4 to 8 show the role of IF. In addition, bile carries cobalamin into the duodenum. **D**, The IF/cobalamin complex is thought to be endocytosed. The cobalamin is liberated within the enterocyte by mechanisms that have not been established. Within the enterocyte, cobalamin binds to transcobalamin II (TCII), which is required for cobalamin's exit from the enterocyte.

Cobalamin's primary function is to serve as a coenzyme for homocysteine : methionine methyltransferase (see [Fig. 45-16B](#)), which transfers a methyl group from methyltetrafolate to homocysteine, thereby converting homocysteine to methionine. Methionine is an essential amino acid and in an altered form serves as an important donor of methyl groups in several important enzymatic reactions. If cobalamin is deficient and methionine levels fall, then the body converts its stores of intracellular folate (e.g., PteGlu1, THF, 5,10-methylene-THF) into N⁵-methyl-THF (see [Fig. 45-15D](#)) in an effort to produce more methionine. As a result, levels of 5,10-methylene-THF (the form of folate needed for DNA synthesis) falls, an effect that explains why folate and cobalamin deficiencies cause identical hematological abnormalities (i.e., megaloblastic anemia). In addition, cobalamin deficiency causes various neurological and psychological abnormalities that are not part of the syndrome of folate deficiency. Some of these abnormalities may be linked to deficient activity of methylmalonyl-CoA mutase, another cobalamin-dependent coenzyme.

Cobalamin reaches the stomach bound to proteins in ingested food. In the stomach, pepsin and the low gastric pH release the cobalamin from the ingested proteins (see [Fig. 45-16C](#)). The now-free cobalamin binds to **haptocorrin** (formerly known as R-type binder), a glycoprotein secreted by the salivary and gastric glands. The parietal cells of the stomach secrete a second protein, **intrinsic factor (IF)**, crucial for the absorption of cobalamin. However, cobalamin and IF do not interact in the acidic milieu of the stomach. Rather, gastric acidity enhances the binding of cobalamin to haptocorrin. When this cobalamin-haptocorrin complex reaches the duodenum, the haptocorrin is degraded by pancreatic proteases (see [Fig. 45-16C](#)).

After the release of cobalamin from the cobalamin-haptocorrin complex in the proximal small intestine—made alkaline by the secretion of HCO_3^- from the pancreas and duodenum—both dietary cobalamin and cobalamin derived from bile bind to IF. The cobalamin-IF complex is highly resistant to enzyme degradation. As noted above, the gastric parietal cells secrete IF, a 45-kDa glycoprotein. Acetylcholine, gastrin, and histamine stimulate gastric acid secretion (see [p. 866](#)), and they also stimulate IF secretion. IF secretion parallels proton secretion, but with three important differences. First, as in pepsinogen secretion, histamine triggers an IF release that peaks within minutes and then continues at a reduced rate. This secretory pattern is related to the secretion of preformed IF; histamine has no effect on IF synthesis. Second, although cAMP is important in IF secretion, a role for intracellular Ca^{2+} has not yet been established. Third, H₂ histamine-receptor antagonists block IF secretion, but omeprazole, an inhibitor of the parietal-cell H-K pump, does not affect IF secretion.

The next step in the absorption of cobalamin is the binding of the cobalamin-IF complex to specific receptors on the apical membranes of enterocytes in the ileum. Cobalamin without IF neither binds to ileal receptors nor is absorbed. The binding of the cobalamin-IF complex is selective and rapid and requires Ca^{2+} , but it is not energy dependent. The enterocyte next internalizes the cobalamin-IF complex in a process that is energy dependent but has not been well characterized. Inside the cell, cobalamin and IF dissociate; lysosomal degradation may play a role here. Within the enterocyte, cobalamin binds to another transport protein—transcobalamin II—which is required for cobalamin's exit from the enterocyte. The

cobalamin exits the ileal enterocyte across the basolateral membrane bound to transcobalamin II, possibly by an exocytotic mechanism. The transcobalamin II–cobalamin complex enters the portal circulation, where it is delivered to the liver for storage and for secretion into the bile.

Total-body cobalamin stores are large (~5 mg), particularly when compared with the daily rate of cobalamin absorption and loss. (The daily cobalamin requirement for normal adults is only 2 micrograms.) The load of cobalamin presented to the small intestine is derived about equally from two sources: the diet and biliary secretions. The latter is the result of the enterohepatic circulation (see pp. 962–964) of cobalamin; after its absorption, cobalamin is delivered throughout the body, and the excess is secreted by the liver into the bile, where it once again can be reabsorbed by the small intestine and recirculated.

Cobalamin deficiency has many possible causes. As already mentioned, a strict vegetarian diet is deficient in cobalamin. In **pernicious anemia**, a disorder seen primarily in the elderly, the absence of gastric parietal cells results in the absence of gastric acid and IF secretion. Consequently, cobalamin absorption is markedly reduced, and cobalamin deficiency develops. Other causes of cobalamin deficiency include related problems in the intestine. Bacterial overgrowth in the small intestine as a result of stasis (e.g., multiple jejunal diverticulosis) can be associated with cobalamin deficiency as a consequence of bacterial binding and metabolism of cobalamin. Crohn disease affecting the ileum and ileal resection are other possible causes of cobalamin malabsorption and deficiency as a result of an absence of ileal receptors for the cobalamin-IF complex.

Ca²⁺ absorption, regulated primarily by vitamin D, occurs by active transport in the duodenum and by diffusion throughout the small intestine

The physiological importance and complex regulation of Ca²⁺ and vitamin D are discussed in Chapter 52. The Ca²⁺ load presented to the small intestine is derived from dietary sources and digestive secretions. Most of the dietary Ca²⁺ (~1000 mg/day) comes from milk and milk products (see Fig. 52-1). Not all of the ingested Ca²⁺ is bioavailable. For example, only very little of the Ca²⁺ present in leafy vegetables is absorbed because of the concomitant presence of oxalate, a salt that binds Ca²⁺ and reduces its availability for absorption. The small intestine absorbs ~500 mg/day of Ca²⁺, but also secretes ~325 mg/day of Ca²⁺. Thus, the net uptake is ~175 mg/day.

Active transcellular uptake of Ca²⁺ occurs only in the epithelial cells of the duodenum, but Ca²⁺ is absorbed by passive paracellular diffusion throughout the small intestine. More Ca²⁺ is absorbed in the jejunum and ileum by diffusion than in the duodenum by active transport; this difference arises largely because the duodenum has a smaller total surface area and because the flow of Ca²⁺-containing fluid through the duodenum is faster.

The *active* transport of Ca²⁺ across the villous epithelial cells of the duodenum is transcellular and is under the control of vitamin D—primarily via genomic effects (see pp. 71–72). Transcellular Ca²⁺ absorption involves three steps (Fig. 45-17). The uptake of Ca²⁺ across the apical membrane occurs via **TRPV6 Ca²⁺ channels** (see Table 6-2, family No. 5), driven by the electrochemical gradient between the lumen and the cell. Cytosolic Ca²⁺ then binds to a protein called **calbindin**, which buffers intracellular Ca²⁺. This step is important because it allows levels of unbound (i.e., free) intracellular Ca²⁺ to remain rather low despite large transcellular fluxes of Ca²⁺. A **Ca pump** and an **Na-Ca exchanger** on the basolateral membrane then extrude the Ca²⁺ from the cell into the interstitial fluid. The active form of

vitamin D—1,25-dihydroxyvitamin D—stimulates all three steps of the transcellular pathway, but its most important effect is to enhance the second step by increasing the synthesis of calbindin.

FIGURE 45-17 Active Ca²⁺ uptake in the duodenum. The small intestine absorbs Ca²⁺ by two mechanisms. The passive paracellular absorption of Ca²⁺ occurs throughout the small intestine. This pathway is the predominant one but is *not* under the control of vitamin D. The second mechanism—the active transcellular absorption of Ca²⁺—occurs only in the duodenum. Ca²⁺ enters the cell across the apical membrane via a channel. Inside the cell, the Ca²⁺ is buffered by binding proteins such as calbindin and is also taken up into intracellular organelles such as the endoplasmic reticulum. The enterocyte then extrudes Ca²⁺ across the basolateral membrane via a Ca pump and an Na-Ca exchanger. Thus, the net effect is Ca²⁺ absorption. The active form of vitamin D (1,25-dihydroxyvitamin D) stimulates all three steps of transcellular Ca²⁺ absorption. NCX1, Na-Ca exchanger 1.

The passive absorption of Ca²⁺ throughout the small intestine occurs via the paracellular pathway, which is *not* under the control of vitamin D. Ca²⁺ absorption is also enhanced by low plasma [Ca²⁺] and during pregnancy and lactation. Absorption tends to diminish with aging.

Vitamin D itself is a fat-soluble vitamin that is absorbed mainly in the jejunum. Of course, the skin synthesizes vitamin D₃ from cholesterol in a process that requires ultraviolet light (see [p. 1064](#)). Thus, dietary vitamin D (both vitamin D₂ and D₃) is most important in regions of the world that do not receive much sunlight and during long, dark winters.

Mg²⁺ absorption occurs by an active process in the ileum

Mg²⁺ is an important intracellular ion that is required as an enzyme cofactor—many enzymes using ATP actually require that the ATP be complexed with Mg²⁺—and is critical for neurotransmission and muscular contractions. Mg²⁺ deficiency can affect neuromuscular, cardiovascular, and gastrointestinal function. Mg²⁺ is also important for the proper secretion of, and end-organ response to, parathyroid hormone. Thus, Mg²⁺ depletion is typically associated with hypocalcemia.

Mg²⁺ is widely available in different foods but is present in particularly large amounts in green vegetables, cereals, and meats. The RDA for Mg²⁺ in young adults is ~350 mg/day for men and ~280 mg/day for women (Table 45-4). The Mg²⁺ load to the small intestine is derived from both dietary sources and digestive secretions.

TABLE 45-4
Essential Minerals

MINERAL	ROLE	RDA
Ca	Bone mineralization (see pp. 1056–1058), intracellular signaling (see p. 60)	800–1200 mg
Cr	Possibly a cofactor in metabolism of carbohydrates, protein, lipids	50–200 µg
Cu	Enzyme cofactor (e.g., superoxide dismutase)	1.5–3 mg
Fe	Constituent of hemoglobin (see p. 647) and cytochromes (see p. 955)	Male: 10 mg Female (childbearing age): 15 mg
I	Constituent of thyroid hormones (see p. 1006)	150 µg
Mg	Complexes with ATP (see p. 82)	Male: ~350 mg Female: ~280 mg
Mn	Antioxidant	2–5 mg
Mo	Cofactor in carbon, nitrogen, and sulfur metabolism	75–250 µg
P	Bone mineralization (see pp. 1056–1058)	800–1000 mg
Se	Antioxidant	Male: 70 µg Female: 55 µg
Zn	Antioxidant, component of transcription factors (see p. 82), enzyme cofactor  N18-3	Male: 15 mg Female: 12 mg

Mg²⁺ absorption by the gastrointestinal tract is not yet well understood, but it appears to differ substantially from the absorption of the other key divalent cation, Ca²⁺, in three important respects. First, an active transport process for Mg²⁺ absorption appears to exist in the ileum, rather than in the duodenum, as is the case for Ca²⁺. Second, 1,25-dihydroxyvitamin D does not consistently increase Mg²⁺ absorption. Third, patients with increased intestinal Ca²⁺ absorption (e.g., absorptive hypercalciuria) have normal Mg²⁺ absorption. Along with active Mg²⁺ absorption in the ileum, passive absorption of Mg²⁺ occurs in the rest of the small intestine.

Heme and nonheme iron are absorbed in the duodenum by distinct cellular mechanisms

Iron plays several critical roles in human physiology, both in the heme groups of the cytochromes and as a key component of the oxygen-carrying heme moieties of hemoglobin and myoglobin. The most important complication of iron depletion is anemia. Iron overload produces **hemochromatosis**, a not-uncommon genetic disease (Box 45-6).

Box 45-6

Hemochromatosis

Hereditary hemochromatosis (HH) is a relatively common inherited disorder (3 to 5 persons in 1000 of northwestern European ancestry are homozygous) in which the body absorbs excessive iron from the

diet. This autosomal recessive disease becomes clinically significant only in homozygotes. If left untreated, HH can be fatal. The excess iron is stored in the liver, where it reaches toxic concentrations. Cirrhosis eventually results, greatly increasing the risk of hepatoma. Iron also ultimately accumulates in other organ systems, causing pancreatic damage (diabetes mellitus), bronze pigmentation of the skin, pituitary and gonadal failure, arthritis, and cardiomyopathy. The disease hardly ever becomes apparent before the individual enters the third decade of life. Women are relatively protected as long they are premenopausal, because their monthly menstrual flow keeps total-body iron stores at relatively normal levels.

The diagnosis can be made by detection of elevated iron and transferrin-saturation levels and elevated ferritin level. A liver biopsy is confirmatory.

Treatment, reminiscent of the medieval approach to disease, is to remove (by phlebotomy) one or even several units of blood (1 unit = 500 mL) from the patient on a regular basis until the iron overload is corrected, as evidenced by normal plasma ferritin levels. Afterward, most patients require phlebotomy only once every few months to maintain low iron stores.

The ***HFE* gene** that is associated with HH is related to the major histocompatibility complex (MHC) class I family. More than 80% of patients with HH are homozygous for a *missense* mutation (C282Y) in *HFE*. However, the role of this mutated gene in hemochromatosis is not yet clear because the penetrance of hemochromatosis in individuals with the C282Y allele is very low (<5%).

Attention has focused on **hepcidin**, a hepatic peptide hormone that is the primary regulator of body iron stores. In response to elevated iron stores, Kupffer cells increase their production of hepcidin; the hepcidin binds to basolateral FPN1 in duodenal enterocytes, which leads to FPN1 internalization, ubiquitination, and degradation. The result is a decrease in Fe^{2+} absorption (see Fig. 45-18). Hemochromatosis may represent a defect in the regulation of hepcidin. It is possible that a mutated *HFE* gene causes an inappropriately low hepatic hepcidin expression, thus resulting in hemochromatosis.

The relationship between hepcidin and iron absorption has also been identified in the **anemia of inflammation**, caused by a reduction in duodenal iron absorption. In this setting, the cytokine interleukin-6 stimulates hepcidin expression and thus decreased iron absorption.

Dietary iron takes two major forms: iron that is part of a heme moiety and iron that is not. These two types of dietary iron are absorbed by distinctly different mechanisms (Fig. 45-18). Overall iron absorption is low; 10% to 20% of ingested iron is absorbed. Heme iron is absorbed more efficiently than nonheme iron. Body stores of iron depend almost exclusively on iron absorption because no regulated pathway for iron excretion exists. Except in menstruating women, who require ~50% more iron in their diets, very little iron is lost from the body. Dietary iron comes primarily from meat—especially liver and fish—as well as vegetables. The RDA for iron in young adults is ~10 mg/day for men and ~15 mg/day for women (see Table 45-4).

FIGURE 45-18 Absorption of nonheme and heme iron in the duodenum. The absorption of nonheme iron occurs almost exclusively in the form of Fe^{2+} , which crosses the duodenal apical membrane via DMT1, driven by a H^{+} gradient that is maintained by Na-H exchange. Heme enters the enterocyte by an unknown mechanism. Inside the cell, heme oxygenase releases Fe^{3+} , which is then reduced to Fe^{2+} . Cytoplasmic Fe^{2+} then binds to mobilferrin for transit across the cell to the basolateral membrane. Fe^{2+} probably exits the enterocyte via basolateral ferroportin. The ferroxidase activity of hephaestin converts Fe^{2+} to Fe^{3+} for carriage in the blood plasma bound to transferrin.

Nonheme Iron

Nonheme iron may be either ferric (Fe^{3+}) or ferrous (Fe^{2+}). Ferric iron tends to form salt complexes with anions quite easily and thus is not readily absorbed; it is not soluble at pH values >3 . Ferrous iron does not complex easily and is soluble at pH values as high as 8. Ascorbic acid (vitamin C) forms soluble complexes with iron and reduces iron from the ferric to the ferrous state, thereby enhancing iron absorption. Tannins, present in tea, form insoluble complexes with iron and lower its absorption.

Iron movement does not occur passively but requires one or more proteins for facilitation of movement into and out of cells (especially enterocytes, hepatocytes, and macrophages) as well as for intracellular binding. The absorption of nonheme iron is restricted to the duodenum. The enterocyte takes up nonheme iron across the apical membrane via the **divalent metal cotransporter DMT1** (SLC11A2), which cotransports Fe^{2+} and H^{+} into the cell (see p. 123). DMT1, as well as the oligopeptide cotransporter that we discussed above, is unusual in being energized by the inwardly directed H^{+} gradient. DMT1 also efficiently absorbs a host of other divalent metals, including several that are highly toxic (e.g., Cd^{2+} , Pb^{2+}). In the case of dietary ferric iron, the **ferric reductase Dcytb** (duodenal cytochrome b) presumably reduces Fe^{3+} to Fe^{2+} at the extracellular surface of the apical membrane before uptake via DMT1.

Fe^{2+} moves into the cytoplasm of the enterocyte, where it binds to **mobilferrin**, an intracellular protein

that ferries the Fe^{2+} to the basolateral membrane. The enterocyte then translocates the Fe^{2+} across the basolateral membrane, possibly via **ferroportin transporter 1 (FPN1, SLC40A1)**. The mRNA encoding FPN1 has an iron response element (see [p. 99](#)) in its 5' untranslated region; thus, an increase in intracellular iron levels would be expected to decrease FPN1 synthesis. Following the exit of Fe^{2+} from the enterocyte via FPN1, the **ferroxidase hephaestin**—a homolog of the plasma protein ceruloplasmin, which carries copper (see [p. 970](#))—apparently oxidizes the Fe^{2+} to Fe^{3+} , which then binds to plasma **transferrin** (see [p. 42](#)) for carriage in the blood.

Once in the circulation, nonheme iron bound to transferrin is ultimately deposited in all the tissues of the body, but it has a particular predilection for the liver and reticuloendothelial system. Inside these cells, it binds to the protein apoferritin to form **ferritin** (see [p. 971](#)), the major storage form of iron. Smaller amounts of storage iron exist in an insoluble form called *hemosiderin*.

Heme Iron

Derived from myoglobin and hemoglobin, heme iron is also absorbed by duodenal epithelial cells. Heme iron enters the cells either by binding to a brush-border protein or through an endocytotic mechanism. Inside the cell, **heme oxygenase** enzymatically splits the heme iron, thus releasing free Fe^{2+} , CO, and biliverdin (see [Fig. 46-6A](#)). The cell reduces the biliverdin to bilirubin, which the liver eventually excretes in bile (see [Box 46-1](#)). The enterocyte then handles the Fe^{2+} in the same manner as nonheme iron.

Iron absorption is tightly regulated by the size of existing body iron stores. In physiologically normal subjects, iron absorption is limited but is markedly *increased* in states of iron deficiency, caused most often by gastrointestinal bleeding or excessive menstrual flow. For example, the expression of DMT1 and FPN1 increases in iron deficiency. Conversely, an increase in iron stores modestly reduces iron absorption.

The molecular mechanisms by which iron stores regulate iron absorption play a role in the pathophysiology of hemochromatosis (see [Box 45-6](#)). **Hepcidin**, a 25–amino-acid peptide secreted by hepatocytes, reduces duodenal iron absorption by downregulating the iron exporter ferroportin (FPN1). Hepcidin is a negative regulator of iron absorption. Indeed, mice that fail to express hepcidin have elevated body iron stores, whereas mice with enhanced hepcidin expression have profound iron deficiency.

Nutritional Requirements

No absolute daily requirement for carbohydrate or fat intake exists

Nutritionists recommend that the daily intake of carbohydrate relative to fat should not differ with age, gender, or activity level. Of the total caloric intake in a Western diet, 55% to 60% is typically carbohydrate, 25% to 30% is fat, and the remaining 10% to 15% is protein.

The requirements for **total** caloric intake vary among individuals and depend on certain factors, including a person's ability to use and store energy (efficiency) and the daily activity level. Differences in the efficiency of energy use among individuals are the result, in part, of variations in muscle mass but also of genetic factors. Because adipose tissue has a low metabolic rate, people with a large fat mass require less caloric intake per kilogram of body weight. Stated differently, the requirement for energy intake is greater per kilogram of *lean* body mass than per kilogram of *total* body mass (which includes fat). Thus, men generally require a greater daily caloric intake per kilogram of body weight than do women, who have relatively less muscle and more fat.

Activity level is the primary factor determining the daily energy requirement, assuming a stable body weight. For example, in a steady state, athletes must consume more than nonathletes not only because of a higher muscle-to-fat ratio but also because of a higher energy expenditure. Manual labor necessitates greater energy intake than does sedentary activity, again to maintain energy balance and body weight. Excess energy intake over output, over time, causes weight gain in the form of fat (see [p. 1173](#)). Using 9.4 kcal/g as the conversion factor, 1 kg of fat stores 9400 kcal, sufficient energy to support the basal metabolic rate for 4 days.

In addition to serving as a source of energy, fatty acids are also important for membrane structure (see [p. 8–9](#)) as well as signal transduction by pathways such as those involving DAGs (see [p. 60–61](#)) and arachidonic acid (see [p. 62](#)). In mammalian cells, fatty-acid synthase produces two major fatty acids: palmitic acid and oleic acid. Palmitic acid, which has 16 carbons and is fully saturated, is referred to as 16 : 0. Oleic acid has 18 carbons and a single *cis* double bond between carbons 9 and 10. This unsaturated fatty acid is referred to as 18 : 1 *cis*- Δ^9 . Because mammals cannot insert double bonds beyond carbon 9, they need two fatty acids in the diet: linoleate (18 : 2 *cis*- $\Delta^9\Delta^{12}$) and linolenate (18 : 3 *cis*- $\Delta^9\Delta^{12}\Delta^{15}$). These **essential fatty acids** serve as precursors for other unsaturated fatty acids, including arachidonic acid, which is a precursor to prostaglandins, leukotrienes, and thromboxanes.

The current recommendations favoring low fat intake are based on the view that a high fat intake is associated with chronic diseases such as atherosclerosis and non-insulin-dependent diabetes (see [Box 51-5](#)). However, fats have a positive side. In addition to playing the roles we have discussed in this chapter, fats enhance satiety and aid in the absorption of certain vitamins (see [p. 933](#)). Finally, the so-called omega-3 polyunsaturated fatty acids—in which the first double bond is three carbons from the terminal methyl group (or “omega carbon”)—appear to protect against cardiovascular disease and some forms of cancer.

The daily protein requirement for adult humans is typically 0.8 g/kg body weight but is higher in pregnant women,

postsurgical patients, and athletes

The diet must contain the nine essential amino acids (see [Table 58-2](#)) because the body cannot synthesize them. Eleven other amino acids are necessary for protein synthesis, but the body can synthesize their carbon skeletons from intermediates of carbohydrate metabolism. **Vegetarian diets** can meet the protein needs of the body provided the protein consumed contains adequate amounts of essential amino acids. Food protein is “scored” based on its content of essential amino acids compared with that of a reference protein, usually egg protein, which is given a score of 100. For example, a food containing protein with a score of 40 for threonine, 80 for phenylalanine, and 100 for lysine—all three of which are essential amino acids—receives a protein score of 40 because, relative to the standard, threonine is present in the lowest amount.

Protein intake is most important to meet the needs for tissue maintenance and repair, for muscle and neural function, and for maintenance of host defense mechanisms. The daily requirement for protein intake depends on one's nutritional status. The average human needs ~0.6 g of protein per kilogram of body weight per day to maintain nitrogen balance. The RDA for protein is ~0.8 g/kg of body weight for adults, ~1 g/kg for adolescents, and ~2 g/kg in the first 6 months of life. Pregnant and lactating women require extra protein intake to ensure adequate fetal development and milk production. Athletes require >1 g/kg to maintain a greater lean body mass and to fuel a highly active metabolism. Well-balanced but larger meals usually provide adequate protein for those with a greater need. Burn victims, patients recovering from surgery, and patients with disorders of protein absorption all require increased daily protein intake.

The distribution of amino acids required for protein accretion by growing infants and children is different from that for tissue maintenance. Moreover, the requirements change throughout development. The child uses 25% of amino-acid intake for protein accretion at 6 months of age but only 10% by 18 months of age. More than 40% of a child's protein intake must consist of essential amino acids versus only 20% of an adult's.

Proteins play a key role in host defenses. For example, proteins provide the structural backbone for skin and mucus. Protein synthesis is essential for phagocytes and lymphocytes that are responsible for antibody and cell-mediated immunity. The skin, lungs, and intestinal tract are the main structural defenses against invading organisms. In both the lungs and the gastrointestinal tract, mucus (containing glycoproteins) coats the surface of the passageways and aids in defending against disease by catching most foreign particles. Protein-depleted individuals, regardless of age, have impaired immune competence. Protein depletion limits the availability of amino acids for synthesis of the cellular proteins of the immune system, including glutathione, mucus glycoproteins, and metallothionein. The acute-phase response to invading organisms is suboptimal in a protein-deficient state.

The impaired immune competence of patients with acquired immunodeficiency syndrome (AIDS) is a function of poor nutrition in addition to the effects of the virus itself. During infection, the body mobilizes amino acids to synthesize proteins for defense against invading organisms. Thus, improving protein and energy intake may be beneficial for some AIDS patients.

Aside from being the backbone of proteins, amino acids play a variety of physiological roles. For example, arginine is a precursor to **nitric oxide** (see [p. 66](#)). Glutamate is a major **excitatory neurotransmitter** in the brain (see [pp. 318–319](#)), whereas glycine is a major **inhibitory neurotransmitter** (see [p. 319](#)). Glutamine is a major source of **NH₃ production** in the kidney (see [pp. 829–831](#)) and it also regulates **protein turnover** in muscle. The decrease in muscle glutamine concentration that occurs during trauma and infection is associated with a general decline of muscle function. Research in anorectic patients shows that the most important factor affecting muscle function is

insufficient nutrient intake. Increasing total nutrient intake in these patients by total parenteral nutrition increases muscle function before it has a measurable effect on muscle mass.

Minerals and vitamins are not energy sources but are necessary for certain enzymatic reactions, for protein complexes, or as precursors for biomolecules

Vitamins and minerals do not provide energy but are essential for such functions as metabolism, immune competence, muscle-force production, and blood clotting.

Minerals

Table 45-4 lists the essential minerals. The current recommendations for daily mineral intake are based on a mix of *balance studies* and usual dietary intakes in the United States. The recommendation for copper, for example, is based on balance studies, whereas those for manganese, chromium, and molybdenum are based on dietary intakes.

Assigning daily mineral intakes is problematic because some methods of determining mineral status do not always expose functional deficiencies. For example, a frank deficiency in Ca^{2+} intake leads to bone loss even though blood Ca^{2+} levels remain normal. Iron deficiency is difficult to detect because no clinical signs appear until iron stores are depleted. It is difficult to base recommendations simply on absorption because, for some minerals, absorption varies with intake. For example, copper deficiency or toxicity is unlikely in humans because absorption is *inversely* related to intake. Furthermore, interactions among minerals must be taken into account when establishing recommendations.

The goal is to base recommendations on scientific evidence. Radioisotopes can be used to monitor storage, absorption, and excretion. Another approach is to establish the physiological role of the mineral and then determine the mineral intake required for maintaining that physiological role. However, because of redundancy in function, it is often difficult to assess which mineral is deficient when function is compromised. For example, both iron and copper are involved in energy metabolism at the level of the electron transport chain. The blood clotting cascade involves Ca^{2+} , copper, and vitamin K. Zinc, selenium, and manganese all have antioxidant activities.

Vitamins

Even though vitamins are not energy sources themselves, they play an integral role as cofactors in many metabolic processes. Some vitamins are involved in group-transfer reactions, such as decarboxylations and carboxylations in fatty-acid and glucose metabolism, and transaminations in amino-acid metabolism. Vitamins act as oxidizing and reducing agents in the generation of ATP and also as antioxidants to quench free radicals produced as a byproduct of oxidation.

Of the 13 identified vitamins, RDAs have been established for 11 (see Table 45-3). Safe and allowable ranges are estimated for the remaining two—biotin and pantothenic acid. Recommendations differ widely among countries. Lower recommendations are generally based on scientific evidence. For each vitamin, a person's nutritional *status* falls into one of five categories: deficient, marginal, satisfactory, excessive, and toxic. Although “marginal” and “excessive” are not usually associated with overt clinical signs, people whose vitamin status falls into one of these categories are at increased risk of various diseases.

In the past, recommendations for the intake of vitamins and minerals were based largely on levels necessary to promote normal growth and development. However, the role of vitamins and minerals in

optimizing body function and in promoting longevity is becoming an area of intense interest both to researchers and to the general public. Older people generally have a less vigorous immune response than do young people, in large part because of deficiencies in iron, zinc, and vitamin C. Correcting these deficiencies improves immune competence significantly. In addition, older people with poor dietary habits may have inadequate intake of Ca^{2+} , vitamin D, and other nutrients involved in bone deposition and strength (see [pp. 1056–1058](#)), which puts them at greater risk of hip fracture.

Mineral deficiencies usually do not occur without extreme abnormalities in diet, and even then, a mineral deficiency may not impair function (see [Table 45-4](#)). However, a deficiency of almost any vitamin can cause functional impairment (see [Table 45-3](#)).

Excessive intake of vitamins and minerals has mixed effects on bodily function

A current controversy surrounds the use of so-called megadoses of certain vitamins and minerals. Such excessive intake has mixed effects. Slight excesses of vitamins A and E, zinc, and selenium are associated with an enhanced immune response, especially in patients with burns, trauma, or sepsis. In these conditions, “excess” intake may not be an excess at all but rather the intake that meets the greater need. Increased intake of fruits and vegetables—which contain a variety of vitamins as well as “fiber”—clearly decreases the risk of various cancers. However, efforts to link these effects specifically to dietary carotenoid levels have failed to show a correlation; indeed, the excessive intake of β -carotene supplements may even increase the risk of some cancers. Antioxidants (e.g., β -carotene, vitamins C and E) quench peroxy radicals of lipids, suppress tumor growth, and decrease atherosclerotic lesions in rabbits. Enhanced vitamin E intake lowers the risk of coronary heart disease by nearly one half.

The excessive intake of certain minerals and vitamins may compromise the immune response. Excess vitamin E intake in infants may increase the risk of infection, possibly by quenching superoxide radicals that are important for leukocytes to kill bacteria. Excess lipids can impair the immune response, too. High intake of saturated and polyunsaturated fatty acids leads to decreases in cell-mediated immunity. Excessive Ca^{2+} intake interferes with the ability to use iron, zinc, and Mg^{2+} , whereas high dietary copper affects zinc absorption and excretion.

Because the kidneys readily excrete water-soluble vitamins in the urine, toxicity from excessive intake is not common. Because fat-soluble vitamins are not easily excreted in the urine, it is easier to develop toxicity for these vitamins. In particular, polar bear liver, a component of the Inuit diet, contains extraordinarily high levels of vitamin A (35,000 IU/g versus the RDA of 5000 IU), which can lead to acute hypervitaminosis A and death.

Hepatobiliary Function

Frederick J. Suchy

Overview of Liver Physiology

After the skin, the liver and the brain are the largest organs in the human body. The liver weighs between 1200 and 1500 g, representing 2% to 5% of body weight in the adult and ~4% to 5% in the newborn. The liver is strategically situated in the circulatory system to receive the portal blood that drains the stomach, small intestine, large intestine, pancreas, and spleen (see [Fig. 24-7A](#)). In this position, the liver plays a key role in handling foodstuffs assimilated by the small intestine. However, the liver's role is far more diverse; it serves as a chemical factory, an excretory system, an exocrine gland, and an endocrine gland.

The liver biotransforms and degrades substances taken up from blood and either returns them to the circulation or excretes them into bile

A major function of the liver is to metabolize, detoxify, and inactivate both endogenous compounds (e.g., steroids and other hormones) and exogenous substances (e.g., drugs and toxins). In addition, by virtue of its large vascular capacity and abundance of phagocytes (Kupffer cells), the liver provides an important filtering mechanism for the circulation by removing foreign particulate matter, including bacteria, endotoxins, parasites, and aging red blood cells. Kupffer cells constitute 80% to 90% of the fixed macrophages of the reticuloendothelial system.

The liver has the capacity to convert important hormones and vitamins into a more active form. Examples include the initial hydroxylation of vitamin D and the deiodination of the thyroid hormone thyroxine (T_4) to triiodothyronine (T_3). Moreover, numerous enzymes in the liver process lipophilic chemicals into more polar, water-soluble metabolites, which are more readily excreted into bile.

Bile is a complex secretory product produced by the liver. Biliary secretion has two principal functions: (1) elimination from the body of many endogenous and exogenous waste products, such as bilirubin and cholesterol; and (2) promotion of digestion and absorption of lipids from the intestine. The composition of bile is modified significantly as a result of the absorptive and secretory properties of epithelial cells that line the intrahepatic and extrahepatic bile ducts. Moreover, bile solutes are further concentrated as bile is stored in the gallbladder.

The liver stores carbohydrates, lipids, vitamins, and minerals; it synthesizes carbohydrates, protein, and intermediary metabolites

The products of digested food, including carbohydrates, peptides, vitamins, and some lipids, are avidly extracted from portal blood by the liver. Depending on the metabolic requirements of the body, these substrates may be stored by the hepatocytes or released into the bloodstream either unbound (e.g., glucose) or associated with a carrier molecule (e.g., a triacylglycerol molecule complexed to a lipoprotein).

The liver also synthesizes—in a highly regulated fashion—many substances that are essential to the metabolic demands of the body. These substances include albumin, coagulation factors, and other plasma proteins; glucose; cholesterol; fatty acids for triacylglycerol biosynthesis; and phospholipids. The liver

must provide a supply of substrates as fuels for other organs, particularly in the fasted state. For example, the liver produces ketone bodies, which can be used by the central nervous system during periods of fasting; this use of ketone bodies as fuel spares ~50% of the amount of glucose that would otherwise be used by this tissue. Thus, the liver has a critical and unique role in the energy metabolism of all nonhepatic organs.

Functional Anatomy of the Liver and Biliary Tree

Hepatocytes are secretory epithelial cells separating the lumen of bile canaliculi from the fenestrated endothelium of sinusoids

One way of looking at the organization of the liver is to imagine that a classic lobule is a hexagon in cross section ([Fig. 46-1A](#)) with a branch of the hepatic vein at its center and, at each of the six corners, triads composed of branches of the hepatic artery, portal vein, and bile duct. Hepatocytes account for ~80% of the parenchymal volume in human liver. Hepatocytes form an epithelium, one cell thick, that constitutes a functional barrier between two fluid compartments with differing ionic compositions: the tiny **canalicular lumen** containing bile, and the much larger **sinusoid** containing blood (see [Fig. 46-1B](#)). Moreover, hepatocytes significantly alter the composition of these fluids by vectorial transport of solutes across the hepatocyte. This vectorial transport depends critically on the polarized distribution of specific transport mechanisms and receptors that are localized to the **apical membrane** that faces the canalicular lumen and the **basolateral membrane** that faces the pericellular space between hepatocytes and the blood-filled sinusoid (see [Fig. 46-1B, C](#)). As in other epithelia, the apical and basolateral membrane domains of hepatocytes are structurally, biochemically, and physiologically distinct.

FIGURE 46-1 Hepatocytes, sinusoids, and the intrahepatic bile system.

The **space of Disse**, or perisinusoidal space, is the extracellular gap between the endothelial cells lining the sinusoids and the basolateral membranes of the hepatocytes. These basolateral membranes have microvilli that project into the space of Disse to facilitate contact with the solutes in sinusoidal blood. The microvilli greatly amplify the surface of the basolateral membrane, which accounts for ~85% of the total surface area of the hepatocyte.

The bile canaliculi, into which bile is initially secreted, are formed by the apical membranes of adjoining hepatocytes. The apical membrane of the hepatocyte runs as a narrow belt that encircles and grooves into the polygonal hepatocyte (see Fig. 46-1B, C). Two adjacent hepatocytes form a canaliculus that is ~1 μm in diameter by juxtaposing their groove-like apical membranes along their common face (i.e., one side of the polygon). Because a hepatocyte has many sides and a different neighbor on each side,

the canaliculi form a chicken wire–like pattern along the contiguous surfaces of hepatocytes and communicate to form a three-dimensional tubular network. Although the apical membrane belt is very narrow (i.e., $\sim 1\ \mu\text{m}$), its extensive microvillous structure amplifies its surface area so that the canalicular membrane constitutes as much as 15% of the total membrane surface area. Because of this high surface-to-volume ratio, the total apical surface area available for the movement of water and solutes in the human liver is in excess of $10.5\ \text{m}^2$.

The seal that joins the apical membranes of two juxtaposed hepatocytes and that separates the canalicular lumen from the pericellular space—which is contiguous with the space of Disse—comprises several elements, including **tight junctions** (see [Fig. 46-1D](#)) and desmosomes (see [p. 45](#)). By virtue of their permeability and morphology, hepatic junctions can be classified as having an intermediate tightness, somewhere between that of tight epithelia (e.g., toad bladder) and leaky epithelia (e.g., proximal tubule). Specialized structures called *gap junctions* (see [pp. 158–159](#)) allow functional communication between adjacent hepatocytes.

Hepatocytes do not have a true basement membrane, but rather they rest on complex scaffolding provided by the **extracellular matrix** in the space of Disse, which includes several types of collagens (I, III, IV, V, and VI), fibronectin, undulin, laminin, and proteoglycans. Cells are linked to the matrix through specific adhesion proteins on the cell surface. The extracellular matrix not only provides structural support for liver cells but also seems to influence and maintain the phenotypic expression of hepatocytes and sinusoidal lining cells.

The liver contains endothelial cells, macrophages (Kupffer cells), and stellate cells (Ito cells) within the sinusoidal spaces

Slightly more than 6% of the volume of the liver parenchyma is made up of cells other than hepatocytes, including endothelial cells (2.8%), Kupffer cells (2.1%), and stellate cells (fat-storing or Ito cells, 1.4%). The **endothelial cells** that line the vascular channels or sinusoids form a fenestrated structure with their bodies and cytoplasmic extensions. Plasma solutes, but not blood cells, can move freely into the space of Disse through pores, or fenestrae, in the endothelial cells. Some evidence indicates that the fenestrae may regulate access into the perisinusoidal space of Disse by means of their capacity to contract.

The **Kupffer cells** are present within the sinusoidal vascular space.  **N46-1** This population of fixed macrophages removes particulate matter from the circulation. **Stellate cells** are in the space of Disse and are characterized morphologically by the presence of large fat droplets in their cytoplasm. These cells play a central role in the storage of vitamin A, and evidence suggests that they can be transformed into proliferative, fibrogenic, and contractile myofibroblasts. On liver injury, these activated cells participate in fibrogenesis through remodeling of the extracellular matrix, production of cytokines, and deposition of type I collagen, which can lead to cirrhosis.

N46-1

Kupffer Cells

Contributed by Emile Boulpaep, Walter Boron

Kupffer cells—or **Browicz-Kupffer cells**—are part of the reticuloendothelial system. They were originally described in 1876 by Karl Wilhelm von Kupffer, who incorrectly thought that they were part of the endothelium of the liver. In 1898, Tadeusz Browicz correctly identified them as macrophages.

The liver has a dual blood supply, but a single venous drainage system

The blood supply to the liver has two sources. The **portal vein** contributes ~75% of the total circulation to the liver; the **hepatic artery** contributes the other 25% (Fig. 46-2A). Blood from portal venules and hepatic arterioles combines in a complex network of hepatic sinusoids (see Fig. 46-2B). Blood from these sinusoids converges on terminal hepatic venules (or **central veins**), which, in turn, join to form the **hepatic veins** (see Fig. 46-2C). Branches of the portal vein, hepatic artery, and a bile duct (i.e., the triad), as well as lymphatics and nerves, travel together as a **portal tract**.

FIGURE 46-2 Blood supply to the liver.

The arterial supply for the bile ducts arises mainly from the right hepatic artery (see Fig. 46-2C). These arterioles give rise to an extraordinarily rich plexus of capillaries that surround the bile ducts as they pass through the portal tracts. Blood flowing through this peribiliary plexus empties into the sinusoids by way

of branches of the portal vein so that this blood may pick up solutes from the bile ducts and cycle them back to the hepatocytes. Thus, the peribiliary plexus may provide the means for modifying biliary secretions through the bidirectional exchange of compounds such as proteins, inorganic ions, and bile acids between the bile and blood within the portal tract.

Hepatocytes can be thought of as being arranged as classic hepatic lobules, portal lobules, or acinar units

The complex structure of the liver makes it difficult to define a single unit—something analogous to the nephron in the kidney—that is capable of performing the functions of the entire liver. One way of viewing the organization of the liver is depicted in [Figures 46-1](#) and [46-2](#), in which we regard the central vein as the core of the **classic hepatic lobule**. Thus, the classic hepatic lobule ([Fig. 46-3A](#)) includes all hepatocytes drained by a single central vein, and it is bounded by two or more portal triads. Alternatively, we can view the liver as though the triad is the core of a **portal lobule** (see [Fig. 46-3B](#)). Thus, the portal lobule includes all hepatocytes drained by a single bile ductule and is bounded by two or more central veins. A third way of viewing the liver is to group the hepatocytes according to their supply of arterial blood (see [Fig. 46-3C](#)). Thus, the **portal acinus** is a small three-dimensional mass of hepatocytes that are irregular in size and shape, with one axis formed by a line between two triads (i.e., high P_{O_2}) and another axis formed by a line between two central veins (i.e., low P_{O_2}).

FIGURE 46-3 Zones in the acinus. **A**, The classic lobule includes all hepatocytes drained by a single central vein. At each corner of the hexagon are triads composed of branches of the hepatic artery, portal vein, and bile duct. **B**, The portal lobule includes all hepatocytes drained by a bile ductule. **C**, The portal acinus emphasizes the arterial blood supply to the hepatocytes and thus the oxygenation gradient between a branch of the hepatic artery and branches of the hepatic vein (i.e., central vein).

Periportal hepatocytes specialize in oxidative metabolism, whereas pericentral hepatocytes detoxify drugs

Rappaport first proposed that a zonal relationship exists between cells that constitute the portal acini and their blood supply (see Fig. 46-3C). Hepatocytes close to the vascular core formed by the terminal portal venule and **terminal** hepatic arteriole are perfused first and thus receive the highest concentrations of oxygen and solutes. These **periportal** hepatocytes are said to reside in **zone I**, and as a consequence of their location, they are the most resistant to the effects of circulatory compromise or nutritional deficiency. These cells are also more resistant to other forms of cellular injury and are the first to regenerate. Hepatocytes in the intermediate **zone II** and the most distal population of **pericentral** hepatocytes located near the terminal hepatic venule (central vein) in **zone III** are sequentially perfused with blood that is already modified by the preceding hepatocytes; thus, they are exposed to progressively lower concentrations of nutrients and oxygen. The exact boundaries of these zones are difficult to define.

The concept of zonal heterogeneity of liver function has evolved as a result of these differences in access to substrate. Because of the specialized microenvironments of cells in different zones, some enzymes are preferentially expressed in one zone or another (Table 46-1). For example, in zone I, oxidative energy metabolism with β -oxidation, amino-acid metabolism, ureagenesis, gluconeogenesis, cholesterol synthesis, and bile formation is particularly important. Localized in zone III are glycogen synthesis from glucose, glycolysis, liponeogenesis, ketogenesis, xenobiotic metabolism, and glutamine

formation. Molecular techniques have allowed an even more precise definition of which hepatocytes express particular messenger RNA (mRNA) and proteins. For example, the enzyme glutamine synthetase is expressed exclusively in only one or two hepatocytes immediately adjacent to the hepatic venules. Hepatocytes of zone III also seem to be important for general detoxification mechanisms and the biotransformation of drugs. The zonal distribution of drug-induced toxicity manifested as cell necrosis may be attributed to zone III localization of the enzymatic pathways involved in the biotransformation of substrates by oxidation, reduction, or hydrolysis. Although it appears that each hepatocyte is potentially capable of multiple metabolic functions, the predominant enzymatic activity appears to result from adaptation to the microenvironment provided by the hepatic microcirculation. In some cases, it has been possible to reverse the zone I-to-zone III gradient of hepatocyte function by experimentally reversing the direction of blood supply (i.e., nutrient flow).

TABLE 46-1
Zonal Heterogeneity of Preferential Hepatocyte Function

ZONE I	ZONE III
Amino-acid catabolism	Glycolysis
Gluconeogenesis	Glycogen synthesis from glucose
Glycogen degradation	Liponeogenesis
Cholesterol synthesis (HMG-CoA reductase)	Bile acid biosynthesis (Cholesterol 7 α -hydroxylase)
Ureagenesis (all hepatocytes with the exception of the last one or two rows encircling the hepatic venules)	Ketogenesis
Bile acid-dependent canalicular bile flow	Glutamine synthesis
Oxidative energy metabolism and probably β -oxidation of fatty acids	Bile acid-independent canalicular bile flow
	Biotransformation of drugs

Bile drains from canaliculi into small terminal ductules, then into larger ducts, and eventually, via a single common duct, into the duodenum

The adult human liver has >2 km of bile ductules and ducts, with a volume of ~20 cm³ and a macroscopic surface area of ~400 cm². Microvilli at the apical surface magnify this area by ~5.5-fold.

As noted above, the **canaliculi** into which bile is secreted form a three-dimensional polygonal meshwork of tubes between hepatocytes, with many anastomotic interconnections (see [Fig. 46-1](#)). From the canaliculi, the bile enters the small terminal bile **ductules** (i.e., **canals of Hering**), which have a basement membrane and in cross section are surrounded by three to six ductal epithelial cells or hepatocytes ([Fig. 46-4A](#)). The canals of Hering then empty into a system of **perilobular ducts**, which, in turn, drain into interlobular bile ducts. The **interlobular bile ducts** form a richly anastomosing network that closely surrounds the branches of the portal vein. These bile ducts are lined by a layer of cuboidal or columnar epithelium that has microvillous architecture on its luminal surface. The cells have a prominent Golgi apparatus and numerous vesicles, which probably participate in the exchange of substances among the cytoplasm, bile, and blood plasma through exocytosis and endocytosis.

A DUCTULES AND SMALL DUCTS**B LARGE DUCTS AND GALLBLADDER**

FIGURE 46-4 Structure of the biliary tree. **A**, The bile canaliculi, which are formed by the apical membranes of adjacent hepatocytes, eventually merge with terminal bile ductules (canals of Hering). The ductules eventually merge into perilobular ducts, and then interlobular ducts. **B**, The interlobular ducts merge into septal ducts and lobar ducts (not shown), and eventually the right and left hepatic ducts, which combine as the common hepatic duct. The confluence of the common hepatic duct and the cystic duct gives rise to the common bile duct. The common bile duct may merge with the pancreatic duct and form the ampulla of Vater before entering the duodenum, as shown in the figure, or have a completely independent lumen. In either case, there is a common sphincter—the sphincter of Oddi—that simultaneously regulates flow out of the common bile duct and the pancreatic duct.

The interlobular bile ducts unite to form larger and larger ducts, first the septal ducts and then the lobar ducts, two hepatic ducts, and finally a common hepatic duct (see Fig. 46-4B). Along the biliary tree, the biliary epithelial cells, or **cholangiocytes**, are similar in their fine structure except for size and height. However, as discussed below (see pp. 960–961), in terms of their functional properties, cholangiocytes and bile ducts of different sizes are heterogeneous in their expression of enzymes, receptors, and transporters. Increasing emphasis has been placed on the absorptive and secretory properties of the biliary epithelial cells, properties that contribute significantly to the process of bile formation. As with other epithelial cells, cholangiocytes are highly cohesive, with the lateral plasma membranes of contiguous cells forming tortuous interdigitations. Tight junctions seal contacts between cells that are close to the luminal region and thus limit the exchange of water and solutes between plasma and bile.

The **common hepatic duct** emerges from the porta hepatis after the union of the right and left hepatic ducts. It merges with the cystic duct emanating from the gallbladder to form the common bile duct. In adults, the **common bile duct** is quite large, ~7 cm in length and ~0.5 to 1.5 cm in diameter. In most individuals, the common bile duct and the pancreatic duct merge before forming a common antrum known as the **ampulla of Vater**. At the point of transit through the duodenal wall, this common channel is surrounded by a thickening of both the longitudinal and the circular layers of smooth muscle, the so-called **sphincter of Oddi**. This sphincter constricts the lumen of the bile duct and thus regulates the flow of bile

into the duodenum. The hormone cholecystokinin (CCK) relaxes the sphincter of Oddi via a nonadrenergic, noncholinergic neural pathway (see [pp. 344–345](#)) involving vasoactive intestinal peptide (VIP).

The **gallbladder** lies in a fossa beneath the right lobe of the liver. This distensible pear-shaped structure has a capacity of 30 to 50 mL in adults. The absorptive surface of the gallbladder is enhanced by numerous prominent folds that are important for concentrative transport activity, as discussed below. The gallbladder is connected at its neck to the **cystic duct**, which empties into the common bile duct (see [Fig. 46-4B](#)). The cystic duct maintains continuity with the surface columnar epithelium, lamina propria, muscularis, and serosa of the gallbladder. Instead of a sphincter, the gallbladder has, at its neck, a spiral valve—**the valve of Heister**—formed by the mucous membrane. This valve regulates flow into and out of the gallbladder.

Uptake, Processing, and Secretion of Compounds by Hepatocytes

The liver metabolizes an enormous variety of compounds that are brought to it by the portal and systemic circulations. These compounds include endogenous molecules (e.g., bile salts and bilirubin, which are key ingredients of bile) and exogenous molecules (e.g., drugs and toxins). The hepatocyte handles these molecules in four major steps ([Fig. 46-5A](#)): (1) the hepatocyte imports the compound from the blood across its basolateral (i.e., sinusoidal) membrane, (2) the hepatocyte transports the material within the cell, (3) the hepatocyte may chemically modify or degrade the compound intracellularly, and (4) the hepatocyte excretes the molecule or its product or products into the bile across the apical (i.e., canalicular) membrane. Thus, compounds are secreted in a vectorial manner through the hepatocyte.

A HEPATOCYTE

B HOUSEKEEPING TRANSPORTERS

C SECRETION OF BILE ACIDS AND SALTS

D SECRETION OF OTHER ORGANIC ANIONS

FIGURE 46-5 Transporters in hepatocyte. **A**, The hepatocyte can process compounds in four steps: (1) uptake from blood across the basolateral (i.e., sinusoidal) membrane; (2) transport within the cell; (3) control chemical modification or degradation; and (4) export into the bile across the apical (i.e., canalicular) membrane. **B**, The hepatocyte has a full complement of housekeeping transporters. **C**, Bile acids can enter the hepatocyte in any of several forms: the unconjugated salt (BA^-); the neutral, protonated bile acid ($\text{H} \cdot \text{BA}$); or the bile salt conjugated to taurine or glycine (BA-Z^- , where Z represents taurine or glycine). The three pathways for bile acid entry across the basolateral membrane are the Na^+ -driven transporter NTCP, which prefers BA-Z^- but also carries BA^- ; nonionic diffusion of $\text{H} \cdot \text{BA}$; and an OATP. Binding proteins (BPs) may ferry conjugated bile acids across the cytoplasm. Some bile acids are conjugated to sulfate or glucuronate (Y); these exit the cell across the canalicular membrane via the MRP2 (multidrug resistance-associated protein 2) transporter. Most bile acids are conjugated to glycine or taurine (Z) prior to their extrusion into the bile via BSEP. **D**, Organic anions (OA), including bile acids and

bilirubin, may enter across the basolateral membrane via an OATP. After conjugation with sulfate or glucuronate (Y), these compounds may be extruded into the bile by MRP2. GSH synthesized in the hepatocyte, after conjugation to Y, can enter the canaliculus via MRP2. Unconjugated GSH can enter the canaliculus via an unidentified transporter. GSH can exit the hepatocyte across the basolateral membrane via an OATP. AA, amino acid.

An Na-K pump at the basolateral membranes of hepatocytes provides the energy for transporting a wide variety of solutes via channels and transporters

Like other epithelial cells, the hepatocyte is endowed with a host of transporters that are necessary for basic housekeeping functions. **N46-2** To the extent that these transporters are restricted to either the apical or basolateral membrane, they have the potential of participating in net transepithelial transport. For example, the Na-K pump (see pp. 115–117) at the basolateral membrane of hepatocytes maintains a low $[\text{Na}^+]_i$ and high $[\text{K}^+]_i$ (see Fig. 46-5B). A basolateral Ca pump (see p. 118) maintains $[\text{Ca}^{2+}]_i$ at an extremely low level, ~100 nM, as in other cells. The hepatocyte uses the inwardly directed Na^+ gradient to fuel numerous active transporters, such as the Na-H exchanger, Na/ HCO_3 cotransporter, and Na^+ -driven amino-acid transporters. As discussed below, the Na^+ gradient also drives one of the bile acid transporters. The hepatocyte takes up glucose via the GLUT2 facilitated-diffusion mechanism (see p. 114), which is insensitive to regulation by insulin.

N46-2

Hepatocyte Housekeeping Functions

Contributed by Fred Suchy

As noted in the text, the basolateral membrane of the hepatocyte has both K^+ and Cl^- channels. The basolateral K^+ conductance is high and is regulated by cAMP, $[\text{Ca}^{2+}]_i$, cell volume, and temperature. The basolateral Cl^- conductance is under the regulation of hormones and cell volume.

As is the case for most cells, hepatocytes actively regulate their intracellular pH (see pp. 644–645) using two acid extruders, the basolateral (i.e., sinusoidal) Na-H exchanger and an electrogenic Na/ HCO_3 cotransporter. The apical (i.e., canalicular) Cl^- - HCO_3 exchanger may contribute as an acid loader. The pH gradient across the canalicular membrane also drives the transport of inorganic solutes (e.g., HCO_3 - SO_4 exchange) and maintains the transmembrane gradients of weak acids and bases that cross the membrane by nonionic diffusion (see p. 784).

The basolateral membrane has both K^+ and Cl^- channels. The resting membrane potential (V_m) of -30 to -40 mV is considerably more positive than the equilibrium potential for K^+ (E_K) because of the presence of numerous “leak” pathways, such as the aforementioned electrogenic Na^+ -driven transporters as well as Cl^- channels ($E_{\text{Cl}} = V_m$).

Hepatocytes take up bile acids, other organic anions, and

organic cations across their basolateral (sinusoidal) membranes

Bile Acids and Salts

The primary bile acids are cholic acid and chenodeoxycholic acid, both of which are synthesized by hepatocytes (see p. 959, below). Other “secondary” bile acids form in the intestinal tract as bacteria dehydroxylate the primary bile acids. Because the pK values of the primary bile acids are near neutrality, most of the bile acid molecules are neutral; that is, they are *bile acids* ($H \cdot BA$) and thus are not very water soluble. Of course, some of these molecules are deprotonated and hence are *bile salts* (BA^-). The liver may conjugate the primary bile acids and salts to glycine or taurine (Z in Fig. 46-5C), as well as to sulfate or glucuronate (Y in Fig. 46-5C). Most of the bile acids that the liver secretes into the bile are conjugated, such as taurocholate (the result of conjugating cholic acid to taurine). These conjugated derivatives have a negative charge and hence they, too, are *bile salts* ($BA-Z^-$ and $BA-Y^-$). Bile salts are far more water soluble than the corresponding bile acids.

Because the small intestine absorbs some bile acids and salts, they appear in the blood plasma, mainly bound to albumin, and are presented to the hepatocytes for re-uptake. This recycling of bile acids, an example of **enterohepatic circulation** (see p. 962 below). Dissociation from albumin occurs before uptake. Surprisingly, the presence of albumin actually stimulates Na^+ -dependent taurocholate uptake, perhaps by increasing the affinity of the transporter for taurocholate.

Uptake of bile acids has been studied extensively and is mediated predominantly by an Na^+ -coupled transporter known as **Na/taurocholate cotransporting polypeptide** or **NTCP** (a member of the SLC10A1 family; see Fig. 46-5C). This transporter is a 50-kDa glycosylated protein, and it appears to have seven membrane-spanning segments. NTCP handles unconjugated bile acids, but it has a particularly high affinity for conjugated bile acids. In addition, NTCP can also transport other compounds, including neutral steroids (e.g., progesterone, 17β -estradiol sulfate), cyclic oligopeptides (e.g., amantadine and phalloidin), and a wide variety of drugs (e.g., verapamil, furosemide). 🍷N46-3

N46-3

Regulation of Na/Taurocholate Cotransport

Contributed by Emile Boulpaep, Walter Boron

Bile acid uptake via the **Na/taurocholate cotransporting polypeptide (NTCP)** is under the regulation of several second messengers. For example, cAMP stimulates taurocholate uptake, whereas this effect is blocked by inhibitors of protein kinase A. This direct stimulation presumably reflects the phosphorylation of the transporter or an essential activator. cAMP also stimulates uptake indirectly by increasing translocation of the transport protein to the membrane.

Certain hormones, such as prolactin, also stimulate bile acid uptake directly.

As is the case for many other transporters, NTCP activity is low in the fetus and neonate and increases with development.

NTCP has now been classified as a member of the **SLC10 gene family** (see Table 5-4) of Na/bile-salt cotransporters. For a detailed discussion of the family members, consult the review by Hagenbuch and Dawson listed below.

Reference

Hagenbuch B, Dawson P. The sodium bile salt cotransport family SLC10. *Pflügers Arch.* 2004;447:566–570.

Although NTCP also carries unconjugated bile acids, as much as 50% of these *unconjugated* bile acids may enter the hepatocyte by passive nonionic diffusion (see [Fig. 46-5B](#)). Because unconjugated bile acids are weak acids of the form

the neutral $\text{H} \cdot \text{BA}$ form can diffuse into the cell. Conjugation of bile acids enhances their hydrophilicity (taurine more so than glycine) and promotes dissociation of the proton from the side chain (i.e., lowers the pK_a), thus raising the concentration of BA^- . Both properties decrease the ability of bile acid to traverse membranes via passive nonionic diffusion.

Organic Anions

The **organic anion–transporting polypeptides (OATPs)** are members of the SLC21 family (see [p. 125](#)) [N46-4](#) and mediate the Na^+ -independent uptake of a wide spectrum of endogenous and exogenous amphipathic compounds—including bile acids, bilirubin, eicosanoids, steroid and thyroid hormones, prostaglandins, statin drugs, methotrexate, bromosulphophthalein, and many xenobiotics. Individual OATPs share considerable overlap in substrate specificity and can substantially influence the pharmacokinetics and pharmacological efficacy of drugs they carry. OATPs—predicted to have 12 membrane-spanning segments, with intracellular amino and carboxy termini—appear to exchange organic anions for intracellular HCO_3^- (see [Fig. 46-5C, D](#)). Expression of OATPs is under the control, in a cell- and tissue-specific way, of nuclear receptors (FXR, LXR, SXR, CAR; see [Table 3-6](#)) and hepatocyte nuclear factor 4 (HNF4). OATP1B1, OATP1B3, and OATP2B1 are liver specific and are located on the sinusoidal (basolateral) membrane of hepatocytes.

N46-4

Organic Anion Transporters

Contributed by Emile Boulpaep, Walter Boron

The **organic-anion transporting proteins (OATPs)** have now been classified as members of the **SLC21 gene family** (see [Table 5-4](#)). For a detailed discussion of the family members, consult the review by Hagenbuch and Meier listed below.

Note that some have inappropriately stated that because this family has an immense number of genes, it really ought to be treated as a superfamily, with the designation *SLCO* (here the *O* refers to “organic”). However, the superfamily is large only when one includes genes from all known organisms. The actual number of OATP genes in any given vertebrate organism (humans have 11 such genes) is about the same as for other SLC families. Thus, the OATPs are appropriately described as a “family.”

Reference

Hagenbuch B, Meier PJ. Organic anion transporting polypeptides of the OATP/SLC21 family: Phylogenetic classification as OATP/SLC0 superfamily, new nomenclature and molecular/functional properties. *Pflugers Arch.* 2004;447:653–665.

Thus, the basolateral uptake of **bile acids** into the hepatocyte is a complex process that involves both an Na⁺-dependent transporter (NTCP) and Na⁺-independent transporters (OATPs), as well as nonionic diffusion of unconjugated bile acids.

Bilirubin

Senescent erythrocytes are taken up by macrophages in the reticuloendothelial system, where the degradation of hemoglobin leads to the release of bilirubin into the blood ([Fig. 46-6A](#) and [Box 46-1](#)). The mechanism by which hepatocytes take up unconjugated bilirubin remains controversial. As evidenced by yellow staining of the sclerae and skin in the jaundiced patient, bilirubin can leave the circulation and enter tissues by diffusion. However, uptake of albumin-bound bilirubin by the isolated, perfused rat liver and isolated rat hepatocytes is faster than can occur by diffusion and is consistent with a carrier-mediated process. Electroneutral, electrogenic, and Cl⁻-dependent transport have been proposed (see [Fig. 46-6B](#)).

A HEME METABOLISM

B BILIRUBIN SECRETION

FIGURE 46-6 Excretion of bilirubin. **A**, Macrophages phagocytose senescent red blood cells and break the heme down to bilirubin, which travels in the blood, linked to albumin, to the liver. The conversion to the colorless urobilinogen occurs in the terminal ileum and colon, whereas the oxidation to the yellowish urobilin occurs in the urine. **B**, The hepatocyte takes up bilirubin across its basolateral membrane via an OATP and other unidentified mechanisms. The hepatocyte then conjugates the bilirubin with one or two glucuronic acid residues and exports this conjugated form of bilirubin into the bile. Bacteria in the terminal ileum and colon convert some of this bilirubin glucuronide back to bilirubin. This bilirubin is further

converted to the colorless urobilinogen. If it remains in the colon, the compound is further converted to stercobilin, which is the main pigment of feces. If the urobilinogen enters the plasma and is filtered by the kidney, it is converted to urobilin and gives urine its characteristic yellow color. NADP⁺, oxidized form of nicotinamide adenine dinucleotide phosphate; NADPH, reduced form of nicotinamide adenine dinucleotide phosphate.

Box 46-1

Jaundice

Jaundice denotes a yellowish discoloration of body tissues, most notable in the skin and sclera of the eyes. The condition is caused by an accumulation of bilirubin in extracellular fluid, either in free form or after conjugation. Bilirubin is a yellow-green pigment that is the principal degradation product of heme (see Fig. 46-6A), a prosthetic group in several proteins, including hemoglobin.

The metabolism of **hemoglobin (Hb)** of senescent red cells accounts for 65% to 80% of total bilirubin production. Hb released into the circulation is phagocytized by macrophages throughout the body, which split Hb into globin and heme. Cleavage of the heme ring releases both free iron, which travels in the blood by transferrin, and a straight chain of 4-pyrrole nuclei called **biliverdin** (see Fig. 46-6A), which the cell rapidly reduces to free bilirubin. This lipophilic form of bilirubin is often referred to as **unconjugated bilirubin**. After it enters the circulation, unconjugated bilirubin binds reversibly to albumin and travels to the liver, which avidly removes it from the plasma (see Fig. 46-6B). After hepatocytes take up bilirubin, they use UGT1A1 to convert the bilirubin to monoglucuronide and diglucuronide conjugates. These two forms of water-soluble, **conjugated bilirubin**—which make up the **direct bilirubin** measured in clinical laboratories—enter the bile canaliculus via MRP2 (see Table 5-6). Although suitable for excretion into bile, conjugated bilirubin cannot be absorbed by the biliary or intestinal epithelia.

Because of avid extraction and conjugation of bilirubin by the liver, the normal plasma concentration of bilirubin, which is mostly of the *unconjugated* variety, is ~0.5 mg/dL or lower. The skin or eyes may begin to appear jaundiced when the bilirubin level rises to 1.5 to 3 mg/dL.

Jaundice occurs under several circumstances. Increased destruction of red blood cells or hemolysis may cause **unconjugated hyperbilirubinemia**. Transient physiological neonatal jaundice results from an increased turnover of red blood cells combined with the immaturity of the pathways for conjugation of bilirubin (exacerbated in premature infants). Pathological conditions that can increase bilirubin production in neonates include isoimmunization, heritable hemolytic disorders, and extravasated blood (e.g., from bruises and cephalhematomas). Genetic disorders of bilirubin conjugation include the mild deficiency of UGT1A1 seen in the common Gilbert syndrome and the near-complete or complete deficiency of UGT1A1 seen in the rare Crigler-Najjar syndrome. Extreme unconjugated hyperbilirubinemia can lead to a form of brain damage called kernicterus (from the Dutch *kern* [nucleus, as in a brain nucleus] + the Greek *icteros* [jaundice]). Neonatal hyperbilirubinemia is often treated with phototherapy, which converts bilirubin to photoisomers and colorless oxidation products that are less lipophilic than bilirubin and do not require hepatic conjugation for excretion. Photoisomers are excreted mainly in the bile, and oxidation products, predominantly in the urine.

Jaundice can also result from defects in the secretion of **conjugated bilirubin** from hepatocytes into bile canaliculi (as with certain types of liver damage) or from defects in transiting the bilirubin to the small intestine (as with obstruction of the bile ducts). In either case, conjugated bilirubin refluxes back into the systemic circulation, where it now accounts for most of the bilirubin in plasma. Because the

kidneys can filter the highly soluble conjugated bilirubin—in contrast to the poorly soluble free form of bilirubin mostly bound to albumin—it appears in the urine. Thus, in obstructive jaundice, conjugated bilirubin imparts a dark yellow color to the urine. Measurement of free and conjugated bilirubin in serum serves as a sensitive test for detecting liver disease.

Under normal conditions, approximately half of the bilirubin reaching the intestinal lumen is metabolized by bacteria into the colorless **urobilinogen** (see Fig. 46-6A). The intestinal mucosa reabsorbs ~20% of this soluble compound into the portal circulation. The liver then extracts most of the urobilinogen and re-excretes it into the gastrointestinal tract. The kidneys excrete a small fraction (~20% of daily urobilinogen production) into the urine. Urobilinogen may be detected in urine by using a clinical dipstick test. Oxidation of urobilinogen yields **urobilin**, which gives urine its yellow color. In the feces, metabolism of urobilinogen yields **stercobilin**, which contributes to the color of feces. In obstructive jaundice, no bilirubin reaches the intestine for conversion into urobilinogen, and therefore no urobilinogen appears in the blood for excretion by the kidney. As a result, tests for urobilinogen in urine are negative in obstructive jaundice. Because of the lack of stercobilin and other bile pigments in obstructive jaundice, the stool becomes clay colored.

OATP1B1 and OATP1B3 can transport conjugated, and possibly unconjugated, bilirubin in vitro. Indeed, human mutations resulting in the complete deficiency of OATP1B1 or OATP1B3 cause **Rotor syndrome**, a relatively benign autosomal recessive disorder characterized by *conjugated*—not *unconjugated*—hyperbilirubinemia. How did this conjugated bilirubin—made only in hepatocytes—get into the blood? It is now clear that hepatocytes secrete substantial amounts of glucuronidated bilirubin across the sinusoidal membrane into the space of Disse and that OATP1B1/OATP1B3 is responsible for the reuptake of this conjugated bilirubin under physiological conditions. Other hepatic mechanisms may mediate the uptake of *unconjugated* bilirubin.

Organic Cations

The major organic cations transported by the liver are aromatic and aliphatic amines, including important drugs such as cholinergics, local anesthetics, and antibiotics, as well as endogenous solutes such as choline, thiamine, and nicotinamide (Fig. 46-7). At physiological pH, ~40% of drugs are organic cations, in equilibrium with their respective conjugate weak bases (see p. 628). Members of the **organic cation transporter (OCT)** family mediate the uptake of a variety of structurally diverse lipophilic organic cations of endogenous or xenobiotic origin (see p. 115). OCT-mediated transport is electrogenic, independent of an Na^+ ion or proton gradient, and may occur in either direction across the plasma membrane. Human hepatocytes express only OCT1 (SLC22A1) and OCT3 (SLC22A3), localized to the sinusoidal membrane. OCT1 and OCT3 have partly overlapping substrate specificities. OCT1 is also present in the plasma membrane of cholangiocytes. Acyclovir and lidocaine are examples of OCT1 substrates. The neurotransmitters epinephrine, norepinephrine, and histamine are exclusive OCT3 substrates. In addition to the OCTs, members of the OATP family as well as an electroneutral proton-cation exchanger may contribute to organic cation uptake across the basolateral membrane.

FIGURE 46-7 Excretion of organic cations and lipids. APL, aminophospholipid; C, cholesterol; PL, phospholipid.

Neutral Organic Compounds

This group of molecules is also taken up by an Na⁺-independent, energy-dependent process, although the nature of the driving force is not known. The best-characterized substrate is ouabain, uptake of which is inhibited by other neutral steroids, such as cortisol, aldosterone, estradiol, and testosterone. OATP1B1 transports some of these compounds.

We return to [Figures 46-5 through 46-7](#) below, when we discuss the movement of solutes into the bile canaliculus.

Inside the hepatocyte, the basolateral-to-apical movement of many compounds occurs by protein-bound or vesicular routes

Bile Salts

Some compounds traverse the cell while bound to **intracellular “binding” proteins** (see [Fig. 46-5C](#)). The binding may serve to trap the molecule within the cell, or it may be involved in intracellular transport. For bile salts, three such proteins have been identified. In humans, the main bile acid-binding protein appears to be the hepatic **dihydrodiol dehydrogenase**, one of a large family of dehydrogenases, the catalytic and binding properties of which are organ and species specific. The two others are **glutathione-S-transferase B** and **fatty acid-binding protein**. Intracellular sequestration of bile salts by these proteins may serve an important role in bile acid transport or regulation of bile acid synthesis.

Transcellular diffusion of bile salts bound to proteins can be detected within seconds after bile salts are applied to hepatocytes; this mechanism may be the primary mode of cytoplasmic transport under basal conditions. Free, unbound bile acids may also traverse the hepatocyte by rapid diffusion.

At high sinusoidal concentrations, hydrophobic bile acids may partition into membranes of intracellular vesicles. These conditions may also cause increased targeting of the vesicles to the canalicular membrane—that is, transcellular bile acid transport by a **vesicular pathway**. Whether transcellular transport occurs by protein-binding or vesicular pathways, it is unknown how bile acids are so efficiently targeted to the canalicular membrane for excretion into bile.

Bilirubin

After uptake at the basolateral membrane, unconjugated bilirubin is transported to the endoplasmic reticulum (ER), where it is conjugated to glucuronic acid (see Fig. 46-6). Because the resulting bilirubin glucuronide is markedly hydrophobic, it was thought that intracellular transport was mediated by binding proteins such as glutathione-S-transferase B. However, spontaneous transfer of bilirubin between phospholipid vesicles occurs by rapid movement through the aqueous phase, in the absence of soluble proteins. Thus, direct membrane-to-membrane transfer may be the principal mode of bilirubin transport within the hepatocyte. In addition, the membrane-to-membrane flux of bilirubin is biased toward the membrane with the higher cholesterol/phospholipid ratio. Hence, the inherent gradient for cholesterol from the basolateral membrane to the ER membrane may direct the flux of bilirubin to the ER.

In phase I of the biotransformation of organic anions and other compounds, hepatocytes use mainly cytochrome P-450 enzymes

The liver is responsible for the metabolism and detoxification of many endogenous and exogenous compounds. Some compounds taken up by hepatocytes (e.g., proteins and other ligands) are completely digested within lysosomes. Specific carriers exist for the lysosomal uptake of sialic acid, cysteine, and vitamin B₁₂. Clinical syndromes resulting from an absence of these carriers have also been identified. The lysosomal acid hydrolases cleave sulfates, fatty acids, and sugar moieties from larger molecules.

Hepatocytes handle other compounds by biotransformation reactions that usually occur in three phases. Phase I reactions represent oxidation or reduction reactions in large part catalyzed by the P-450 cytochromes. The diverse array of phase I reactions includes hydroxylation, dealkylation, and dehalogenation, among others. The common feature of all of these reactions is that one atom of oxygen is inserted into the substrate. Hence, these monooxygenases make the substrate (RH) a more polar compound, poised for further modification by a phase II reaction. For example, when the phase I reaction creates a hydroxyl group (ROH), the phase II reaction may increase the water solubility of ROH by conjugating it to a highly hydrophilic compound such as glucuronate, sulfate, or glutathione:

Finally, in phase III, the conjugated compound moves out of the liver via transporters on the sinusoidal

and canalicular membranes.

The **P-450 cytochromes** are the major enzymes involved in phase I reactions. **Cytochromes** are colored proteins that contain heme for use in the transfer of electrons. Some cytochromes—not the P-450 system—are essential for the electron transport events that culminate in oxidative phosphorylation in the mitochondria. The P-450 cytochromes, so named because they absorb light at 450 nm when bound to CO, are a diverse but related group of enzymes that reside mainly in the ER and typically catalyze **hydroxylation** reactions. Fifty-seven human *CYP* genes encode hundreds of variants of cytochrome P-450 enzymes (see [Table 50-2](#)). Genetic polymorphisms exist in the genes encoding all the main P-450 enzymes that contribute to drug and other xenobiotic metabolism, and the distribution and frequency of variant alleles can vary markedly among populations.

In this text, we encounter P-450 oxidases in two sets of organs. In cells that synthesize steroid hormones—the adrenal cortex (see [p. 1021](#)), testes (see [p. 1097](#)), and ovary (see [p. 1117](#)) and placenta (see [Table 56-5](#))—the P-450 oxidases are localized either in the mitochondria or in the ER, where they catalyze various steps in steroidogenesis. In the liver, these enzymes are located in the ER, where they catalyze a vast array of hydroxylation reactions involving the metabolism of drugs and chemical carcinogens, bile acid synthesis, and the activation and inactivation of vitamins. The same reactions occur in other tissues, such as the intestines and the lungs.

Hepatic microsomal P-450 enzymes have similar molecular weights (48 to 56 kDa). The functional protein is a holoenzyme that consists of an apoprotein and a heme prosthetic group. The apoprotein region confers substrate specificity, which differs among the many P-450 enzymes. These substrates include RH moieties that are as wide ranging as the terminal methyl group of fatty acids, carbons in the rings of steroid molecules, complex heterocyclic compounds, and phenobarbital. In general, phase I processes add or expose a functional group, a hydroxyl group in the case of the P-450 oxidases, which renders the molecule reactive with phase II enzymes. The metabolic products of phase I may be directly excreted, but more commonly, because of only a modest increment in solubility, further metabolism by phase II reactions is required.

In phase II of biotransformation, conjugation of phase I products makes them more water soluble for secretion into blood or bile

In phase II, the hepatocyte conjugates the metabolites generated in phase I to produce more hydrophilic compounds, such as glucuronides, sulfates, and mercapturic acids. These phase II products are readily secreted into the blood or bile. Conjugation reactions are generally considered to be the critical step in detoxification. Either a defect in a particular enzyme, which may result from a genetic defect, or saturation of the enzyme with excess substrate may result in a decrease in the overall elimination of a compound. One example is *gray syndrome*, a potentially fatal condition that occurs after the administration of chloramphenicol to newborns who have low glucuronidation capacity. Infants have an ashen gray appearance and become weak and apathetic, and complete circulatory collapse may ensue.

Hepatocytes use three major conjugation reactions:

1. **Conjugation to glucuronate.** The uridine diphosphate–glucuronosyltransferases (UGTs), which reside in the smooth endoplasmic reticulum (SER) of the liver, are divided into two families based on their substrate specificity. The UGT1 family consists of at least nine members encoded by genes located on

chromosome 2. These UGTs catalyze the conjugation of glucuronic acid with phenols or bilirubin (see Fig. 46-6B). The UGT2 family contains at least nine UGTs encoded by genes on chromosome 4. These UGTs catalyze the glucuronidation of steroids or bile acids. The two members of the UGT3 family reside on chromosome 5. Because UGT1s are essential for the dual conjugation of bilirubin (see Fig. 46-6B) and because only *conjugated* bilirubin can be excreted in bile, congenital absence of UGT1A1 activity results in jaundice from birth and bilirubin encephalopathy, as seen in patients with Crigler-Najjar syndrome type I.

2. Conjugation to sulfate. The sulfotransferases—which are located in the cytosol rather than in the SER—catalyze the sulfation of steroids, catechols, and foreign compounds such as alcohol and metabolites of carcinogenic hydrocarbons. Their substrate specificity is greater than that of the UGTs. The different cellular localization of these two groups of enzymes suggests that they act cooperatively rather than competitively. In general, sulfates are not toxic and are readily eliminated, with the exception of sulfate esters of certain carcinogens.

3. Conjugation to glutathione. Hepatocytes also conjugate a range of compounds to **reduced glutathione (GSH)** for excretion and later processing in either the bile ducts or kidney (Fig. 46-8). Glutathione is a tripeptide composed of glutamate γ -linked to cysteine, which, in turn, is α -linked to glycine. The liver has the highest concentration of glutathione (~5 mM), with ~90% found in the cytoplasm and 10% in the mitochondria. Glutathione-S-transferases, which are mainly cytosolic, catalyze the conjugation of certain substrates to the cysteine moiety of GSH. Substrates include the electrophilic metabolites of lipophilic compounds (e.g., epoxides of polycyclic aromatic hydrocarbons), products of lipid peroxidation, and alkyl and aryl halides. In some cases, the conjugates are then secreted into bile and are further modified by removing the glutamyl residue from the glutathione by γ -glutamyl transpeptidase on the bile duct epithelial cell. The fate of glutathione-S-conjugates in bile is largely unknown. Some (e.g., the leukotrienes) undergo enterohepatic circulation. In other cases, the glutathione conjugates are secreted into plasma and are filtered by the kidney, where a γ -glutamyl transpeptidase on the proximal tubule brush border again removes the glutamyl residue. Next, a dipeptidase removes the glycine residue to produce a cysteine-S-conjugate. The cysteine-S-conjugate is either excreted in the urine or is acetylated in the kidney or liver to form a mercapturic acid derivative, which is also excreted in the urine. Although glutathione conjugation is generally considered a detoxification reaction, several such conjugates undergo activation into highly reactive intermediates.

FIGURE 46-8 Conjugation to GSH and formation of mercapturic acids. The first step is for glutathione-S-transferase to couple the target compound (R) to the S on the cysteine residue of GSH. After MRP2 transports this GSH conjugate into the canalicular lumen (see Fig. 46-5D), a γ -glutamyl transpeptidase may remove the terminal glutamate residue. Alternatively, the conjugate may reach the blood and be filtered by the kidney where a γ -glutamyl transpeptidase at the brush border and a dipeptidase generate a cysteine derivative of R. Acetylation yields the mercapturic acid derivative, which appears in the urine.

Other forms of conjugation include methylation (e.g., catechols, amines, and thiols), acetylation (e.g., amines and hydrazines), and conjugation (e.g., bile acids) with amino acids such as taurine, glycine, or glutamine.

The involvement of multiple enzyme systems in these detoxification reactions facilitates the rapid removal of toxic species and provides alternative pathways in the event of failure of the preferred detoxification mechanism.

In phase III of biotransformation, hepatocytes excrete products of phase I and II into bile or sinusoidal blood

Phase III involves multidrug transporters of the ATP-binding cassette (ABC) family (see Table 5-6)—such as MDR1 (ABCB1), MRP1 (ABCC1), and MRP2 (ABCC2)—located on the *canalicular membrane*. These transporters have broad substrate specificity and play an important role in protecting tissues from toxic xenobiotics and endogenous metabolites. However, their overexpression often leads to the development of resistance to anticancer drugs and can adversely affect therapy with other drugs, such as antibiotics. MRP2, which transports conjugated bilirubin, can also transport other conjugated substrates, including drugs and xenobiotics conjugated to glutathione.

ABC proteins of broad substrate specificity—such as MRP4 (ABCC4) and MRP6 (ABCC6)—are also expressed on the basolateral or *sinusoidal membrane* of hepatocytes. MRP4, which has been studied best, facilitates the efflux of bile-salt conjugates (see Fig. 46-5C), conjugated steroids, nucleoside analogs, eicosanoids, and cardiovascular drugs into sinusoidal blood. These sinusoidal efflux pumps are upregulated in cholestasis, which enables renal elimination of substances with compromised canalicular transport.

The interactions of xenobiotics with nuclear receptors control

phase I, II, and III

The nuclear receptors (see [Table 3-6](#)) for xenobiotics, the steroid and xenobiotic receptor (SXR, also known as the pregnane X receptor, or PXR), the constitutive androstane receptor (CAR), and the aryl hydrocarbon receptor (AhR) coordinately induce genes involved in the three phases of xenobiotic biotransformation. Many xenobiotics are ligands for orphan NRs, CAR, and SXR, which heterodimerize with the retinoid X receptor (RXR) and transcriptionally activate the promoters of many genes (see [pp. 90–92](#)) involved in drug metabolism. Similarly, many polycyclic aromatic hydrocarbons bind to AhR, which then dimerizes with the AhR nuclear translocator (ARNT), inducing cytochrome P-450 genes.

Enzymes upregulated by SXR include the phase I drug-metabolizing enzymes of the P-450 family, such as CYP3A, which metabolizes >50% of all drugs in humans. SXR also activates the phase II enzyme glutathione-S-transferase, which is critical for catalyzing conjugation of many substrates to glutathione. SXR also upregulates MDR1 (see [Table 5-6](#)). Although these pathways are for the most part hepatoprotective, a particular compound may elicit SXR-mediated alterations in CYP3A activity that may profoundly influence the metabolism of another drug—perhaps thereby compromising the therapeutic efficacy of that drug or enhancing the production of a toxic metabolite.

The **constitutive androstane receptor (CAR)** is also an important regulator of drug metabolism. CAR regulates all the components of bilirubin metabolism, including uptake (possibly through OATP), conjugation (UTG1A1), and excretion (MRP2).

Hepatocytes secrete bile acids, organic anions, organic cations, and lipids across their apical (canalicular) membranes

At the apical membrane, the transport of compounds is generally unidirectional, from cell to canalicular lumen. An exception is certain precious solutes, such as amino acids and adenosine, which are reabsorbed from bile by Na⁺-dependent secondary active transport systems.

Bile Salts

Bile-salt transport from hepatocyte to canalicular lumen (see [Fig. 46-5C](#)) occurs via an ATP-dependent transporter called the **bile-salt export pump (BSEP or ABCB11; see Table 5-6)**. BSEP has a very high affinity for bile salts (taurochenodeoxycholate > taurocholate > tauroursodeoxycholate > glycocholate). The electrical charge of the side chain is an important determinant of canalicular transport inasmuch as only negatively charged bile salts are effectively excreted. Secretion of bile salts occurs against a significant cell-to-canalculus concentration gradient, which may range from 1 : 100 to 1 : 1000. Mutations in the **BSEP** gene can, in children, cause a form of progressive intrahepatic cholestasis that is characterized by extremely low bile acid concentrations in the bile.

Organic Anions

Organic anions that are *not bile salts* move from the cytoplasm of the hepatocyte to the canalicular lumen largely via **MRP2 (ABCC2, see Table 5-6 and Fig. 46-5D)**. MRP2 is electrogenic, ATP dependent, and has a broad substrate specificity [N46-5](#) —particularly for divalent, amphipathic, phase II conjugates with glutathione, glucuronide, glucuronate, and sulfates. Its substrates include bilirubin diglucuronide, sulfated bile acids, glucuronidated bile acids, and several xenobiotics. In general, transported substrates

must have a hydrophobic core and at least two negative charges separated by a specific distance. MRP2 is critical for the transport of GSH conjugates across the canalicular membrane into bile. Although MRP2 has a low affinity for GSH, functional studies suggest that other mechanisms for GSH transport exist. Animal models of defective MRP2 exhibit conjugated hyperbilirubinemia, which corresponds phenotypically to Dubin-Johnson syndrome in humans. Another canalicular efflux pump for sulfated conjugates is **breast cancer resistance protein (BCRP or ABCG2)**, which transports estrone-3-sulfate (see Fig. 55-8) and dehydroepiandrosterone sulfate (see Fig. 54-6)—breakdown products of sex steroids. Other anions, such as HCO_3^- and SO_4^{2-} , are excreted by anion exchangers.

N46-5

MRP2 (ABCC2)

Contributed by Emile Boulpaep, Walter Boron

A member of the ABC family (see Table 5-6), MRP2 has a broad substrate specificity but has the highest affinities for the bilirubin conjugated to monoglucuronide or diglucuronide. The affinity is also high for leukotriene C_4 .

The congenital deficiency of MRP2 causes **Dubin-Johnson syndrome**, an autosomal recessive disorder characterized by **conjugated hyperbilirubinemia** (i.e., high levels of conjugated bilirubin in the blood).

Organic Cations

Biliary excretion of organic cations is poorly understood. **MDR1** (ABCB1; see Table 5-6) is present in the canalicular membrane, where it secretes into the bile canaliculus (see Fig. 46-7) bulky organic cations, including xenobiotics, cytotoxins, anticancer drugs, and other drugs (e.g., colchicine, quinidine, verapamil, cyclosporine).

Other organic cations move into the canaliculus via the **multidrug and toxin extrusion 1 (MATE1)** transporters, which are driven by a pH gradient (see Fig. 46-7). The MATEs are one of the most highly conserved transporter families in nature, and MATE1 is highly expressed in many tissues. Thus, transcellular cation movement in liver is mediated by the combined action of electrogenic OCT-type uptake systems and MATE-type efflux systems.

In some cases, organic cations appear to move passively across the apical membrane into the canaliculus, sequestered by biliary micelles.

Biliary Lipids

Phospholipid is a major component of bile. **MDR3** (ABCB4; see Table 5-6) is a flippase that promotes

the active translocation of **phosphatidylcholine (PC)** from the inner to the outer leaflet of the canalicular membrane. Bile salts then extract the PC from the outer leaflet so that the PC becomes a component of bile, where it participates in micelle formation. Indeed, in humans with an inherited deficiency of MDR3, progressive liver disease develops, characterized by extremely low concentrations of phospholipids in the bile.

Lipid asymmetry in the canalicular membrane is essential for protection against the detergent properties of bile salts. The **P-type ATPase ATP8B1** in the canalicular membrane translocates aminophospholipids—such as phosphatidylserine (PS) and phosphatidylethanolamine (PE)—from the *outer* to the *inner* leaflet of the bilayer, thereby leaving behind an outer leaflet that is depleted of PC, PS, and PE but enriched in sphingomyelin and cholesterol. The resulting lipid asymmetry renders the membrane virtually detergent insoluble and helps to maintain the functional complement of enzymes and transporters within the lipid bilayer. ATP8B1 is also present in the apical membranes of several other epithelia, including cholangiocytes and the epithelia of gallbladder, pancreas, and intestine. Mutations in ATP8B1 produce a chronic, progressive cholestatic liver disease (progressive familial intrahepatic cholestasis type 1).

Bile is also the main pathway for elimination of **cholesterol**. A heterodimer composed of the “half” ABC transporters **ABCG5** and **ABCG8** (see [Table 5-6](#)) is located on the canalicular membrane. This transporter is responsible for the secretion of cholesterol into bile. Although the mechanism is uncertain, the ABCG5/ABCG8 complex may form a channel for cholesterol translocation or alternatively may undergo a conformational change following ATP hydrolysis, thereby flipping a cholesterol molecule into the outer membrane leaflet in a configuration favoring release into the canalicular lumen. Mutations in the genes encoding either of the two ABC monomers lead to sitosterolemia, a disorder associated with defective secretion of dietary sterols into the bile, increased intestinal absorption of plant and dietary sterols, hypercholesterolemia, and early-onset atherosclerosis.

Hepatocytes take up proteins across their basolateral membranes by receptor-mediated endocytosis and fluid-phase endocytosis

The hepatocyte takes up macromolecules, such as plasma proteins, from the blood plasma through endocytosis, transports these molecules across the cytoplasm, and then secretes them into the bile through exocytosis. Three forms of endocytosis have been identified in the basolateral (sinusoidal) membrane: fluid-phase endocytosis (nonspecific), adsorptive endocytosis (nonspecific), and receptor-mediated endocytosis (specific). 📌[N46-6](#)

N46-6

Protein Transport by Hepatocytes

Contributed by Fred Suchy

As noted in the text, hepatocytes take up proteins across their basolateral (i.e., sinusoidal) membranes via three forms of endocytosis. We discuss the fate of these endocytosed proteins in the next two paragraphs.

Intracellular Transport

Once proteins move into the hepatocyte by basolateral endocytosis, they can be transported across the cytoplasm within vesicles. This process, known as **transcytosis**, requires microtubules and is blocked by microtubule inhibitors, such as colchicine. Vesicular carriers transport the endocytosed proteins from the basolateral to the apical (i.e., canalicular) plasma membrane, where they exit via exocytosis. These same transcytotic vesicular carriers also ferry newly synthesized apical-membrane and secretory proteins. In the liver, most proteins destined for the apical membrane are initially transported from the *trans*-Golgi network to the basolateral membrane and subsequently transcytosed to the apical surface. It is believed that certain signal sequences on the protein (see p. 28) designate it as an apical membrane protein and are responsible for its correct targeting. The constitutive expression, rapid transport, and slow turnover of apical proteins mean that few are in the biosynthetic pipeline at steady state. During perturbations of liver function, such as cholestasis, the process of protein sorting is disturbed, and newly synthesized apical membrane proteins may accumulate in a subapical vesicular compartment or may be missorted to the basolateral domain.

Apical Exocytosis

The principal pathway for secretion of high-molecular-weight proteins, whether they originate *de novo* from within the hepatocyte or come from the plasma, is exocytosis at the apical membrane. Exocytosis may also be used to recruit transport proteins to the plasma membrane. For example, cAMP stimulates sorting of MRP2 (multidrug resistance–associated protein 2, ABCC2) to the canalicular membrane, a process that is accompanied by increases in canalicular membrane area and that can be inhibited by nocodazole, a microtubule inhibitor. Thus, the targeting of vesicles to the apical membrane may be a highly regulated (rather than constitutive) process and may be an important determinant of organic anion excretion into bile. A similar mechanism of both exocytosis and endocytosis at the apical membrane may be involved in the cell volume-regulatory responses to hyperosmotic stress (see p. 131) and hypo-osmotic stress (see pp. 131–132).

Fluid-phase endocytosis involves the uptake of a small amount of extracellular fluid with its solutes and is a result of the constitutive process of membrane invagination and internalization (see [pp. 41–42](#)). The process is nondiscriminatory and inefficient.

Adsorptive endocytosis involves nonspecific binding of the protein to the plasma membrane before endocytosis, and it results in more efficient protein uptake.

Receptor-mediated endocytosis is quantitatively the most important mechanism for the uptake of macromolecules (see [p. 42](#)). After endocytosis, the receptor recycles to the plasma membrane, and the ligand may be excreted directly into bile by exocytosis or delivered to lysosomes for degradation. Receptor-mediated endocytosis is involved in the hepatic removal from the blood of proteins such as insulin, polymeric immunoglobulin A (IgA), asialoglycoproteins, and epidermal growth factor.

Bile Formation

The secretion of canalicular bile is active and isotonic

The formation of bile occurs in three discrete steps. First, the hepatocytes actively secrete bile into the bile canaliculi. Second, intrahepatic and extrahepatic bile ducts not only transport this bile but also secrete into it a watery, HCO_3^- -rich fluid. These first two steps may produce ~900 mL/day of so-called hepatic bile (Table 46-2). Third, between meals, approximately half the hepatic bile—perhaps 450 mL/day—is diverted to the gallbladder, which stores the bile and isosmotically removes salts and water. The result is that the gallbladder concentrates the key remaining solutes in bile fluid—bile salts, bilirubin, cholesterol, and lecithin—by 10- to 20-fold. The 500 mL/day of bile that reaches the duodenum through the ampulla of Vater is thus a mixture of relatively “dilute” hepatic bile and “concentrated” gallbladder bile.

TABLE 46-2
Composition of Bile

PARAMETER	HEPATIC BILE	GALLBLADDER BILE
pH	7.5	6.0
Na ⁺ (mM)	141–165	220
K ⁺ (mM)	2.7–6.7	14
Ca ²⁺ (mM)	1.2–3.2	15
Cl ⁻ (mM)	77–117	31
HCO ₃ ⁻ (mM)	12–55	19
Total phosphorus (g/L)	0.15	1.4
Bile acids (g/L)	3–45	32
Total fatty acids (g/L)	2.7	24
Bilirubin (g/L)	1–2	3
Phospholipids (g/L)	1.4–8.1	34
Cholesterol (g/L)	1–3.2	6.3
Proteins (g/L)	2–20	4.5

Data from Boyer JL: Mechanisms of bile secretion and hepatic transport. In Andreoli TE, Hoffman JF, Fanestil DD, Schultz SG (eds): Physiology of Membrane Disorders. New York, Plenum, 1986.

The first step in bile formation cannot be ultrafiltration because the hydrostatic pressure in the canaliculi is significantly higher than the sinusoidal perfusion pressure. This situation is in marked contrast to glomerular filtration by the kidney (see pp. 743–745), which relies predominantly on passive hydrostatic forces for producing the fluid in Bowman's space. Instead, bile formation is an *active process*. It is sensitive to changes in temperature and to metabolic inhibitors. Bile formation by hepatocytes requires the active, energy-dependent secretion of inorganic and organic solutes into the canalicular lumen, followed by the passive movement of water.

Canalicular bile is an isosmotic fluid. Water movement into the bile canaliculus can follow both paracellular and transcellular pathways. As far as the *paracellular* pathway is concerned, the movement of water through the tight junctions between hepatocytes carries with it solutes by solvent drag (see p. 467). Further down the biliary tree (i.e., ducts and gallbladder), where the pore size of paracellular junctions is significantly smaller, solvent drag is not as important. Organic solutes do not readily enter bile distal to the canaliculi.

As far as the *transcellular* pathway is concerned, water enters hepatocytes via aquaporin 9 (AQP9), found exclusively on the sinusoidal membrane. AQP9 also allows the passage of a wide variety of neutral

solutes such as urea, glycerol, purines, and pyrimidines. The canalicular membrane expresses AQP8. Under basal conditions, AQP8 is predominantly localized to intracellular vesicles so that water permeability in the canalicular membrane is lower than that in the sinusoidal membrane and is rate limiting for transcellular water transport. However, upon cAMP stimulation, AQP8 from the intracellular pool inserts into the canalicular membrane, which substantially increased the water permeability of this membrane. With cAMP stimulation, transcellular water permeability in the hepatocyte is similar to that in the renal proximal tubule, where water flow is largely transcellular. Indeed, the transcellular pathway accounts for most of the water entering the bile canaliculus during choleresis.

Major organic molecules in bile include bile acids, cholesterol, and phospholipids

Bile has two important functions: (1) bile provides the sole excretory route for many solutes that are not excreted by the kidney, and (2) secreted bile salts and acids are required for normal lipid digestion (see pp. 925–929) and absorption (see pp. 929–933).

Both hepatic bile and gallbladder bile are complex fluids that are isosmotic with plasma (~300 mOsm) and consist of water, inorganic electrolytes, and a variety of organic solutes, including bilirubin, cholesterol, fatty acids, and phospholipid (see Table 46-2). The predominant cation in bile is Na^+ , and the major inorganic anions are Cl^- and HCO_3^- . Solutes whose presence in bile is functionally important include micelle-forming bile acids, phospholipids, and IgA.

Bile acids promote dietary lipid absorption through their micelle-forming properties (see p. 929). As shown in Figure 46-9, hepatocytes synthesize the so-called **primary bile acids**—cholic acid and chenodeoxycholic acid—from cholesterol. Indeed, biliary excretion of cholesterol and conversion of **cholesterol** to bile acids are the principal routes of cholesterol excretion and catabolism, so that bile formation is pivotal for total-body cholesterol balance. The first step in this conversion is catalyzed by **cholesterol 7 α -hydroxylase (CYP7A1)**,  **N46-7** a specific cytochrome P-450 enzyme located in the SER. As we see below, **secondary bile acids** are the products of bacterial dehydroxylation in the terminal ileum and colon. After being absorbed and returning to the liver (enterohepatic circulation, discussed below), these secondary bile acids may also undergo conjugation. Figure 46-9 shows typical examples of conjugation reactions.

FIGURE 46-9 Synthesis of bile acids. The liver converts cholesterol to the primary bile acids—cholic acid and chenodeoxycholic acid—in a series of 14 reactions occurring in four different cellular organelles. Bacteria in the terminal ileum and colon may dehydroxylate bile acids, yielding the secondary bile acids deoxycholic acid and lithocholic acid. The hepatocytes conjugate most of the primary bile acids to small molecules such as glycine and taurine before secreting them into the bile. In addition, those secondary bile acids that return to the liver via the enterohepatic circulation may also be conjugated to glycine or taurine

N46-7

Cholesterol 7α-Hydroxylase

Contributed by Fred Suchy

As noted in the text, the first step in the conversion of cholesterol to bile acids is the hydroxylation of cholesterol at position 7 by **cholesterol 7α-hydroxylase**. Bile acid levels regulate the activity of this enzyme, probably by both positive and negative feedback. Negative feedback in a cultured rat hepatocyte model occurs partly at the transcriptional level.

Phospholipids in bile help to solubilize cholesterol as well as diminish the cytotoxic effects of other bile acids on hepatocytes and bile duct cells. **IgA** inhibits bacterial growth in bile.

Excretory or **waste products** found in bile include cholesterol, bile pigments, trace minerals, plant sterols, lipophilic drugs and metabolites, antigen-antibody complexes, and oxidized glutathione.

Bile is also the excretory route for compounds that do not readily enter the renal glomerular filtrate, either because they are associated with proteins such as albumin or because they are associated with formed elements in blood. Although these compounds are generally lipophilic, they also include the heavy metals. Some bile acids (e.g., the trihydroxy bile acid cholic acid) are only partly bound to serum albumin and may therefore enter the glomerular filtrate. However, they are actively reabsorbed by the renal tubule. In health, bile acids are virtually absent from the urine.

Canalicular bile flow has a constant component driven by the secretion of small organic molecules and a variable

component driven by the secretion of bile acids

Total bile flow is the sum of the bile flow from hepatocytes into the canaliculi (canalicular flow) and the additional flow from cholangiocytes into the bile ducts (ductular flow). In most species, the rate of **canalicular bile secretion** (i.e., milliliters per minute) increases more or less linearly with the rate of bile acid secretion (i.e., moles per minute). Canalicular bile flow is the sum of two components (Fig. 46-10): (1) a “constant” component that is independent of bile acid secretion (bile acid–independent flow) and (2) a rising component that increases linearly with bile acid secretion (bile acid–dependent flow). In humans, most of the canalicular bile flow is bile acid dependent. If we now add the **ductular secretion**, which is also “constant,” we have the **total bile flow** in Figure 46-10. We discuss the canalicular secretion in the remainder of this section and ductular secretion in the following section.

FIGURE 46-10 Components of bile flow.

Bile Acid–Independent Flow in the Canaliculi

The secretion of *organic* compounds probably provides the major driving force for bile acid–independent flow. For example, glutathione, present in bile in high concentrations, may generate a potent osmotic driving force for canalicular bile formation. **N46-8**

N46-8

Contribution of Inorganic Solutes to Bile Acid–Independent Flow

Contributed by Fred Suchy

In addition to organic solutes, inorganic solutes also contribute to bile acid–independent flow of bile. The secretion of these *inorganic* electrolytes occurs primarily by solvent drag (see p. 467) and passive diffusion (e.g., through canalicular Cl^- channels; see Fig. 46-5B). To the extent that these inorganic electrolytes enter the canalicular lumen by passive diffusion, they pull in water osmotically and thus

contribute to bile acid–independent flow. However, this is not a major effect.

Bile Acid–Dependent Flow in the Canaliculi

The negatively charged bile salts in bile are in a micellar form and are—in a sense—large polyanions. Thus, they are effectively out of solution and have a low **osmotic activity coefficient**. However, the positively charged counterions accompanying these micellar bile acids are still in aqueous solution and may thus represent the predominant osmotic driving force for water movement in bile acid–dependent flow. If one infuses an animal with a nonphysiological bile acid that does not form micelles or one that forms micelles only at a rather high concentration, the osmotic activity will be higher, and thus the exogenous bile acid will be more effective in producing bile acid–dependent flow. In other words, the slope of the *blue* bile acid–dependent line in [Figure 46-10](#) would be steeper than for physiological bile acids.

Bile flow does not always correlate with the osmotic activity of the bile acid. In some cases, bile acids increase electrolyte and water flux by other mechanisms, such as by stimulating Na^+ -coupled cotransport mechanisms or by modulating the activity of other solute transporters. For example, the bile acid ursodeoxycholic acid produces a substantial increase in bile flow by markedly stimulating biliary HCO_3^- excretion.

Bile acids in the lumen may also stimulate the secretion of other solutes by trapping them in the lumen. These solutes include bilirubin and other organic anions, as well as lipids such as cholesterol and phospholipids. The mixed micelles formed by the bile acids apparently sequester these other solutes, thus lowering their effective luminal concentration and favoring their entry. Therefore, excretion of cholesterol and phospholipid is negligible when bile acid output is low, but it increases and approaches maximum values as bile acid output increases.

Secretin stimulates the cholangiocytes of ductules and ducts to secrete a watery, HCO_3^- -rich fluid

As discussed in the previous section, biliary epithelial cells, or **cholangiocytes**, are the second major source of the fluid in hepatic bile. Experimentally, one can isolate cholangiocytes from normal liver or from the liver of experimental animals in which ductular hyperplasia has been induced by ligating the bile duct. These cholangiocytes ([Fig. 46-11](#)) have 6 of the 13 known human aquaporins, an apical Cl^- - HCO_3^- exchanger AE2, and several apical Cl^- channels, including the cystic fibrosis transmembrane conductance regulator (CFTR; see [p. 120](#)). In a mechanism that may be similar to that in pancreatic duct cells (see [Fig. 43-6](#)), the Cl^- - HCO_3^- exchanger, in parallel with the Cl^- channels for Cl^- recycling, can secrete an HCO_3^- -rich fluid. [N46-9](#) AQP1, CFTR, and AE2 colocalize to intracellular vesicles in cholangiocytes; secretory agonists cause all three to co-redistribute to the apical membrane.

FIGURE 46-11 Secretion of an HCO_3^- -rich fluid by cholangiocytes. Secretin, glucagon, VIP, and gastrin-releasing peptide (GRP) all are choleretics. Somatostatin either enhances fluid absorption or inhibits secretion. CA, carbonic anhydrase.

HCO_3^- Secretion by Cholangiocytes

Contributed by Fred Suchy

As noted in the text, the mechanism of HCO_3^- secretion by cholangiocytes may be similar to that of secretion by pancreatic duct cells. For a discussion of the latter process, see [N46-20](#).

In addition, cholangiocytes transport water into bile via an aquaporin water channel. Na-H exchangers are expressed on both the basolateral membrane (NHE1) and the apical membrane (NHE2) of cholangiocytes.

N46-20

HCO_3^- Secretion by the Pancreatic Duct

Contributed by Emile Boulpaep, Walter Boron

The current model for HCO_3^- secretion by the pancreatic duct is very similar to that outlined in Figure 43-6. However, we can now add some important details about the apical step of HCO_3^- secretion. The Cl^- - HCO_3^- exchanger at the apical membrane is a member of the SLC26 family (Mount and Romero, 2004)—previously known as the SAT family—specifically, SLC26A6 (also known as CFEX). We now appreciate that SLC26A6, which is capable of exchanging several different anions (e.g., Cl^- , HCO_3^- , oxalate), is electrogenic (Jiang et al, 2002). When mediating Cl^- - HCO_3^- exchange, it appears that SLC26A6 exchanges two HCO_3^- ions for every Cl^- ion. This stoichiometry would strongly favor the efflux of HCO_3^- across the apical membrane of the pancreatic duct cell.

As noted in the text, the Cl^- that enters the cell via SLC26A exits the cell via apical Cl^- channels, principally CFTR. Interestingly, it appears that an interaction between the SLC26A6 protein and CFTR greatly increases the open probability of CFTR (Ko et al, 2004).

Another member of the SLC26 family—SLC26A3—also is present in the apical membrane of pancreatic duct cells. SLC26A3 is also electrogenic but has a stoichiometry opposite to that of SLC26A6, two Cl^- ions for every HCO_3^- . This transporter would extrude Cl^- (and take up HCO_3^-) from the duct cell across the apical membrane. Its physiological function might be to reabsorb HCO_3^- at times when the duct is not secreting HCO_3^- or to contribute to the recycling of Cl^- when the duct is secreting HCO_3^- .

A complex network of hormones, mainly acting via cAMP, regulates cholangiocyte secretory function. Secretin receptors (see pp. 886–887) are present on the cholangiocyte basolateral membrane, a fact that explains why **secretin** produces a watery choleresis—that is, a bile rich in HCO_3^- (i.e., alkaline) but poor in bile acids. The hormones **glucagon** (see pp. 1050–1053) and **vasoactive intestinal peptide (VIP)** (see Fig. 13-9) have similar actions.  **N46-10** These hormones raise $[\text{cAMP}]_i$ and thus stimulate apical Cl^- channels and the Cl^- - HCO_3^- exchanger. A Ca^{2+} -activated Cl^- channel is also present in the apical membrane.  **N46-11**

N46-10

Regulation of Cholangiocyte Secretion

Contributed by Fred Suchy

In addition to the hormones mentioned on pages 960–961, **gastrin-releasing peptide (GRP)** also stimulates fluid and HCO_3^- secretion from cholangiocytes, but through mechanisms other than cAMP, cGMP, and Ca^{2+} . Exposure of polarized cholangiocytes to **ATP** results in luminal secretion through activation of $\text{P}_2\mu$ receptors on the apical membrane. Release of ATP into bile appears to serve as an autocrine or paracrine signal regulating cholangiocyte secretory function.

N46-11

Ca^{2+} -Activated Cl^- Channels

Contributed by Emile Boulpaep, Walter Boron

Ca^{2+} -activated Cl^- channels (CaCCs) play important physiological roles. One group of CaCCs are encoded by the *ANO* genes (see Table 6-2, family No. 17). The bestrophins, encoded by at least four *BEST* genes, constitute another family of CaCCs. The molecular identity of CaCCs in the liver is unknown.

Cholangiocytes are also capable of reabsorbing fluid and electrolytes, as suggested by the adaptation that occurs after removal of the gallbladder (i.e., cholecystectomy). Bile found within the common bile duct of fasting cholecystectomized animals is similar in composition to the concentrated bile typically found in the gallbladder. Thus, the ducts have partially taken over the function of the gallbladder (see below).

The hormone **somatostatin** inhibits bile flow by lowering $[\text{cAMP}]_i$, an effect opposite that of secretin. This inhibition may be caused by enhancing fluid reabsorption by bile ducts or by inhibiting ductular secretion of the HCO_3^- -rich fluid discussed above.

Solutes reabsorbed from bile by cholangiocytes are recycled. As shown in [Figure 46-2](#), the intralobular bile ducts are endowed with a rich peribiliary vascular plexus that is supplied by the hepatic artery. The blood draining this plexus finds its way into the hepatic sinusoids. This plexus is analogous to the capillaries of the gut, which, via the portal vein, also find their way into the hepatic sinusoids. Thus, some solutes, such as the hydrophilic bile acid ursodeoxycholic acid, may be absorbed by the cholangiocytes from bile and returned to the hepatocytes for repeat secretion, a process that induces significant choleresis.

The gallbladder stores bile and delivers it to the duodenum during a meal

The gallbladder is not an essential structure of bile secretion. Tonic contraction of the sphincter of Oddi facilitates gallbladder filling by maintaining a positive pressure within the common bile duct. As we noted above, up to 50% of hepatic bile—or ~450 mL/day—is diverted to the gallbladder during fasting. The remaining ~450 mL/day passes directly into the duodenum. Periods of gallbladder filling between meals are interrupted by brief periods of partial emptying of concentrated bile and probably aspiration of dilute hepatic bile in a process analogous to the function of a bellows.

Gallbladder emptying and filling is under feedback control. During feeding, CCK secreted by duodenal I cells (see [Table 41-1](#)) causes gallbladder contraction and the release of bile into the duodenum, where the bile promotes fat digestion and suppresses further CCK secretion. On reaching the ileum, bile acids induce synthesis of fibroblast growth factor 19 (FGF19); FGF19, after transit in portal blood, causes relaxation of gallbladder smooth muscle, which allows gallbladder refilling. Thus, CCK and FGF19 control the periodicity of gallbladder emptying and filling.

During the interdigestive period, the gallbladder concentrates bile acids—and certain other components of bile—up to 10- or even 20-fold within the gallbladder lumen because they are left behind during the isotonic reabsorption of NaCl and NaHCO₃ by the leaky gallbladder epithelium ([Fig. 46-12](#)). The apical step of NaCl uptake and transport is electroneutral and is mediated by parallel Na-H and Cl-HCO₃ exchangers. At the basolateral membrane, Na⁺ exits through the Na-K pump, whereas Cl⁻ most likely exits by Cl⁻ channels. Both water and HCO₃⁻ move passively from lumen to blood through the tight junctions. Water can also move through the cell via AQP1 (expressed on apical and basolateral membranes) and AQP8 (found only apically). The net transport is isotonic, which leaves behind gallbladder bile that is also isotonic but has a higher concentration of bile salts, K⁺, and Ca²⁺. Net fluid and electrolyte transport across the gallbladder epithelium is under hormonal regulation. Both VIP (released from neurons innervating the gallbladder) and serotonin inhibit net fluid and electrolyte absorption. Conversely, α-adrenergic blockade of neuronal VIP release increases fluid absorption.

FIGURE 46-12 Isotonic fluid reabsorption by the gallbladder epithelium.

Although the gallbladder reabsorbs NaCl by parallel Na-H and Cl-HCO₃ exchange at the apical

membrane, Na-H exchange outstrips Cl-HCO₃ exchange; the end result is net secretion of **H⁺ ions**. This action neutralizes the HCO₃⁻ and acidifies the bile. The H⁺ secreted by the gallbladder protonates the intraluminal contents. This action greatly increases the solubility of calcium salts in bile and reduces the likelihood of calcium salt precipitation and **gallstone formation**. Common “pigment gallstones” contain one or more of several calcium salts, including carbonate, bilirubinate, phosphate, and fatty acids. The solubility of each of these compounds is significantly increased by the acidification of bile.

Mucus secretion by gallbladder epithelial cells results in the formation of a polymeric gel that protects the apical surface of the gallbladder epithelium from the potentially toxic effects of bile salts. However, excessive mucin synthesis can be deleterious. For example, in animal models of cholesterol cholelithiasis (i.e., formation of gallstones made of cholesterol), a marked increase in mucin release precedes crystal and stone formation.

The relative tones of the gallbladder and sphincter of Oddi determine whether bile flows from the common hepatic duct into the gallbladder or into the duodenum

Bile exiting the liver and flowing down the common hepatic duct reaches a bifurcation that permits flow either into the cystic duct and then into the gallbladder or into the common bile duct, through the sphincter of Oddi, and into the duodenum (see [Fig. 46-4](#)). The extent to which bile takes either path depends on the relative resistances of the two pathways.

The sphincter of Oddi—which also controls the flow of pancreatic secretions into the duodenum—corresponds functionally to a short (4- to 6-mm) zone within the wall of the duodenum. The basal pressure within the lumen of the duct at the level of the sphincter is 5 to 10 mm Hg. The pressure in the lumen of the resting common bile duct is also 5 to 10 mm Hg, compared with a pressure of ~0 mm Hg inside the duodenum.

The basal contraction of the sphincter prevents reflux of the duodenal contents into the common bile duct. In its basal state, the sphincter exhibits high-pressure, phasic contractions several times per minute. These contractions are primarily peristaltic and directed in antegrade fashion to provide a motive force toward the duodenum. Thus, the sphincter of Oddi acts principally as an adjustable occluding mechanism and a regulator of bile flow.

Both hormonal and cholinergic mechanisms appear to be involved in gallbladder emptying. Dietary lipid stimulates the release of CCK from duodenal I cells (see [pp. 889–890](#)). This CCK not only stimulates pancreatic secretion but also causes smooth-muscle contraction and evacuation of the gallbladder. The coordinated response to CCK also includes relaxation of the sphincter of Oddi, which enhances bile flow into the duodenum ([Box 46-2](#)).

Box 46-2

Cholestasis

The term *cholestasis* refers to the suppression of bile secretion. Biliary constituents may therefore be retained within the hepatocyte and regurgitated into the systemic circulation. Cholestasis causes three major groups of negative effects: first, regurgitation of bile components (bile acids, bilirubin) into the systemic circulation gives rise to the symptoms of jaundice and pruritus (itching). Second, cholestasis damages hepatocytes, as evidenced by the release of clinically important liver enzymes (e.g., alkaline

phosphatase) into the plasma. Third, because the bile acids do not arrive in the duodenum, lipid digestion and absorption may be impaired.

Many acute and chronic liver diseases produce cholestasis by mechanically obstructing the **extrahepatic** bile ducts or by impairing bile flow at the level of the hepatocytes or **intrahepatic** bile ducts. The mechanisms underlying the obstructive and functional forms of cholestasis are complex and have not been completely defined. Experimental modeling of cholestasis has produced multiple abnormalities: (1) altered plasma-membrane composition and fluidity; (2) inhibition of membrane proteins, including the Na-K pump and aquaporins; (3) reduced expression of genes encoding transporters for bile acids and other organic anions; (4) altered expression of nuclear receptors and associated epigenetic modifications that regulate transporters; (5) increased permeability of the paracellular pathway, with backdiffusion of biliary solutes into the plasma; (6) altered function of microfilaments, with decreased contractions of bile canaliculi; and (7) loss of the polarized distribution of some plasma-membrane proteins. Cholestatic conditions, such as bile duct obstruction, markedly increase the basolateral expression of MRP4 and MRP6 as well as OST α -OST β —which normally are expressed only minimally. The induction of these transporters allows the efflux of bile acids and other cholephilic anions from the hepatocyte into sinusoidal blood.

Enterohepatic Circulation of Bile Acids

The enterohepatic circulation of bile acids is a loop consisting of secretion by the liver, reabsorption by the intestine, and return to the liver in portal blood for repeat secretion into bile

Bile acids are important for promoting the absorption of dietary lipids in the intestine. The quantity of bile acid that the liver normally *secretes* in a day varies with the number of meals and the fat content of these meals, but it typically ranges between 12 and 36 g. The liver's basal rate of *synthesis* of bile acids from cholesterol (see [Fig. 46-9](#)) is only ~600 mg/day in healthy humans, sufficient to replace the equivalent losses of bile acid in the feces. Obviously, the gastrointestinal tract must have an extremely efficient mechanism for recycling the bile acids secreted by the liver ([Fig. 46-13](#)). This recycling, known as the **enterohepatic circulation**, occurs as the terminal ileum and colon reabsorb bile acids and return them to the liver in the portal blood. The total pool of bile acids in the gastrointestinal tract is ~3 g. This pool must recirculate ~4 to 12 times per day, or as many as 5 or more times for a single fat-rich meal. If reabsorption of bile acids is defective, as can happen after resection of the ileum, de novo synthesis of bile acids by the liver can be as high as 4 to 6 g/day.

FIGURE 46-13 Enterohepatic circulation of bile acids. The bile acids that the liver delivers to the duodenum in the bile are primarily conjugated to taurine or glycine (BA-Z^-), and these conjugates enter the portal blood in the terminal ileum to return to the liver. Some unconjugated bile acids and secondary bile acids also return to the hepatocyte for resecretion.

Efficient intestinal conservation of bile acids depends on active apical absorption in the terminal ileum and passive absorption throughout the intestinal tract

Most of the bile secreted into the duodenum is in the conjugated form. Very little of these bile salts is reabsorbed into the intestinal tract until they reach the terminal ileum, an arrangement that allows the bile salts to remain at high levels throughout most of the small intestine, where they can participate in lipid digestion (see pp. 925–929) and absorption (see pp. 929–933). However, the enterohepatic circulation must eventually reclaim 95% or more of these secreted bile salts. Some of the absorption of bile acids by

the intestines is passive and occurs along the entire small intestine and colon. Nevertheless, the major component of bile acid absorption is active and occurs only in the terminal ileum (see Fig. 46-13).

Passive absorption of bile acids occurs along the entire small intestine and colon (see Fig. 46-13), but it is less intensive than active absorption. The mechanism of bile acid uptake across the apical membrane may consist of either **ionic** or **nonionic diffusion** (see pp. 784–785). Nonionic diffusion—or passive diffusion of the protonated or neutral form of the bile acid—is 10-fold greater than ionic diffusion. The extent of nonionic diffusion for a given bile acid depends on the concentration of its neutral, protonated form, which is maximized when the luminal pH is low and the pK of the bile acid is high. At the normal intestinal pH of 5.5 to 6.5, few of the taurine-conjugated bile salts are protonated, a small amount of the glycine-conjugated bile salts are protonated, and ~50% of unconjugated bile acids are protonated. Thus, the unconjugated bile acids are in the best position to be reabsorbed by nonionic diffusion, followed by the glycine-conjugated bile acids and then finally by the taurine-conjugated bile acids. Among these unconjugated bile acids, more lipophilic bile acids, such as chenodeoxycholate and deoxycholate, diffuse more readily through the apical membrane than do hydrophilic bile acids such as cholic acid. Nonionic diffusion also depends on the total concentration of the bile acid (i.e., neutral plus charged form), which, in turn, depends on the maximum solubilizing capacity of bile-salt micelles for that bile acid.

Active absorption of bile acids in the intestine is restricted to the *terminal ileum* (see Fig. 46-13). This active process preferentially absorbs the negatively charged *conjugated* bile salts—the form *not* well absorbed by the passive mechanisms. Active uptake of bile salts involves saturation kinetics, competitive inhibition, and a requirement for Na⁺. The Na⁺-dependent transporter responsible for the apical step of active absorption is known as the **apical Na/bile-salt transporter (ASBT or SLC10A2)**, a close relative of the hepatocyte transporter NTCP (see Fig. 46-5C). After bile salts enter ileal enterocytes across the apical membrane, they exit across the basolateral membrane via the heteromeric **organic solute transporter OST α -OST β** .

Because the most polar bile salts are poorly absorbed by nonionic diffusion, it is not surprising that the ASBT in the apical membrane of the enterocytes of the terminal ileum has the highest affinity and maximal transport rates for these salts. For example, ASBT is primarily responsible for absorbing the ionized, taurine-conjugated bile salts in the ileum. Conversely, ASBT in the ileum is relatively poor at absorbing the more lipophilic bile acids, which tend to be absorbed passively in the upper intestine.

On their entry into portal blood, the bile acids are predominantly bound to albumin and, to a lesser extent, lipoproteins. The liver removes or clears these bile acids from portal blood by the transport mechanisms outlined above in Figure 46-5C. Hepatic clearance of bile acids is often expressed as the percentage of bile acids removed during a single pass through the liver. The hepatic extraction of bile acids is related to bile acid structure and the degree of albumin binding. It is greatest for hydrophilic bile acids and lowest for protein-bound, hydrophobic bile acids.

The small fraction of bile acids that escapes active or passive absorption in the small intestine is subject to *bacterial modification* in the *colon*. This bacterial modification takes two forms. First, the bacteria deconjugate the bile. Second, the bacteria perform a 7 α -dehydroxylation reaction with the formation of *secondary bile acids*. These secondary bile acids include **deoxycholate** and **lithocholate** (see Fig. 46-9). The deconjugated secondary bile acids may then be either absorbed passively in the colon or excreted in the feces; their fate depends on their physicochemical properties and their binding to luminal contents. Up to one third of the deoxycholate formed in the colon may be reabsorbed by nonionic diffusion. Lithocholate, which is relatively insoluble, is absorbed to a much lesser extent. The secondary bile acids formed by colonic bacteria and recycled back to the liver may undergo biotransformation through conjugation to glycine and taurine.

Thus, the enterohepatic circulation of bile acids is driven by two *mechanical* pumps: (1) the motor activity of the gallbladder, and (2) peristalsis of the intestines to propel the bile acids to the terminal ileum and colon. It is also driven by two *chemical* pumps: (1) energy-dependent transporters located in the terminal ileum, and (2) energy-dependent transporters in the hepatocyte.

The **bile acid receptor FXR**, a member of the nuclear receptor family (see [Table 3-6](#)), controls multiple components of the enterohepatic circulation of bile acids. Primary bile acids are potent agonists of FXR, which transcriptionally regulates several genes involved in bile acid homeostasis, producing negative feedback by four mechanisms:

1. FXR in hepatocytes induces expression of a transcription factor called the **small heterodimer partner (SHP)**; SHP, in turn, inhibits another nuclear receptor, the liver receptor homolog 1 (LRH-1), which is required for CYP7A1 expression. The result is that FXR inhibits the expression of cholesterol 7 α -hydroxylase (CYP7A1)—the rate-limiting enzyme for bile acid synthesis (see [Fig. 46-9](#)).
2. FXR in the ileum increases the synthesis and secretion into portal blood of FGF19, which then activates the FGF receptor 4 signaling pathway in the liver, repressing CYP7A1.
3. FXR in hepatocytes upregulates BSEP (which *increases* bile acid secretion; see [Fig. 46-5C](#)) and downregulates NTCP (which *decreases* bile acid uptake; see [Fig. 46-5C](#)) by SHP-dependent mechanisms. The net result is a reduction of intracellular bile acids.
4. FXR in the ileum, via SHP, downregulates ASBT (see [Fig. 46-13](#), inset), thereby reducing bile acid uptake. FXR also induces the expression of basolateral OST α -OST β , thereby increasing bile acid efflux. The net result is a reduction of intracellular bile acids.

Thus, FXR coordinates bile acid synthesis and transport by the liver and intestine. The bile acid signaling network also includes the G protein–coupled receptor TGR5, which is highly expressed in the apical membrane and primary cilium of cholangiocytes and gallbladder epithelial cells, but minimally in hepatocytes. Activation of TGR5 by bile acids in the biliary tract leads to a rise in [cAMP]_i, which causes Cl[−] secretion to increase ([Box 46-3](#)).

Box 46-3

Gallstones

During hemolytic anemias, small, dark *pigment gallstones* may form secondary to the excess production and excretion of bilirubin. However, most gallstones (~80%) consist mainly of cholesterol. Thus, cholelithiasis is largely a disturbance of bile secretion and cholesterol elimination. When cholesterol and phospholipids are secreted together into the bile, they form unilamellar bilayered vesicles. These vesicles become incorporated into mixed micelles that form because of the amphiphilic properties of bile acids. Micellation allows cholesterol to remain in solution in its passage through the biliary tree. However, if the concentration of bile acids is insufficient to maintain all the cholesterol in the form of mixed micelles, the excess cholesterol is left behind as vesicles in the aqueous phase. These cholesterol-enriched vesicles are relatively unstable and are prone to aggregate and form large multilamellar vesicles, from which cholesterol crystals nucleate. Growth of crystals may result in the formation of gallstones. An excess of biliary cholesterol in relation to the amount of phospholipids and bile acids can

result from hypersecretion of cholesterol, inadequate secretion of bile acids, or both. Cholelithiasis may be further promoted by other factors, such as gallbladder mucin and other nonmucous glycoproteins, as well as by stasis of bile in the gallbladder. Polymorphisms in the hepatic cholesterol transporter ABCG5/G8 and the bilirubin-conjugating enzyme UGT1A1 (see p. 955) contribute to the formation of gallstones in humans.

The Liver as a Metabolic Organ

The liver is a metabolically active and highly aerobic organ. It receives ~28% of the total blood flow and extracts ~20% of the oxygen used by the body. The liver is responsible for the synthesis and degradation of carbohydrates, proteins, and lipids. The small molecules that are products of digestion are efficiently sorted in the liver for metabolism, storage, or distribution to extrahepatic tissues for energy. The liver provides energy to other tissues mainly by exporting two substrates that are critical for oxidization in the peripheral tissues, glucose and ketone bodies (e.g., acetoacetate).

The liver can serve as either a source or a sink for glucose

The liver is one of the key organs that maintain blood glucose concentrations within a narrow range, in a dynamic process involving endogenous glucose production and glucose utilization. The fasting blood [glucose] is normally 4 to 5 mM. Between meals, when levels of insulin are relatively low (see [p. 1036](#)) and levels of glucagon are high (see [p. 1052](#)), the liver serves as a source of plasma glucose, both by synthesizing glucose and by generating it from the breakdown of glycogen. The *de novo* synthesis of glucose from lactate, pyruvate, and amino acids—**gluconeogenesis** (see [p. 1176](#))—is one of the liver's most important functions; it is essential for maintaining a normal plasma concentration of glucose, which is the primary energy source for most tissues.

The second way in which the liver delivers glucose to blood plasma is by **glycogenolysis** (see [p. 1182](#)). Stored glycogen may account for as much as 7% to 10% of the total weight of the liver. Glycogenolysis in the *liver* yields glucose as its major product, whereas glycogen breakdown in *muscle* produces lactic acid (see [Fig. 58-9](#)).

After a meal, when levels of insulin are relatively high, the liver does just the opposite: it acts as a sink for glucose by taking it up from the portal blood and either breaking it down to pyruvate or using it to synthesize glycogen (see [Fig. 51-8](#) and [pp. 1179–1181](#)). Glucose oxidation has two phases. In the anaerobic phase, glucose is broken down to pyruvic acid (**glycolysis**). In the aerobic phase, pyruvic acid is completely oxidized to H₂O and CO₂ through the citric acid cycle.

The liver also consumes glucose by using it for **glycogen synthesis**. Carbohydrate that is not stored as glycogen or oxidized is metabolized to **fat**.

All the aforementioned processes are regulated by hormones such as insulin (see [Fig. 51-8](#)) and glucagon (see [Fig. 51-12](#)), which enable rapid responses to changes in the metabolic requirements of the body.

The liver synthesizes a variety of important plasma proteins (e.g., albumin, coagulation factors, and carriage proteins) and metabolizes dietary amino acids

Protein Synthesis

One of the major functions of the liver is to produce a wide array of proteins for export to the blood plasma ([Table 46-3](#)). These products include major plasma proteins that are important for maintaining the colloid osmotic pressure of plasma (see [p. 470](#)). Other products include factors involved in hemostasis (blood clotting) and fibrinolysis (breakdown of blood clots), carriage proteins that bind and transport

hormones and other substances in the blood, prohormones, and lipoproteins ([Table 46-4](#)). The liver synthesizes plasma proteins at a maximum rate of 15 to 50 g/day. 🍌**N46-12**

TABLE 46-3
Proteins Made by the Liver for Export

Major Plasma Proteins
Albumin
α ₁ -fetoprotein
Plasma fibronectin (an α ₂ -glycoprotein)
C-reactive protein
α ₂ -microglobulin
Various other globulins
Factors Involved in Hemostasis/Fibrinolysis
<i>Coagulation:</i> fibrinogen and all others except for factor VIII
<i>Inhibitors of coagulation:</i> α ₁ -antitrypsin and antithrombin III, α ₂ -macroglobulin, protein S, protein C
<i>Fibrinolysis:</i> plasminogen
<i>Inhibitors of fibrinolysis:</i> α ₂ -antiplasmin
Complement C3
Carriage Proteins (Binding Proteins)
Ceruloplasmin (see pp. 970–971)
Corticosteroid-binding globulin (CBG, also called transcortin; see p. 1021)
Growth hormone–binding protein (low-affinity form; see p. 994)
Haptoglobin
Hemopexin
Insulin-like growth factor 1–binding proteins (see p. 996)
Retinol-binding protein (RBP; see p. 970)
Sex hormone–binding globulin (SHBG; see p. 1099)
Thyroxine-binding globulin (TBG; see pp. 1008–1009)
Transferrin (see p. 941)
Transthyretin (see pp. 1008–1009)
Vitamin D–binding protein (see p. 1064)
Prohormones
Angiotensinogen (see p. 1028)
Apolipoproteins
Apo A-I
Apo A-II

The synthesis of the hepatic proteins for secretion into the blood plasma occurs via the secretory pathway (see pp. 34–35). The synthesis begins in the rough endoplasmic reticulum (RER). Nearly all proteins secreted by the liver are glycosylated. N-linked glycosylation occurs in the RER (see p. 32), and further remodeling occurs in the Golgi (see pp. 37–38). O-linked glycosylation also occurs in the Golgi (see pp. 38–39). The ER can also conjugate proteins with lipid.

Amino-Acid Uptake

A major role of the liver is to take up and metabolize dietary amino acids that are absorbed by the gastrointestinal tract (see p. 923) and are transported to the liver in portal blood. These amino acids are taken up by both Na^+ -dependent and Na^+ -independent transporters that are identical to some of the amino-acid transporters in the kidney, small intestine, and other tissues (see Table 36-1). An unusual feature of the liver is that, with few exceptions, the same amino-acid transporter may be located on *both* the basolateral and apical membranes. For example, Na^+ -dependent glutamate uptake by the excitatory amino-acid transporters SLC1A1 (EAAT3) and SLC1A2 (EAAT2) occurs primarily at the apical membrane, but dexamethasone (corticosteroid) treatment can induce their expression at the basolateral membrane. In general, hepatic amino-acid transporters are highly regulated at the transcriptional and post-translational levels. N46-13

N46-13

Glutamate Transporters

Contributed by Emile Boulpaep, Walter Boron

The high-affinity glutamate transporters are classified as members of the SLC1 gene family (see Table 5-4).

Gene Name	Transporter Names
SLC1A1	EAAT3 or EAAC1
SLC1A2	EAAT2 or GLT-1

For a detailed discussion of the family members, consult the review by Kanai and Hediger. listed below

Amino-Acid Metabolism

Under physiological conditions, total and individual plasma concentrations of amino acids are tightly regulated. The liver controls the availability of amino acids in the systemic blood, activating ureagenesis after a high-protein meal and repressing it during fasting or low protein intake. Unlike glucose, which can be stored, amino acids must either be used immediately (e.g., for the synthesis of proteins) or broken down. The breakdown of α -amino acids occurs by deamination to α -keto acids and NH_4^+ (Fig. 46-14). The α -keto acids (“carbon skeleton”), depending on the structure of the parent amino acid, are

metabolized to pyruvate, various intermediates of the citric acid cycle (see Fig. 58-11), acetyl coenzyme A (acetyl CoA), or acetoacetyl CoA. The liver detoxifies ~95% of the NH_4^+ through a series of reactions known as the urea cycle (see Fig. 46-14); the liver can also use NH_4^+ —together with glutamate—to generate glutamine. **N46-14** Individual deficiencies in each of the enzymes involved in the urea cycle have been described and result in life-threatening hyperammonemia. The urea generated by the urea cycle exits the hepatocyte via a urea channel, which is, in fact, AQP9. The urea then enters the blood and is ultimately excreted by the kidneys (see pp. 770–772). The glutamine synthesized by the liver also enters the blood. Some of this glutamine is metabolized by the kidney to yield glutamate and NH_4^+ , which is exported in the urine (see pp. 829–831).

FIGURE 46-14 Amino-acid metabolism and urea formation in hepatocytes. When a hepatocyte takes up an α -amino acid, it either must use it immediately in protein synthesis or deaminate it. The deamination reaction transfers the amino group of the α -amino acid to α -ketoglutarate, yielding glutamate and the corresponding α -keto acid. Depending on the backbone of the α -keto acid, it may be metabolized into acetoacetyl CoA, acetyl CoA, pyruvate, or a variety of citric acid cycle intermediates. The NH_4^+ that results from the regeneration of the α -ketoglutarate is consumed in the urea cycle. The other amino group of the urea is derived from the amino group of aspartate. The CO moiety of urea is derived from CO_2 . The liver then exports the urea, which exits the hepatocyte via AQP9. NAD^+ , oxidized form of nicotinamide adenine dinucleotide; NADH , reduced form of nicotinamide adenine dinucleotide; P_i , inorganic phosphate; UT-B, urea transporter B. **N46-19**

N46-14

Hepatic Detoxification of NH_4^+ by Formation of Glutamine

Contributed by Emile Boulpaep, Walter Boron

Each day, as part of protein catabolism, the liver detoxifies ~940 mmol of amino groups that are derived from the breakdown of amino acids. The liver detoxifies NH_4^+ by converting it to urea (95% of the total) and glutamine (the remaining 5%). Both products leave the liver and reach the kidney, which disposes of

them—directly or indirectly—in the urine.

As indicated in Figure 39-6, the liver consumes ~40 mmol of these amino groups in the reaction

Glutamine is the most prevalent amino acid in the body. The liver detoxifies the remainder via the **urea cycle**.

The enzyme required for the conversion in Equation NE 46-1 is **glutamine synthetase** (see p. 290). In the liver, this enzyme is restricted to the last one or two hepatocytes contiguous with the hepatic venule (zone III; see Fig. 46-3). This strict localization is thought to play an important role in glutamine metabolism. The uptake of an individual amino acid into the hepatocyte may represent the rate-limiting step in its own metabolism and may therefore be an important target for regulation. This type of regulation of uptake occurs for alanine, a critical substrate of gluconeogenesis, and also for glutamine.

N46-19

NADH/NAD⁺ versus NADPH/NADP⁺

Contributed by Alisha Bouzaher

NADH and NAD⁺ are, respectively, the reduced and oxidized forms of nicotinamide adenine dinucleotide (NAD) and their close analogs are NADPH and NADP⁺, the reduced and oxidized forms of nicotinamide adenine dinucleotide phosphate (NADP). The coenzymes NADH and NADPH each consist of two nucleotides joined at their phosphate groups by a phosphoanhydride bond. NADPH is structurally distinguishable from NADH by the additional phosphate group residing on the ribose ring of the nucleotide, which allows enzymes to preferentially interact with either molecule.

Total concentrations of NAD⁺/NADH (10⁻⁵M) are higher in the cell by ~10-fold compared to NADP⁺/NADPH (10⁻⁶M). Ratios of the oxidized and reduced forms of these coenzymes offer perspective into the metabolic activity of the cell. The high NAD⁺/NADH ratio favors the transfer of a hydride from a substrate to NAD⁺ to form NADH, the reduced form of the molecule and oxidizing agent. Therefore, NAD⁺ is highly prevalent within catabolic reaction pathways where reducing equivalents (carbohydrate, fats, and proteins) transfer protons and electrons to NAD⁺. NADH acts as an energy carrier, transferring electrons from one reaction to another. Conversely, the NADP⁺/NADPH ratio is low, favoring the transfer of a hydride to a substrate oxidizing NADPH to NADP⁺. Thus, NADPH is utilized as a reducing agent within anabolic reactions, particularly the biosynthesis of fatty acids.

The liver is also the main site for the synthesis and secretion of **glutathione**. GSH is critical for

detoxification (in conjugation reactions in the liver) and for protection against oxidative stress in multiple organs. Thus, erythrocytes that have low levels of GSH are more prone to hemolysis. Because >90% of the GSH in the circulation is synthesized in the liver, GSH efflux across the basolateral membrane from the hepatocyte to the sinusoid is important. Bidirectional transport of glutathione across the *basolateral membrane* may occur in part by one of the OATPs as well as MRP4 by cotransport with bile acids. In addition, MRP2 exports some conjugated GSH across the *canalicular membrane* into bile, as stated above, and an unidentified transporter can similarly export smaller amounts of unconjugated GSH.

The liver obtains dietary triacylglycerols and cholesterol by taking up remnant chylomicrons via receptor-mediated endocytosis

As discussed beginning on [pages 929–933](#), enterocytes in the small intestine process fatty acids consumed as dietary triacylglycerols and secrete them into the lymph primarily in the form of extremely large proteolipid aggregates called chylomicrons ([Fig. 46-15](#)). These **chylomicrons**—made up of triacylglycerols, phospholipids, cholesterol, and several apolipoproteins (see [Table 46-4](#))—are synthesized in the intestine and pass from the lymph to the blood via the thoracic duct. As discussed on [page 1182](#), lipoprotein lipase (LPL) on the walls of the capillary endothelium in adipose tissue and muscle then partially digests the triacylglycerols in these chylomicrons. The results of this digestion are glycerol, fatty acids, and smaller or “remnant” chylomicrons, which are triacylglycerol depleted and thus enriched in cholesterol. The glycerol and fatty acids generated by LPL enter adipocytes and muscle cells. The cholesterol-rich **remnant chylomicrons**, conversely, remain in the blood and make their way to the liver, where they enter hepatocytes by basolateral receptor-mediated endocytosis (see [p. 42](#)) involving multiple endocytic receptors, primarily the cell-surface heparan sulfate proteoglycan **syndecan-1**, other heparan sulfate proteoglycans, and low-density lipoprotein-related receptors. The binding of apolipoprotein E on the surface of chylomicron remnants promotes efficient clearance of apolipoprotein E-containing lipoprotein remnants. After entry, the chylomicron remnants undergo degradation in lysosomes. Thus, chylomicrons transport dietary triacylglycerols to adipose tissue and muscle, whereas their remnants transport dietary triglycerides and cholesterol to hepatocytes.

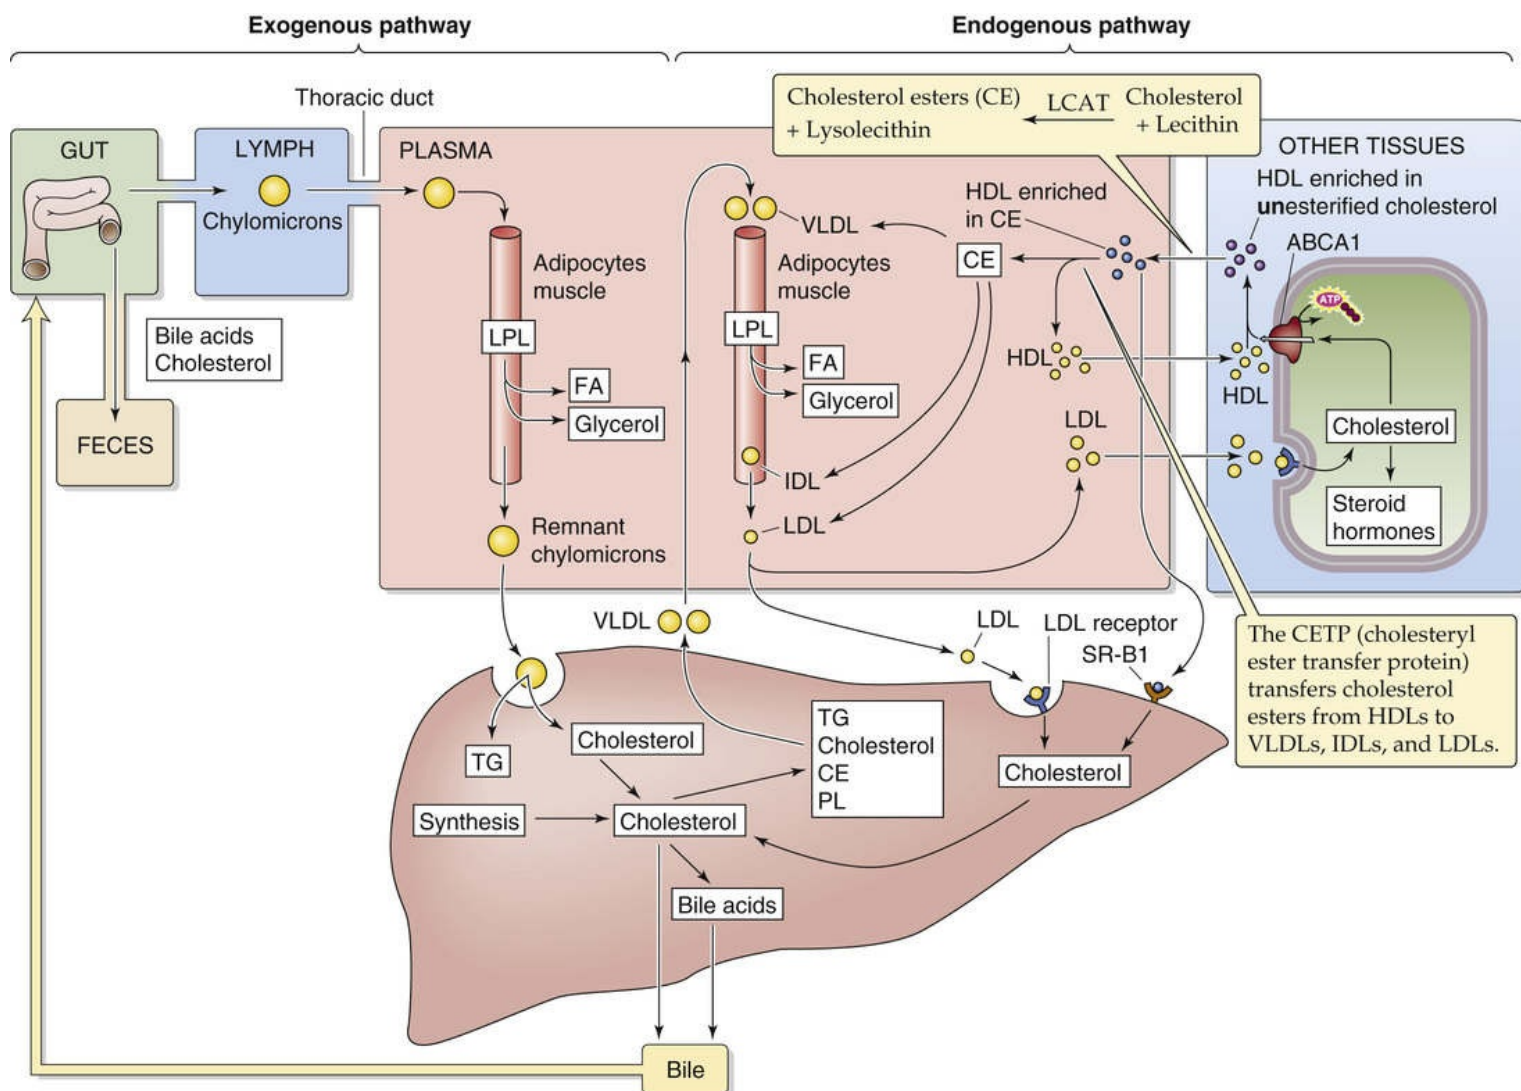

FIGURE 46-15 Cholesterol metabolism. FA, fatty acid; PL, phospholipid; TG, triacylglycerol.

The hepatocyte can also take up across its basolateral membrane the **long-chain fatty acids (LCFAs)** liberated by LPL but not used by other tissues. Although LCFAs can diffuse rapidly across *artificial* phospholipid bilayers, it is clear that LCFA integral or membrane-associated proteins can mediate LCFA uptake by a wide variety of mammalian cells. In the liver, three proteins participate in fatty-acid uptake:

- 1. Fatty-acid translocase (FAT or CD36; see p. 930).** FAT is an 88-kDa membrane protein that takes up modified forms of **low-density lipoproteins (LDLs)** and fatty acids from circulation. The basal expression of FAT in hepatocytes is low but is induced significantly by a high-fat diet or by the activation of nuclear receptors (see Table 3-6), including SXR, peroxisome proliferator-activated receptor- γ (PPAR γ), and LXR. FAT is also expressed in Kupffer cells and hepatic stellate cells.
- 2. Fatty-acid transport protein 5 (FATP5 or SLC27A5).** FATP5 is exclusively expressed in the liver, where it localizes to the basolateral plasma membrane and accounts for ~50% of fatty-acid uptake by hepatocytes.
- 3. Liver-type fatty acid-binding protein 1 (FABP1).** FABP1 is a cytosolic protein.

Fatty Acids

Chain Length

Contributed by Emile Boulpaep, Walter Boron

Name	Abbreviation	Number of Carbon Atoms
Short-chain fatty acid	SCFA	<6
Medium-chain fatty acid	MCFA	6–12
Long-chain fatty acid	LCFA	13–21
Very-long-chain fatty acid	VLCFA	>21

To derive energy from the neutral fats in the remnant chylomicrons, hepatocytes must first split the triacylglycerols into glycerol and fatty acids. The fatty acids thus derived from remnant chylomicrons, as well as those that enter the hepatocyte directly, mainly undergo β -oxidation in mitochondria (see [pp. 1183–1185](#)). 🟡N46-16

N46-16

α - and ω -Oxidation of Fatty Acids

Contributed by Fred Suchy

α -oxidation occurs in peroxisomes and is used for branched fatty acids that cannot directly undergo β -oxidation. In the case of very-long-chains fatty acids, 🟡N46-15 these must first be reduced in length by *peroxisomes*.

ω -oxidation occurs in the SER of the liver for detoxification and assumes great importance when β -oxidation is defective.

The acetyl CoA derived from β -oxidation can enter the citric acid cycle (see [p. 1185](#)), where it is oxidized to produce large amounts of energy. The acetyl CoA that is not used by the liver is converted by the condensation of two molecules of acetyl CoA to yield acetoacetic acid. The liver is the only organ that produces **acetoacetate** for metabolism by muscle, brain, and kidney, but it does not use this substrate for its own energy needs. In fasting states or in poorly controlled diabetes, in which the supply of acetyl CoA is in excess, the acetyl CoA is diverted to produce acetoacetate, which in turn can yield β -hydroxybutyrate and acetone. Together, acetoacetate, β -hydroxybutyrate, and acetone are referred to as **ketone bodies**. Another fate of fatty acids in the liver is that they can be re-esterified to glycerol, with the formation of triacylglycerols that can either be stored or exported as **very-low-density lipoproteins (VLDLs)** and released into the circulation for use by peripheral tissues.

Cholesterol, synthesized primarily in the liver, is an important component of cell membranes and serves as a precursor for bile acids and steroid hormones

The body's major pools of cholesterol include the cholesterol and cholesterol derivatives in bile, cholesterol in membranes, cholesterol carried as lipoproteins in blood (see [Table 46-4](#)), and cholesterol-

rich tissues. Cholesterol is present in membranes and bile mainly as free cholesterol. In plasma and in some tissues, cholesterol is esterified with LCFAs. The major *sources* of cholesterol are dietary uptake of cholesterol and de novo synthesis of cholesterol by various cells ([Table 46-5](#)). The major *fates* of cholesterol are secretion into bile, excretion in the feces when intestinal cells are sloughed, sloughing of skin, and synthesis of steroid hormones. However, in mammals, the most important route for the elimination of cholesterol is the hepatic conversion of cholesterol into bile acids. In the steady state, the liver must excrete an amount of sterol (as cholesterol and bile acids) that equals the amount of cholesterol that is synthesized in the various organs and absorbed from the diet.

TABLE 46-5
Sources and Fates of Cholesterol in Humans

PROCESS	FLOW (g/day for a 70-kg human)
Intestinal absorption	0.1–0.5
Synthesis	1.05
Biliary secretion	0.9
Cholesterol consumed in synthesis of bile acids	0.5
Cholesterol secreted in VLDLs by the liver	0.25–1.75

Modified from Cooper AD, Ellsworth JL: Lipoprotein metabolism. In Zakim D, Boyer TD (eds): Hepatology. Philadelphia, WB Saunders, 1996.

The liver is the major organ for controlling cholesterol metabolism (see [Fig. 46-15](#)). The liver obtains cholesterol from three major sources: (1) The intestine packages dietary cholesterol as chylomicrons, which travel via the lymph to blood vessels in adipocytes and muscle, where LPL hydrolyzes triacylglycerols to fatty acids and glycerol. The resultant cholesterol-enriched remnant chylomicrons are then delivered as cholesterol to the liver. (2) The liver synthesizes cholesterol de novo. (3) The liver takes up cholesterol in the guise of **LDL**. In contrast, the liver exports cholesterol in two major ways: (1) The liver uses cholesterol to synthesize bile acids and also includes cholesterol and cholesteryl esters in the bile. (2) The liver also exports cholesterol to the blood in the form of VLDLs.

Synthesis of Cholesterol

The de novo synthesis of cholesterol occurs in many extrahepatic tissues, as well as in the intestine and liver. The synthesis of cholesterol proceeds from acetyl CoA in a multistep process that takes place in the SER and cytosol ([Fig. 46-16](#)). The hepatic synthesis of cholesterol is inhibited by dietary cholesterol and by fasting and is increased with bile drainage (fistula) and bile duct obstruction. The rate-limiting step in cholesterol synthesis is the conversion of 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) to mevalonate by HMG-CoA reductase, the level of which is decreased—in typical negative-feedback fashion—by cholesterol levels in the cell ([Box 46-4](#)). The most potent cholesterol-lowering agents that are clinically available today—the “statins”—are inhibitors of HMG-CoA reductase. 📖[N46-17](#)

FIGURE 46-16 Cholesterol synthesis. The liver synthesizes cholesterol de novo from acetyl CoA in a multistep process that occurs in the SER and cytosol.

Box 46-4

Control of Cholesterol Synthesis

A series of 29 enzymatic reactions (Diwan, 1998–2008) converts acetyl CoA to cholesterol (see Fig. 46-16). Biosynthetic pathways, as well as uptake pathways for precursors, are under tight negative-feedback control. HMG-CoA reductase, the rate-limiting enzyme in cholesterol biosynthesis, is a 97-kDa enzyme intrinsic to the ER. The protein is anchored in the ER by a 339-amino-acid domain that spans the membrane eight times and is required for activity of the protein. In the short term, decreased intracellular levels of ATP—via AMP kinase (AMPK; see pp. 1220–1222)—lead to phosphorylation of HMG-CoA reductase, which reduces the activity of the enzyme and thereby presumably preserves energy stores in the cell.

Far more important is the long-term control of the amount of HMG-CoA reductase, which can increase as much as 200-fold. The amount of HMG-CoA reductase protein increases after cells are depleted of mevalonate or when the demand for mevalonate-derived metabolites rises. HMG-CoA reductase activity is upregulated by a combination of enhanced gene transcription, increased mRNA translation, and increased stability of the enzyme. These changes are reversed by the addition of the sterol cholesterol or of mevalonate to the cells. The transmembrane domain of HMG-CoA reductase may serve as a receptor for the regulatory effects of sterols.

The repression by sterols of the genes encoding HMG-CoA reductase—as well as HMG-CoA synthase and the LDL receptor—is mediated by specific transcription factors and specific sequence elements within the 5' upstream region to which the transcription factors bind. The transcription factors, which belong to a family known as **sterol regulatory element-binding proteins (SREBPs)** (see pp. 87–88), are central to feedback control of cholesterol homeostasis. These SREBPs are membrane-bound basic helix-loop-helix transcriptional activators (see p. 83) that control genes involved in the synthesis and receptor-mediated uptake of cholesterol and fatty acids. SREBP-1 is most abundant in the liver, whereas SREBP-

2 is expressed ubiquitously. However, it is SREBP-2 that regulates most genes that encode enzymes of cholesterol biosynthesis.

Treatment of Hyperlipidemia

Contributed by Fred Suchy

Several approaches are available to treat hyperlipidemia in patients. These approaches include the following:

1. **Bile acid sequestrants**, which enhance the excretion of sterols in the feces.
2. **Nicotinic acid** (e.g., niacin), which decreases the production of VLDL cholesterol.
3. **Fibric-acid derivatives** (e.g., clofibrate), which decrease the production of VLDL cholesterol.
4. **HMG-CoA reductase inhibitors** (i.e., the “statins”), which decrease cholesterol synthesis.

HMG-CoA reductase, the rate-limiting enzyme in cholesterol biosynthesis, is a 97-kDa enzyme intrinsic to the ER. The protein is anchored in the ER by a 339–amino-acid domain that spans the membrane eight times and is required for activity of the protein. In the short term, decreased levels of $[ATP]_i$ lead to a phosphorylation of HMG-CoA reductase, which reduces the activity of the enzyme and thereby presumably preserves energy stores in the cell.

Far more important than the short-term regulation of HMG-CoA reductase is the long-term control of the amount of the enzyme, which can increase as much as 200-fold. The amount of HMG-CoA reductase protein increases after cells are depleted of mevalonate or when the demand for mevalonate-derived metabolites is increased. HMG-CoA reductase activity is upregulated by a combination of enhanced gene transcription, increased mRNA translation, and increased stability of the enzyme. These changes are reversed by the addition of cholesterol or mevalonate to the cells. The transmembrane domain of HMG-CoA reductase may serve as a receptor for the post-translational regulatory effects of sterols.

Sterol repression of HMG-CoA reductase gene expression—as well as the expression of LDL and HMG-CoA synthase genes—is mediated by specific transcription factors (i.e., proteins) that bind to specific DNA sequence elements within the 5′ upstream region of target genes. The DNA-binding proteins are called **sterol regulatory element–binding proteins (SREBPs)**; see pp. 87–88); they are membrane-bound **basic helix-loop-helix** transcriptional activators (see p. 83 and Fig. 4-9C). The DNA to which these transcription factors bind are called **sterol regulatory elements** (such as SRE-1). The binding of SREBPs to SREs controls genes involved in the synthesis and receptor-mediated uptake of cholesterol and fatty acids.

The liver is the central organ for cholesterol homeostasis and for the synthesis and degradation of LDL

The liver is the hub of an *exogenous* loop in which the liver takes up dietary cholesterol as remnant chylomicrons and exports cholesterol and cholesterol metabolites into bile. The liver is also the hub of an *endogenous* loop in which the liver exports cholesterol and other lipids as VLDLs and takes them up from the blood as LDLs. [Table 46-4](#) summarizes the properties of these lipoproteins, as well as of two others: the intermediate-density lipoproteins (IDLs) and the **high-density lipoproteins (HDLs)**. As we move from left to right in [Table 46-4](#), the size of the particles decreases, the density increases (because the fractional mass of protein increases), the fractional amount of triacylglycerols decreases, and the fractional amount of phospholipids increases.

Regardless of the source of the cholesterol, the liver can package cholesterol along with other lipids and apolipoproteins as **VLDLs**—the liver's transit system for exporting endogenous triacylglycerols, phospholipids, cholesterol, and cholesteryl esters. The VLDLs are large—and therefore less dense—when the availability of triacylglycerols is high (e.g., obesity, diabetes), but they are small when triacylglycerol availability is low. VLDLs enter the bloodstream from the liver (see [Fig. 46-15](#)) and eventually make their way to the blood vessels of adipose tissue and muscle, where the same LPL that degrades chylomicrons degrades the VLDLs on the luminal surface of blood vessel endothelial cells. In the process, fatty acids are released to the tissues. Thus, VLDLs act as lipid shuttles that transport endogenous triacylglycerols to adipose tissue for storage as fat or to muscle for immediate use. As a result of the LPL activity, the large, buoyant VLDLs rapidly shrink to become the smaller **IDLs** and the even smaller **LDLs**. The half-life of VLDLs is less than an hour. In plasma, only minute amounts of IDLs are present.

Both the liver and extrahepatic tissue can take up LDLs—and to a lesser extent, IDLs—by the process of receptor-mediated endocytosis (see [p. 42](#)). **LDLs** are the major carriers of cholesterol in plasma. The half-life of LDLs is 2 to 3 days. Of course, uptake of LDL by the liver is a major pathway of cholesterol input to the liver. The liver degrades ~40% to 60% of LDLs, and no other tissue takes up more than ~10%. LDL uptake by other tissues provides a mechanism for the delivery of cholesterol that can be used for the synthesis of cell membranes and steroid hormones or for storage as cholesteryl ester droplets.

The other major player in cholesterol metabolism is **HDL**, which is composed of cholesterol, phospholipids, triacylglycerols, and apolipoproteins (see [Table 46-4](#)). The two major apolipoproteins of HDLs, A-I and A-II, are made by the intestines as part of chylomicrons, as well as by the liver. As LPL digests VLDLs on endothelial cells, some excess surface material (i.e., cholesterol and phospholipids) of these rapidly shrinking particles is transferred to the HDLs. In peripheral cells such as macrophages, the cholesterol transporter ABCA1 facilitates the efflux of cholesterol, which then combines with lipid-poor HDLs. An enzyme that is associated with HDL, **lecithin-cholesterol acyltransferase (LCAT)**—synthesized in the liver, then takes an acyl group from lecithin and esterifies it to cholesterol to produce a **cholesterol ester (CE)**.

When the CE-enriched HDL (HDL-CE) reaches the liver, it binds to **scavenger receptor class B type 1 (SR-B1)**, [N46-18](#) which mediates selective uptake of HDL-CE. The cholesterol moiety is targeted for biliary excretion. This pathway may also process LDL-CE and free cholesterol. In contrast to uptake by the LDL receptor, the selective uptake of CE by **SR-B1** does not involve endocytosis. Instead, a poorly defined mechanism first moves CE to a reversible plasma-membrane pool and then to an irreversible pool within the cell.

Scavenger Receptor Class B Type 1

Contributed by Emile Boulpaep, Walter Boron

The scavenger receptors can bind a very broad range of polyanionic ligands. SR-B1 does not just bind but also transports cholesterol-enriched HDL and LDL into the cell.

References

Krieger M. Scavenger receptor class B type I is a multiligand HDL receptor that influences diverse physiologic systems. *J Clin Invest.* 2001;108:793–797.

Rhainds D, Brissette L. The role of scavenger receptor class B type I (SR-BI) in lipid trafficking: Defining the rules for lipid traders. *Int J Biochem Cell Biol.* 2004;36:39–77.

Not only does SR-B1 mediate the hepatic uptake of HDL-CE, but **cholesteryl ester transfer protein (CETP)** in blood plasma can mediate the transfer of CE from HDL-CE to VLDLs, IDLs, and LDLs—all of which contain apolipoprotein B-100. These less-dense lipoproteins can now move to the liver for uptake by the LDL receptor. The HDL-mediated removal of cholesterol from peripheral tissues via both SR-B1 and CETP for transport to the liver and excretion in bile is known as **reverse cholesterol transport**. This process is thought to protect against atherosclerosis.

The liver is the prime site for metabolism and storage of the fat-soluble vitamins A, D, E, and K

We discuss the intestinal uptake of the fat-soluble vitamins on [page 933](#).

Vitamin A

Vitamin A (retinol and its derivatives)—like dietary vitamin D, as well as vitamins E and K—is absorbed from the intestine and is then transported in newly synthesized chylomicrons or VLDLs. After some peripheral hydrolysis of its triacylglycerol, the remnant chylomicrons are taken up by the liver. In the hepatocyte, retinyl esters may be hydrolyzed to release free retinol, which can then be transported into the sinusoids bound to **retinol-binding protein (RBP)** and prealbumin. Alternatively, retinyl esters may be stored in the hepatocyte or transported as RBP-bound retinol to **stellate (Ito) cells**, the storage site of >80% of hepatic vitamin A under normal conditions. Retinol may also undergo oxidation to **retinal** and conversion to **retinoic acid**, which plays a key role in phototransduction (see [p. 367](#)). Retinoic acid is conjugated to glucuronide and is secreted into bile, where it undergoes enterohepatic circulation and excretion. Liver disease resulting in cholestasis may lead to a secondary vitamin A deficiency by interfering with absorption in the intestine (lack of the bile needed for digestion/absorption of vitamin A) or by impairing delivery to target tissues because of reduced hepatic synthesis of RBP.

Vitamin D

Skin cells—under the influence of ultraviolet light—synthesize vitamin D₃ (see [p. 1064](#)). Dietary vitamin

D can come from either animal sources (D_3) or plant sources (D_2). In either case, the first step in activation of vitamin D is the 25-hydroxylation of vitamin D, catalyzed by a hepatic cytochrome P-450 enzyme. This hydroxylation is followed by 1-hydroxylation in the kidney to yield a product (1,25-dihydroxyvitamin D) with full biological activity. Termination of the activity of 1,25-dihydroxyvitamin D also occurs in the liver by hydroxylation at carbon 24, mediated by another cytochrome P-450 enzyme.

Vitamin E

The fat-soluble vitamin E is absorbed from the intestine primarily in the form of α - and γ -tocopherol. It is incorporated into chylomicrons and VLDLs with other products of dietary lipid digestion. As noted above, these particles reach the systemic circulation via the lymphatics and undergo some triacylglycerol hydrolysis. In the process, some vitamin E is transferred to other tissues. The α - and γ -tocopherol remaining in the remnant chylomicrons is transported into the liver, which is the major site of discrimination between the two forms. The α -tocopherol is secreted again as a component of hepatically derived VLDL and perhaps HDL. The γ -tocopherol appears to be metabolized or excreted by the liver. A hepatic tocopherol-binding protein may play a role in this discriminatory process.

Vitamin K

Vitamin K is a fat-soluble vitamin produced by intestinal bacteria. This vitamin is essential for the γ -carboxylation—by the ER enzyme γ -glutamyl carboxylase—of certain glutamate residues in coagulation factors II, VII, IX, and X as well as anticoagulants protein C and protein S (see [Table 18-4](#)) and certain other proteins. Intestinal absorption and handling of vitamin K—which is present in two forms, K_1 and K_2 —are similar to those of the other fat-soluble vitamins, A, D, and E. Common causes of vitamin K deficiency, which can lead to a serious bleeding disorder, include extrahepatic or intrahepatic cholestasis, fat malabsorption, biliary fistulas, and dietary deficiency, particularly in association with antibiotic therapy.

The liver stores copper and iron

Copper

The trace element copper is essential for the function of cuproenzymes such as cytochrome C oxidase and superoxide dismutase (see [p. 1238](#)). Approximately half the copper in the diet (recommended dietary allowance, 1.5 to 3 mg/day) is absorbed in the jejunum and reaches the liver in the portal blood, mostly bound to albumin. A small fraction is also bound to amino acids, especially histidine.

High-affinity copper import across the hepatocyte basolateral membrane is mediated by the copper transport protein CTR1 (SLC31A1). Copper then binds to members of a family of intracellular metallochaperones that direct the metal to the appropriate pathway for incorporation into cuproenzymes or for biliary excretion. It is unknown how hepatocytes distribute copper to the different intracellular routes. The copper chaperone Atox1 ferries the copper through the cytosol to the Wilson disease P-type ATPase ATP7B ([Box 46-5](#); see also [p. 118](#)), which is located predominantly in the *trans*-Golgi network and late endosomes. Intracellular copper levels modulate the activity, post-translational modification, and intracellular localization of ATP7B. Once inside the vesicular lumen, copper can couple with **apo-ceruloplasmin (apo-Cp)** to form **holo-ceruloplasmin holo-Cp**, which the hepatocyte secretes across the sinusoidal membrane into the blood. Alternatively, the hepatocyte can secrete the copper—perhaps with hepatic copper-binding proteins such as COMMD1 (copper metabolism MURR1 domain)—across the

canalicular membrane into the bile. More than 80% of the copper absorbed each day is excreted in bile, for a total of 1.2 to 2.4 mg/day. The small intestine cannot reabsorb the secreted Cu-protein complexes. Processes that impair the biliary excretion of copper result in the accumulation of copper, initially in the lysosomal fraction of hepatocytes, with subsequent elevation of plasma copper levels.

Box 46-5

Wilson Disease

Wilson disease is inherited as an autosomal recessive illness caused by a mutation in ATP7B, the pump responsible for copper accumulation in the *trans*-Golgi network. The impaired biliary excretion of copper causes a buildup of copper in cells, which produces toxic effects in the liver, brain, kidney, cornea, and other tissues. The disease is rare, but it must be considered in the differential diagnosis of anyone younger than 30 years with evidence of significant liver disease. Patients most often have neuropsychiatric complications, including ataxia, tremors, increased salivation, and behavioral changes. Slit-lamp examination of the cornea reveals the diagnostic Kayser-Fleischer rings at the limbus of the cornea.

Because of the lack of functional ATP7B, the apoceruloplasmin in the *trans*-Golgi network cannot bind copper to form ceruloplasmin. As a result, the hepatocytes secrete **apoceruloplasmin**, which lacks the ferroxidase activity of ceruloplasmin. Moreover, the serum concentrations of ceruloplasmin are low. Indeed, the best way to confirm the diagnosis of Wilson disease is the detection of a low serum ceruloplasmin level and elevated urinary copper excretion. A few affected patients have normal ceruloplasmin levels, and the diagnosis must then be sought through liver biopsy. The disease can be treated by chelating the excess copper with penicillamine.

Ceruloplasmin, an α_2 -globulin synthesized by the liver, binds 95% of copper present in the systemic circulation. Ceruloplasmin has ferroxidase activity but has no critical role in the membrane transport or metabolism of copper.

Iron

Dietary iron is absorbed by the duodenal mucosa and then transported through the blood bound to transferrin (see p. 941), a protein synthesized in the liver. The liver also takes up, secretes, and stores iron. Entry of iron into hepatocytes is mediated through specific cell-surface transferrin receptors (see p. 42). Within the cell, a small pool of soluble iron is maintained for intracellular enzymatic reactions, primarily for those involved in electron transport. However, iron is also toxic to the cell. Hence, most intracellular iron is complexed to ferritin (see p. 941). The toxicity of iron is clearly evident when normal storage mechanisms become overwhelmed, as occurs in hemochromatosis (see Box 45-6), an autosomal recessive disease in which regulation of iron absorption is uncoupled from total-body storage levels.

Hepatocytes also play a critical role in iron homeostasis by synthesizing **hepcidin** (see p. 941), which lowers plasma iron levels by downregulating the iron-efflux pump FPN1 (see p. 941) in the intestine and macrophages, thereby blocking the release of iron into the circulation. The consequent iron retention in duodenal enterocytes effectively blocks dietary iron absorption and leads to iron retention in reticuloendothelial macrophages. The expression of the *HAMP* gene, which encodes hepcidin, increases with iron loading and inflammatory cytokines, and decreases with anemia and hypoxia (consistent with enhanced erythropoiesis; see pp. 440–442).

CHAPTER 47

Organization of Endocrine Control

Eugene J. Barrett

With the development of multicellular organisms that have specialized tissues and organs, two major systems evolved to communicate and coordinate body functions:

1. The **nervous system** integrates tissue functions by a network of cells and cell processes that constitute the nervous system and all subdivisions, as discussed in [Chapters 10](#) through [16](#).
2. The **endocrine system** integrates organ function via chemicals that are secreted from endocrine tissues or “glands” into the extracellular fluid. These chemicals, called **hormones**, are then carried through the blood to distant target tissues where they are recognized by specific high-affinity receptors. As discussed in [Chapter 3](#), these receptors may be located either on the surface of the target tissue, within the cytosol, or in the target cell's nucleus. These receptor molecules allow the target cell to recognize a unique hormonal signal from among the numerous chemicals that are carried through the blood and bathe the body's tissues. The accuracy and sensitivity of this recognition are remarkable in view of the very low concentration (10^{-9} to 10^{-12} M) at which many hormones circulate.

Once a hormone is recognized by its target tissue or tissues, it can exert its biological action by a process known as **signal transduction** (see [Chapter 3](#)). Here in Chapter 47, we discuss how the signal-transduction cascades couple the hormone to its appropriate end responses. Some hormones elicit responses within seconds (e.g., the increased heart rate provoked by epinephrine or the stimulation of hepatic glycogen breakdown caused by glucagon), whereas others may require many hours or days (e.g., the changes in salt retention elicited by aldosterone or the increases in protein synthesis caused by growth hormone [GH]). We also examine the principles underlying the feedback mechanisms that control endocrine function.

In [Chapters 48](#) through [52](#), we see how the principles introduced in this chapter apply to some specific endocrine systems.

Principles of Endocrine Function

Chemical signaling can occur through endocrine, paracrine, or autocrine pathways

As shown in [Figure 3-1A](#), in classic endocrine signaling, a hormone carries a signal from a secretory gland across a large distance to a target tissue. Hormones secreted into the extracellular space can also regulate nearby cells without ever passing through the systemic circulation. This regulation is referred to as paracrine action of a hormone (see [Fig. 3-1B](#)). Finally, chemicals can also bind to receptors on or in the cell that is actually secreting the hormone and thus affect the function of the hormone-secreting cell itself. This action is referred to as autocrine regulation (see [Fig. 3-1C](#)). All three mechanisms are illustrated for individual endocrine systems in subsequent chapters. At the outset, it can be appreciated that summation of the endocrine, paracrine, and autocrine actions of a hormone can provide the framework for a complex regulatory system.

Endocrine Glands

The major hormones of the human body are produced by one of seven classic endocrine glands or gland pairs: the pituitary, the thyroid, the parathyroids, the testes, the ovaries, the adrenals (cortex and medulla), and the endocrine pancreas. In addition, other tissues that are not classically recognized as part of the endocrine system produce hormones and play a vital role in endocrine regulation. These tissues include the central nervous system (CNS), particularly the hypothalamus, as well as the gastrointestinal tract, adipose tissue, liver, heart, and kidney.

In some circumstances, particularly with certain neoplasms, nonendocrine tissues can produce hormones that are usually thought to be made only by endocrine glands ([Box 47-1](#)).

Box 47-1

Neoplastic Hormone Production

The ability of nonendocrine tissue to produce hormones first became apparent with the description of clinical syndromes in which some patients with lung cancer were found to make excessive amounts of AVP, a hormone usually made by the hypothalamus. Shortly afterward, people with other lung or gastrointestinal tumors were found to make ACTH, which is normally made only in the pituitary. Subsequently, many hormone-secreting neoplastic tissues were described. As the ability to measure hormones in tissues has improved and, in particular, as the capability of measuring mRNA that codes for specific peptide hormones has developed, it has become clear that hormone production by neoplastic tissue is quite common, although most tumors produce only small amounts that may have no clinical consequence.

The production of hormones by nonendocrine neoplastic cells has been most clearly defined for cancers of the lung. Several different types of lung cancer occur, each deriving from a different cell line, and yet each is capable of producing one or several hormones. The clinical syndromes that result from secretion of these hormones are often called **paraneoplastic syndromes**. Thus, lung cancers arising from squamous cells are sometimes associated with hypercalcemia, which results from the secretion of a protein—parathyroid hormone-related peptide—that can mimic the activity of PTH (see p. 1069). Small-

cell lung cancers are notorious for their ability to secrete numerous hormones, including AVP (with resultant hyponatremia; see Box 38-3), ACTH (with resultant Cushing syndrome; see Box 50-1), and many others. Still other types of lung cancer produce other paraneoplastic syndromes.

Nearly all these ectopic, neoplastic sources of hormone produce *peptide* hormones. Other sources of hormone production, in addition to lung cancer, include gastrointestinal tumors, renal and bladder cancer, neural tumors, unique tumors called **carcinoid tumors** that can arise almost anywhere in the body, and even lymphomas and melanomas. In some patients, the symptoms and signs resulting from ectopic hormone production may appear before any other reason exists to suspect an underlying neoplasm, and these symptoms may be the key clues to the correct diagnosis.

Paracrine Factors

Numerous specialized tissues that are not part of the classic endocrine system release “factors” into the extracellular fluid that can signal neighboring cells to effect a biological response. The interleukins, or lymphokines, are an example of such paracrine factors, as are several of the growth factors, such as platelet-derived growth factor (PDGF), fibroblast growth factor, and others. These factors are not hormones in the usual sense. They are not secreted by glandular tissue, and their sites of action are usually (but not always) within the local environment. However, these signaling molecules share many properties of the classic peptide and amine hormones in that they bind to surface receptors and regulate one or more of the specific intracellular signaling mechanisms described in [Chapter 3](#).

The distinction between the hormones of the classic endocrine systems and other biologically active secreted peptides blurs even further in the case of neuropeptides. For example, the hormone somatostatin, a 28–amino-acid peptide secreted by the δ cells of the pancreatic islet, acts in paracrine fashion on other islet cells to regulate insulin and glucagon secretion (see [p. 1053](#)). However, somatostatin is also made by hypothalamic neurons. Nerve terminals in the hypothalamus release somatostatin into the pituitary portal bloodstream (see [pp. 993–994](#)). This specialized segment of the circulatory system then carries the somatostatin from the hypothalamus to the **anterior pituitary**, where it inhibits the secretion of GH. Somatostatin in the hypothalamus is one of several neuropeptides that bridge the body's two major communication systems.

Hormones may be peptides, metabolites of single amino acids, or metabolites of cholesterol

Although the chemical nature of hormones is diverse, most commonly recognized mammalian hormones can be grouped into one of several classes. [Table 47-1](#) is a list of many of the recognized classic mammalian hormones, which are divided into three groups based on their chemical structure and how they are made in the body.

TABLE 47-1
Chemical Classification of Selected Hormones
Peptide Hormones
Adrenocorticotrophic hormone (ACTH)
Atrial natriuretic peptide (ANP)

Arginine vasopressin (AVP), also known as antidiuretic hormone (ADH)

Calcitonin

Cholecystokinin (CCK)

Corticotropin-releasing hormone (CRH)

Follicle-stimulating hormone (FSH)

Glucagon

Gonadotropin-releasing hormone (GnRH)

Growth hormone (GH)

Growth hormone–releasing hormone (GHRH)

Inhibin

Insulin

Insulin-like growth factors 1 and 2 (IGF-1 and IGF-2)

Luteinizing hormone (LH)

Oxytocin (OT)

Parathyroid hormone (PTH)

Prolactin (PRL)

Secretin

Somatostatin

Thyrotropin (TSH)

Thyrotropin-releasing hormone (TRH)

Vasoactive intestinal peptide (VIP)

Amino Acid–Derived Hormones

Dopamine (DA)

Epinephrine (Epi), also known as adrenaline

Norepinephrine (NE), also known as noradrenaline

Serotonin, also known as 5-hydroxytryptamine (5-HT)

Thyroxine (T_4)

Triiodothyronine (T_3)

Steroid Hormones

Aldosterone

Cortisol

Estradiol (E2)

Progesterone

Testosterone

Peptide hormones include a large group of hormones made by a variety of endocrine tissues. Insulin, glucagon, and somatostatin are made in the pancreas. The pituitary gland makes GH; the two gonadotropin hormones, luteinizing hormone (LH) and follicle-stimulating hormone (FSH); adrenocorticotrophic hormone (ACTH); thyrotropin (also called thyroid-stimulating hormone or TSH); and prolactin (PRL). The parathyroid glands make parathyroid hormone (PTH), and the thyroid gland make calcitonin.

In addition, other peptide hormones, such as somatostatin and several releasing hormones (e.g., growth hormone–releasing hormone [GHRH]), are made by the hypothalamus. Secretin, cholecystokinin,

glucagon-like peptide 1 (GLP-1) and other hormones are made by the gastrointestinal tract, which is not considered a classic endocrine gland.

The synthesis of **catecholamines** (from tyrosine) and **steroid hormones** (from cholesterol) requires a number of enzymes present in only very specialized tissues. Synthesis of **thyroid hormone** is even more complex and is essentially restricted to the thyroid gland.

Several glands make two or more hormones. Examples are the pituitary, the pancreatic islets, and the adrenal glands. However, for the most part, individual cells within these glands are specialized to secrete a single hormone. One exception is the gonadotropin-producing cells of the pituitary, which secrete both FSH and LH.

Hormones can circulate either free or bound to carrier proteins

Once secreted, many hormones circulate freely in the blood until they reach their target tissue. Others form complexes with circulating **binding protein**; this use of binding proteins is particularly applicable for thyroid hormones (thyroxine [T_4] and triiodothyronine [T_3]), steroid hormones, insulin-like growth factor types 1 and 2 (IGF-1 and IGF-2), and GH.

Formation of a complex between a hormone and a circulating binding protein serves several functions. First, it provides the blood with a reservoir or pool of the hormone and thus minimizes minute-to-minute fluctuations in hormone concentration. Second, it extends the half-life of the hormone in the circulation. For example, >99.99% of T_4 circulates bound to one of three binding proteins (see [pp. 1008–1009](#)); the half-life of circulating bound T_4 is 7 to 8 days, whereas the half-life of free T_4 is only several minutes. The hormones bound to plasma binding proteins appear to be those whose actions are *long term*—in particular, those involving induction of the synthesis of new protein in target tissues. Hormones that play a major *short-term* role in the regulation of body metabolism (e.g., catecholamines, many peptide hormones) circulate freely without associated binding proteins.

The presence of plasma binding proteins can affect the total circulating concentration of a hormone without necessarily affecting the concentration of unbound or **free hormone** in the blood. For example, during pregnancy the liver's synthesis of T_4 -binding globulin increases. Because this protein avidly binds T_4 , the free T_4 concentration ordinarily would fall. However, the pituitary senses the small decline in free T_4 levels and secretes more TSH. As a result, the thyroid makes more T_4 , so plasma levels of total T_4 rise. However, the free T_4 level does not rise.

Immunoassays allow measurement of circulating hormones

In the late 1950s, Solomon Berson and Rosalyn Yalow demonstrated that patients who receive insulin form antibodies directed against the insulin molecule. This observation was important in two respects:

1. It advanced the principle that the body's immune system can react to endogenous compounds; therefore, autoimmunity or reaction to self-antigens does occur. This notion is a fundamental tenet of our current understanding of many autoimmune diseases, among which are endocrine diseases such as type 1 diabetes mellitus, autoimmune hypothyroidism, Graves disease (a common form of autoimmune hyperthyroidism), and Addison disease (one form of adrenal insufficiency). Before the description of insulin autoantibodies, it was thought that the immune system simply did not react to self-antigens.

2. Because antibodies with a high affinity for insulin were induced in patients who were treated with insulin, Berson and Yalow reasoned that these antibodies could be used to measure the amount of insulin in serum. [Figure 47-1](#) illustrates the principle of a radioimmunoassay and how it is used to measure the concentration of a hormone (or other chemicals). If we incubate increasing amounts of a radiolabeled hormone with an antibody to that hormone, the quantity of labeled hormone that is bound to the antibody yields a saturation plot (see [Fig. 47-1A](#)). If we now add *unlabeled* hormone to the incubation mixture, less radioactively labeled hormone remains complexed to the antibody as unlabeled hormone takes its place. The more unlabeled hormone we add, the less labeled hormone is bound to the antibody (see [Fig. 47-1B](#)). A displacement curve is created by plotting the amount of radioactively labeled hormone complexed to the antibody as a function of the concentration of unlabeled hormone that is added (see [Fig. 47-1C](#)). This displacement curve can then be used as a standard curve to estimate the amount of hormone present in unknown samples. This estimate is accurate only if two assumptions hold true: first, that nothing else in the unknown mixture binds with the antibody other than the hormone under study, and second, that nothing in the unknown sample interferes with normal binding of the hormone to the antibody.

A SATURATION PLOT**C DISPLACEMENT CURVE****B DISPLACEMENT OF A LABELED HORMONE BY AN UNLABELED HORMONE****FIGURE 47-1** Principles of the radioimmunoassay.

Antibodies that are highly specific for the chemical structure of interest can frequently be obtained. Moreover, these antibodies are of sufficiently high affinity to bind even the often minute amounts of hormone that is circulating in blood. Thus, radioimmunoassays—and recent adaptations that substitute chemiluminescent or enzymatic detection for radioactivity—have emerged as a potent and popular tool. Immunoassays are now used for the measurement of virtually all hormones, as well as many drugs, viruses, and toxins. Much of our understanding of the physiology of hormone secretion and action has been gained by the use of immunoassay methodology. Yalow shared the 1977 Nobel Prize in Medicine or Physiology for the discovery of the radioimmunoassay (Berson died before the honor was bestowed). 🏆 **N47-1**

N47-1**Rosalyn Yalow**

For more information about Rosalyn Yalow and the work that led to her Nobel Prize, visit http://www.nobelprize.org/nobel_prizes/medicine/laureates/1977/# (accessed September 2014).

Hormones can have complementary and antagonistic actions

Regulation of many complex physiological functions necessitates the **complementary action** of several hormones. This principle is true both for minute-to-minute homeostasis and for more long-term processes. For example, epinephrine (adrenaline), cortisol, and glucagon each contribute to the body's response to a short-term bout of exercise (e.g., swimming the 50-m butterfly or running the 100-m dash). If any of these hormones is missing, exercise performance is adversely affected, and even more seriously, severe hypoglycemia and hyperkalemia (elevated plasma $[K^+]$) may develop. On a longer time scale, GH, insulin, IGF-1, thyroid hormone, and sex steroids are all needed for normal growth. Deficiency of GH, IGF-1, or thyroid hormone results in dwarfism. Deficiency of sex steroids, cortisol, or insulin produces less severe disturbances of growth.

Integration of hormone action can also involve hormones that exert **antagonistic actions**. In this case, the overall effect on an end organ depends on the balance between opposing influences. One example is the counterpoised effects of insulin and glucagon on blood glucose levels. Insulin lowers glucose levels by *inhibiting* glycogenolysis and gluconeogenesis in the liver and by stimulating glucose uptake into muscle and adipose tissue. Glucagon, in contrast, *stimulates* hepatic glycogenolysis and gluconeogenesis. Whereas glucagon does not appear to directly antagonize glucose uptake by muscle or fat, epinephrine (which, like glucagon, is released in response to hypoglycemia) does. Balancing of tissue function by opposing humoral effector mechanisms appears to be an important regulatory strategy for refining the control of many cellular functions.

Endocrine regulation occurs through feedback control

The key to any regulatory system is its ability to sense when it should increase or decrease its activity. For the endocrine system, this function is accomplished by feedback control of hormone secretion (Fig. 47-2A). The hormone-secreting cell functions as a “sensor” that continually monitors the circulating concentration of some regulated variable. This variable may be a metabolic factor (e.g., glucose concentration) or the activity of another hormone. When the endocrine gland senses that too much (or too little) of the regulated variable is circulating in blood, it responds by decreasing (or increasing) the rate of hormone secretion. This response in turn affects the metabolic or secretory behavior of the target tissue, which may either directly feed back to the sensing cell or stimulate some other cell that eventually signals the sensor regarding whether the altered function of the endocrine gland has been effective.

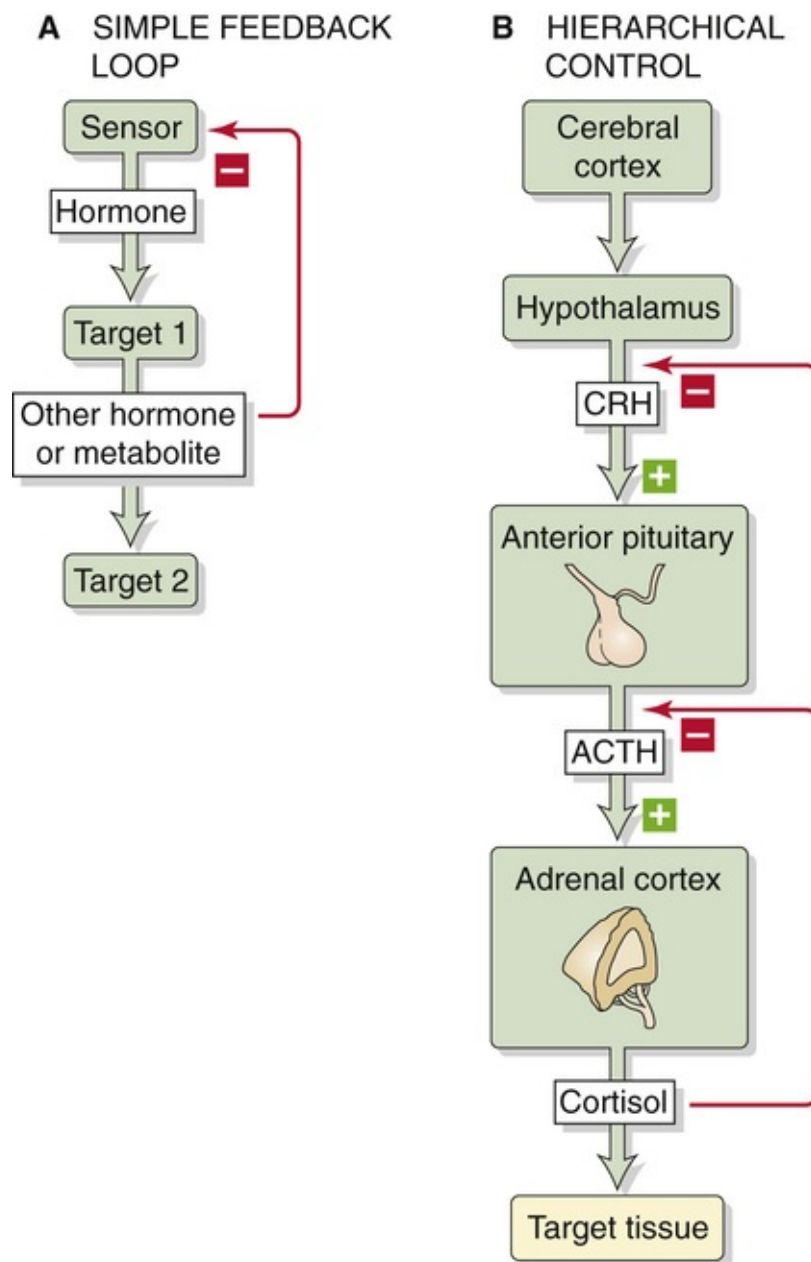

FIGURE 47-2 Feedback control of hormone secretion. **A**, A sensor (e.g., a β cell in a pancreatic islet) detects some regulated variable (e.g., plasma [glucose]) and responds by modulating its secretion of a hormone (e.g., insulin). This hormone, in turn, acts on target 1 (e.g., liver or muscle) to modulate its production of another hormone or a metabolite (e.g., reducing [glucose]), which may affect target 2 (e.g., making less glucose available to the brain). In addition, the other hormone or metabolite feeds back on the original sensor cell. **B**, Under the influence of the cerebral cortex, the hypothalamus releases CRH, which stimulates the anterior pituitary to release ACTH, which in turn stimulates the adrenal cortex to release cortisol. The cortisol acts on a number of effector organs. In addition, the cortisol feeds back on both the anterior pituitary and the hypothalamus.

A simple example is insulin secretion by the β cells of the pancreas. Increases in plasma [glucose] are sensed by the β cell, which secretes insulin in response. The rise in plasma [insulin] acts on the liver to decrease the synthesis of glucose and on the muscle to promote the storage of glucose. As a result, plasma [glucose] falls, and this decrease is sensed by the β cell, which reduces the rate of insulin secretion. This arrangement represents a very simple feedback system. Other systems can be quite complex; however, even this simple system involves the recognition of two circulating signals. The liver and muscle recognize the increase in plasma [insulin] as one signal, and the pancreatic β cell (the cell responsible for insulin secretion) recognizes the signal of a rise or decline in blood [glucose] as the other signal. In each case, the sensing system within a particular tissue is linked to an effector system that transduces the signal to the appropriate biological response.

Endocrine regulation can involve hierarchic levels of control

Faced with a stress (e.g., a severe infection or extensive blood loss), the cerebral cortex stimulates the hypothalamus to release a neuropeptide called corticotropin-releasing hormone (CRH; see [Fig. 47-2B](#)). Carried by the pituitary portal system (blood vessels that connect the hypothalamus to the anterior pituitary), CRH stimulates the anterior pituitary to release another hormone, ACTH, which in turn stimulates the adrenal cortical cells to synthesize cortisol. Cortisol regulates vascular tone as well as metabolic and growth functions in a variety of tissues.

This *stress response* therefore involves the cerebral cortex, specialized *neuroendocrine tissue* in the **hypothalamus**, as well as two glands, the pituitary and the adrenal cortex. This hierarchic control is regulated by feedback, just as in the simple feedback between plasma [glucose] and insulin. Within this CRH-ACTH-cortisol axis, feedback can occur at several levels. Cortisol inhibits the production of CRH by the hypothalamus as well as the sensitivity of the pituitary to a standard dose of CRH, which directly reduces ACTH release.

Feedback in hierarchic endocrine control systems can be quite complex and frequently involves interaction between the CNS and the endocrine system. Other examples are regulation of the female menstrual cycle (see [pp.1110–1116](#)) and regulation of GH secretion (see [pp. 992–994](#)).

Among the classic endocrine tissues, the **pituitary** (also known as the hypophysis) plays a special role ([Fig. 47-3](#)). Located at the base of the brain, just below the hypothalamus, the pituitary resides within a saddle-shaped cavity called the *sella turcica* (from the Latin *sella* [saddle] + *turcica* [Turkish]), which has bony anterior, posterior, and inferior borders and fibrous tissue that separate it from venous sinuses on either side. The human pituitary is composed of both an anterior lobe and a posterior lobe. Through vascular and neural connections, the pituitary bridges and integrates neural and endocrine mechanisms of homeostasis. The pituitary is a highly vascular tissue. The posterior pituitary receives arterial blood, whereas the anterior pituitary receives only portal venous inflow from the median eminence. The **pituitary portal system** is particularly important in carrying neuropeptides from the hypothalamus and pituitary stalk to the anterior pituitary.

FIGURE 47-3 Hypothalamic-pituitary axis. The pituitary (or hypophysis) is actually two glands—an anterior pituitary and a posterior pituitary (or neurohypophysis). Although in both cases the hypothalamus controls the secretion of hormones by the pituitary, the mechanisms are very different. *Anterior pituitary:* Small-bodied neurons in the hypothalamus secrete *releasing* and *inhibiting* factors into a rich, funnel-shaped plexus of capillaries that penetrates the median eminence and surrounds the infundibular recess. The cell bodies of these neurons are in several nuclei that surround the third ventricle. These include the

arcuate nucleus, the paraventricular and ventromedial nuclei, and the medial preoptic and periventricular regions. The capillaries (primary plexus), which are outside of the blood-brain barrier, coalesce into *long* portal veins that carry the releasing and inhibitory factors down the pituitary stalk to the anterior pituitary. Other neurons secrete their releasing factors into a capillary plexus that is much further down the pituitary stalk; *short* portal veins carry these releasing factors to the anterior pituitary. There, the portal veins break up into the secondary capillary plexus of the anterior pituitary and deliver the releasing and inhibitory factors to the “troph” cells that actually secrete the anterior pituitary hormones (GH, TSH, ACTH, LH, FSH, and PRL) that enter the systemic bloodstream and distribute throughout the body. *Posterior pituitary:* Large neurons in the paraventricular and supraoptic nuclei of the hypothalamus actually synthesize the hormones AVP and oxytocin (OT). These hormones travel down the axons of the hypothalamic neurons to the posterior pituitary, where the nerve terminals release the hormones, like neurotransmitters, into a rich plexus of vessels.

The anterior pituitary regulates reproduction, growth, energy metabolism, and stress responses

Glandular tissue in the anterior lobe of the pituitary synthesizes and secretes six peptide hormones: GH, TSH, ACTH, LH, FSH, and PRL. In each case, secretion of these hormones is under the control of hypothalamic releasing hormones ([Table 47-2](#)). The sources of these releasing hormones are small-diameter neurons located mainly in the “periventricular” portion of the hypothalamus that surrounds the third ventricle (see [pp. 275–277](#)). These small-diameter neurons synthesize the releasing hormones and discharge them into the median eminence and neural stalk, where they enter leaky capillaries—which are not part of the blood-brain barrier (see [pp. 284–287](#)). The releasing hormones then travel via the pituitary portal veins to the anterior pituitary. Once in the anterior pituitary, a releasing factor (e.g., GHRH) stimulates specialized cells to release a particular peptide hormone (e.g., GH) into the systemic bloodstream. The integrative function of the anterior pituitary can be appreciated by realizing that the main target for four of the anterior pituitary hormones (i.e., TSH, ACTH, and LH/FSH) is other endocrine tissue. Thus, these four anterior pituitary hormones are themselves “releasing hormones” that trigger the secretion of specific hormones. For example, TSH causes the follicular cells in the thyroid gland to synthesize and release thyroid hormones. The mechanism by which the pituitary regulates these endocrine glands is discussed in detail in [Chapters 48](#) through [50](#).

TABLE 47-2
Hypothalamic and Pituitary Hormones

Anterior Pituitary			
Releasing (Inhibitory) Factor Made by Hypothalamus	Target Cell in Anterior Pituitary	Hormone Released by Anterior Pituitary	Target of Anterior Pituitary Hormone
GHRH (inhibited by somatostatin)	Somatotroph	GH	Stimulates IGF-1 production by multiple somatic tissues, especially liver
TRH	Thyrotroph	TSH	Thyroid follicular cells, stimulated to make thyroid hormone
CRH	Corticotroph	ACTH	Fasciculata and reticularis cells of the adrenal cortex, to make corticosteroids
GnRH	Gonadotroph	FSH	Ovarian follicular cells, to make estrogens and progestins Sertoli cells, to initiate spermatogenesis
GnRH	Gonadotroph	LH	Leydig cells, to make testosterone
(inhibited by dopamine)	Lactotroph	PRL	Mammary glands, initiates and maintains milk production

Posterior Pituitary		
Hormone Synthesized in Hypothalamus	Hormone Released into Posterior Pituitary	Target of Posterior Pituitary Hormone
AVP	AVP	Collecting duct, to increase water permeability
OT	OT	Uterus, to contract Mammary gland, to eject milk

GnRH, gonadotropin-releasing hormone; OT, oxytocin.

GH also acts as a releasing factor in that it regulates the production of another hormone, IGF-1. IGF-1 is made in principally *nonendocrine* tissues (e.g., liver, kidney, muscle, and cartilage). Nevertheless, IGF-1 in the circulation feeds back on the hypothalamus to decrease GHRH level and on the pituitary to inhibit GH secretion. In this respect, the GH–IGF-1 axis is similar to axes involving classic pituitary pathways, such as the thyrotropin-releasing hormone (TRH)–TSH axis.

Regulation of PRL secretion differs from that of other anterior pituitary hormones in that no endocrine feedback mechanism has yet been identified. In humans, the pituitary secretes **PRL** at relatively low levels throughout life. However, its major biological action is important only in women during lactation. Although PRL is not part of an identified *feedback* system, its release is controlled. Left to its own devices, the anterior pituitary would secrete high levels of PRL. However, secretion of PRL is normally inhibited by the release of dopamine (DA) from the hypothalamus (see [pp. 993–994](#)). During breast stimulation, neural afferents inhibit hypothalamic DA release, thus inhibiting release of the inhibitor and permitting lactation to proceed. PRL receptors are present on multiple tissues other than the breast. However, other physiological actions beyond lactation have not been well characterized.

The posterior pituitary regulates water balance and uterine contraction

Unlike the anterior pituitary, the posterior lobe of the pituitary is actually part of the brain. The posterior pituitary (or neurohypophysis) contains the nerve endings of *large*-diameter neurons whose cell bodies are in the supraoptic and paraventricular nuclei of the hypothalamus (see [Fig. 47-3](#)). Recall that the hypothalamic neurons that produce releasing factors, which act on “troph” cells in the anterior pituitary, are *small*-diameter neurons. The large-diameter hypothalamic neurons synthesize arginine vasopressin (AVP) and oxytocin and then transport these hormones along their axons to the site of release in the posterior pituitary. Thus, like the anterior pituitary, the posterior pituitary releases peptide hormones. Also as in the anterior pituitary, release of these hormones is under ultimate control of the hypothalamus.

However, the hypothalamic axons traveling to the posterior pituitary replace both the transport of releasing factors by the portal system of the anterior pituitary and the synthesis of hormones by the anterior pituitary “troph” cells. Although the posterior pituitary is part of the brain, it is one of the so-called circumventricular organs (see [pp. 284–285](#)) whose vessels breach the blood-brain barrier and allow the secreted AVP and oxytocin to reach the systemic circulation.

AVP (or antidiuretic hormone, ADH) is a neuropeptide hormone that acts on the collecting duct of the kidney to increase water reabsorption (see [pp. 817–820](#)). **Oxytocin (OT)** is the other neuropeptide secreted by the posterior pituitary. However, its principal biological action relates to stimulation of smooth-muscle contraction by the uterus during parturition (see [pp. 1145–1146](#)) and by the mammary gland during suckling (see [p. 1150](#)).

These two posterior pituitary hormones appear to have a common ancestor—vasotocin—in amphibians and other submammalian species. The two peptide hormones secreted by the posterior pituitary are each made by hypothalamic neurons as a precursor molecule that is transported along the axons of the hypothalamic neurons to the posterior pituitary. For AVP, this precursor protein is proneurophysin II (see [p. 845](#) and [Fig. 40-8](#)), whereas for oxytocin it is proneurophysin I. In each case, cleavage of the precursor occurs during transport along the axons from the hypothalamus to the posterior pituitary. At the time that the active neurohormone (e.g., AVP) is secreted, its residual neurophysin is co-secreted stoichiometrically. Defects in the processing of the neurophysin precursor can lead to impaired secretion of active hormone. In the case of AVP, the result is partial or complete diabetes insipidus.

Peptide Hormones

Specialized endocrine cells synthesize, store, and secrete peptide hormones

Organisms as primitive as fungi secrete proteins or peptides in an effort to respond to and affect their environment. In more complex organisms, peptide hormones play important developmental and other regulatory roles. Transcription of peptide hormones is regulated by both *cis*- and *trans*-acting elements (see p. 78). When transcription is active, the mRNA is processed in the nucleus and the capped message moves to the cytosol, where it associates with ribosomes on the rough endoplasmic reticulum. These peptides are destined for secretion because an amino-acid *signal sequence* (see p. 28) present near the N terminus targets the protein to the endoplasmic reticulum while the protein is still associated with the ribosome.

With minor modification, the **secretory pathway** illustrated in Figure 2-18 can describe the synthesis, processing, storage, and secretion of peptides by a wide variety of endocrine tissues. Once the protein is in the lumen of the endoplasmic reticulum, processing (e.g., glycosylation or further proteolytic cleavage) yields the mature, biologically active hormone. This processing occurs in a very dynamic setting. The protein is first transferred to the *cis*-Golgi domain, then through to the *trans*-Golgi domain, and finally to the membrane-bound secretory vesicle or granule in which the mature hormone is stored before secretion. This pathway is referred to as the **regulated pathway** of hormone synthesis because external stimuli can trigger the cell to release hormone that is stored in the secretory granule as well as to increase synthesis of additional hormone. For example, binding of GHRH to somatotrophs causes them to release GH.

A second pathway of hormone synthesis is the **constitutive pathway**. Here, secretion occurs more directly from the endoplasmic reticulum or vesicles formed in the *cis* Golgi. Secretion of hormone, both mature and partially processed, by the constitutive pathway is less responsive to secretory stimuli than is secretion by the regulated pathway.

In both the regulated and constitutive pathways, fusion of the vesicular membrane with the plasma membrane—exocytosis of the vesicular contents—is the final common pathway for hormone secretion. In general, the regulated pathway is capable of secreting much larger amounts of hormone—on demand—than is the constitutive pathway. However, even when stimulated to secrete its peptide hormone, the cell typically secretes only a very small amount of the total hormone present in the secretory granules. To maintain this secretory reserve, many endocrine cells increase the synthesis of peptide hormones in response to the same stimuli that trigger secretion.

Peptide hormones bind to cell-surface receptors and activate a variety of signal-transduction systems

Once secreted, most peptide hormones exist free in the circulation. As noted above, this lack of binding proteins contrasts with the situation for steroid and thyroid hormones, which circulate bound to plasma proteins. IGF-1 and IGF-2 are an exception to this rule: at least six plasma proteins bind these peptide growth factors.

While traversing the circulation, peptide hormones encounter receptors on the surface of target cells. These receptors are intrinsic membrane proteins that bind the hormone with very high affinity (typically,

K_D ranges from 10^{-8} to 10^{-12} M). Examples of several types of peptide hormone receptors are shown in [Figure 47-4](#). Each of these receptors has already been introduced in [Chapter 3](#). The primary sequence of most peptide hormone receptors is known from molecular cloning, mutant receptors have been synthesized, and the properties of native and mutant receptors have been compared to assess primary structural requirements for receptor function. Despite this elegant work, too little information is available on the three-dimensional structure of these membrane proteins for us to know just how the message that a hormone has bound to the receptor is transmitted to the internal surface of the cell membrane. However, regardless of the details, occupancy of the receptor can activate many different intracellular signal-transduction systems ([Table 47-3](#)) that transfer the signal of cell activation from the internal surface of the membrane to intracellular targets. The receptor provides the link between a specific extracellular hormone and the activation of a specific signal-transduction system. We discussed each of these signal-transduction systems in [Chapter 3](#). Here, we briefly review the various signal-transduction systems through which peptide hormones act.

FIGURE 47-4 Receptors and downstream effectors for peptide hormones. AC, adenylyl cyclase.

TABLE 47-3

Peptide Hormones and Their Signal-Transduction Pathways

AGONISTS	RECEPTOR	LINKED ENZYME	SECOND MESSENGER
PTH	Coupled to $G\alpha_s$	Adenylyl cyclase	cAMP
ANG II	Coupled to $G\alpha_i$	Adenylyl cyclase (inhibited)	cAMP
AVP, ANG II, TRH	Coupled to $G\alpha_q$	PLC	IP_3 and DAG
ANG II	Coupled to G_i/G_o	PLA_2	Arachidonic acid metabolites
ANP	Guanylyl cyclase	Guanylyl cyclase	cGMP
Insulin, IGF-1, IGF-2, EGF, PDGF	Tyrosine kinase	Tyrosine kinase	Phosphoproteins
GH, erythropoietin, LIF	Associated with tyrosine kinase	JAK/STAT family of tyrosine kinases	Phosphoproteins

ANG II, angiotensin II; ANP, atrial natriuretic peptide; EGF, epidermal growth factor; LIF, leukemia inhibitory factor; STAT, signal transducer and activator of transcription.

G Proteins Coupled to Adenylyl Cyclase

cAMP, the prototypical second messenger, was discovered during an investigation of the action of glucagon on glycogenolysis in the liver. In addition to playing a role in hormone action, cAMP is involved in such diverse processes as lymphocyte activation, mast cell degranulation, and even slime mold aggregation.

As summarized in [Figure 47-4A](#), binding of the appropriate hormone (e.g., PTH) to its receptor initiates a cascade of events (see [pp. 56–57](#)): (1) activation of a heterotrimeric G protein (α_s or α_i); (2) activation (by α_s) or inhibition (by α_i) of a membrane-bound adenylyl cyclase; (3) formation of intracellular cAMP from ATP, catalyzed by adenylyl cyclase; (4) binding of cAMP to the enzyme protein kinase A (PKA); (5) separation of the two catalytic subunits of PKA from the two regulatory subunits; (6) phosphorylation of *serine* and *threonine* residues on a variety of cellular enzymes and other proteins by the free catalytic subunits of PKA that are no longer restrained; and (7) modification of cellular function by these phosphorylations. The activation is terminated in two ways. First, phosphodiesterases in the cell degrade cAMP. Second, *serine/threonine*-specific phosphoprotein phosphatases can dephosphorylate enzymes and proteins that had previously been phosphorylated by PKA ([Box 47-2](#)).

Box 47-2

Pseudohypoparathyroidism

Inasmuch as G proteins are part of the signaling system involved in large numbers of hormone responses, molecular alterations in G proteins could be expected to affect a number of signaling systems. In the disorder **pseudohypoparathyroidism**, the key defect is an abnormality in a stimulatory α subunit (α_s) of a heterotrimeric G protein. The result is an impairment in the ability of PTH to regulate body calcium and phosphorus homeostasis (see pp. 1058–1063). Patients with this disorder have a low serum calcium level and high serum phosphate level, just like patients whose parathyroid glands have been surgically removed. However, patients with pseudohypoparathyroidism have **increased** circulating concentrations of PTH; the hormone simply cannot act normally on its target tissue, hence the term *pseudohypoparathyroidism*. These individuals also have an increased risk of hypothyroidism, as well as of gonadal dysfunction. These additional endocrine deficiencies arise from the same defect in signaling.

G Proteins Coupled to Phospholipase C

As summarized in [Figure 47-4B](#), binding of the appropriate peptide hormone (e.g., AVP) to its receptor initiates the following cascade of events (see [pp. 58–61](#)): (1) activation of $G\alpha_q$; (2) activation of a membrane-bound phospholipase C (PLC); and (3) cleavage of phosphatidylinositol 4,5-bisphosphate (PIP_2) by this PLC, with the generation of *two* signaling molecules, inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG).

The IP_3 fork of the pathway includes (4a) binding of IP_3 to a receptor on the cytosolic surface of the endoplasmic reticulum; (5a) release of Ca^{2+} from internal stores, which causes $[Ca^{2+}]_i$ to rise by several-fold; and (6a) activation of Ca^{2+} -dependent kinases (e.g., Ca^{2+} -calmodulin-dependent protein kinases, protein kinase C [PKC]) by the increases in $[Ca^{2+}]_i$.

The DAG fork of the pathway includes (4b) allosteric activation of PKC by DAG (the activity of this enzyme is also stimulated by the increased $[Ca^{2+}]_i$); and (5b) phosphorylation of a variety of proteins by PKC, which is activated in the plane of the cell membrane. An example of a hormone whose actions are in part mediated by DAG is TSH.

G Proteins Coupled to Phospholipase A_2

As summarized in [Figure 47-4C](#), some peptide hormones (e.g., TRH) activate phospholipase A_2 (PLA_2) through the following cascade (see [pp. 58–61](#)): (1) activation of $G\alpha_q$ or $G\alpha_{11}$, (2) stimulation of membrane-bound PLA_2 by the activated $G\alpha$, (3) cleavage of membrane phospholipids by PLA_2 to produce lysophospholipid and arachidonic acid, and (4) conversion—by several enzymes—of arachidonic acid into a variety of biologically active eicosanoids (e.g., prostaglandins, prostacyclins, thromboxanes, and leukotrienes).

Guanylyl Cyclase

Other peptide hormones (e.g., atrial natriuretic peptide) bind to a receptor (see [Fig. 47-4D](#)) that is itself a guanylyl cyclase that converts cytoplasmic GTP to cGMP (see [pp. 66–67](#)). In turn, cGMP can activate cGMP-dependent kinases, phosphatases, or ion channels.

Receptor Tyrosine Kinases

For some peptide hormones, notably insulin and IGF-1 and IGF-2, the hormone receptor (see [Fig. 47-4E](#)) itself possesses tyrosine kinase activity (see [pp. 68–70](#)). This is also a property of other growth factors, including PDGF and epidermal growth factor. Occupancy of the receptor by the appropriate hormone increases kinase activity. For the insulin and IGF-1 receptor, as well as for others, this kinase autophosphorylates tyrosines within the hormone receptor, as well as substrates within the cytosol, thus initiating a cascade of phosphorylation reactions.

Tyrosine Kinase–Associated Receptors

Some peptide hormones (e.g., GH) bind to a receptor that, when occupied, activates a cytoplasmic tyrosine kinase (see [Fig. 47-4F](#)), such as a member of the JAK (Janus kinase, or just another kinase) family of kinases (see [pp. 70–71](#)). As for the receptor tyrosine kinases, activation of these receptor-associated kinases initiates a cascade of phosphorylation reactions.

Amine Hormones

Amine hormones are made from tyrosine and tryptophan

Four major amine hormones are recognized. The adrenal medulla makes the catecholamine hormones **epinephrine** and **norepinephrine** from the amino acid tyrosine (see Fig. 13-8C). These hormones are the principal active amine hormones made by the endocrine system. In addition to acting as a hormone, norepinephrine also serves as a neurotransmitter in the CNS (see p. 312) and in postganglionic sympathetic neurons (see pp. 342–343). **Dopamine**, which is also synthesized from tyrosine, acts as a neurotransmitter in the CNS (see p. 313); it is synthesized in other tissues, but its functional role outside the nervous system is not well clarified. Finally, the hormone **serotonin** is made from tryptophan (see Fig. 13-8B) by endocrine cells that are located within the gut mucosa. Serotonin appears to act locally to regulate both motor and secretory function in the gut, and also acts as a neurotransmitter in the CNS (see pp. 312–313).

The human **adrenal medulla** secretes principally epinephrine (see pp. 1030–1033). The final products are stored in vesicles called **chromaffin granules**. Secretion of catecholamines by the adrenal medulla appears to be mediated entirely by stimulation of the sympathetic division of the autonomic nervous system (see p. 343). Unlike the situation for many peptide hormones, in which the circulating concentration of the hormone (e.g., TSH) negatively feeds back on secretion of the releasing hormone (e.g., TRH), the amine hormones do not have such a hierarchic feedback system. Rather, the feedback of amine hormones is indirect. The higher control center does not sense circulating levels of the amine hormones (e.g., epinephrine) but rather a physiological end effect of that amine hormone (e.g., blood pressure; see pp. 534–536). The sensor of the end effect may be a peripheral receptor (e.g., stretch receptor) that communicates to the higher center (e.g., the CNS), and the efferent limb is the sympathetic outflow that determines release of the amine.

Serotonin (5-hydroxytryptamine, or 5-HT), in addition to being an important neurotransmitter in the CNS (see pp. 312–313 and Fig. 13-7B), is a hormone made by **neuroendocrine cells**, principally located within the lining of the small intestine and larger bronchi. Unlike the other hormones that we discuss in this chapter, serotonin is not made by a specific gland. Little is known about feedback regulation or even regulation of secretion of this hormone. Serotonin arouses considerable clinical interest because of the dramatic clinical presentation of patients with unusual tumors—called **carcinoid tumors**—of serotonin-secreting cells. Individuals with these tumors frequently present with *carcinoid syndrome*, characterized by episodes of spontaneous intense flushing in a typical pattern involving the head and neck and associated with diarrhea, bronchospasm, and occasionally right-sided valvular heart disease. The primary tumors involved can occur within the intestinal tract, in the bronchial tree, or more rarely at other sites.

Amine hormones act via surface receptors

Once secreted, circulating epinephrine is free to associate with specific adrenergic receptors, or **adrenoceptors**, located on the surface membranes of target cells. Numerous types of adrenoceptors exist and are generically grouped as α or β , each of which has several subtypes (see Table 14-2). Epinephrine has a greater affinity for β -adrenergic receptors than for α -adrenergic receptors, whereas norepinephrine acts predominantly through α -adrenergic receptors. All adrenoceptors that have been isolated from a

variety of tissues and species are classic G protein–coupled receptors (GPCRs). β -adrenergic stimulation occurs through the adenylyl cyclase system. The α_2 receptor also usually acts through adenylyl cyclase. However, α_1 -adrenergic stimulation is linked to $G\alpha_q$, which activates a membrane-associated PLC that liberates IP_3 and DAG. IP_3 can release Ca^{2+} from intracellular stores, and DAG directly enhances the activity of PKC. Combined, these actions enhance the cellular activity of Ca^{2+} -dependent kinases, which produce a metabolic response that is characteristic of the specific cell.

As indicated in Figure 47-5, the intracellular action of a specific catecholamine is determined by the complement of receptors present on the surface of a specific cell. For example, when epinephrine binds to the β_1 -adrenergic receptor, it activates a $G\alpha_s$ protein, which stimulates adenylyl cyclase, promotes increases in $[cAMP]_i$, and thus enhances the activity of PKA (see Table 14-2). In contrast, when the same hormone binds to a cell displaying principally α_2 receptors, it activates a $G\alpha_i$ protein, which inhibits adenylyl cyclase, diminishes $[cAMP]_i$, and therefore reduces PKA activity. Thus, the response of a specific cell to adrenergic stimulation (whether via circulating epinephrine or via norepinephrine released locally by sympathetic neurons) depends on the receptor repertoire displayed by the cell. As a result, the response to adrenergic agonists varies among tissues; for example, glycogenolysis in the liver or muscle (predominantly a β effect), contraction (an α_1 effect) or relaxation (a β_2 effect) in vascular smooth muscle, or a change in the inotropic or chronotropic state of the heart (a β_1 effect).

FIGURE 47-5 Catecholamine receptors. The β_1 , β_2 , and D1 receptors all interact with $G\alpha_s$, which activates adenylyl cyclase (AC) and raises levels of cAMP. The α_2 and D2 receptors interact with $G\alpha_i$, which inhibits AC. Additionally, the α_1 receptor interacts with $G\alpha_q$, which activates PLC, which in turn converts phosphoinositides in the cell membrane to IP_3 and DAG.

Dopamine also can interact with several GPCRs. The D1 receptor is coupled to $G\alpha_s$ and the D2 receptor is linked to $G\alpha_i$.

Steroid and Thyroid Hormones

Cholesterol is the precursor for the steroid hormones: cortisol, aldosterone, estradiol, progesterone, and testosterone

Members of the family of hormones called **steroids** share a common biochemical parentage: all are synthesized from cholesterol. Only two tissues in the body possess the enzymatic apparatus to convert cholesterol to active hormones. The **adrenal cortex** makes cortisol (the main glucocorticoid hormone), aldosterone (the principal mineralocorticoid in humans), and androgens. The **gonads** make either estrogen and progesterone (ovary) or testosterone (testis). In each case, production of steroid hormones is regulated by trophic hormones released from the pituitary. For aldosterone, the renin-angiotensin system also plays an important regulatory role.

The pathways involved in steroid synthesis are summarized in [Figure 47-6](#). Cells that produce steroid hormones can use, as a starting material for hormone synthesis, the cholesterol that is circulating in the blood in association with low-density lipoprotein (LDL; see [p. 968](#)). Alternatively, these cells can synthesize cholesterol de novo from acetate (see [Fig. 46-16](#)). In humans, LDL cholesterol appears to furnish ~80% of the cholesterol used for steroid synthesis (see [Fig. 47-6](#)). An LDL particle contains both free cholesterol and cholesteryl esters, in addition to phospholipids and protein. The cell takes up this LDL particle via the LDL receptor and receptor-mediated endocytosis (see [p. 42](#)) into clathrin-coated vesicles. Lysosomal hydrolases then act on the cholesteryl esters to release free cholesterol. The cholesterol nucleus, whether taken up or synthesized de novo, subsequently undergoes a series of reactions that culminate in the formation of **pregnenolone**, the common precursor of all steroid hormones. Via divergent pathways, pregnenolone is then further metabolized to the major steroid hormones: the mineralocorticoid aldosterone (see [Fig. 50-2](#)), the glucocorticoid cortisol (see [Fig. 50-2](#)), the androgen testosterone (see [Fig. 54-6](#)), and the estrogen estradiol (see [Fig. 55-8](#)).

FIGURE 47-6 Uptake of cholesterol and synthesis of steroid hormones from cholesterol. The cholesterol needed as the starting material in the synthesis of steroid hormones comes from two sources. Approximately 80% is taken up as LDL particles via receptor-mediated endocytosis. The cell synthesizes the remaining cholesterol de novo from acetyl coenzyme A (Acetyl CoA). Apo B-100, apolipoprotein B-100; VLDL, very-low-density lipoprotein.

Unlike the peptide and amine hormones considered above, steroid hormones are not stored in secretory vesicles before their secretion (Table 47-4). For these hormones, synthesis and secretion are very closely linked temporally. Steroid-secreting cells are capable of increasing the secretion of steroid hormones many-fold within several hours. The lack of a preformed storage pool of steroid hormones does not appear to limit the effectiveness of these cells as an endocrine regulatory system. Furthermore, steroid hormones, unlike peptide and amine hormones, mediate nearly all their actions on target tissues by regulating gene transcription. As a result, the response of target tissues to steroids typically occurs over hours to days.

TABLE 47-4

Differences Between Steroid and Peptide/Amine Hormones

PROPERTY	STEROID HORMONES	PEPTIDE/AMINE HORMONES
Storage pools	None	Secretory vesicles
Interaction with cell membrane	Diffusion through cell membrane	Binding to receptor on cell membrane
Receptor	In cytoplasm or nucleus	On cell membrane
Action	Regulation of gene transcription (primarily)	Signal-transduction cascade(s) that affect a variety of cell processes
Response time	Hours to days (primarily)	Seconds to minutes

Like cholesterol itself, steroid hormones are poorly soluble in water. On their release into the circulation, some steroid hormones associate with specific binding proteins (e.g., cortisol-binding globulin) that transport the steroid hormones through the circulatory system to their target tissues. The presence of these binding proteins, whose concentration in the circulation can change in response to a variety of physiological conditions, can complicate efforts to measure the amount of active steroid hormone in the circulation.

Steroid hormones bind to intracellular receptors that regulate gene transcription

Steroid hormones appear to enter their target cell by simple diffusion across the plasma membrane (Fig. 47-7). Once within the cell, steroid hormones are bound with high affinity (K_D in the range of 1 nM) to receptor proteins located in the cytosol or the nucleus. As detailed in Chapter 4, binding of steroid hormone to its receptor results in a change in the receptor conformation so that the “active” receptor-hormone complex now binds with high affinity to specific DNA sequences called **hormone response elements** (see p. 90) or **steroid response elements (SREs)**, also called sterol regulatory elements. These sequences are within the 5' region of target genes whose transcription is regulated by the specific steroid hormone–receptor complex. *Termination* of gene regulation by the steroid hormone–receptor complex is not as well understood as *initiation* of the signal. The receptor protein may be modified in a manner that permits dissociation of the hormone and DNA. The receptor itself could then be recycled and the steroid molecule metabolized or otherwise cleared from the cell.

FIGURE 47-7 Action of steroid hormones. The activated steroid hormone receptor binds to specific stretches of DNA called steroid response elements (SREs), which stimulates the transcription of appropriate genes. hsp, heat shock protein.

Steroid receptors are monomeric phosphoproteins with a molecular weight that is between 80 and 100 kDa. A remarkable similarity is seen among receptors for the glucocorticoids, sex steroids, retinoic acid, the steroid-like vitamin 1,25-dihydroxyvitamin D, and thyroid hormone. The genes encoding the receptors for these diverse hormones are considered part of a gene superfamily (see pp. 71–72). Each of these receptors has a similar modular construction with six domains (A through F). The homology among receptors is especially striking for the C domain, particularly the C1 subdomain, which is the part of the receptor molecule that is responsible for binding to DNA (see Fig. 3-14).

Steroid hormone receptors dimerize on binding to their target sites on DNA. Dimerization appears essential for the regulation of gene transcription. Within the C1 DNA-binding domain of the steroid receptor monomer are two zinc fingers that are involved in binding of the receptor to DNA (see p. 82). Even receptors with very different biological actions have a striking sequence similarity in this domain of the receptor. Because the specificity with which genes are regulated by a specific steroid receptor arises from the specificity of the DNA-binding domain, mutations in this region can greatly alter hormone function. For example, substitution of two amino acids in the *glucocorticoid* receptor causes the mutated

glucocorticoid receptor to bind to DNA to which the *estrogen* receptor normally binds. In such a system, a glucocorticoid could have an estrogen-like effect.

The activated steroid receptor, binding as a dimer to SREs in the 5' region of a gene, regulates the rate of transcription of that gene. Each response element is identifiable as a consensus sequence of nucleotides, or a region of regulatory DNA in which the nucleotide sequences are preserved through different cell types. The effect of gene regulation by activated steroid receptors binding to an SRE is dramatically illustrated by the chick ovalbumin gene. Chicks that are not exposed to estrogen have approximately four copies of the ovalbumin mRNA per cell in the oviduct. A 7-day course of estrogen treatment increases the number of copies of message 10,000-fold! This increase in message is principally the result of an increased rate of gene transcription. However, steroid hormones can also stabilize specific mRNA molecules and increase their half-life. [N47-2](#)

N47-2

Stabilization of mRNA by Estrogen

Contributed by Gene Barrett

For example, in frogs, estrogen increases the half-life of the mRNA for vitellogen (which is formed by *Xenopus* liver) from <20 hours to ~500 hours.

The 5' flanking region of the gene typically has one or more SREs upstream of the TATA box, a nucleotide sequence rich in adenine and thymine that is located near the starting point for transcription (see [p. 78](#)). The activated steroid hormone receptors recognize these SREs from their specific consensus sequences. For example, one particular consensus sequence designates a site as a *glucocorticoid* response element if the SRE is in a cell with a glucocorticoid receptor. This same consensus sequence in a cell of the endometrium would be recognized by the activated *progesterone* receptor or, in the renal distal tubule, by the activated *mineralocorticoid* receptor. The specificity of the response thus depends on the cell's expression of particular steroid receptors, not simply the consensus sequence. For example, the renal distal tubule cell expresses relatively more mineralocorticoid receptors than it does progesterone receptors when compared with the endometrium. As a result, changes in plasma aldosterone regulate Na^+ reabsorption in the kidney with greater sensitivity than does circulating progesterone. However, very high levels of progesterone can, like aldosterone, promote salt reabsorption.

From the foregoing it should be apparent that the specificity of response of a tissue to steroid hormones depends on the abundance of specific steroid receptors expressed within a cell. Because all somatic cells have the full complement of DNA with genes possessing SREs, whether a cell responds to circulating estrogen (e.g., breast), androgen (e.g., prostate), or mineralocorticoid (e.g., renal collecting duct) depends on the receptors present in the cell. This specificity raises the obvious, but as yet unanswered, question of what regulates the expression of specific steroid receptors by specific tissues.

Within a given tissue, several factors control the concentration of steroid hormone receptors. In the cytosol of all steroid-responsive tissues, steroid receptor levels usually drop dramatically immediately after exposure of the tissue to the agonist hormone. This decrease in receptor level is the result of net movement of the agonist-receptor complex to the nucleus. Eventually, the cytosolic receptors are repopulated. Depending on the tissue, this repopulation may involve new synthesis of steroid hormone receptors or simply recycling of receptors from the nucleus after dissociation of the agonist from the receptor. In addition, some steroids reduce the synthesis of their own receptor in target tissues. For

example, progesterone reduces the synthesis of progesterone receptor by the uterus, thus leading to an overall net reduction or downregulation of progesterone receptor concentration in a target tissue. An interesting observation in this regard is that the genes for steroid receptor proteins do *not* appear to have SREs in their 5' flanking region. Thus, this regulation of receptor number probably involves *trans*-acting transcriptional factors other than the steroid hormones themselves.

Other factors that affect the concentration of steroid receptors in target tissues include the state of differentiation of the tissue, the presence of other hormones that affect steroid receptor synthesis, and whether the steroid hormone has previously stimulated the tissue. For example, estrogen receptor concentrations are low in an unstimulated uterus but rise dramatically in an estrogen-primed uterus (receptor upregulation). Regulation of steroid receptor number is clearly one factor that alters overall tissue sensitivity to these hormones ([Box 47-3](#)).

Box 47-3

Quantitation of Steroid Receptors in Patients with Cancer

The affinity of steroid molecules for their receptors can be studied *in vitro* in a manner analogous to that described for the radioimmunoassay of peptide hormones (see Fig. 47-1). In a typical immunoassay, an antibody with high affinity for a hormone or other compound binds to a radioactively labeled hormone or other molecule. A sample containing an unknown amount of the compound to be measured is added to the antibody-labeled hormone mixture and displaces the radioisotope from the antibody in proportion to the concentration of the unknown. The amount of unknown can be quantitated by comparison to the displacing activity of known standards.

For quantitating *steroid receptors*, cell extracts containing an unknown amount of steroid receptors are incubated with increasing concentrations of labeled steroid hormone. At each concentration, hormone that is bound by the receptor is separated from that remaining free in the extract. The result is a saturation curve (Fig. 47-8A), provided the tissue extract has a finite number of specific hormone receptors. This saturation curve can often be linearized by a simple arithmetic manipulation called a *Scatchard plot* (see Fig. 47-8B). This analysis allows quantitation of the affinity of the receptor for the hormone and provides an estimate of the number of receptors (actually, the *concentration* of receptors) for that particular hormone.

A SATURATION CURVE**B SCATCHARD PLOT**

FIGURE 47-8 Quantitating receptor affinity and number of receptors. **A**, A plot of bound hormone (i.e., hormone-receptor complex) on the y-axis versus free steroid concentration on the x-axis. In this example, we have assumed that the K_D for hormone binding is 3 nM and that the maximal bound-hormone concentration is 0.5 nM. **B**, This plot is a transformation of the data in **A**. The colored points in the plot match the points of like color in **A**. Plotted on the y-axis is the ratio of [bound hormone] to [free hormone]. Plotted on the x-axis is [bound hormone]. The slope of this relationship gives the $-1/K_D$, where K_D is the dissociation constant (3 nM). The x-axis intercept gives the total number of receptors (0.5 nM).

The technique of quantitating receptor number has found an important application in determining the number of estrogen and progesterone receptors present in breast cancer cells. The number of estrogen and progesterone receptors per milligram of breast cancer tissue (obtained by biopsy of the breast or involved lymph node) is quantitated with radiolabeled estrogen (or progesterone). For postmenopausal women with estrogen receptor-positive breast cancer (i.e., a tumor with a high level of estrogen receptors), treatment with an antiestrogen (e.g., tamoxifen) is effective therapy. For premenopausal women, an antiestrogen may be used as well, or the ovaries can be removed surgically. The woman might be given an aromatase inhibitor that blocks estradiol synthesis or a long-acting gonadotropin-releasing hormone (GnRH) agonist, which paradoxically blocks both LH and FSH production by the anterior pituitary and thereby reduces estradiol production and accomplishes a medical oophorectomy. The continuous (as opposed to the normally pulsatile) administration of GnRH downregulates GnRH receptors in the anterior pituitary (see Box 55-2).

These therapies are not effective in patients with cancers that do not express significant numbers of estrogen receptors. The presence of abundant estrogen and progesterone receptors in breast tumors correlates with a more favorable prognosis, possibly because of the relatively advanced state of differentiation of the tumor, as well as the tumor's responsiveness to manipulation by estrogen or progesterone therapy.

Thyroid hormones bind to intracellular receptors that regulate metabolic rate

In many respects, the thyroid gland and thyroid hormone are unique among the classic endocrine axes. In [Chapter 49](#), we will see that this uniqueness begins with the structure of the thyroid gland, which is composed of follicles. Each follicle is an epithelial monolayer encircling a protein-rich fluid. The principal protein component of the follicular fluid is an extremely large protein, thyroglobulin. Neither of the two thyroid hormones— T_4 nor T_3 —is free in the follicular fluid. Rather, these hormones are formed by the iodination of tyrosine residues within the primary structure of the thyroglobulin molecule.

T_4 and T_3 remain part of the thyroglobulin molecule in the follicle lumen until thyroid secretion is

stimulated. The entire thyroglobulin molecule then undergoes endocytosis by the follicular cell and is degraded within the lysosomes of these cells. Finally, the follicular cell releases the free T_4 and T_3 into the circulation. Once secreted, T_4 is tightly bound to one of several binding proteins. It is carried to its sites of action, which include nearly all the cells in the body. In the process of this transport, the liver and other tissues take up some of the T_4 and partially deiodinate it to T_3 ; this T_3 can then re-enter the circulation.

Both T_3 and T_4 enter target cells and bind to cytosolic and nuclear receptors. These receptors are similar to those for steroid hormones (see pp. 71–72). T_3 has higher affinity than T_4 for the thyroid hormone receptor. Even though it accounts for only ~5% of the circulating thyroid hormone, T_3 is probably the main effector of thyroid hormone signaling. The activated thyroid hormone receptor binds to thyroid hormone response elements in the 5' region of responsive genes and regulates the transcription of multiple target genes.

Thyroid hormone receptors are present in many tissues, including the heart, vascular smooth muscle, skeletal muscle, liver, kidney, skin, and CNS. A major role for thyroid hormone is overall regulation of metabolic rate. Because T_4 affects multiple tissues, individuals affected by disorders involving oversecretion or undersecretion of thyroid hormone manifest a host of varied symptoms that reflect the involvement of multiple organ systems.

Steroid and thyroid hormones can also have nongenomic actions

A central dogma has been that all the diverse actions of steroid and thyroid hormones are due to genomic regulation. However, the very rapid onset of some effects (occurring within 2 to 15 minutes) appear incompatible with a mechanism requiring new protein synthesis. Such accumulating evidence suggests that steroid and thyroid hormones can bind to receptors that modulate the activity of cytosolic proteins and thereby regulate their activity or behavior via a *nongenomic* action. An example is the binding of extracellular estrogen or aldosterone to the GPCR called **GPR30**, also known as the G-protein estrogen receptor (GPER). Receptor occupancy rapidly activates $G\alpha_s$ and then adenylyl cyclase (see p. 53), thereby raising $[cAMP]_i$ and stimulating PKA (see p. 57). In addition, GPR30 indirectly activates the epidermal growth factor receptor (EGFR), a receptor tyrosine kinase (see pp. 68–70), and some of its downstream effectors, such as **phosphatidylinositol 3-kinase (PI3K)** (see pp. 69–70) and the **mitogen-activated protein kinases (MAPKs)** (see pp. 68–69). Besides estrogen and aldosterone, other ligands of nuclear receptors have nongenomic actions: thyroid hormones, testosterone, and glucocorticoids.

CHAPTER 48

Endocrine Regulation of Growth and Body Mass

Eugene J. Barrett

Growth from the fertilized ovum to the adult is an exceedingly complex process involving both **hyperplasia** (an increase in the number of cells) and **hypertrophy** (an increase in the size of cells) as well as turnover of the cellular elements of body tissues. The timing and capacity for cell division vary among tissues. In the human central nervous system (CNS), neuronal division is essentially complete by 1 year of age, whereas bone, muscle, and fat cells continue to divide until later in childhood. Other tissues—such as skin, blood, and liver—retain the capacity for hyperplasia throughout life.

In humans, the genetic contribution to growth is evident from the observation that midparental height (i.e., the average of paternal and maternal heights) is one of the better predictors of a child's ultimate stature. For domestic animals, breeding based on desired growth characteristics has been a mainstay of animal husbandry for millennia. For humans, in whom such planned breeding does not occur, body-height differences among different populations suggest a genetic contribution. Even more striking are some of the differences seen with specific genetic mutations that affect skeletal growth (e.g., achondroplasia). The basis of these population height differences, and those related to genetic syndromes, is beyond the scope of this chapter. Rather we will focus on nutritional and hormonal processes in which physiological regulation appears to play an important role across individuals. The impact of environmental and nutritional factors, such as emotional or nutritional deprivation, on growth is most profound when it occurs during periods of tissue hyperplasia, most critically during the first 2 years of life.

In this chapter, the first two subchapters deal with factors that affect **linear growth**, whereas the third deals with factors that regulate **body mass**. This division is somewhat artificial because changes in linear growth and body mass often occur simultaneously. The control of linear growth in humans depends on multiple hormones, including growth hormone (GH), insulin-like growth factors 1 and 2 (IGF-1 and IGF-2), insulin, thyroid hormones, glucocorticoids, androgens, and estrogens. Among these, GH and IGF-1 have been implicated as the major determinants of growth in normal postuterine life. However, deficiencies (or excesses) of each of the other hormones can seriously affect the normal growth of the musculoskeletal system as well as the growth and maturation of other tissues. The control of body mass depends on many newly discovered humoral factors made in adipose tissue, intestine, hypothalamus, and other tissues that regulate appetite and energy expenditure.

Growth Hormone

GH, secreted by somatotrophs in the anterior pituitary, is the principal endocrine regulator of growth

Individuals with excessive GH secretion during childhood develop **gigantism**, and those with a deficiency of GH develop **pituitary dwarfism**. It is thus quite clear that GH profoundly affects somatic size. Dramatic examples of the somatotrophic action of GH can be found in the descriptions of General Tom Thumb N48-1 and the Alton giant. GH deficiency resulted in Tom Thumb's achieving an adult height of ~1.0 m. In contrast, the Alton giant had a GH-secreting pituitary tumor present from early childhood and reached an adult height of >2.7 m. It is important that, in both cases, the abnormality of GH secretion was present from early life. Children with GH deficiency are of normal size at birth and only subsequently fall behind their peers in stature.

N48-1

General Tom Thumb

Contributed by Emile Boulpaep, Walter Boron

Charles S. Stratton (1838–1883), whose stage name was General Tom Thumb, was a famous performer in the P.T. Barnum circus. Stratton's maternal and paternal grandmothers were twin sisters of short stature. At birth, Stratton was somewhat larger than average (4.3 kg, or 9 pounds, 8 ounces) and he continued to grow normally until about 6 months of age, when he was 64 cm (25 inches) tall and weighed 6.8 kg (15 pounds). After that, he virtually ceased to grow for several years, although he was otherwise completely normal. He had siblings of normal size.

At the age of 9, Stratton began to grow very slowly, reaching the height of 74 cm (2 feet, 5 inches) at age 13 and 82.6 cm (2 feet, 8.5 inches) at age 18. At age 25, Stratton married Mercy Lavinia Bumpus (stage name, Lavinia Warren), who was also a short person. They had no children, and the cause of Stratton's short stature is not known.

The American circus impresario P.T. Barnum heard of Stratton and recruited him for his circus when Stratton was age 5. Barnum coached Stratton, who became a song-and-dance man and comedian. Tours of both the United States and Europe were great successes, and Stratton became an international celebrity and, under the guidance of Barnum, a wealthy man.

A deficiency of GH beginning in adult life does not result in any major clinical illness. However, it is now appreciated that *replacement* of GH (clinically available as a recombinant protein) in adults with

GH deficiency leads to increased lean body mass, decreased body fat, and perhaps an increased sense of vigor or well-being. An *excess* of GH after puberty results in the clinical syndrome of **acromegaly** (from the Greek *akron* [top] + *megas* [large]). This condition is characterized by the growth of bone and many other somatic tissues, including skin, muscle, heart, liver, and the gastrointestinal (GI) tract. The lengthening of long bones is not part of the syndrome because the epiphyseal growth plates close at the end of puberty. Thus, acromegaly causes a progressive thickening of bones and soft tissues of the head, hands, feet, and other parts of the body. If untreated, these somatic changes cause significant morbidity and shorten life as a result of joint deformity, hypertension, pulmonary insufficiency, and heart failure.

GH is made by **somatotrophs** throughout the anterior pituitary (see [pp. 978–979](#)). Like other peptide hormones, GH is synthesized as a larger “prehormone” ([Fig. 48-1](#)). During processing through the endoplasmic reticulum and Golgi system, several small peptides are removed. GH exists in at least three molecular forms. The predominant form is a 22-kDa polypeptide with two intramolecular sulfhydryl bonds. Alternative splicing generates a 20-kDa form of GH. Other GH forms include a 45-kDa protein, which is a dimer of the 22-kDa form, as well as larger forms that are multimers of monomeric GH. There is little information to suggest that the different principal forms of GH (i.e., the 20- and 22-kDa versions) vary in their activity, but the 20-kDa form may exert fewer of the acute metabolic actions of GH. Once synthesized, GH is stored in secretory granules in the cytosol of the somatotrophs until secreted.

FIGURE 48-1 Synthesis of GH. Somatotrophic cells in the anterior pituitary are responsible for the synthesis of GH. The cell transcribes five exons to form GH mRNA for either the 22-kDa protein (191 amino acids) or the 20-kDa protein (176 amino acids). Alternative splicing in the third exon, which removes the RNA-encoding amino acids 32 to 46, is responsible for the two isoforms found in the pituitary. Both mRNAs have a signal sequence that causes them to be translated in the rough endoplasmic reticulum (ER) and enter the secretory pathway. Subsequent processing converts the two pre-pro-GHs first to the pro-GHs and then to the mature GHs. The cleavage of the pro sequence and disulfide-bond formation occur during transit through the Golgi bodies. The somatotroph stores mature GH in granules until GHRH

GH is in a family of hormones with overlapping activity

GH appears to be a single-copy gene, but four other hormones have significant homology to GH. Most striking are three hormones made by the placenta: placental-variant GH (pvGH) and human chorionic somatomammotropins 1 and 2 (hCS1 and hCS2; [Table 48-1](#)). Human genes for these hormones are located in the GH gene cluster on the long arm of chromosome 17. The multiple genes in this cluster have an identical intron structure and encode proteins of similar size with substantial amino-acid sequence homology.

TABLE 48-1
Homology of GH to Chorionic Hormones and Prolactin

HORMONE	NUMBER OF AMINO ACIDS	HOMOLOGY (%)	CHROMOSOME
hGH (human growth hormone)	191	100	17
pvGH (placental-variant GH)	191	93	17
hCS1 (human chorionic somatomammotropin 1)	191	84	17
hCS2 (human chorionic somatomammotropin 2)	191	84	17
hPRL (human prolactin)	199	16	6

pvGH is a 191–amino-acid peptide that is 93% identical to the 22-kDa form of GH. With virtually the same affinity as GH for the hepatic GH receptor, pvGH mimics some of the biological actions of GH and may be an important modulator of systemic IGF-1 production during pregnancy. (As discussed below, a major action of GH is to stimulate secretion of IGF-1.)

The **hCSs** are also called human placental lactogens (hPLs). The affinity of the two forms of hCS for the GH receptor is 100- to 1000-fold less than that of either GH or pvGH. As a result, the hCSs are less effective in promoting production of IGF-1 or IGF-2. The somatomammotropins are primarily lactogenic, priming the breast for lactation after birth (see [Table 56-6](#)).

The pituitary hormone **prolactin (PRL)**; see [Table 48-1](#)) is the fourth hormone with homology to GH. The principal physiological role of PRL involves promotion of milk production in lactating women (see [pp. 1148–1150](#)). PRL is made by *lactotrophs* in the anterior pituitary. Its homology to GH suggests that the two hormones, despite their divergent actions, arose from some common precursor by a gene-duplication event. The sequence homology between these proteins is underscored by the observation that GH and PRL have similar affinities for the PRL receptor. The converse is not true—that is, PRL has no significant affinity for the GH receptor and thus has no growth-promoting activity. As discussed below, the PRL and GH receptors are coupled to an intracellular signaling system that involves stimulation of the JAK family of tyrosine kinases (see [p. 70](#)) as an early postreceptor event.

Men, like women, make PRL throughout their lives. However, no physiological role for PRL in males has been defined. Both men and women with disorders involving hypersecretion of GH or PRL can develop galactorrhea (breast milk secretion). Although GH and PRL are normally secreted by distinct cell populations in the anterior pituitary, some benign GH-producing pituitary adenomas (i.e., tumors) secrete PRL along with GH.

Somatotrophs secrete GH in pulses

Whereas growth occurs slowly over months and years, the secretion of GH is highly episodic, varying on

a minute-to-minute basis. Most physiologically normal children experience episodes or bursts of GH secretion throughout the day, most prominently within the first several hours of sleep. Underlying each peak in plasma levels of GH, illustrated for an adult in [Figure 48-2](#), are bursts of many hundreds of pulses of GH secretion by the somatotrophs in the anterior pituitary. With the induction of slow-wave sleep, several volleys of GH pulses may occur; it is estimated that >70% of total daily GH secretion occurs during these periods. This pulsatile secretion underlines the prominent role of the CNS in the regulation of GH secretion and growth. The circulating GH concentrations may be up to 100-fold higher during the bursts of GH secretion (i.e., the peaks in [Fig. 48-2](#)) than during intervening periods. The pattern of bursts depends on sleep-wake patterns, not on light-dark patterns. Exercise, stress, high-protein meals, and fasting also cause a rise in the mean GH level in humans. In circumstances in which GH secretion is stimulated (e.g., fasting or consumption of a high-protein diet), the increased GH output results from an increase in the frequency—rather than the amplitude—of pulses of GH secretion by the somatotrophs.

FIGURE 48-2 Bursts in plasma levels of GH, sampled in the blood plasma of a 23-year-old woman every 5 minutes over a 24-hour period. Each peak in the plasma GH concentration reflects bursts of hundreds of GH-secretory pulses by the somatotrophs of the anterior pituitary. These bursts are most common during the first few hours of sleep. The integrated amount of GH secreted each day is higher during pubertal growth than in younger children or in adults. (Data from Hartman ML, Veldhuis JD, Vance ML, et al: Somatotropin pulse frequency and basal concentrations are increased in acromegaly and are reduced by successful therapy. *J Clin Endocrinol Metab* 70:1375, 1990.)

GH secretion is under hierarchical control by GH-releasing hormone and somatostatin

The coordination of GH secretion by the somatotrophs during a secretory pulse presumably occurs in response to both positive and negative hypothalamic control signals.

GH-Releasing Hormone

Small-diameter neurons in the arcuate nucleus of the hypothalamus secrete **growth hormone–releasing hormone (GHRH)**, a 43–amino-acid peptide that reaches the somatotrophs in the anterior pituitary via

the hypophyseal portal blood ([Fig. 48-3](#)). As the name implies, this neuropeptide promotes GH secretion by the somatotrophs. GHRH is made principally in the hypothalamus, but it can also be found in neuroectodermal tissue outside the CNS; it was first isolated and purified from a pancreatic islet cell tumor of a patient with acromegaly.

FIGURE 48-3 Synthesis and release of GHRH and SS, and the control of GH release. GHRH raises $[\text{cAMP}]_i$ and $[\text{Ca}^{2+}]_i$ in the somatotrophs and thereby stimulates release of GH stored in secretory granules. SS inhibits adenyl cyclase (AC), lowers $[\text{Ca}^{2+}]_i$, and thereby inhibits release of GH. PKA, protein kinase A.

GHRH Receptor

GHRH binds to a G protein–coupled receptor (GPCR) on the somatotrophs and activates $\text{G}\alpha_s$, which in

turn stimulates adenylyl cyclase (see pp. 56–57). The subsequent rise in $[cAMP]_i$ causes increased gene transcription and synthesis of GH. In addition, the rise in $[cAMP]_i$ opens Ca^{2+} channels in the plasma membrane and causes $[Ca^{2+}]_i$ to rise. This increase in $[Ca^{2+}]_i$ stimulates the release of preformed GH.

Ghrelin

A relatively newly discovered hormone, ghrelin consists of 28 amino acids. One of the serine residues is linked to an octanol group, and only this acylated form of the peptide is biologically active.  **N48-2** Distinct endocrine cells within the mucosal layer of the stomach release ghrelin in response to fasting. Endocrine cells throughout the GI tract also make ghrelin, although the highest ghrelin concentrations are in the fundus of the stomach. The arcuate nucleus of the hypothalamus also makes small amounts of ghrelin. Infusion of ghrelin either into the bloodstream or into the cerebral ventricles markedly increases growth hormone secretion. Indeed, ghrelin appears to be involved in the postmeal stimulation of growth hormone secretion. It has been more difficult to define the extent to which ghrelin—versus GHRH and somatostatin (SS)—contributes to the changes in normal growth hormone secretion in response to fasting, amino-acid feeding, and carbohydrate feeding. Ghrelin also is orexigenic (i.e., it stimulates appetite; see p. 1003), thereby contributing to body mass regulation as well as linear growth.

N48-2

Ghrelin

Contributed by Emile Boulpaep, Walter Boron

Circulating forms of ghrelin include both the acyl and deacylated species, and this has complicated efforts to define the physiological responses of ghrelin to dietary manipulation as well as the responses to exogenously administered hormone. Ghrelin has 28 amino acids and is also known as ghrelin-28. The sequence of human ghrelin (amino acids 24 to 51 of the full, immature peptide), using the single-letter code, is as follows: GSSFLSP EHQRVQQRKE SKKPPAKLQP R. Ghrelin-27 has only 27 amino acids, lacking the C-terminal arginine of ghrelin-28.

Reference

UniProt Knowledgebase [results for ghrelin]. <http://www.uniprot.org/uniprot/?query=ghrelin&sort=score> [Accessed September 2014].

Ghrelin Receptor

The hormone ghrelin binds to a GPCR designated GH secretagogue receptor 1a (GHSR1a). This receptor was first identified because it binds synthetic peptide ligands that stimulate GH secretion. In this regard, GHSR1a is like the GHRH receptor (GHRHR); however, GHSR1a does not bind GHRH.

Somatostatin

The hypothalamus also synthesizes **SS**, a 14–amino-acid neuropeptide. SS is made in the periventricular region of the hypothalamus and is secreted into the hypophyseal portal blood supply. It is a potent inhibitor of GH secretion. SS is also made elsewhere in the brain and in selected tissues outside the CNS,

such as the pancreatic islet δ cells (see p. 1053) and D cells in the GI tract (see pp. 868–870 and Table 41-1). Within the CNS, the 14–amino-acid form of SS (SS-14) dominates. The GI tract predominantly expresses a 28–amino-acid splice variant; the C-terminal 14 amino acids of SS-28 are identical to those of SS-14.

It appears that the primary regulation of GH secretion is stimulatory, because sectioning the pituitary stalk, and thereby interrupting the portal blood flow from the hypothalamus to the pituitary, leads to a decline in GH secretion. Conversely, sectioning of the stalk leads to a *rise* in PRL levels, presumably because dopamine made in the hypothalamus normally inhibits PRL secretion in the anterior pituitary (see pp. 1149–1150). It also appears that the pulses of GH secretion are entrained by the pulsatile secretion of GHRH (as opposed to the periodic loss of SS inhibition).

SS Receptor

SS binds to a GPCR called SSTR found on somatotrophs and activates $G\alpha_i$, which inhibits adenylyl cyclase. As a result, $[Ca^{2+}]_i$ decreases, which diminishes the responsiveness of the somatotroph to GHRH. When somatotrophs are exposed to both GHRH and SS, the inhibitory action of SS prevails.

Both GH and IGF-1 negatively feed back on GH secretion by somatotrophs

In addition to being controlled by GHRH, ghrelin, and SS, somatotroph secretion of GH is under negative-feedback control via IGF-1. As discussed below, GH triggers the secretion of IGF-1 from GH target tissues throughout the body (Fig. 48-4, No. 1). Indeed, IGF-1 mediates many of the growth-promoting actions of GH. IGF-1 synthesized in tissues such as muscle, cartilage, and bone may act in a **paracrine** or **autocrine** fashion to promote local tissue growth. In contrast, circulating IGF-1, largely derived from hepatic secretion, exerts **endocrine** effects. Circulating IGF-1 suppresses GH secretion through both direct and indirect mechanisms.

FIGURE 48-4 GH and IGF-1 (also called somatomedin C) negative-feedback loops. Both GH and IGF-1 feed back—either directly or indirectly—on the somatotrophs in the anterior pituitary to decrease GH secretion. GH itself inhibits GH secretion (“short loop”). IGF-1, whose release is stimulated by GH, inhibits GH release by three routes, one of which is direct and two of which are indirect. The direct action is for IGF-1 to inhibit the somatotroph. The first indirect pathway is for IGF-1 to suppress GHRH release in the hypothalamus. The second is for IGF-1 to increase secretion of SS, which in turn inhibits the somatotroph.

First, circulating IGF-1 exerts a *direct* action on the pituitary to suppress GH secretion by the somatotrophs (see Fig. 48-4, No. 2), probably inhibiting GH secretion by a mechanism different from that of SS. In its peripheral target cells, IGF-1 acts through a receptor tyrosine kinase (see pp. 68–70) and not by either the Ca^{2+} or cAMP messenger systems. IGF-1 presumably acts by this same mechanism to inhibit GH secretion in somatotrophs.

Second, circulating IGF-1 inhibits GH secretion via two *indirect* feedback pathways, both targeting the hypothalamus. IGF-1 suppresses GHRH release (see Fig. 48-4, No. 3) and also increases SS secretion (see Fig. 48-4, No. 4).

Yet another feedback system, independent of IGF-1, reduces GH secretion. Namely, GH itself appears to inhibit GH secretion in a short-loop feedback system (see Fig. 48-4, No. 5).

GH has short-term anti-insulin metabolic effects as well as long-term growth-promoting effects mediated by IGF-1

Once secreted, most GH circulates free in the plasma. However, a significant fraction (~40% for the 22-kDa GH) is complexed to a **GH-binding protein** formed by proteolytic cleavage of the extracellular domain of GH receptors in GH target tissues. This protein fragment binds to GH with high affinity, thereby increasing the half-life of GH and competing with GH target tissues for GH. In the circulation, GH has a half-life of ~25 minutes.

GH Receptor

GH binds to a receptor (GHR) on the surface of multiple target tissues. The monomeric GHR is a 620–amino-acid protein with a single membrane-spanning segment. The molecular weight of GHR (~130 kDa) greatly exceeds that predicted from its amino-acid composition (~70 kDa) as a result of extensive glycosylation. Like other members of the type I cytokine receptor family, GHR is a **tyrosine kinase-associated receptor** (see pp. 70–71). When one GH molecule simultaneously binds to sites on two GHR monomers and acts as a bridge, the monomers dimerize (see Fig. 3-12D). Receptor occupancy increases the activity of a tyrosine kinase (JAK2 family) that is associated with, but is not an integral part of, the GH receptor. This tyrosine kinase triggers a series of protein phosphorylations that modulate target cell activity.

Short-Term Effects of GH

GH has certain short-term (minutes to hours) actions on muscle, adipose tissue, and liver that may not necessarily be related to the more long-term growth-promoting actions of GH. These acute metabolic effects (Table 48-2) include stimulation of lipolysis in adipose tissue, inhibition of glucose uptake by muscle, and stimulation of gluconeogenesis by hepatocytes. These actions oppose the normal effects of insulin (see pp. 1035–1050) on these same tissues and have been termed the **anti-insulin** or **diabetogenic** actions of GH. Chronic oversecretion of GH, such as occurs in patients with GH-producing tumors in acromegaly, is accompanied by insulin resistance and often by glucose intolerance or frank diabetes.

TABLE 48-2

Diabetogenic Effects of GH

TARGET	EFFECT
Muscle	↓ Glucose uptake
Fat	↑ Lipolysis
Liver	↑ Gluconeogenesis
Muscle, fat, and liver	Insulin resistance

Long-Term Effects of GH via IGF-1

Distinct from these acute actions of GH is its action to promote tissue growth by stimulating target tissues to produce IGFs. In 1957, Salmon and Daughaday reported that GH itself does not have growth-promoting action on epiphyseal cartilage (the site where longitudinal bone growth occurs). In those experiments, the addition of serum from normal animals, but not from hypophysectomized (GH-deficient) animals, stimulated cartilage growth in vitro (assayed as incorporation of radiolabeled sulfate into cartilage). The addition of GH to GH-deficient serum did not restore the growth-promoting activity seen with normal serum. However, when the GH-deficient animals were treated in vivo with GH, their plasma promoted cartilage growth in vitro. This finding led to the hypothesis that, in animals, GH provokes the secretion of another circulating factor that mediates the action of GH. Initially called *sulfation factor* because of how it was assayed, this intermediate was subsequently termed **somatomedin** because it mediates the somatic effects of GH. We now know that somatomedin is in fact two peptides resembling proinsulin and thus termed **insulin-like growth factors 1 and 2** (Fig. 48-5). Indeed, the IGFs exert insulin-like actions in isolated adipocytes and can produce hypoglycemia in animals and humans. IGF-1 and IGF-2 are made in various tissues, including the liver, kidney, muscle, cartilage, and bone. As noted above, the liver produces most of the circulating IGF-1, which more closely relates to GH secretion than does IGF-2.

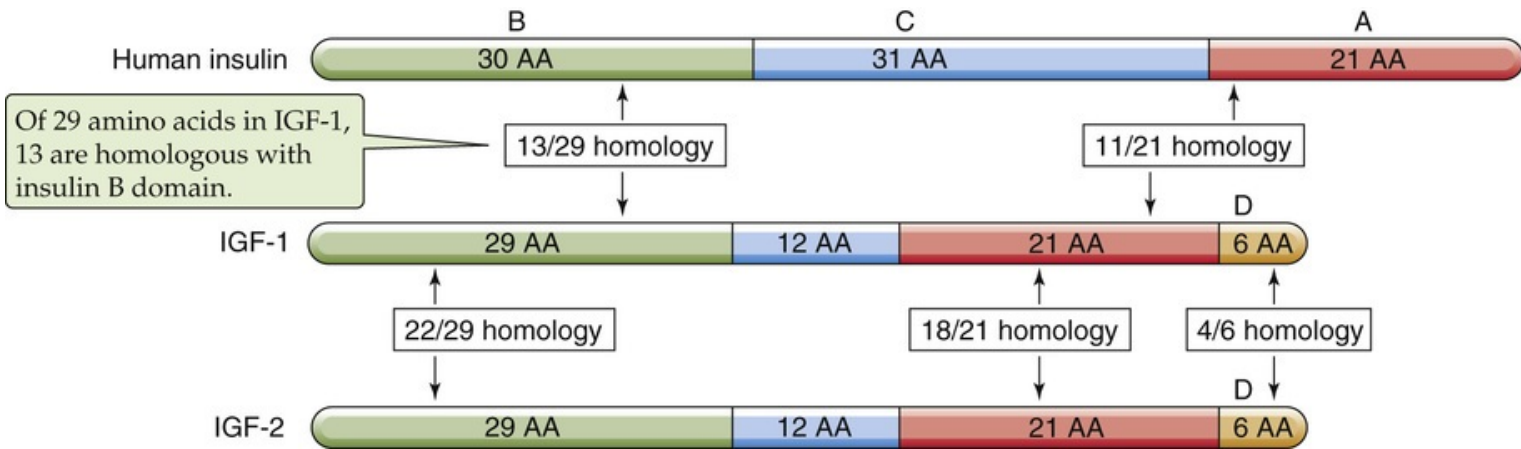

FIGURE 48-5 Structure of the IGFs. Insulin, IGF-1, and IGF-2 share three domains (A, B, and C), which have a high degree of amino-acid (AA) sequence homology. The C region is cleaved from insulin (as the C peptide) during processing, but is not cleaved from either IGF-1 or IGF-2. In addition, IGF-1 and IGF-2 also have a short D domain.

Growth-Promoting Hormones

IGF-1 is the principal mediator of the growth-promoting action of GH

The synthesis of IGF-1 and, to a lesser extent, IGF-2 depends on circulating GH. As described above, the periodic nature of GH secretion results in a wide range of plasma GH concentrations. In contrast, plasma [IGF-1] does not vary by more than ~2-fold over a 24-hour period. The plasma [IGF-1] in effect integrates the pulsatile, highly fluctuating GH concentration. The reason for the relatively steady plasma levels of IGF-1 is that like GH—but unlike most peptide hormones—IGF-1 circulates bound to several **IGF-1-binding proteins**. These binding proteins are made principally in the liver, but they are also manufactured by other tissues. More than 90% of IGF-1 measured in the serum is bound to these proteins. At least six distinct IGF-binding proteins have been identified. In addition to providing a buffer pool in plasma of bound IGF, these proteins may aid the transfer of IGF to the tissue receptors, thereby facilitating the action of these hormones. The local free fraction of IGF-1 is probably the more biologically active component that binds to the receptor and stimulates tissue growth.

Like other peptide hormones, IGF-1 and IGF-2 are synthesized via the secretory pathway (see pp. 34–35) and are secreted into the extracellular space, where they may act locally in a paracrine fashion. In the extracellular space, the IGFs encounter binding proteins that may promote local retention of the secreted hormone by increasing the overall molecular size of the complex. This action inhibits the entry of the IGFs into the vascular system. Thus, local concentrations of the IGFs are likely to be much higher than plasma concentrations.

Whether made locally or reaching tissues through the circulation, IGF-1 acts via a specific **receptor tyrosine kinase** (see pp. 68–70), a heterotetramer that is structurally related to the insulin receptor (Fig. 48-6). Like the insulin receptor (see pp. 1041–1042), the **IGF-1 receptor (IGF1R)** has two completely extracellular α chains and two transmembrane β chains. Also like in the insulin receptor, the β chains have intrinsic tyrosine kinase activity. Binding of IGF-1 to its receptor enhances receptor autophosphorylation as well as phosphorylation of downstream effectors. The structural homology between the insulin and IGF-1 receptors is sufficiently high that insulin can bind to the IGF-1 receptor, although with an affinity that is about two orders of magnitude less than that for IGF-1. The same is true for the binding of IGF-1 to insulin receptors. In fact, the homology between the insulin and IGF-1 receptors is so strong that hybrid receptors containing one α - β chain of the insulin receptor and one α - β chain of the IGF-1 receptor are present in many tissues. These hybrid receptors bind both insulin and IGF-1, but their affinity for IGF-1 is greater.

FIGURE 48-6 Comparison of insulin, IGF-1, and IGF-2 receptors. Both the insulin and IGF-1 receptors are heterotetramers joined by disulfide bonds. For both, the cytoplasmic portions of the β subunits have tyrosine kinase domains as well as autophosphorylation sites. The IGF-2 receptor (also called the mannose-6-phosphate [M6P] receptor) is a single polypeptide chain with no kinase domain.

Given the structural similarity between insulin and IGFs and between the insulin receptor and the IGF-1 receptor, it is not surprising that IGFs can exert insulin-like actions *in vivo*. This effect has been particularly well studied for IGF-1, which, like insulin, induces hypoglycemia when injected into animals. This action is largely the result of increased uptake of glucose into muscle tissue. IGF-1 is less effective in mimicking insulin's action on adipose and liver tissue; in humans, these tissues have few IGF-1 receptors. In muscle, IGF-1 promotes the uptake of radiolabeled amino acids and stimulates protein synthesis at concentrations that do not stimulate glucose uptake. Thus, IGF-1 promotes growth at lower circulating concentrations than those required to produce hypoglycemia ([Box 48-1](#)).

Plasma Level of IGF-1 as a Measure of GH Secretion

The plasma concentration of IGF-1 is a valuable measure of GH secretion. The wide swings in plasma [GH] that result from the pulsatile secretion of this hormone have confounded efforts to use GH measurements to diagnose disorders of GH deficiency or excess. However, an increased circulating concentration of IGF-1 is one of the most useful clinical measures of the excess GH secretion that occurs in acromegaly (i.e., GH excess in adults) and gigantism (i.e., GH excess in children). Measurement of plasma [IGF-1] has also helped to explain the genesis of a particular type of dwarfism known as **Laron dwarfism**. These patients were initially identified as persons with growth failure mimicking that of typical pituitary dwarfism; however, plasma [GH] is normal or elevated, and treatment with GH is ineffective in reversing the growth failure. It was subsequently demonstrated that these individuals have mutations of their GH receptors that make the receptors nonfunctional. Thus, the mutant GH receptors cannot trigger the production of IGFs. With the availability of recombinant IGF-1, effective treatment of these children may be possible with restoration of growth.

Despite the structural similarity of their receptors, IGF-1 and insulin exert different actions on tissues. IGF-1 has a more marked effect on growth, and insulin has a more significant effect on glucose and lipid metabolism. However, the differences in the postreceptor signaling pathways triggered by the two hormones have not been fully defined.

IGF-2 acts similarly to IGF-1 but is less dependent on GH

The physiology of IGF-2 differs from that of IGF-1 both in terms of control of secretion and receptor biology. Regarding control of secretion, IGF-2 levels depend less on circulating GH than do IGF-1 levels. In GH deficiency—as seen in pituitary dwarfism—circulating levels of IGF-1, but not IGF-2, are decreased. In states of excessive GH secretion, plasma IGF-1 level is reliably elevated, whereas plasma IGF-2 level is not.

Regarding receptor biology, although IGF-2 binds to the IGF-1 receptor, it preferentially binds to the so-called **IGF-2 receptor (IGF2R)**. This IGF-2 receptor is a single-chain polypeptide that is structurally very distinct from the IGF-1 receptor and is not a receptor tyrosine kinase (see [Fig. 48-6](#)). After IGF2R binds IGF-2, the internalization of the complex clears IGF-2 from the blood plasma. In an unrelated function, IGF2R in the *trans* Golgi binds—at a site different from that for IGF-2 binding—newly synthesized lysosomal hydrolases tagged with mannose-6-phosphate (M6P) for trafficking to the lysosomes.

Despite these differences, IGF-2 does share with IGF-1 (and also with insulin) the ability to promote tissue growth and to cause acute hypoglycemia. These properties appear to result from IGF-2's structural similarity to proinsulin and its ability to bind to the IGF-1 receptor.

Growth rate parallels plasma levels of IGF-1 except early and late in life

Illustrated in [Figure 48-7](#) is the mean concentration of total IGF-1 (both free and bound) found in human serum as a function of age. Also shown is the normal rate of height increase (cm/yr). During puberty, the greatest growth rates are observed at times when plasma [IGF-1] is highest. A similar comparison can be made using GH, provided care is taken to obtain multiple measurements at each age and thereby account

for the pulsatile secretion and marked diurnal changes that occur in plasma [GH].

FIGURE 48-7 Serum IGF-1 levels and height velocity as a function of age. The red curve shows the mean plasma concentrations of IGF-1 as a function of age in human females. The curve for males is similar, but the peak is shifted to an older age by 3 to 4 years. The brown curve indicates for females the mean height velocity—the rate at which height increases (cm/yr). The pubertal peak rate of growth corresponds to the peak serum concentrations of IGF-1. (Data from Reiter EO, Rosenfeld RG: Normal and aberrant growth. In Wilson JD, Foster DW, Kronenberg HM, Larsen PR [eds]: *Williams Textbook of Endocrinology*, 9th ed. Philadelphia, WB Saunders, 1998, pp 1427–1507.)

Whereas, during puberty, growth rate parallels plasma [IGF-1], the two diverge at both younger and older ages. A first period of life for this divergence is very early childhood (see Fig. 48-7), which is characterized by a very rapid longitudinal growth rate, but quite low IGF-1 levels. If this time frame is extended back to intrauterine life, then the discordance is even greater. Indeed, children with complete GH deficiency have very low plasma [IGF-1] levels but are of normal length and weight at birth. This observation suggests that during intrauterine life, factors other than GH and IGF-1 are important regulators of growth. One of these additional factors may be insulin, as discussed below. Another explanation for the divergence between growth rate and IGF-1 levels may be that IGF-2 is an important mediator of intrauterine growth. Plasma [IGF-2] is greater during fetal life than later and peaks just before birth. Plasma [IGF-2] plummets soon after birth, but then it gradually doubles between birth and age 1 year, and remains at this level until at least the age of 80 years. Thus, IGF-2 levels are at adult levels during the first several years of life, when IGF-1 levels are low but growth is rapid. However, several other hormones may also contribute to somatic growth during the first several years of life.

By age 3 or 4 years, GH and IGF-1 begin to play major roles in the regulation of growth. The concentrations of these hormones rise throughout childhood and peak during the time of the pubertal growth spurt. The rate of long-bone growth in the pubertal growth spurt is exceeded only during intrauterine life and early childhood. The frequency of pituitary GH secretory pulses increases markedly

at puberty. The factors responsible for this acceleration are not clear. However, the accompanying sexual maturation likely plays some role, because both estradiol and testosterone appear to promote GH secretion.

During adulthood, longitudinal growth essentially ceases, yet secretion of GH and of IGF-1 continues to be highly regulated, although the circulating concentrations of both hormones decline during aging. For many years, the continued secretion of these hormones in adults was considered to be largely vestigial. This belief was reinforced by the observation that cessation of GH secretion and the consequent decline of IGF-1 after trauma, a pituitary tumor, or surgical removal of the pituitary did not result in any clear clinical syndrome. However, in GH-deficient adults replacement with recombinant human GH leads to remarkable increases in body muscle mass, decreases in fat mass, and improved nitrogen balance (a measure of protein nutrition). These findings support the conclusion that—even after linear growth ceases after puberty—GH and IGF-1 remain important regulators of body composition and appear to promote anabolic actions in muscle. Indeed, some investigators have suggested that supplementing physiologically normal adults with GH or IGF-1 may reverse some of the effects of aging, including loss of muscle mass, negative nitrogen balance, and osteoporosis.

Nutritional factors also modulate both GH secretion and IGF-1 production. In both children and adults, GH secretion is triggered by high dietary protein intake. Teleologically, this is intriguing in that it may provide linkage between the availability of amino acids to serve as substrates for body protein synthesis (growth) and the endocrine stimulus of cells to grow. This relationship is not simple, however, because the rise in GH levels in the setting of protein intake is not sufficient to stimulate IGF-1 production fully. This principle is well illustrated by **fasting**, which is associated with a decline in IGF-1 even with increased GH. During fasting, insulin levels are low. Thus, increased insulin appears to be required, at least in some tissues, for GH to stimulate IGF-1 effectively.

Thyroid hormones, steroids, and insulin also promote growth

Although the discussion to this point emphasizes the action of GH and the GH-induced growth factors as modulators of somatic growth, we could regard them as necessary but not sufficient agents for normal growth. Certain other hormones, as well as receptive growth-responsive cartilage, are required. Because growth is a difficult phenomenon to study, especially in humans (few scientists want to follow an experiment over 10 to 20 years), much of our understanding of endocrine regulation of normal growth derives from observations of abnormal growth as it occurs in clinical syndromes of endocrine excess or deficiency. Several of the more important of these endocrine influences are illustrated here. The exact mechanism by which growth is regulated by these agents is not always well understood.

Thyroid Hormones

Next to GH, perhaps the most prominent among the growth-promoting hormones are the thyroid hormones thyroxine and triiodothyronine, which we discuss in [Chapter 49](#). In many nonhuman species, thyroid hormone plays a major role in tissue growth and remodeling. For example, resorption of the tadpole tail during morphogenesis requires thyroid hormone. In humans, severe deficiency of thyroid hormones early in life causes dwarfism and mental retardation (cretinism; see [pp. 1013–1014](#)). In children with normal thyroid function at birth, development of hypothyroidism at any time before epiphyseal fusion leads to growth retardation or arrest. Much of the loss in height that occurs can be recovered through thyroid hormone treatment, a phenomenon called *catch-up growth*. However, because the diagnosis of hypothyroidism may elude detection for many months or years, delays in initiating treatment can lead to

some loss of potential growth. A child's growth curve can provide a particularly sensitive early indicator of hypothyroidism.

Sex Steroids

As with thyroid hormones, the importance of sex steroids for growth is most readily understood by considering the effects of deficiency or excess of these hormones. Androgen or estrogen excess occurring before the pubertal growth spurt accelerates bone growth. However, the sex steroids also accelerate the rate at which the skeleton matures and thus shorten the time available for growth before epiphyseal closure occurs. Most of the time, the dominant effect of sex steroids is to narrow the growth window, thereby diminishing ultimate longitudinal bone growth. This effect is well illustrated in settings in which children are exposed to excessive sex steroid at an early age. The sex steroids can come from endogenous sources (e.g., early maturation of the hypothalamic-pituitary-gonadal axis that produces premature puberty, or tumors that secrete estrogen or androgen) or from exogenous sources (e.g., children who take sex steroids prescribed for others). Again, the growth curve is useful in that it typically shows an increase in growth rate, followed by an early leveling off of growth associated with the development of secondary sexual characteristics.

Glucocorticoids

An excess of adrenal glucocorticoids inhibits growth. Growth ceases in children who produce too much cortisol, as a result of either adrenal or pituitary tumors (which secrete adrenocorticotrophic hormone [ACTH] and cause secondary increases in plasma cortisol levels). The use of synthetic glucocorticoids in treating various serious illnesses (e.g., asthma, organ transplantation, various chronic autoimmune processes) also can arrest growth. Restoration of normal growth does not occur until the glucocorticoid levels return toward normal. Neither GH nor IGF-1 concentrations drop significantly during glucocorticoid treatment. The failure of GH administration to correct the growth retardation that occurs in glucocorticoid-treated children further confirms that GH deficiency cannot account for the growth failure associated with glucocorticoid excess. Because linear growth is related to cartilage and bone synthesis at the growth plates, glucocorticoids presumably are acting at least in part at these sites to impair growth. However, the specific biochemical locus at which glucocorticoids act remains unclear. In adults, as in children, glucocorticoid excess impairs tissue anabolism and thus may manifest as wasting in some tissues (e.g., bone, muscle, subcutaneous connective tissue), rather than growth failure. This tissue wasting results in some of the major clinical morbidity associated with glucocorticoid excess (i.e., osteoporosis, muscle weakness, and bruising).

In glucocorticoid *deficiency*, growth is not substantially affected. However, other deleterious effects of cortisol deficiency (e.g., hypoglycemia, hypotension, weakness; see [p. 1019](#)) dominate.

Insulin

Insulin is also an important growth factor, particularly in utero. For example, women with diabetes frequently have high blood levels of glucose during pregnancy and deliver babies of high birth weight (fetal macrosomia). The developing fetus exposed to glucose concentrations that are higher than normal secretes additional insulin. Hyperinsulinemia results in increased fetal growth. Fetal macrosomia can create significant obstetric difficulties at the time of delivery.

Conversely, infants born with pancreatic agenesis or with one of several forms of severe insulin resistance are very small at birth. One form of this condition, **leprechaunism**, is the result of a defect in

the insulin receptor (see [Box 51-4](#)). Thus, it appears that insulin, acting through its own receptor, is an intrauterine growth factor.

Severe insulin deficiency produces a marked catabolic effect associated with wasting of lean body mass in both children and adults. The acute adverse effects of such deficiency (dehydration and acidosis) dominate the clinical picture. Mild insulin deficiency, as seen in patients with chronically undertreated diabetes, diminishes growth in affected children. Improved diabetes management may allow restoration of normal growth rates and possibly even some transient accelerated or catch-up growth. Thus, with good care, children with diabetes can expect to achieve normal adult height ([Box 48-2](#)).

Box 48-2

Anabolic-Androgenic Steroids

We are all unfortunately familiar with the potential for abuse of anabolic-androgenic steroids by bodybuilders and competitive athletes. Illicit use of these agents appears to be widespread in sports, where strength is closely linked to overall performance. Not only naturally occurring androgens (e.g., testosterone, dihydrotestosterone, androstenedione, and dehydroepiandrosterone), but also many synthetic androgenic steroids—as well as GH—serve as performance enhancers. In addition to the sought-after “beneficial” effects of increasing muscle mass and strength, each of these agents carries with it a plethora of adverse side effects. Some—such as oily skin, acne, and hair growth—are principally cosmetic. Others—including liver function abnormalities, mood changes with aggressive behavior, and hepatocellular carcinoma—are much more serious. Illicit use of these agents by younger athletes, especially teenagers, is also problematic with regard to alterations in growth and sexual maturation.

The musculoskeletal system responds to growth stimuli of the GHRH–GH–IGF-1 axis

Longitudinal growth involves lengthening of the somatic tissues (including bone, muscle, tendons, and skin) through a combination of tissue hyperplasia and hypertrophy. Each of these tissues remodels its structure throughout life. For bone, **longitudinal growth** occurs by the hyperplasia of chondrocytes at the growth plates of the long bones, followed by endochondral ossification. The calcified cartilage is remodeled as it moves toward the metaphyses of the bone, where it is eventually replaced by cortical bone (see [pp. 1056–1057](#)) and trabecular bone (see [p. 1057](#)). This process continues until epiphyseal closure occurs toward the completion of puberty.

The process of cartilage formation and longitudinal bone growth begins as the cellular elements capable of forming cartilage divide along the growth plate and then migrate toward the more mature bone. These cells synthesize the extracellular matrix of cartilage, which includes type II collagen, hyaluronic acid, and mucopolysaccharides. These cells appear to respond directly to GH by proliferating and increasing production of the extracellular matrix. This response involves local generation of IGF-1 within the cartilage as an early event in the growth process. As the cells more closely approach the already formed cortical and trabecular bone, ossification of the extracellular matrix begins, and eventually the cellular elements become isolated by the calcifying cartilage. However, this calcified cartilage is not structurally the same as normal bone, and soon after formation it begins to be remodeled by an ingrowth of cellular elements (osteoclasts and osteoblasts) from adjacent bone. Eventually, it is replaced by normal bone, and becomes part of the metaphysis of the long bone.

In most children, growth ceases within several years after completion of puberty, when the chondrocytes at the growth plates of the long bones cease dividing and calcify the previously cartilaginous surrounding matrix. After puberty, **radial growth** occurs as bones increase their *diameter* through a process of endosteal bone resorption and periosteal bone deposition. This process is not strictly compartmentalized; that is, resorption and deposition of bone occur at both the periosteal and endosteal surfaces. However, during periods of growth, the rate of periosteal deposition exceeds the rate of endosteal resorption, and the bone shafts grow in width and thickness.

As may be expected, numerous disorders disrupt the complex process of endochondral bone growth on a genetic or congenital basis (e.g., defects in collagen or mucopolysaccharide synthesis) and lead to genetic forms of dwarfism. In these settings, the GHRH–GH–IGF-1 axis is entirely intact and appears to regulate normally. No apparent compensation occurs for the short stature by increased GH secretion, a finding suggesting that the axis is not sensitive to the growth process per se, but simply to the intermediate chemical mediator IGF-1.

GH and IGF-1 clearly play important roles in mediating longitudinal bone growth and also modulate growth of other tissues. Thus, proportional growth of muscle occurs as bones elongate, and the visceral organs enlarge as the torso increases in size. The mechanisms by which GH and IGF-1 coordinate this process and the way in which other hormones or growth factors may be involved continue to be investigated. It is clear that, whereas GH and, more recently, IGF-1 have been considered the major hormones responsible for somatic growth, other tissue growth factors play an important, albeit incompletely defined, role. [Table 48-3](#) lists some of these growth factors. In general, the tissue growth factors have more tissue-specific actions on organogenesis and their growth-promoting activity than the IGFs, and they appear to act largely in a paracrine or autocrine fashion.

Regulation of Body Mass

The multiple hormonal factors that influence longitudinal growth—discussed in the previous two subchapters—are themselves responsive to the nutritional intake of a growing individual. For example, amino acids and carbohydrates promote insulin secretion, and amino acids stimulate GH secretion (see pp. 992–994). In addition, the availability of an adequate balanced nutrient supply likely exerts both direct and indirect influences to promote tissue growth. Independent of any hormonal factors, glucose, fatty acids, and amino acids can each influence the transcription of specific genes. Similarly, amino acids can directly activate the signaling pathways involved in regulating messenger RNA (mRNA) translation.

Beyond the effects of macronutrients, the effects of micronutrients can be similarly important in regulating cell growth and, by extension, growth of the organism. An example is iodine, a deficiency of which can produce dwarfism (see p. 1009). In a more global fashion, the effect of nutrient limitation on height can be appreciated by considering the differences in mean height between men in North Korea (165 cm) and South Korea (171 cm). As mentioned on page 990, nutritional deprivation early in life can markedly limit longitudinal growth. Perhaps equally fascinating, and only recently appreciated, is that nutritional deprivation early in life also appears to predispose affected individuals to *obesity* when they reach middle age. This phenomenon was first noted in epidemiological studies in several European countries that revealed a positive correlation between middle-aged obesity and being born during periods of deprivation during and immediately following the Second World War. Such findings suggest that some level of genetic programming occurs early in life that both diminishes longitudinal growth and predisposes persons to body mass accretion.

The balance between energy intake and expenditure determines body mass

At any age or stage of life the factors that govern body mass accretion relate specifically to the energy balance between intake and expenditure. If energy intake exceeds expenditure over time—**positive energy balance** (see p. 1173)—body mass will increase, assuming the diet is not deficient in essential macronutrients or micronutrients. Small positive deviations from a perfect energy balance, over time, contribute to the major increase in body weight—the “obesity epidemic”—that affects many middle-aged adults, and increasingly adolescents, in developed societies. For example, if energy intake in the form of feeding exceeds energy expenditure by only 20 kcal (1 tsp of sugar) daily, over 1 year a person would gain ~1 kg of fat, and over 2 decades, ~20 kg.

Indeed, it is remarkable that many adults maintain a consistent body weight for decades essentially in the absence of conscious effort. Thus, a finely tuned regulatory system must in some manner “monitor” one or more aspects of body mass, direct the complex process of feeding (appetite and satiety) to replete perceived deficiencies, and yet avoid excesses.

Energy expenditure comprises resting metabolic rate, activity-related energy expenditure, and diet-induced thermogenesis

We can group energy expenditure into three components:

- 1. Resting metabolic rate (RMR).** The metabolism of an individual who is doing essentially nothing (e.g., sleeping) is known as the RMR (see [p. 1170](#)), which amounts to ~2100 kcal/day for a young 70-kg adult. The RMR supports maintenance of body temperature, the basal functioning of multiple body systems (e.g., heartbeat, GI motility, ventilation), and basic cellular processes (e.g., synthesizing and degrading proteins, maintaining ion gradients, metabolizing nutrients).
- 2. Activity-related energy expenditure.** As we wake up in the morning and begin to move about, we expend more energy than resting metabolism. Exercise or physical work can have a major impact on total daily energy expenditure and varies widely across individuals, and within an individual on a day-to-day basis. We also expend energy in activities not classically regarded as exercise or heavy work, such as tapping the foot while sitting in a chair, looking about the room during a physiology lecture, typing at a keyboard—activities dubbed non-exercise-associated thermogenesis or **NEAT**. Such energy expenditures can vary 3- to 10-fold across individuals and can account for 500 kcal or more of daily energy expenditure. NEAT differences, over time, could contribute considerably to differences in weight gain by individuals with identical caloric intake.
- 3. Diet-induced thermogenesis.** Eating requires an additional component of energy expenditure for digesting, absorbing, and storing food. Typically, diet-induced thermogenesis accounts for 10% of daily energy expenditure. Proteins have a higher *thermic effect* than either carbohydrates or fats (i.e., the metabolism and storage of proteins requires more energy).

Each of these three components of energy expenditure can vary considerably from day to day and is subject to regulation. For example, thyroid hormone is a major regulator of thermogenesis (see [p. 1013](#)). Overproduction of thyroid hormone increases both RMR and NEAT, whereas thyroid hormone deficiency has the opposite effect. 🟡N48-3

N48-3

Effect of Hyperthyroidism on Basal Metabolic Rate

Contributed by Emile Boulpaep, Walter Boron

One of the earliest tests for hyperthyroidism was to measure **basal metabolic rate (BMR)**, as discussed in the text on page 1170. This method is not used today because BMR can be affected by other factors (e.g., body size, fever, catecholamines, fasting), so changes cannot be related specifically to the thyroid. In addition, it is cumbersome to measure BMR accurately compared with obtaining serum estimates of thyroid hormone concentrations or activity.

Nevertheless, all things being equal, thyroid hormone increases the **BMR**. The difference between BMR and **RMR** is discussed on page 1170.

Hypothalamic centers control the sensations of satiety and hunger

Classic studies in which investigators made lesions in, or electrically stimulated, specific brain regions identified two areas in the hypothalamus that are important for controlling eating. A **satiety center** is located in the ventromedial nucleus (VMN; see [Fig. 47-3](#)). Electrical stimulation of the satiety center

elicits sensations of satiety, even when an animal is in the presence of food. Conversely, a lesion of the satiety center causes continuous food intake (*hyperphagia*) even in the absence of need. A **hunger** (or feeding) **center** is located in the lateral hypothalamic area (see [Fig. 47-3](#)). Electrical stimulation of this center elicits a voracious appetite, even after an animal has ingested adequate amounts of food. A lesion of the hunger center causes complete and lasting cessation of food intake (*aphagia*).

Leptin tells the brain how much fat is stored

Only in the last 2 decades have we begun to understand regulatory mechanisms that maintain body mass, an advance made possible by the study of mouse models of obesity. One monogenic model is the Ob/Ob strain of hyperphagic mice that develop morbid obesity; affected mice typically weigh >100% more than unaffected animals of the same strain. In parabiosis experiments in which an Ob/Ob mouse was surgically connected to a wild-type mouse ([Fig. 48-8A](#)), the Ob/Ob mouse lost weight, which suggests that such mice lack a blood-borne factor. Another model of monogenic obesity is the (Db/Db) mouse, named Db because it secondarily develops type 2 diabetes (see [Box 51-5](#)). Like Ob/Ob mice, Db/Db mice are hyperphagic, with adult body weights ~100% greater than those of lean littermates. However, in parabiosis experiments connecting a Db/Db and a wild-type mouse (see [Fig. 48-8B](#)), the wild-type mouse starved. Finally, in parabiosis experiment connecting an Ob/Ob to a Db/Db mouse (see [Fig. 48-8C](#)), the Ob mouse lost weight but the Db mouse remained obese. These results indicate the following:

1. The Db mouse makes an excess of the blood-borne factor that cures the Ob mouse.
2. The Db mouse lacks the receptor for this factor.
3. Absence of the receptor in the Db mouse removes the negative feedback, which leads to high levels of the blood-borne factor.

FIGURE 48-8 Parabiosis experiments. In parabiotically coupled mice, ~1% of the cardiac output of one mouse goes to the other, and vice versa, so that the animals exchange blood-borne factors. Wt, wild type.

In 1994, Jeffrey Friedman and his colleagues used positional cloning to identify **leptin** (from the Greek *leptos* [thin]), the blood-borne factor lacked by Ob mice. Leptin is a 17-kDa protein made almost exclusively in adipocytes. The replacement of leptin in Ob/Ob mice leads to rapid weight loss. In 1995, Tepper and collaborators cloned the **leptin receptor (LEP-R)**. The deficiency of this receptor in Db mice makes them leptin resistant. LEP-R is a tyrosine kinase–associated receptor (see Fig. 3-12D) that signals through JAK2 and STAT (see Fig. 4-14). Among the several splice variants of LEP-R, the “long-form” is richly expressed in the arcuate nucleus of the hypothalamus and several other CNS sites.

Although leptin acts on numerous tissues, it somehow crosses the blood-brain barrier (see pp. 284–287) and modulates neurons in the arcuate nucleus of the hypothalamus that secrete pro-opiomelanocortin (see Fig. 50-4) and influence feeding behavior. These same neurons also have insulin receptors. Plasma leptin levels in humans appear to rise in proportion to the mass of adipose tissue (Box 48-3). Conversely, the absence of leptin produces extreme hyperphagia, as in Ob/Ob mice. Plasma leptin has a half-time of ~75 minutes, and acute changes in food intake or fasting do not appreciably affect leptin levels. In contrast, **insulin** concentrations change dramatically throughout the day in response to dietary intake. Thus, it appears that leptin in some fashion acts as an *intermediate- to long-term regulator* of CNS feeding behavior, whereas insulin (in addition to intestinal hormones like glucagon-like peptide 1 [GLP-1] and cholecystokinin [CCK]) is a *short-term regulator* of the activity of hypothalamic feeding centers.

Box 48-3

Human Obesity

One approach for gauging the extent to which human body mass is appropriate for body height is to compute the **body mass index (BMI)**:

$$\text{BMI} = \frac{\text{Weight in kg}}{(\text{Height in m})^2}$$

BMI fall into four major categories: **N48-4**

1. **Underweight:** <18.5
2. **Normal weight:** 18.5 to 24.9
3. **Overweight:** 25 to 29.9
4. **Obesity:** ≥30

A caution in using BMI is that it takes no account of an excess or deficiency in body water content, and thus its use is inappropriate in edematous states like cirrhosis or heart failure. Although a BMI of ≥30 is an indication of obesity, BMI is not a direct measure of adipose-tissue fat mass (see p. 1243). Obesity is an area of intense investigation driven in part by the obesity epidemic that is adversely affecting the health of a large fraction of the human population.

The demonstration that replacement of leptin in Ob/Ob mice led to rapid weight loss raised considerable enthusiasm for the potential of leptin as a pharmacological agent in the treatment of human obesity. Indeed, extremely rare individuals have been identified with autosomal recessive monogenic obesity secondary to leptin deficiency, like the Ob/Ob mouse. As expected, these individuals respond to exogenous leptin administration with a marked reduction in body weight. However, investigators soon appreciated that the vast majority of obese humans are *not* leptin deficient. Quite the contrary, plasma leptin concentrations increase proportionately to BMI, which is a rough estimate of adipose-tissue fat mass.

Although obese people generally are not leptin deficient, approximately one third of the obese lose weight in response to exogenous leptin. These individuals are **leptin resistant**, but they eventually respond to sufficiently high levels of the hormone. In the other two thirds of obese people, the leptin resistance is so severe that they fail to respond to the exogenous hormone. Lean people lose weight in response to leptin. Persons with congenital lipodystrophy lack adipocytes and thus are leptin deficient. Affected individuals are lean but have excess triacylglycerols in muscle and liver, are very insulin resistant, and develop diabetes. Treatment with leptin corrects this metabolic disorder.

Other mutations besides those of the leptin gene cause monogenic human obesity. Extremely rare are mutations of the leptin receptor gene (analogous to the defect in the Db mouse) and mutations of the POMC gene (leading to loss of the anorexigenic α-MSH). A more common cause of monogenic human obesity is a mutation in the melanocortin receptor MC4R, the target of α-MSH.

Currently no satisfactory pharmacological approaches are available to treat obesity. Given the prevalence of obesity and the likelihood that any pharmacological intervention would need to be long-term, antiobesity drugs are of significant interest within the pharmaceutical industry. Among the agents in late stages of clinical testing, none directly targets the hypothalamic pathways described here. However, because feeding is such a complex behavior—being influenced by hunger, reward and pleasure centers in the CNS, as well as peripheral signals (e.g., gastric distention)—agents may be effective even if they only secondarily affect the hypothalamic control system.

Body Mass Index

Contributed by Emile Boulpaep, Walter Boron

To see how to compute BMI, visit <http://nhlbi/support.com/bmi/>. However, the simplistic formula for computing BMI can be misleading in some cases. For example, in the **cachexia of cancer**, the patient loses not only adipose tissue, but also fat-free mass. Thus, the fall in the BMI is greater than the fall in adipose mass. On the other hand, the accumulation of extracellular fluid in a patient with **ascites** (see Box 24-2) or **interstitial edema** (see Box 20-1) does not reflect an increase in adipose tissue. Thus, the rise in BMI can be greater than any rise in the mass of adipose tissue.

In addition to acting to control appetite, leptin promotes fuel utilization. Indeed, leptin-deficient humans paradoxically exhibit some characteristics of starvation (e.g., fuel conservation via decreased thermogenesis and basal metabolic rate).

Leptin and insulin are anorexigenic (i.e., satiety) signals for the hypothalamus

At least two classes of neurons within the arcuate nucleus contain receptors for leptin and insulin. These neurons, in turn, express neuropeptides. One class of neurons produces pro-opiomelanocortin (POMC), whereas the other produces neuropeptide Y (NPY) and agouti-related protein (AgRP).

POMC Neurons

Insulin and leptin each stimulate largely distinct subgroups of **POMC-secreting neurons** (Fig. 48-9), which produce POMC. At their synapses, POMC neurons release a POMC cleavage product, the melanocortin α -melanocyte-stimulating hormone (α -MSH; see Fig. 50-4), which in turn binds to MC3R and MC4R **melanocortin receptors** on second-order neurons. Stimulation of these receptors not only promotes satiety and decreases food intake—that is, α -MSH is **anorexigenic** (from the Greek *a* [no] + *orexis* [appetite])—but also increases energy expenditure via activation of descending sympathetic pathways. An indication of the importance of this pathway is that ~4% of individuals with severe, early-onset obesity have mutations in MC3R or MC4R. POMC neurons also synthesize another protein—**cocaine- and amphetamine-regulated transcript (CART)**—which, like α -MSH, is anorexigenic.

FIGURE 48-9 Control of appetite. ARC, arcuate nucleus; CART, cocaine- and amphetamine-regulated transcript; DMN, dorsomedial hypothalamic nucleus; LHA, lateral hypothalamic area; NTS, nucleus tractus

NPY/AgRP Neurons

In addition to stimulating POMC neurons, both insulin and leptin can also suppress neurons in the arcuate nucleus that release **NPY** and **AgRP** at their synapses (see [Fig. 48-9](#)). NPY activates NPY receptors (which are GPCRs)—predominantly Y1R and Y5R—on secondary neurons, thereby stimulating eating behavior. AgRP binds to and *inhibits* MC4R melanocortin receptors on the secondary neurons in the POMC pathway, thereby inhibiting the anorexigenic effect of α -MSH. Thus, both NPY and AgRP are **orexigenic**. The yellow obese or **agouti mouse** overexpresses the agouti protein, which inhibits melanocortin receptors. Overinhibition of MC1R on melanocytes inhibits the dispersion of pigment granules (leading to yellow rather than dark fur). Overinhibition of MC3R and MC4R on anorexigenic neurons blocks the action of α -MSH (leading to obesity).

Secondary Neurons

The POMC/CART and NPY/AgRP neurons project to secondary neurons in five major locations (see [Fig. 48-9](#); see also [Fig. 47-3](#)):

1. **Lateral hypothalamic area (LHA)**. In this hunger center (see [p. 1001](#)), NPY/AgRP neurons stimulate—but POMC neurons *inhibit*—secondary neurons. These project throughout the brain and release the orexigenic peptides **melanin-concentrating hormone (MCH)** or **orexins A and B**.
2. **Ventromedial hypothalamic nucleus (VMN)**. This nucleus is a satiety center (see [p. 1001](#)).
3. **Dorsomedial hypothalamic nucleus (DMN)**.
4. **Paraventricular nucleus (PVN)**. This nucleus contains neurons that in turn project to both cerebral cortex and areas of the brainstem (see [Fig. 47-3](#)).
5. **Nucleus tractus solitarii (NTS)**. This nucleus (see [p. 348](#)) integrates sensory information from the viscera and also receives input from paraventricular neurons.

Ghrelin is an orexigenic signal for the hypothalamus

Signals originating from the periphery can be not only *anorexigenic* (i.e., promoting satiety)—as in the case of leptin (from adipose tissue) and insulin (from the pancreas)—but also *orexigenic* (i.e., promoting appetite). One of these is **ghrelin** (see [pp. 992–993](#)), made in response to fasting by specialized endocrine cells in the gastric mucosa. Indeed, systemically administered ghrelin acutely increases food intake when it is given at physiological doses in both animals and humans. Circulating ghrelin concentrations, however, appear to be lower in obese than in lean humans, which suggests that ghrelin does not drive the increased caloric intake in the obese. However, gastric bypass procedures in morbidly obese patients cause a dramatic decline in ghrelin levels, along with a decline in body weight and food consumption.

As discussed previously, ghrelin binds to GHSR1a (see [p. 993](#)), which is present in neurons of the arcuate nucleus as well as vagal afferents. Some hypothalamic neurons themselves contain ghrelin, and injection of ghrelin into the cerebral ventricles stimulates feeding. It is not clear to what extent circulating

ghrelin promotes appetite via vagal afferents versus hypothalamic receptors. As noted above, ghrelin also promotes the secretion of GH and thus appears to have a role in both longitudinal growth and body mass accretion.

Plasma nutrient levels and enteric hormones are short-term factors that regulate feeding

Investigators have proposed various theories to explain the *short-term* regulation of food intake, including models focusing on the regulation of levels of blood glucose (glucostatic), amino acids (aminostatic) or lipids (lipostatic). For example, hypoglycemia produces hunger and also increases the firing rate of glucose-sensitive neurons in the hunger center in the LHA, but decreases the firing rate of glucose-sensitive neurons in the satiety center in the VMN. Hypoglycemia also activates orexin-containing neurons in the LHA.

Feedback from the GI tract also controls the short-term desire for food (see [Fig. 48-9](#)). GI distention triggers vagal afferents that, via the NTS (see [p. 348](#)), suppress the hunger center. Peripherally administering any of several GI peptide hormones normally released in response to a meal—gastrin-releasing peptide (GRP; see [p. 868](#)), CCK (see [pp. 882–883](#)), peptide YY (PYY; see [p. 892](#)), SS (see [pp. 993–994](#)), glucagon (see [pp. 1050–1053](#)), GLP-1 (see [p. 1041](#))—reduces meal size (i.e., these substances are anorexigenic). The most important is CCK, which is more effective when injected directly into the peritoneal cavity; this effect requires an intact vagus nerve. Therefore, CCK—like gastric distention—may act via vagal afferents. Additionally, an oropharyngeal reflex responds to chewing and swallowing; it may meter food intake, thus inhibiting further eating after a threshold.

An important aspect of our increasing understanding of the neuroendocrine control systems that regulate appetite, satiety, and energy expenditure and thereby body mass is the further affirmation that these processes have a genetic and biochemical basis. Two other factors that influence body mass are cortical control (e.g., “willpower”) and environment (e.g., the availability of high-calorie foods). Our emerging appreciation of the biological basis of obesity may allow a more scientific and clinical approach to therapeutic interventions—rather than simply blaming affected patients for their obesity.

The Thyroid Gland

Eugene J. Barrett

The thyroid gland is located in the anterior neck, lying like a small bow tie across the front of the trachea. In adults, the normal thyroid weighs ~20 g. It is composed of left and right lobes and a small connecting branch, or isthmus.

The thyroid gland possesses many features unique among endocrine glands, not the least of which is that it is the only endocrine gland common to both sexes that can be easily seen and palpated in the course of a routine clinical examination. At the biochemical level, the thyroid hormones are the only ones that require an essential trace element, iodine, for the production of active hormone. Another unusual feature of thyroid hormone physiology is that the hormone is stored in an extracellular site within a highly proteinaceous material called *thyroid colloid*. The major protein within this material is thyroglobulin, which contains—as part of its primary structure—the thyroid hormones **tetraiodothyronine (T₄ or thyroxine)** and **triiodothyronine (T₃)**. Thyroglobulin, the sequestered prohormone, is entirely surrounded by thyroid follicular cells, which are responsible for the synthesis of thyroid hormones ([Fig. 49-1](#)).

FIGURE 49-1 Structure of the thyroid gland. The thyroid gland is located anterior to the cricoid cartilage in the anterior neck. The gland comprises numerous follicles, which are filled with colloid and lined by follicular cells. These follicular cells are responsible for the trapping of iodine, which they secrete along with thyroglobulin—the major protein of the thyroid colloid—into the lumen of the follicle.

The physiological actions of thyroid hormones also display several unique aspects. Although derived from a large protein (i.e., thyroglobulin), T_4 and T_3 are not peptides. Unlike peptide hormones or hormones derived from single amino acids (e.g., catecholamines), no cell membrane receptors exist for T_4 or T_3 . Instead, like the steroid hormones, thyroid hormones act principally by binding to *nuclear* receptors (see pp. 71–72) and regulate the transcription of cell proteins. T_4 and T_3 act on multiple tissues and are essential for normal development, growth, and metabolism.

The **C cells** (parafollicular cells) of the thyroid, which are not part of the follicular unit, synthesize another hormone, calcitonin (see Fig. 49-1). Calcitonin may play a role in Ca^{2+} and phosphate homeostasis, and we discuss its physiology on pages 1067–1068.

Synthesis of Thyroid Hormones

T_4 and T_3 , made by iodination of tyrosine residues on thyroglobulin, are stored as part of thyroglobulin molecules in thyroid follicles

The structures of T_4 and T_3 , the two active thyroid hormones, are shown in [Figure 49-2](#). T_3 is far more active than T_4 . Also shown is **reverse T_3 (rT_3)**, which has no known biological activity. It has two iodines on its *outer* benzyl ring, rather than two on its *inner* ring, as is the case for T_3 . All three compounds derive from the ether linkage of a tyrosine molecule to the benzyl group of a second tyrosine molecule; one or two iodine atoms are attached to each benzyl group. The bottom panel of [Figure 49-2](#) shows T_4 as part of the thyroglobulin molecule.

Thyroxine (T_4) (3,5,3',5'-tetraiodo-L-thyronine)

Triiodothyronine (T_3) (3,5,3'-triiodo-L-thyronine)

Reverse T_3 (rT_3) (3,3',5'-triiodothyronine)

Peptide backbone of thyroglobulin (Tg) molecule

FIGURE 49-2 Structure of T_4 , T_3 , and rT_3 . T_4 , T_3 , and rT_3 all are products of the coupling of two iodinated tyrosine derivatives. Only T_4 and T_3 are biologically active, and T_3 is far more active than T_4 because of a higher affinity for thyroid hormone receptors. rT_3 forms as an iodine is removed from the inner benzyl ring of T_4 (labeled “A”); rT_3 is present in approximately equal molar amounts with T_3 . However, rT_3 is essentially devoid of biological activity. As shown in the bottom panel, T_4 is part of the peptide backbone of the thyroglobulin molecule, as are T_3 and rT_3 . Cleavage of the two indicated peptide bonds would release T_4 .

The synthesis of thyroid hormones begins with the trapping of iodine by the thyroid gland. Iodine is essential for the formation of thyroid hormones. It exists in nature as a trace element in soil and is incorporated into many foods. The iodide anion (I^-) is rapidly absorbed by the gastrointestinal (GI) tract and is actively taken up via a specialized **Na/I cotransporter** or **symporter (NIS or SLC5A5)**; see [p. 122](#)), located at the basolateral membrane (i.e., facing the blood) of the thyroid **follicular cell** ([Fig. 49-3](#)). NIS is a 65-kDa integral membrane protein that is believed to have 13 membrane-spanning segments. NIS moves two Na^+ and one I^- into the follicular cell against the I^- electrochemical gradient, fueled by the energy of the Na^+ electrochemical gradient (see [pp. 120–123](#)). Several other anions (e.g., perchlorate, pertechnetate, and thiocyanate) can compete with I^- for uptake by the thyroid. Iodide leaves the follicular cell and enters the lumen of the follicle across the apical membrane. The Cl-I exchanger **pendrin** (SLC26A4; see [p. 125](#))  **N49-1** is present on the apical membrane, where it contributes to I^- secretion. Mutations in this protein can lead to a congenital syndrome typically characterized by a large thyroid gland (goiter) and hearing loss. The thyroid enlarges because of deficient I^- delivery to the follicular colloid, just as it would with an I^- -deficient diet ([Box 49-1](#)).

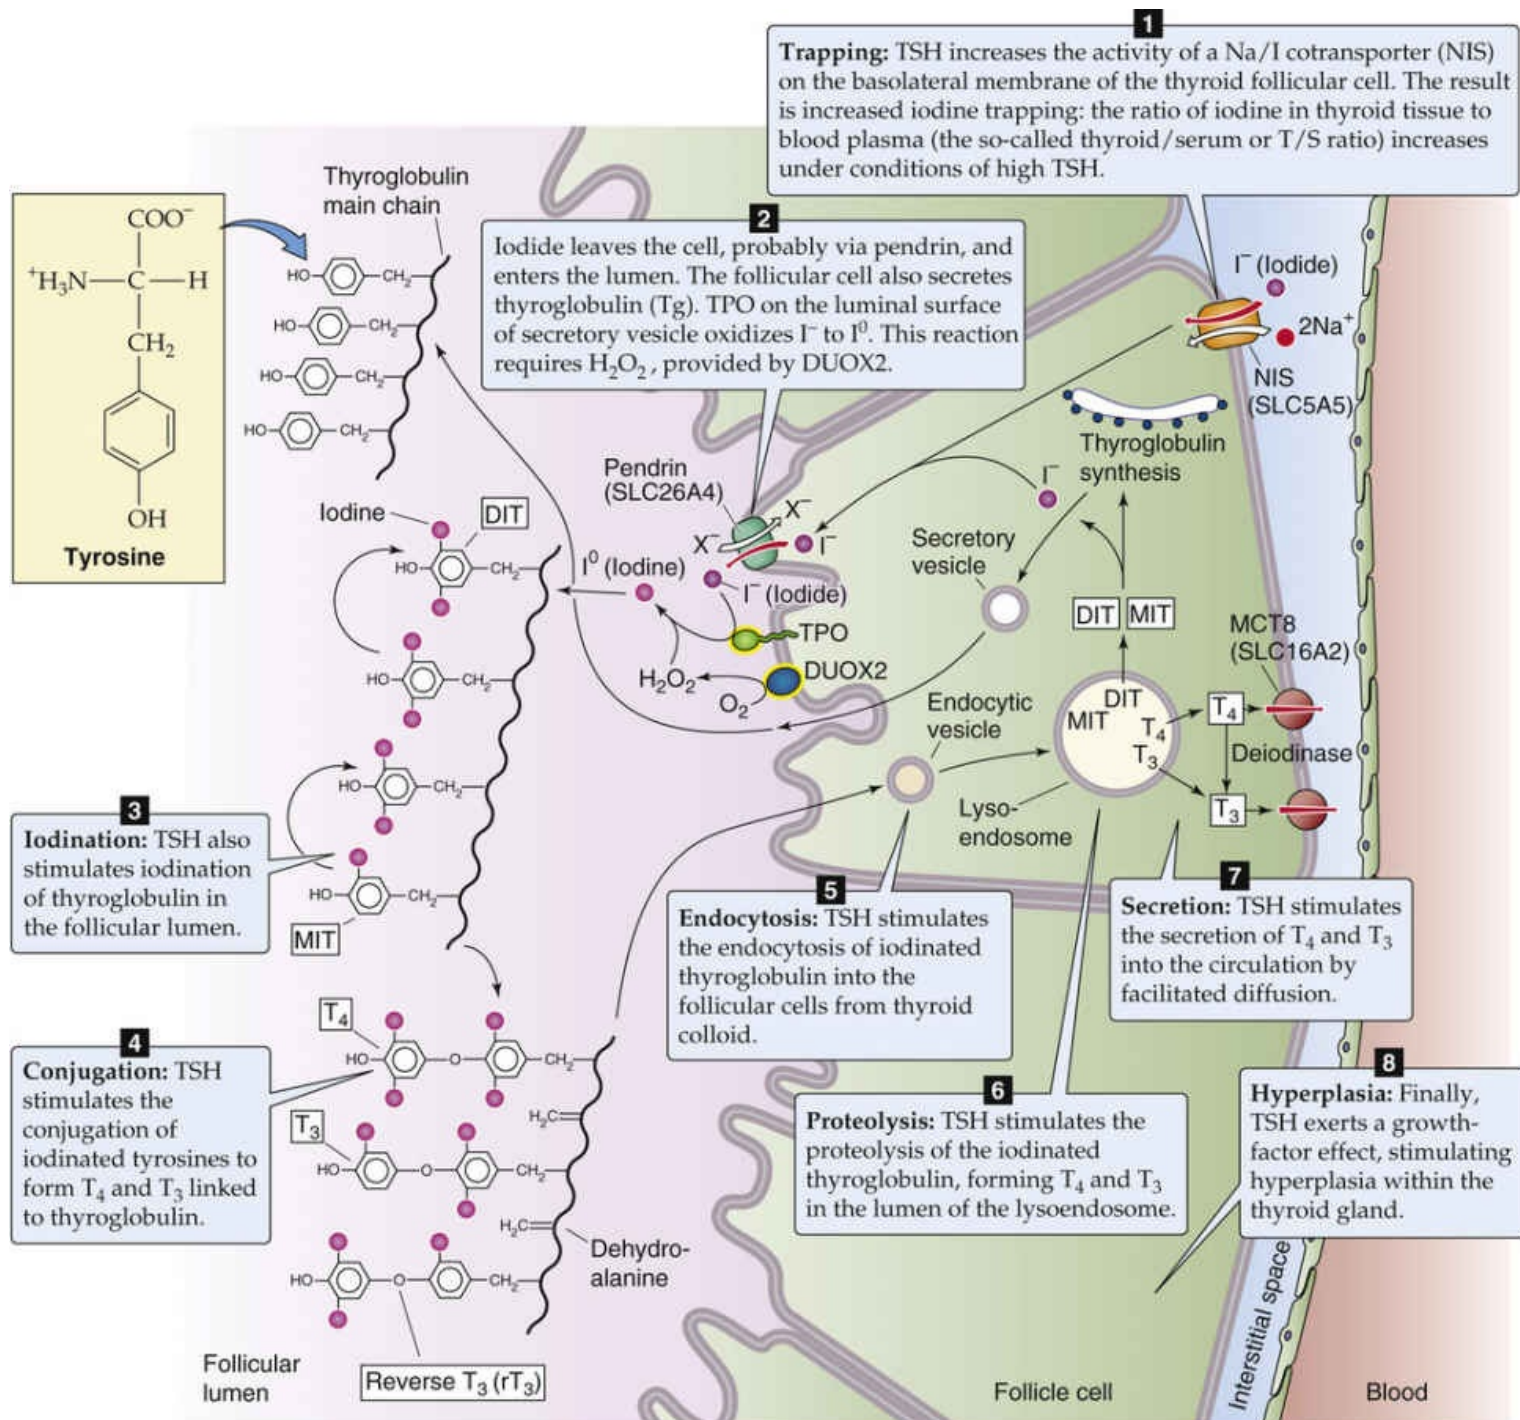

FIGURE 49-3 The follicular cell and its role in the synthesis of T_4 and T_3 . The synthesis and release of T_4 and T_3 occurs in seven steps. Inside the follicular cell, a deiodinase converts some of the T_4 to T_3 . TSH stimulates each of these steps except step 2. In addition, TSH exerts a growth factor or hyperplastic effect on the follicular cells. MCT8, monocarboxylate transporter 8.

Box 49-1

Iodine Deficiency

In areas where soil is relatively iodine deficient, human iodine deficiency is common. Because seawater and seafood contain large amounts of iodide, iodine deficiency is more common in inland areas, particularly in locales that rely on locally grown foods. For example, in inland areas of South America along the Andes Mountains, in central Africa, and in highland regions of Southeast Asia, iodine

deficiency is common. In the early 1900s, investigators first recognized that iodide is present in high concentrations in the thyroid and that iodine deficiency promotes goiter formation. These observations led to efforts to supplement dietary iodine. Iodine deficiency causes thyroid hormone deficiency. The pituitary responds to this deficit by increasing the synthesis of TSH (see p. 1014), which in turn increases the activity of the iodine-trapping mechanism in the follicular cell in an effort to overcome the deficiency. The increased TSH also exerts a trophic effect that increases the *size* of the thyroid gland. If this trophic effect persists for sufficient time, the result is an iodine-deficiency **goiter**. *Goiter* is the generic term for an enlarged thyroid. If this effort at compensation is not successful (i.e., if insufficient thyroid hormone levels persist), the person will develop signs and symptoms of goitrous **hypothyroidism**. When iodine deficiency occurs at critical developmental times in infancy, the effects on the CNS are particularly devastating and produce the syndrome known as **cretinism** (see p. 1013). Persons so affected have a characteristic facial appearance and body habitus, as well as severe mental retardation. Dietary supplementation of iodine in salt and bread has all but eliminated iodine deficiency in North America. In many nations, especially in mountainous and landlocked regions of developing countries, iodine deficiency remains a major cause of preventable illness.

N49-1

Role of Pendrin in Apical Iodide Secretion by Thyroid Follicular Cells

Contributed by Emile Boulpaep, Walter Boron

Pendred syndrome—the combination of congenital hypothyroidism and acoustic nerve deafness—is caused by a mutation in SLC26A4, which encodes an anion exchanger called **pendrin**. The syndrome accounts for as much as 10% of the cases of inherited deafness and is also often associated with a goiter.

In parallel with the secretion of I^- into the follicle lumen, the follicular cell secretes **thyroglobulin (Tg)** into the lumen; Tg contains the tyrosyl groups to which the I^- will ultimately attach. The Tg molecule is a glycoprotein synthesized within the follicular cell and exported to the follicular lumen via the secretory pathway (see p. 28). Tg is a very large protein (>600 kDa), and it accounts for approximately half of the protein content of the thyroid gland. It has relatively few tyrosyl residues (~100 per molecule of Tg), and only a few of these (<20) are subject to iodination. The secretory vesicles that contain Tg also carry the enzyme **thyroid peroxidase (TPO)**—an integral membrane protein, with the catalytic domain facing the vesicle lumen. As the secretory vesicles fuse with the apical membrane, the catalytic domain faces the follicular lumen and catalyzes the oxidation of I^- to I^0 . This reaction requires H_2O , provided by

another apical membrane protein, dual-oxidase 2 (DUOX2). As the Tg is entering the lumen of the thyroid follicle by the process of exocytosis, its tyrosyl groups react with I^0 .

One or two oxidized iodine atoms incorporate selectively into specific tyrosyl residues of Tg. TPO in the presence of H_2O_2 catalyzes the coupling of two iodinated tyrosyl residues within the Tg molecule to form a single iodothyronine as well as a remnant dehydroalanine. Both remain as part of the primary structure of the iodinated Tg until it is later degraded inside the follicular cell. This coupling of two tyrosines, catalyzed by TPO, does not occur unless they are iodinated. Because only a few tyrosyl groups become iodinated, something specific about the structure of the protein near these residues probably facilitates both iodination and conjugation. The thyroid hormones, although still part of the Tg molecule, are stored as colloid in the thyroid follicle.

Follicular cells take up iodinated thyroglobulin, hydrolyze it, and release T_4 and T_3 into the blood for binding to plasma proteins

Thyroid hormones, attached to Tg in the follicular lumen (see Fig. 49-1), remain inactive until the iodinated Tg is hydrolyzed (see Fig. 49-3). Before this proteolysis can begin, the follicular cells must resorb Tg from the follicular lumen by fluid-phase endocytosis (see pp. 41–42). As the endocytic vesicle containing the colloid droplet moves from the apical toward the basolateral membrane, it fuses with lysosomes to form a lysoendosome. Inside this vesicle, lysosomal enzymes hydrolyze the Tg and form T_4 and T_3 , as well as diiodothyronine (DIT) and moniodothyronine (MIT). The vesicle releases both T_4 and T_3 near the basolateral membrane, and these substances exit the cell into the blood by an unknown mechanism. Approximately 90% of the thyroid hormone secreted by the thyroid is released as T_4 , and 10% is released as T_3 . The thyroid releases very little rT_3 into the blood. As discussed in the next section, nonthyroidal tissues metabolize the T_4 released by the thyroid into T_3 and rT_3 . Approximately three fourths of circulating T_3 arises from the peripheral conversion of T_4 , which occurs principally in the liver and kidneys.

In the circulation, both T_4 and T_3 are highly bound to plasma proteins. **Thyroid-binding globulin (TBG)**, albumin, and **transthyretin (TTR)** account for most of this binding. The affinity of these binding proteins is sufficiently high that, for T_4 , >99.98% of the hormone circulates tightly bound to protein. T_3 is bound only slightly less: ~99.5% is protein bound. Because the *free* or *unbound* hormone in the circulation is responsible for the actions of the thyroid hormones on their target tissues, the large amount of bound hormone has considerably confounded our ability to use simple measurements of the total amount of either T_4 or T_3 in the plasma to provide a reliable index of the adequacy of thyroid hormone secretion. For example, the amount of TBG in the serum can change substantially in different physiological states. Pregnancy, oral estrogen therapy, hepatitis, and chronic heroin abuse can all elevate the amount of TBG and hence the *total* concentration of T_4 and T_3 . Decreased levels of TBG, associated with diminished concentration of *total* T_4 and T_3 , can accompany steroid usage and nephrotic syndrome. However, despite the marked increases or decreases in the amounts of circulating TBG, the concentrations of *free* T_4 and T_3 do not change in the aforementioned cases. Box 49-2 indicates how one can calculate levels of free T_4 or T_3 , knowing the concentration of TBG and the concentration of total T_4 or total T_3 .

Free versus Bound Thyroxine

Most of the T_4 and T_3 in the serum is bound to proteins, the most important of which is TBG. For the binding of T_4 to TBG, the reaction is

$$K = \frac{[T_4 TBG]}{[T_4][TBG]}$$

The binding constant K is $\sim 2 \times 10^{10} M^{-1}$ for T_4 . The comparable binding constant for T_3 is $\sim 5 \times 10^8 M^{-1}$. Approximately one third of TBG's binding sites are occupied by T_4 . Therefore, we have all the information we need to compute the concentration of free T_4 :

$$[T_4]_{\text{FREE}} = \frac{[T_4 TBG]}{K[TBG]}$$

A reasonable value for $[T_4 TBG]$ would be 100 nM, and for $[TBG]$, 250 nM. Thus,

$$\begin{aligned} [T_4]_{\text{FREE}} &= \frac{(100 \text{ nM})}{(2 \times 10^{10} M^{-1}) \cdot (250 \text{ nM})} \\ &= 0.20 \times 10^{-10} M \\ &= 20 \text{ pM} \end{aligned}$$

Because the bound T_4 in this example is 100 nM, and the free T_4 is only 20 pM, we can conclude that only $\sim 0.02\%$ of the total T_4 in the plasma is free. Because 99.98% of the total T_4 in the plasma is bound, moderate fluctuations in the rate of T_4 release from the thyroid have only tiny effects on the level of free T_4 . To simplify, we have not included the minor contribution of albumin and TTR in this sample calculation.

The liver makes each of the thyroid-binding proteins. TBG is a 54-kDa glycoprotein consisting of 450 amino acids. It has the highest affinity for T_4 and T_3 and is responsible for most of the thyroid-binding capacity in the plasma. The extensive binding of thyroid hormones to plasma proteins serves several functions. It provides a large buffer pool of thyroid hormones in the circulation, so that the active concentrations of hormone in the circulation change very little on a minute-to-minute basis. The binding to plasma proteins markedly prolongs the half-lives of both T_4 and T_3 . T_4 has a half-life of 8 days, and T_3 , of ~ 24 hours; each is longer than the half-life of steroid or peptide hormones. Finally, because much of the

T_3 in the circulation is formed by the conversion of T_4 to T_3 in extrathyroidal tissues, the presence of a large pool of T_4 in the plasma provides a reserve of prohormone available for synthesis of T_3 . This reserve may be of particular importance because T_3 is responsible for most of the biological activity of thyroid hormones.

Peripheral tissues deiodinate T_4 to produce T_3

The thyroid synthesizes and stores much more T_4 than T_3 , and this is reflected in the $\sim 10 : 1$ ratio of T_4 to T_3 secreted by the thyroid. However, certain tissues in the body have the capacity to selectively deiodinate T_4 , thereby producing either T_3 or rT_3 . T_3 and rT_3 can each be further deiodinated to various DITs and MITs (Fig. 49-4); both DITs and MITs are biologically inactive. Both iodine atoms on the inner ring, and at least one iodine atom on the outer ring, appear essential for biological activity. Similarly, the loss of the amino group renders T_4 or T_3 inactive. The importance of the peripheral deiodination of T_4 to T_3 can be readily appreciated from the observation that persons whose thyroids have been removed have normal circulating concentrations of T_3 when they receive oral T_4 supplementation.

FIGURE 49-4 Peripheral metabolism of T_4 . The 5'/3'-monodeiodinases (type 1 and type 2; green arrows) remove I from the outer benzyl ring, whereas the 5/3-monodeiodinase (type 3; orange arrows) removes I from the inner benzyl ring. Thus, the action of the 5'/3'-monodeiodinases on T_4 yields T_3 , whereas the action of the 5/3-monodeiodinase yields rT_3 . Sequential deiodination yields T_0 (thyronine).

Inasmuch as T_3 is biologically much more active than the far more abundant T_4 , the regulated

conversion of T_4 to T_3 in peripheral tissues—as well the conversion of T_4 and T_3 to inactive metabolites—assumes considerable importance. These conversions are under the control of three **deiodinases**. Two deiodinases are 5'/3'-deiodinases that remove an I from the *outer* ring and thereby convert T_4 to T_3 (see Fig. 49-4). The first of these 5'/3'-deiodinases—**type 1 deiodinase**—is present at high concentrations in the liver, kidneys, skeletal muscle, and thyroid. It appears to be responsible for generating most of the T_3 that reaches the circulation. The second 5'/3'-deiodinase—**type 2 deiodinase**—is found predominantly in the pituitary, central nervous system (CNS), and placenta, and is involved in supplying those tissues with T_3 by local generation from plasma-derived T_4 . As shown below, the type 2 enzyme in the pituitary is of particular importance because the T_3 that is generated there is responsible for the feedback inhibition of the release of **thyrotropin** (or **thyroid-stimulating hormone, TSH**).

A third 5/3-deiodinase—**type 3 deiodinase**—removes an I from the *inner* ring, thereby converting T_4 to the inactive rT_3 . Because the 3' and 5' positions in T_4 are equivalent stereochemically, removing either of these by type 1 or type 2 deiodinase yields T_3 . Similarly, removal of the I from either the 3 or the 5 position of the inner ring of T_4 by type 3 deiodinase yields rT_3 . Further deiodination by any of the three enzymes ultimately yields T_0 (i.e., thyronine).

The relative activity of the outer-ring deiodinases changes in response to physiological and pathological stimuli. Caloric restriction or severe stress inhibits the *type 1* deiodinase; this process decreases the conversion of T_4 to T_3 —and thus reduces the levels of T_3 . In contrast, levels of rT_3 rise by default in these situations, in part because of reduced conversion to DITs. These decreases in T_3 levels are accompanied by a decline in metabolic rate. You may think that because plasma levels of T_3 *fall*, there would be a compensatory *rise* in TSH, the secretion of which is inhibited by T_3 . However, because *type 2* deiodinase mediates the conversion of T_4 to T_3 within the pituitary and CNS, and because caloric restriction does not affect this enzyme, local T_3 levels in the pituitary are normal. Thus, the thyrotrophs in the pituitary continue to have adequate amounts of T_3 , and no compensatory rise in TSH occurs. Teleologically, the rationale to restrain calorie expenditure in settings of decreased caloric intake is appealing. 🍌 [N49-2](#)

N49-2

Effect of Calorie Restriction on Type 1 Deiodinase

Contributed by Eugene Barrett

As noted in the text, calorie restriction inhibits type 1 monodeiodinase, reducing the conversion of T_4 to T_3 and thereby lowering circulating levels of T_3 . This effect of caloric restriction makes sense for someone who is starving because it tends to conserve body stores of fuel. On the other hand, this effect makes it more difficult to lose weight intentionally while dieting.

Action of Thyroid Hormones

Thyroid hormones act through nuclear receptors in target tissues

Thyroid hormones act on many body tissues to exert both metabolic and developmental effects. Once T_4 and T_3 leave the plasma, they enter the cell either by diffusing through the lipid of the cell membrane or by carrier-mediated transport (Fig. 49-5). Most, but not all, of the actions of thyroid hormones occur as thyroid hormones bind to and activate **nuclear receptors** (see pp. 71–72). The multitude of thyroid hormone actions is mirrored by the ubiquitous expression of **thyroid hormone receptors (TRs)** throughout the body's tissues. There are actually two TR genes— α (chromosome 17) and β (chromosome 3)—and at least two isoforms of TR β . The expression of these receptor genes is tissue specific and varies with time of development. The liver expresses TR β , whereas TR α predominates in the brain. During development, the amount of α expressed may vary 10-fold or more. Both receptors bind to DNA response elements, predominately as heterodimers in association with the **retinoid X receptor (RXR)**, and alter the transcription of specific genes.

FIGURE 49-5 Action of thyroid hormones on target cells. Free extracellular T_4 and T_3 enter the target cell via facilitated diffusion. Once T_4 is inside the cell, a cytoplasmic 5'/3'-monodeiodinase converts much of the T_4 to T_3 , so that the cytoplasmic levels of T_4 and T_3 are about equal. T_3 or T_4 activates thyroid hormone receptors—already bound to nuclear DNA at thyroid response elements in the promoter region of certain genes—and thereby regulates the transcription of these genes. Of the total thyroid hormone bound to receptor, ~90% is T_3 . The receptor that binds to the DNA is preferentially a heterodimer of the thyroid hormone receptor and retinoid X receptor. MCT8, monocarboxylate transporter 8.

Biologically, T_3 is much more important than T_4 . This statement may be surprising inasmuch as the *total* concentration of T_4 in the circulation is ~50-fold higher than that of total T_3 . Nevertheless, T_3 has greater

biological activity for three reasons. First, T_4 is bound (only 0.01 to 0.02% is *free*) more tightly to plasma proteins than is T_3 (0.50% is *free*). The net effect is that the amounts of free T_4 and free T_3 in the circulation are comparable. Second, because the target cell converts some T_4 —once it has entered the cell—to T_3 , it turns out that T_4 and T_3 are present at similar concentrations in the cytoplasm of target cells. Third, the TR in the nucleus has ~10-fold greater affinity for T_3 than for T_4 , so that T_3 is more potent on a molar basis. As a result, T_3 is responsible for ~90% of the occupancy of TRs in the euthyroid state. 🍎

N49-3

Sick Euthyroid Syndrome

Contributed by Eugene Barrett

Many hospitalized patients who are extremely ill exhibit abnormal results on thyroid function tests. However, the thyroid activity of most of these patients is actually appropriate and needs no correction. Many of these patients are in an intensive care unit (ICU) setting, and it is extremely important to distinguish true thyroid disease from this so-called *sick euthyroid syndrome*.

Sick euthyroid syndrome can take many forms, but the most common is a low or lower-than-normal total T_4 level and a low T_3 level. In true hypothyroidism, the diminished levels of thyroid hormones decrease feedback inhibition on the pituitary gland and lead to increased levels of TSH (see p. 1014). In sick euthyroid syndrome, the TSH level is usually normal. Although the reasons for this situation are not completely understood, at least one explanation may lie in the distinction between type 1 deiodinase, which is found in the periphery, and type 2 deiodinase, which is present in the pituitary. In sick euthyroid syndrome, the activity of type 1 or peripheral 5'/3' deiodinase decreases, so that there is less conversion of peripheral T_4 to T_3 , but more conversion to rT_3 . As a result, peripheral T_3 levels fall. However, as was described in the main text with regard to starvation, type 2 deiodinase is not affected by stress nearly as much as is type 1 deiodinase; therefore, the pituitary gland continues to sense normal levels of T_3 , and it responds to what it perceives as normal levels of feedback inhibition from local T_3 on the production and release of TSH. However, other factors must also be involved, inasmuch as this mechanism does not adequately account for the decrease in total T_4 .

Patients with sick euthyroid syndrome may appear profoundly hypothyroid, exhibiting hypothermia and a sluggish sensorium, but they are not hypothyroid, and they should not receive thyroid hormone replacement. In fact, treating sick euthyroid patients with thyroid hormone yields either no improvement or a worse outcome.

When T_3 or T_4 binds to the TR in the nucleus, the hormone-bound receptor either activates or represses the transcription of specific genes. As discussed above, TR preferentially binds to DNA as a heterodimer of TR and RXR (see Table 3-6). TR belongs to the superfamily of nuclear receptors that may contain domains A through F (see Fig. 3-14). Three regions are especially important for TR: (1) The amino-terminal A/B region contains the first of two transactivation domains, which are responsible for transducing receptor binding into a conformational change in the DNA and thereby initiating transcription. (2) The middle or C region is responsible for DNA binding through two zinc fingers (see p. 82) as well as dimerization between receptors. (3) the E region, toward the carboxyl terminus, is responsible for

binding the ligand (T_3 or T_4), and also for dimerization.

Thyroid hormones can also act by nongenomic pathways

In addition to binding to receptors in the nucleus, T_4 and T_3 bind to sites in the cytosol, microsomes, and mitochondria. This observation has raised the issue of whether thyroid hormones exert actions through mechanisms *not* involving transcriptional regulation. Nongenomic actions of thyroid hormones have been observed in several tissues, including heart, muscle, fat, and pituitary. Thyroid hormones can act via nongenomic pathways to enhance mitochondrial oxidative phosphorylation—or at least energy expenditure as measured by O_2 consumption. Nongenomic targets of thyroid hormones include ion channels, second messengers, and protein kinases. It is less clear whether these actions occur via $TR\alpha$ or $TR\beta$ —similar to the nongenomic actions of estrogens, which involve the estradiol receptor (see [p. 989](#))—or whether other high-affinity thyroid-binding proteins are involved.

Thyroid hormones increase basal metabolic rate by stimulating futile cycles of catabolism and anabolism

Investigators have long observed that excess thyroid hormone raises the **basal metabolic rate (BMR)** as measured by either heat production (direct calorimetry) or O_2 consumption (indirect calorimetry). Conversely, thyroid hormone deficiency is accompanied by a decrease in BMR. [Figure 49-6](#) illustrates the effect of thyroid hormone levels on BMR, and [Table 49-1](#) summarizes the effect of the thyroid hormones on several parameters. Thyroid hormones increase the BMR by stimulating both catabolic and anabolic reactions in pathways affecting fats, carbohydrates, and proteins.

FIGURE 49-6 Effect of thyroid hormone on BMR. This graph shows the dependence of BMR on the daily rate of thyroid hormone secretion (T_4 and T_3). We use the secretion rate because it is difficult to know whether to use free T_4 or free T_3 . Thus, the secretion rate is a crude measure of effective thyroid hormone levels. (Data from Guyton AC, Hall JE: Textbook of Medical Physiology, 9th ed. Philadelphia, WB Saunders, 1996.)

TABLE 49-1

Physiological Effects of the Thyroid Hormones (T_3 and T_4)

PARAMETER	LOW LEVEL OF THYROID HORMONES (HYPOTHYROID)	HIGH LEVEL OF THYROID HORMONES (HYPERTHYROID)
Basal metabolic rate	↓	↑
Carbohydrate metabolism	↓ Gluconeogenesis ↓ Glycogenolysis Normal serum [glucose]	↑ Gluconeogenesis ↑ Glycogenolysis Normal serum [glucose]
Protein metabolism	↓ Synthesis ↓ Proteolysis	↑ Synthesis ↑ Proteolysis Muscle wasting
Lipid metabolism	↓ Lipogenesis ↓ Lipolysis ↑ Serum [cholesterol]	↑ Lipogenesis ↑ Lipolysis ↓ Serum [cholesterol]
Thermogenesis	↓	↑
Autonomic nervous system	Normal levels of serum catecholamines	↑ Expression of β adrenoreceptors (increased sensitivity to catecholamines, which remain at normal levels)

Carbohydrate Metabolism

Thyroid hormones raise the rate of hepatic glucose production, principally by increasing hepatic gluconeogenic activity (see [p. 1176](#)). This effect generally does not result in increases in plasma [glucose], provided the pancreas responds by augmenting insulin secretion. Thyroid hormones also enhance the availability of the starting materials required for increased gluconeogenic activity (i.e., amino acids and glycerol), and they specifically induce the expression of several key gluconeogenic enzymes, including phosphoenolpyruvate carboxykinase, pyruvate carboxylase, and glucose 6-phosphatase.

Protein Metabolism

The amino acids required for increased hepatic gluconeogenesis stimulated by thyroid hormones come from increased proteolysis, predominantly in muscle. Thyroid hormones also increase protein synthesis. Because the increases in protein degradation usually outweigh the increases in synthesis, a net loss of muscle protein occurs. The catabolic effect is exaggerated when T_3 is present in great excess, so that muscle wasting and weakness, as well as increased nitrogen loss in the urine as urea (see pp. 770–772 and 965), can be prominent features of clinical thyrotoxicosis (hyperthyroidism).

Lipid Metabolism

Thyroid hormones increase the degradation of stored triacylglycerols in adipose tissue, releasing fatty acids (FAs) and glycerol. The FAs provide fuel for the liver to support the energy demand of gluconeogenesis, and the glycerol provides some of the starting material for gluconeogenesis. Thyroid hormones not only increase lipolysis but also enhance lipogenesis. Indeed, modest amounts of thyroid hormones are needed for the normal synthesis of FAs by liver. Very high levels of T_3 shift the balance in favor of lipolysis, with resulting generalized fat mobilization and loss of body fat stores.

By accelerating the rates of glucose production, protein synthesis and degradation, as well as lipogenesis and lipolysis, the thyroid hormones stimulate energy consumption. Therefore, to the extent that thyroid hormones stimulate both synthesis and degradation, they promote **futile cycles** that contribute significantly to the increased O_2 consumption seen in thyrotoxicosis (hyperthyroidism).

How, at the molecular level, thyroid hormones affect the BMR in states of both spontaneous and experimentally induced thyroid hormone excess or deficiency has been a difficult question to answer. The changes in metabolic rate do not appear to be determined by changes in the expression of a single gene. Several specific examples of the effects of thyroid hormones on target tissues serve to illustrate their general mechanism of action.

Na-K Pump Activity

In muscle, liver, and kidney, thyroid hormone–induced increases in oxygen consumption are paralleled by increases in the activity of the **Na-K pump** in the plasma membrane (see pp. 115–117). This increase in transport is the result, at least in part, of an increase in the synthesis of new transporter units that are inserted into the plasma membrane. At least in some tissues, the blockade of the increases in Na-K pump activity with ouabain also blocks the increase in O_2 consumption. T_3 stimulates the transcription of the genes for both the α and β subunits of the Na-K pump. In addition, T_3 increases translation by stabilizing the mRNA that encodes the Na-K pump. Increases in pump activity consume additional ATP, which results in increased O_2 consumption and heat generation. Inasmuch as states of thyroid hormone excess are not accompanied by any noticeable derangement of plasma electrolyte levels, presumably the increase in Na-K pump activity is compensated in some manner by a leak of Na^+ and K^+ , although such pathways have not yet been defined. Overall, the increased activity of the Na-K pump (with an accompanying cation leak) would result in a futile cycle in which energy was consumed without useful work.

Thermogenesis

In rodents, thyroid hormones may affect metabolic rate and thermogenesis through another futile cycle mechanism. Brown fat in these animals expresses a mitochondrial **uncoupling protein (UCP)**, or **thermogenin**, that dissociates **oxidative phosphorylation** from ATP generation. Thus, mitochondria

consume O_2 and produce heat without generating ATP. Both T_3 and β -adrenergic stimulation (acting through the β_3 receptor) enhance respiration in brown adipose tissue by stimulating this uncoupling mechanism. We discuss thermogenin—and the vital role it plays in helping to keep newborn humans warm—on [page 1166](#).

Thyroid hormones also increase the BMR by increasing the thermogenic effects of other processes. An example is the effect of adrenergic stimulation on thermogenesis, discussed above. In humans, plasma *concentrations* of catecholamines are normal in states of both excess and deficient T_3 and T_4 . However, excess thyroid hormone raises the *sensitivity* of tissues to the action of adrenergic hormones. In heart, skeletal muscle, and adipose tissue, this effect is the result, at least in part, of increased expression of **β -adrenergic receptors** by these tissues. In patients who are acutely thyrotoxic, treatment with β -receptor antagonists is one of the first priorities. This treatment blunts the hypersympathetic state induced by the excess of thyroid hormones. Thyroid hormones may also exert postreceptor effects that enhance adrenergic tone. In the heart, thyroid hormones also regulate the expression of specific forms of **myosin heavy chain**. Specifically, in rodents, thyroid hormone increases the expression of the myosin α chain, thereby favoring the α/α isoform of myosin heavy chain (see [Table 9-1](#)). This isoform is associated with greater activity of both actin and Ca^{2+} -activated ATPase, faster fiber shortening, and greater contractility.

Thyroid hormones are essential for normal growth and development

In amphibians, thyroid hormone regulates the process of metamorphosis. Removing the thyroid gland from tadpoles causes development to arrest at the tadpole stage. Early administration of excess thyroid hormone can initiate premature metamorphosis. Iodothyronines are present even farther down the phylogenetic tree, at least as far as primitive chordates, although these animals lack a thyroid gland *per se*. However, the biological actions of iodothyronines in many species are not known.

Thyroid hormones are essential for normal human development as well, as starkly illustrated by the unfortunate condition of cretinism in regions of endemic iodine deficiency. **Cretinism** is characterized by profound mental retardation, short stature, delay in motor development, coarse hair, and a protuberant abdomen. Correction of iodine deficiency has essentially eliminated endemic cretinism in developed nations. Sporadic cases continue to occur, however, as a result of congenital defects in thyroid hormone synthesis. If hypothyroidism ([Box 49-3](#)) is recognized and corrected within 7 to 14 days after birth, development—including mental development—can proceed almost normally. Once the clinical signs of congenital hypothyroidism become apparent, the developmental abnormalities in the CNS are irreversible. For this reason, all U.S. states and territories conduct laboratory screening of newborns for hypothyroidism. This screening has shown that the overall rate of congenital hypothyroidism is ~0.3% and varies considerably across racial and ethnic groups, being lower in African Americans (~0.1%) and higher in Hispanic infants (~0.6%).

Box 49-3

Hypothyroidism

Hypothyroidism is one of the most common of all endocrine illnesses, affecting between 1% and 2% of all adults at some time in their lives. Women are much more commonly affected than men. Although hypothyroidism has several causes, the most common cause worldwide is iodine deficiency. In the United

States, by far the most common cause is an autoimmune disorder called *Hashimoto thyroiditis*. Like Graves disease, Hashimoto thyroiditis is caused by an abnormal immune response that includes the production of antithyroid antibodies—in this case, antibodies against the thyroid follicular cells, microsomes, and TSH receptors. Unlike in Graves disease, the antibodies in Hashimoto thyroiditis are not stimulatory, but rather are part of an immune process that blocks and destroys thyroid function. The titers of these autoantibodies can reach colossal proportions.

Typically, hypothyroidism in Hashimoto thyroiditis is an insidious process that develops slowly; indeed, many patients are diagnosed long before striking clinical manifestations are apparent when routine blood tests reveal an elevated TSH level despite normal levels of T_3 and T_4 . These individuals, although not yet clinically hypothyroid, are sometimes treated with thyroid hormone replacement, so the clinical manifestations of hypothyroidism are never given a chance to develop.

In patients in whom the disease does evolve, the classical presentation consists of painless goiter, skin changes, peripheral edema, constipation, headache, joint aches, fatigue, and, in women, anovulation. The TSH level should be checked in any female patient with secondary amenorrhea. A subset of these Hashimoto thyroiditis patients may also develop other autoimmune endocrine deficiency disorders. Those with **multiple endocrine deficiency type 1** have insufficient production of parathyroid, adrenal, and thyroid hormones. Those with **multiple endocrine deficiency type 2** have insufficiencies in pancreatic islet β -cell (i.e., insulin), adrenal, and thyroid hormones. Other nonendocrine autoimmune diseases (e.g., pernicious anemia, myasthenia gravis) also are associated with autoimmune thyroid disease.

Like patients with hyperthyroidism, who may be threatened by thyroid storm, those with hypothyroidism have their own severe, life-threatening variant, in this case called **myxedema coma**. This malady is quite rare and occurs most commonly in elderly patients with established hypothyroidism. Hypothermia and coma evolve slowly in these patients, and the usual causes are failure to take prescribed thyroid hormone replacement drugs, cold exposure, sepsis, heart failure, and alcohol abuse.

Typically overshadowed by the impaired cognitive development that occurs in cretinism is the **dwarfism** that results from the effects of thyroid hormone deficiency on human growth ([Fig. 49-7](#)). In children with normal thyroid function at birth, development of hypothyroidism at any time before the fusion of the epiphyses of the long bones leads to growth retardation or arrest. Much of the loss in height that occurs can be recovered after thyroid hormone treatment is begun, a phenomenon called *catch-up growth*. If the diagnosis and treatment of hypothyroidism are delayed, loss of potential growth may occur, as indicated in [Figure 49-7](#). However, as noted above, mental development does not catch up unless the treatment is begun within 7 to 14 days of birth. In general, the longer the duration of congenital hypothyroidism, the more profound is the mental retardation. In rodents, thyroid hormone regulates the induction of expression of several neural proteins, including myelin basic protein (MBP; see [Table 11-4](#)). How deficiencies in these proteins result in the generalized cortical atrophy seen in human infantile hypothyroidism is not clear.

FIGURE 49-7 Effect of thyroid hormone on growth and development. The graph shows developmental age—that is, the age that the child appears to be based on height, bone radiography, and mental function—versus chronological age. For a normal child, the relationship is the straight line (red), for which developmental and chronological age are identical. The three green curves are growth curves for a child with thyroid hormone deficiency. Notice that at age 4.5 years, before initiation of therapy, height age, bone age, and mental age are all substantially below normal. Initiating replacement therapy with thyroid hormone at age 4.5 causes a rapid increase in both height age and bone age (“catch-up”) but has no effect on mental age, which remains infantile. Treatment can help mental development only if the therapy is begun within a few days of birth. (Data from Wilkins L: *The Diagnosis and Treatment of Endocrine Disorders of Childhood and Adolescence*. Springfield, IL, Charles C Thomas, 1965.)

The growth curve (i.e., a plot of the child's height and weight versus age) can provide a particularly sensitive early indicator of hypothyroidism in children who develop hypothyroidism after the neonatal period. An overactive thyroid is much less a problem than is an underactive thyroid with regard to its effect on growth; other signs and symptoms of an overactive thyroid predominate.

Cellular explanations of the effects of thyroid hormones on human development are incomplete. In rats, thyroid hormone induces the secretion of pituitary growth hormone (GH); thus, the growth retardation in thyroid-deficient rats may be partly the result of decreased GH secretion. However, in humans, who have no thyroid hormone response element in the promoter region of the GH gene, plasma [GH] is normal in hypothyroidism. Thus, the growth failure of hypothyroid human infants is not as readily explained. In humans, changes in the growth of long bones are more or less characteristic of thyroid hormone deficiency. These changes include a delay in formation of centers of ossification at the growth plate, followed by the appearance of several ossification centers, which eventually merge. Short stature in human juvenile or infantile hypothyroidism may be in part related to these abnormalities of cartilage growth and development as well as to resistance to the normal action of GH to promote growth.

Hypothalamic-Pituitary-Thyroid Axis

The pituitary regulates the synthesis and secretion of thyroid hormones through the release of **thyrotropin**—also known as **thyroid-stimulating hormone (TSH)**—from the anterior pituitary. The hypothalamus, in turn, stimulates the release of TSH through **thyrotropin-releasing hormone (TRH)**. Finally, circulating thyroid hormones exert feedback control on both TRH and TSH secretion.

TRH from the hypothalamus stimulates thyrotrophs of the anterior pituitary to secrete TSH, which stimulates T_4/T_3 synthesis

Thyrotropin-Releasing Hormone

TRH is a tripeptide pyro-Glu-His-Pro containing the modified amino acid pyro-Glu. It is found in many tissues, including the cerebral cortex, multiple areas of the GI tract, and the β cells of the pancreas. However, the arcuate nucleus and the median eminence of the **hypothalamus** appear to be the major sources of the TRH that stimulates TSH synthesis and secretion ([Fig. 49-8](#)). TRH released by neurons in the hypothalamus travels to the anterior pituitary through the hypophyseal portal system (see [p. 978](#)). Hypothalamic lesions that interrupt TRH release or delivery cause a fall in basal TSH levels. Conversely, administering TRH intravenously can cause a rapid, dose-dependent release of TSH from the anterior pituitary. However, it is not clear that such bursts of TRH release and TSH secretion occur physiologically.

FIGURE 49-8 Hypothalamic-pituitary-thyroid axis. Small-bodied neurons in the arcuate nucleus and median eminence of the hypothalamus secrete TRH, a tripeptide that reaches the thyrotrophs in the anterior pituitary via the long portal veins. TRH binds to a G protein–coupled receptor on the thyrotroph membrane, triggering the DAG/IP₃ pathway; stimulation of this pathway leads to protein phosphorylation and a rise in [Ca²⁺]_i. These pathways stimulate the thyrotrophs to synthesize and release TSH, which is a 28-kDa glycoprotein stored in secretory granules. The TSH binds to receptors on the basolateral membrane of thyroid follicular cells, stimulating Gα_s, which in turn activates adenylyl cyclase and raises [cAMP]_i. As outlined in [Figure 49-3](#), TSH stimulates a number of steps in the synthesis and release of T₄ and T₃. Inside the pituitary, the type 2 form of 5′/3′-monodeiodinase converts T₄ to T₃, which negatively feeds back on the thyrotrophs as well as on the TRH-secreting neurons. Somatostatin and dopamine—released by hypothalamic neurons—inhibit TSH release and thus can influence the set-point at which TSH is released in response to a given amount of T₃ in the pituitary. AC, adenylyl cyclase; MCT8, monocarboxylate transporter 8; PKC, protein kinase C; PLC, phospholipase C.

TRH Receptor

Once it reaches the thyrotrophs in the anterior pituitary, TRH binds to the TRH receptor, a G protein–coupled receptor on the cell membranes of the thyrotrophs. TRH binding triggers the phospholipase C pathway (see [p. 58](#)). The formation of diacylglycerols (DAGs) stimulates protein kinase C and leads to protein phosphorylation. The simultaneous release of inositol trisphosphate (IP₃) triggers Ca²⁺ release from internal stores, raising [Ca²⁺]_i. The result is an increase in both the synthesis and release of TSH, which is stored in secretory granules. TRH produces some of its effects by activating phospholipase A₂, a process leading to the release of arachidonic acid and the formation of a variety of biologically active eicosanoids (see [pp. 62–64](#)). In healthy humans, administering TRH also raises plasma [prolactin] by stimulating lactotrophs in the anterior pituitary (see [p. 1150](#)). However, no evidence indicates a regulatory role for TRH in prolactin secretion or milk production.

Thyrotropin

The thyrotrophs represent a relatively small number of cells in the **anterior pituitary**. The TSH that they release is a 28-kDa glycoprotein with α and β chains. The α chain of TSH is identical to that of the other glycoprotein hormones: the gonadotropins luteinizing hormone (LH), follicle-stimulating hormone (FSH), and human chorionic gonadotropin (hCG). The β chain is unique to TSH and confers the specificity of the hormone. Once secreted, TSH acts on the thyroid follicular cell via a specific receptor.

TSH Receptor

The TSH receptor on the thyroid follicular cells is a G protein–coupled receptor. Like receptors for the other glycoprotein hormones (LH, FSH, and hCG), the TSH receptor, via Gα_s, activates adenylyl cyclase (see [p. 53](#)). The rise in [cAMP]_i stimulates a diverse range of physiological processes or events, summarized in [Figure 49-3](#):

1. **Iodide uptake** by NIS on the basolateral membrane of the thyroid follicular cell. Stimulation of this cotransporter allows for trapping of dietary iodine within the thyroid gland (including follicular cells and colloid). The ratio of thyroid to serum iodine (the so-called thyroid/serum or T/S ratio) is 30 : 1 in euthyroid individuals. The T/S ratio decreases under conditions of low TSH (e.g., hypophysectomy), and increases under conditions of high TSH (e.g., a TSH-secreting pituitary adenoma).

2. **Iodination** of thyroglobulin in the follicular lumen.
3. **Conjugation** of iodinated tyrosines to form T_4 and T_3 within the thyroglobulin molecule.
4. **Endocytosis** of iodinated thyroglobulin into the follicular cells from thyroid colloid.
5. **Proteolysis** of the iodinated thyroglobulin in the follicular cell.
6. **Secretion** of T_4 and T_3 into the circulation.
7. **Hyperplasia** of the thyroid gland because of the growth-promoting effects of TSH.

[Figure 49-9](#) illustrates the goiter that occurs when TSH concentrations are elevated for a prolonged period and stimulate an otherwise normal thyroid gland (see [Box 49-1](#)). Hyperplasia of the thyroid gland also occurs in Graves disease ([Box 49-4](#)) because of stimulation of the TSH receptor by a thyroid-stimulating immunoglobulin (see [p. 1017](#)). In contrast, the chronic elevation of TSH typically seen when the thyroid gland undergoes autoimmune destruction of follicular cells (Hashimoto thyroiditis) does not lead to follicular hypertrophy, but the gland may increase modestly in size from infiltration by immune cells.

FIGURE 49-9 Goiter in iodine deficiency. A young woman from a region in Central Africa where iodine deficiency is prevalent exhibits a large goiter secondary to iodine deficiency and the growth-promoting effects of TSH, the levels of which are part of a feedback mechanism for achieving a sufficient amount of thyroid hormone.

Box 49-4

Graves Disease

Surprisingly, it is not uncommon for B lymphocytes to synthesize immunoglobulins that bind to and activate the TSH receptor, thereby reproducing all the actions of TSH on the thyroid. Unfortunately, these errant lymphocytes do not regulate the production of these immunoglobulins in a manner analogous to the regulation of TSH secretion by the pituitary. As a result, iodine trapping by the thyroid increases, the synthesis and secretion of both T_3 and T_4 increase, and the thyroid enlarges to produce a goiter.

Untreated, the affected individual becomes increasingly hyperthyroid. 🟡 **N49-4** The clinical manifestations of hyperthyroidism include an increased metabolic rate with associated weight loss, sweating and heat intolerance, a rapid and more forceful heartbeat, muscle weakness and wasting, tremulousness, difficulty concentrating, and changes in hair growth and skin texture. Because TSH stimulates all areas of the thyroid, the thyroid is symmetrically enlarged, and even the isthmus is

frequently palpable and visible on clinical examination.

The abnormal immunoglobulin is designated **thyroid-stimulating immunoglobulin (TSI)**. The constellation of symptoms noted previously, together with a symmetrical **goiter**, is called Graves disease after Robert Graves, who provided one of the first detailed descriptions of the disorder in the early 19th century. In some patients these antibodies are also able to stimulate connective tissue in the extraocular muscles and in the dermis of the lower extremity to synthesize mucopolysaccharides, which leads to thickening of both the muscle and the dermis. Therefore, in addition to the abnormalities of thyroid growth and hyperfunction, a minority of individuals with Graves disease develop a peculiar infiltrative abnormality in the extraocular muscles. When severe, this *infiltrative ophthalmopathy* impairs muscle function and causes diplopia (double vision) and a forward protrusion of the eyes (**exophthalmos**). Even less frequently, patients with Graves disease develop infiltrating dermopathy in the skin over the lower legs called *pretibial myxedema*. This thickening of the skin occurs in localized patches and is pathologically distinct from the generalized thickening and coarsening of the skin seen in hypothyroidism (*generalized myxedema*).

N49-4

Thyroid Storm

Contributed by Eugene Barrett

Some patients with hyperthyroidism become extremely ill and are said to be in *thyroid storm*. These individuals usually have a severe illness superimposed on their hyperthyroidism, and they develop high fevers, a profound tachycardia, sweating, and restlessness. Altered mental status is common. If untreated, these patients can develop severe circulatory collapse resulting in death. Thyroid storm can be the initial presentation of hyperthyroidism or it can occur in patients already known to be hyperthyroid and treated appropriately. However, when these latter individuals experience the severe stress of a major operation, trauma, or illness, they can develop thyroid storm. This condition is a true emergency. Treatment consists of giving sodium iodide, which over the long term encourages thyroid hormone synthesis but in the short term blocks the release of already-synthesized thyroid hormones; a β blocker to inhibit the β adrenoceptors, whose expression is increased by the elevated levels of thyroid hormones in the blood; and a drug such as propylthiouracil (PTU), which blocks the manufacture of additional thyroid hormone by inhibiting the iodination and conjugation steps. Fluid replacement and stress doses of corticosteroids are also given to support the circulation.

T₃ exerts negative feedback on TSH secretion

Circulating *free* T₄ and T₃ inhibit both the synthesis of TRH by hypothalamic neurons and the release of TSH by the thyrotrophs in the anterior pituitary. Plasma [TSH] is very sensitive to alteration in the levels of free T₄ and T₃; a 50% decline in free T₄ levels can cause plasma [TSH] to increase 50- to 100-fold. Conversely, as may be expected of a well-functioning feedback system, an excess of thyroid hormone leads to a decrease in plasma [TSH].

At the level of the thyrotroph, the sensor in this feedback system monitors the concentration of T₃ *inside* the thyrotroph (see Fig. 49-8). As noted above, either T₃ can enter directly from the blood plasma, or T₃ can form inside the thyrotroph by deiodination of T₄. The negative feedback of T₄ and T₃ on TSH release

occurs at the level of the pituitary thyrotroph by both indirect and direct mechanisms. In the **indirect feedback pathway**, intracellular T_3 decreases the number of TRH receptors on the surface of the thyrotroph. As a result, thyroid hormones *indirectly* inhibit TSH release by reducing the sensitivity of the thyrotrophs to TRH. In the **direct feedback pathway**, intracellular T_3 inhibits the synthesis of both the α and the β chains of TSH. Indeed, both the α and β TSH genes have T_3 response elements in their promoter regions. These response elements, which are *inhibitory*, differ from those found in genes that are *positively* regulated by T_3 (e.g., Na-K pump).

Free T_4 and T_3 concentrations in the plasma, which determine intracellular T_3 levels in the thyrotroph, are relatively constant over the course of 24 hours, a finding reflecting the long half-lives of both T_4 and T_3 (see [p. 1009](#)). Given that the levels of T_4 and T_3 are the primary triggers in the afferent limb of the negative feedback for the hypothalamic-pituitary-thyroid axis, the feedback regulation of TSH secretion by thyroid hormones appears to be a slow process—essentially integrating thyroid hormone levels over time. Indeed, T_3 feeds back on the thyrotroph by modulating *gene transcription*, which by its very nature is a slow process.

The feedback of T_4 and T_3 on the release of TSH may also be under the control of somatostatin and dopamine, which travel from the hypothalamus to the thyrotrophs through the portal vessels (see [Fig. 49-8](#)). Somatostatin and dopamine both inhibit TSH secretion, apparently by making the thyrotroph more sensitive to inhibition by intracellular T_3 —that is, shifting the set-point for T_3 . Thus, somatostatin and dopamine appear to counterbalance the stimulatory effect of TRH. Although these inhibitory effects are readily demonstrated with pharmacological infusion of these agents, their physiological role in the regulation of TSH secretion appears small. In particular, with long-term administration of somatostatin or dopamine, compensatory mechanisms appear to override any inhibition.

A special example of feedback between T_3 and TSH is seen in neonates of mothers with abnormal levels of T_3 . If the mother is *hyperthyroid*, both she and the fetus will have low TSH levels because T_3 crosses the placenta. After birth, the newborn rapidly metabolizes its T_3 , but its TSH remains suppressed, so that the infant temporarily becomes *hypothyroid*. Conversely, if the mother's thyroid gland has been removed and she is *hypothyroid* because she is not receiving sufficient thyroid hormone replacement therapy, both she and the fetus will have high levels of circulating TSH. Immediately after birth, the newborn will be temporarily *hyperthyroid* ([Box 49-5](#)).

Box 49-5

Clinical Assessment of Thyroid Function

Plasma TSH Levels

Direct measurements of T_4/T_3 provide a measure of *total* circulating hormone (i.e., the sum of *free* T_4 and T_3 , as well as T_4 and T_3 *bound* to TBG, TTR, and albumin; see pp. 1008–1009). However, these direct measurements do not allow one to distinguish between bound and free T_4/T_3 . The sensitive response of TSH to changes in thyroid hormone levels provides an extremely valuable tool for assessing whether the free T_4/T_3 levels in the circulation are deficient, sufficient, or excessive. Indeed, the level of TSH reflects the amount of free, biologically active thyroid hormone in the target tissue. As a result, in recent years, measurements of plasma TSH, using very sensitive immunoassay methods, have come to be regarded as the single best measure of thyroid hormone status. Obviously, this approach is valid only if

the thyrotrophs themselves are able to respond to T_3/T_4 —that is, if patients show no evidence of pituitary dysfunction.

The health of the thyrotrophs themselves can be tested by injecting a bolus of synthetic TRH and monitoring changes in plasma [TSH]. In hypothyroid patients, the subsequent rise in plasma [TSH] is more dramatic than in physiologically normal individuals. This test was of great value in confirming the diagnosis of hypothyroidism before the advent of today's ultrasensitive assays, but it has largely been abandoned.

Radioactive Iodine Uptake

Determining the amount of a standard bolus of radioactive iodine— ^{123}I (half-life, 13 hours) or ^{131}I (half-life, 8 days)—that the thyroid can take up was also once widespread as a measure of thyroid function. A hyperactive gland will take up increased amounts of the tracer, whereas an underactive gland will take up subnormal amounts. Today, the test is used mostly for three other purposes. First, radioactive iodine uptake can show whether a solitary thyroid nodule, detected on physical examination, is “hot” (functioning) or “cold” (nonfunctioning). Cold nodules are more likely than hot ones to harbor a malignancy. Second, radioactive iodine uptake can show whether hyperthyroidism is the result of thyroid inflammation (i.e., thyroiditis), in which tracer uptake is minimal because of TSH suppression, or Graves disease, in which tracer uptake is increased because thyroid-stimulating immunoglobulin (see p. 1017) mimics TSH. Third, higher doses of radioactive iodine are commonly used to treat patients with hyperthyroidism. In this circumstance, the use of ^{131}I causes radiolytic destruction of the overactive thyroid tissue. In the setting of thyroid cancer, therapists give very high doses of ^{131}I to deliver sufficient radiation to tumors that retain only a little of the iodine-concentrating ability of the normal thyroid.

CHAPTER 50

The Adrenal Gland

Eugene J. Barrett

The human adrenal glands, each weighing only ~4 g, are located above the upper pole of each kidney in the retroperitoneal space. They produce four principal hormones: cortisol, aldosterone, epinephrine (adrenaline), and norepinephrine. Each adrenal gland is composed of an inner medulla and an outer cortex ([Fig. 50-1](#)). Embryologically, the cortex is derived from mesoderm, whereas the medulla is derived from neural crest cells (see [p. 261](#)) that migrate into the developing cortex. The cortex produces two principal steroid hormones, cortisol and aldosterone, as well as several androgenic steroids. The medulla produces epinephrine and norepinephrine.

FIGURE 50-1 Anatomy of the adrenal gland. An adrenal gland—actually two glands, cortex and medulla—sits upon each kidney. The **adrenal cortex** comprises three layers that surround the medulla: glomerulosa, fasciculata, and reticularis. The blood supply enters the cortex in the subcapsular region and flows through anastomotic capillary beds while coursing through first the cortex and then the medulla. The **adrenal medulla** contains chromaffin cells.

The **adrenal cortex** can be further divided into three cellular layers: the *glomerulosa* layer near the surface, the *fasciculata* layer in the midcortex, and the *reticularis* layer near the cortical-medullary junction. **Aldosterone**, the main mineralocorticoid in humans, is made in the glomerulosa cell layer. **Cortisol**, the principal glucocorticoid, is made in the fasciculata and to a small extent in the reticularis layer. The **adrenal androgens**—dehydroepiandrosterone (DHEA) and its sulfated form DHEAS—are made in the reticularis layer. Although both cortisol and aldosterone are made by enzymatic modification of cholesterol and are structurally quite similar, their actions on the body differ dramatically. Cortisol is considered a **glucocorticoid** because it was recognized early on to increase plasma glucose levels;

deficiency of cortisol can result in hypoglycemia. Aldosterone is considered a **mineralocorticoid** because it promotes salt and water retention by the kidney. The activities of these two hormones overlap, particularly at high hormone levels, but this distinction is still very useful in identifying their most obvious functions. DHEA and DHEAS are weak androgens (compared to testosterone or dihydrotestosterone) and little is known about the regulation of their secretion. Plasma DHEA concentrations follow a diurnal pattern like that of cortisol. DHEAS circulates at much higher concentrations and shows no diurnal fluctuation.

In the **adrenal medulla**, chromaffin cells produce **epinephrine** (or adrenaline), a catecholamine that is synthesized from the amino acid tyrosine. Although the primary product of the medulla is epinephrine, it also produces variable amounts of the epinephrine precursor **norepinephrine**. These catecholamines are distinct from the steroid hormones both structurally and functionally.

The Adrenal Cortex: Cortisol

Cortisol is the primary glucocorticoid hormone in humans

Steroid hormones are divided into three major classes based on their actions: glucocorticoids, mineralocorticoids, and sex steroids. **Cortisol** is the prototypical naturally occurring glucocorticoid. The ability of cortisol to increase plasma [glucose] largely results from its ability to enhance mobilization of amino acids from proteins in many tissues and to enhance the ability of the liver to convert these amino acids into glucose and glycogen by activating gluconeogenesis.

The structures of cortisol and aldosterone ([Fig. 50-2](#)) differ only slightly: aldosterone lacks the –OH group at position 17 and has an aldehyde (aldo) group at position 18. Despite the seemingly minor chemical difference, aldosterone at physiological concentrations has virtually no glucocorticoid activity.

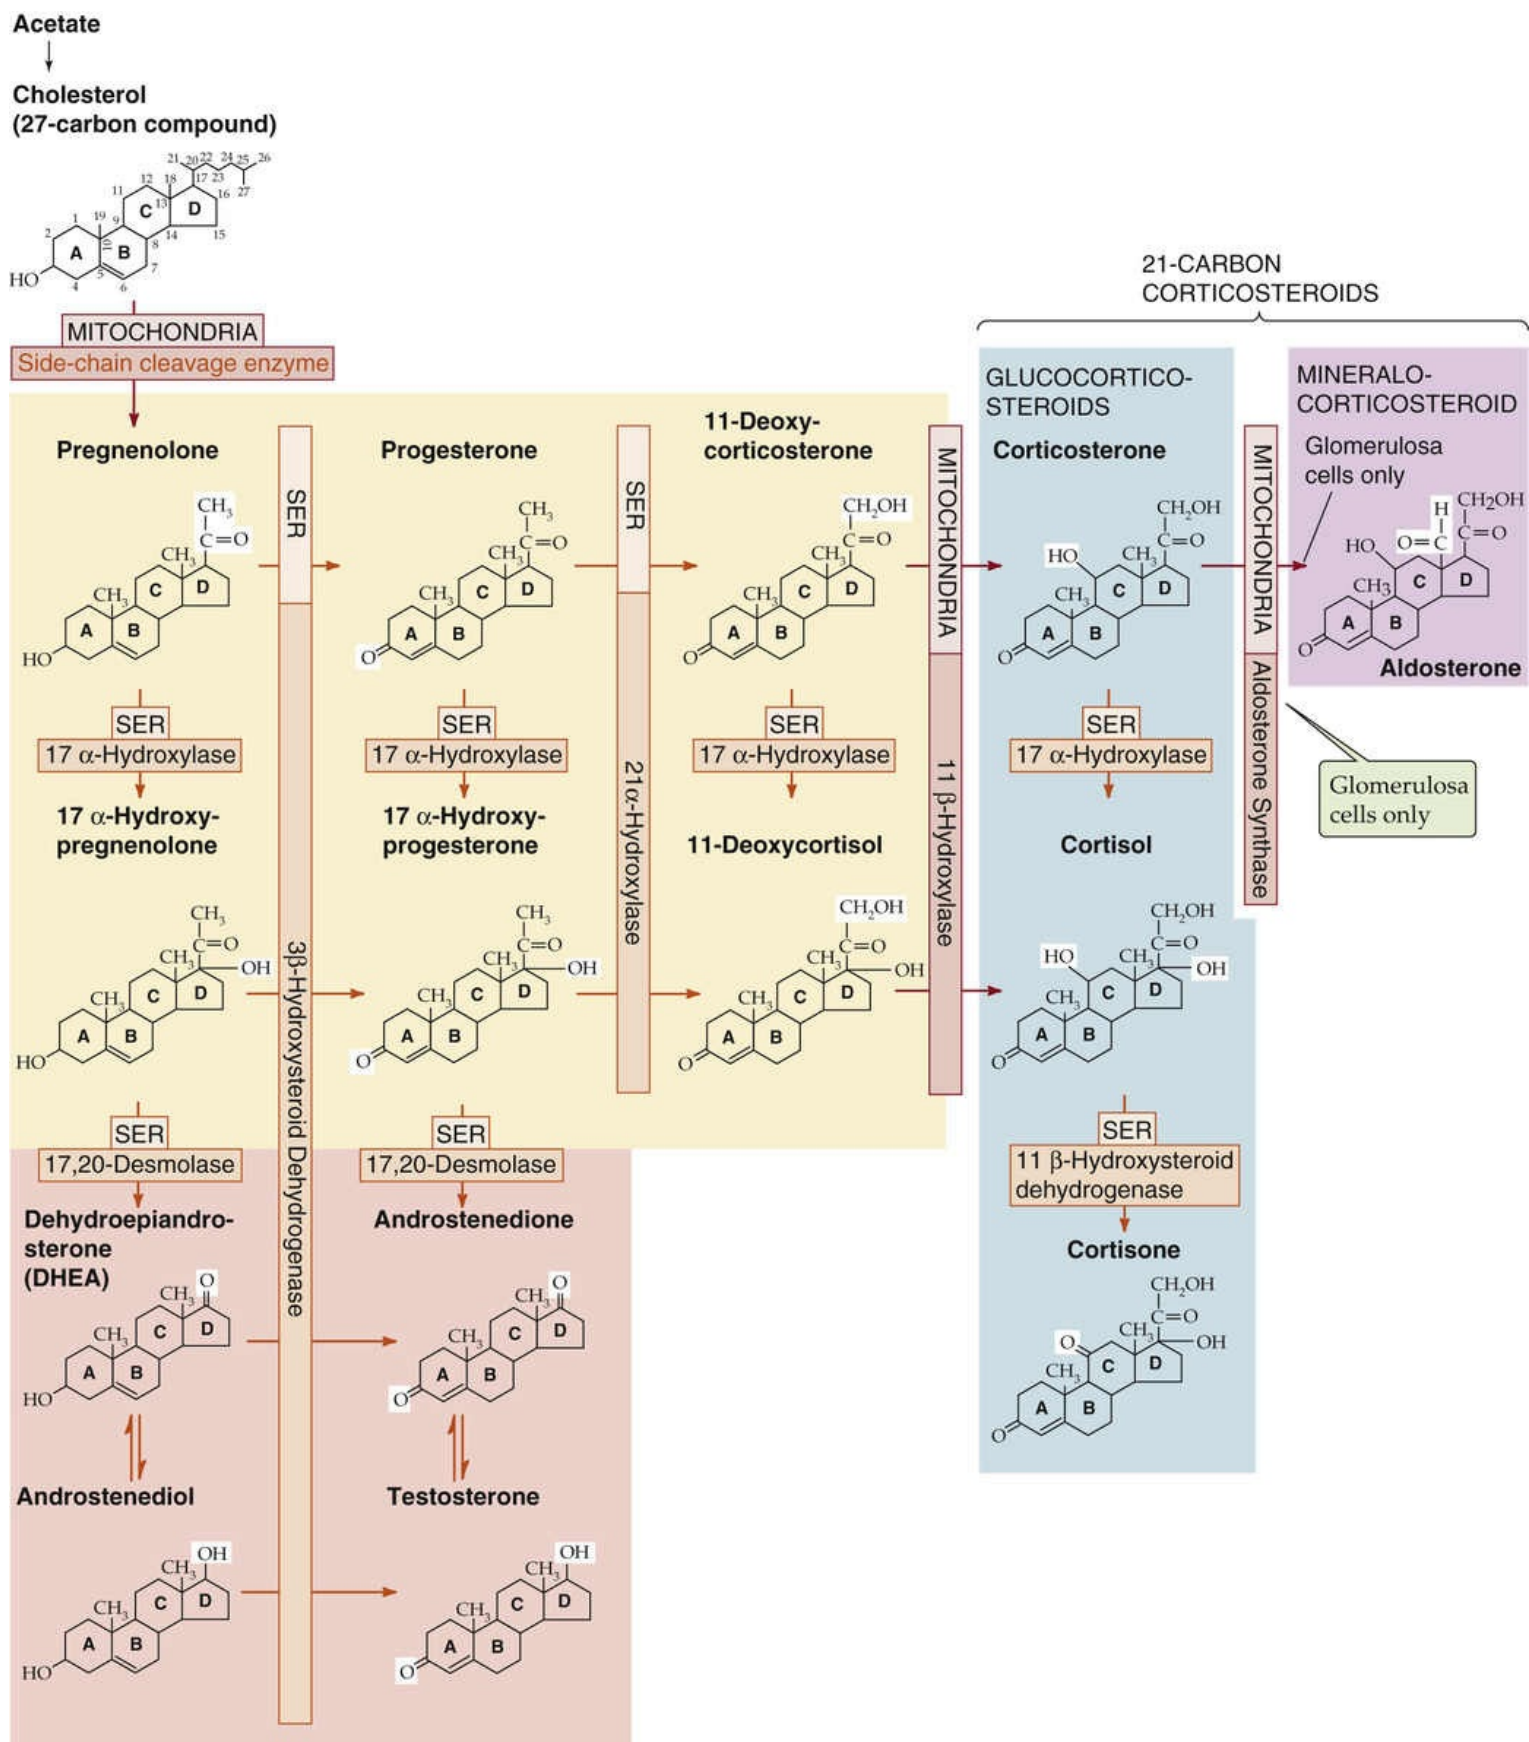

FIGURE 50-2 Biosynthesis of adrenal steroids. This schematic summarizes the synthesis of the adrenal steroids—the mineralocorticoid *aldosterone* and the glucocorticoid *cortisol*—from cholesterol. The individual enzymes are shown in the horizontal and vertical boxes; they are located in either the SER or the mitochondria. The SCC enzyme that produces pregnenolone is also known as 20,22-desmolase. The chemical groups modified by each enzyme are highlighted in the reaction product. If the synthesis of cortisol is prevented by any one of several dysfunctional enzymes, other steroid products might be produced in excess. For example, a block in 21α-hydroxylase will diminish production of both cortisol and aldosterone and increase production of the sex steroids. Certain of these pathways are shared in the biosynthesis of the androgens (see Fig. 54-6) as well as the estrogens (see Fig. 55-8).

Target Tissues

Although classified as a glucocorticoid, cortisol affects more than the principal glucose-regulatory tissues, namely, the liver, fat, and muscle. Most body tissues, including bone, skin, other viscera, hematopoietic and lymphoid tissue, and the central nervous system (CNS), are target sites for glucocorticoid action. Although cortisol is the primary glucocorticoid in humans, in other species (e.g., the rat), corticosterone is the major glucocorticoid.

Actions

Glucocorticoids have numerous actions other than their ability to raise plasma glucose levels. These actions are described below and include potent immunosuppressive and anti-inflammatory activity, effects on protein and fat metabolism, behavioral effects due to actions on the CNS, and important effects on calcium and bone metabolism. Some of the diverse physiological effects of the glucocorticoids can be appreciated from clinical studies of excess glucocorticoid secretion (Cushing syndrome; [Box 50-1](#)) and glucocorticoid deficiency (Addison disease; see [Box 50-1](#)). The multiple actions of glucocorticoids, in particular, their “anti-inflammatory” action on leukocytes, has led to the development of numerous synthetic analogs that are more potent, have a longer half-life, and are more selective in their specific glucocorticoid actions than are either cortisol or corticosterone. [Table 50-1](#) lists some of these compounds and indicates their relative potency as mineralocorticoids and glucocorticoids.

Box 50-1

Cushing Syndrome and Addison Disease

Glucocorticoid excess is most commonly seen clinically in individuals receiving glucocorticoids for treatment of a chronic inflammatory or neoplastic disorder. Less commonly, individuals overproduce cortisol either because of a primary cortisol-producing adrenal tumor or secondary to a pituitary tumor that produces ACTH, which in turn stimulates excess cortisol production by normal adrenal glands. In either case, the cortisol excess causes a constellation of symptoms and signs including adiposity of the trunk, neck, and facies; hypertension; loss of subcutaneous adipose and connective tissue in the extremities with associated easy bruising; loss of bone mineral; muscle weakness and wasting; and hyperglycemia. This constellation is referred to as **Cushing syndrome** after the famous American neurosurgeon who characterized this disorder. The specific therapy is based upon identifying whether the clinical picture arises from a tumor in the adrenal or in the pituitary gland, and then removing the culprit. When the pituitary gland is responsible, the disorder is referred to as **Cushing disease**. In the case of patients receiving glucocorticoid therapy, the signs and symptoms of Cushing syndrome are carefully monitored, and efforts are made to minimize these side effects. Unfortunately, all glucocorticoid drugs with anti-inflammatory actions also produce these other effects.

Glucocorticoid deficiency—which occurs in primary adrenal insufficiency, also called **Addison disease**, and affects both glucocorticoid and mineralocorticoid levels—can produce an array of symptoms and signs. Although tuberculosis was once a common cause of primary adrenal insufficiency, today autoimmune adrenal disease is the most common cause. Failure of adrenal cortical hormone secretion leads to increases in circulating concentrations of ACTH as well as other products of POMC (see p. 1023). Two of these products (α -MSH and γ -MSH) as well as ACTH (see p. 1023) cause skin hyperpigmentation. The lack of glucocorticoid predisposes to hypoglycemia. The combined absence of

glucocorticoid and mineralocorticoid leads to hypotension and hyponatremia, **N50-1** whereas aldosterone deficiency leads to hyperkalemia. Before the development of glucocorticoid and mineralocorticoid therapy, this disorder was uniformly fatal.

TABLE 50-1
Relative Potency* of Glucocorticoid and Mineralocorticoid Analogs

COMPOUND	GLUCOCORTICOID EFFECT	MINERALOCORTICOID EFFECT
Cortisol	1	1.5
Prednisone	3–4	0.5
Methylprednisone	10	0.5
Dexamethasone	20	1
Fludrocortisone	12	125

*Relative potency is determined by a combined consideration of the compound's biological half-life and its affinity for the glucocorticoid or mineralocorticoid receptor.

N50-1

Hyponatremia in Primary Adrenal Insufficiency

Contributed by Emile Boulpaep, Walter Boron

Whereas aldosterone deficiency causes renal salt wasting, hypovolemia and hypotension do not directly cause hyponatremia (i.e., a low plasma $[Na^+]$). Rather, reduced effective circulating volume triggers the release of AVP (see pp. 846–847); AVP in turn provokes thirst and H_2O retention in the collecting ducts, which dilutes plasma Na^+ and creates hyponatremia.

Most of the well-characterized actions of glucocorticoids result from their genomic actions to influence (either positively or negatively) the transcription of a variety of genes through glucocorticoid response elements (see p. 986). However, glucocorticoids also exert nongenomic actions (see p. 989) that occur promptly (0 to 3 hours) and are not inhibited by blockade of gene transcription.

The adrenal zona fasciculata converts cholesterol to cortisol

Synthesis of cortisol, as for all steroid hormones, starts with cholesterol (see Fig. 50-2). Like other cells producing steroid hormones, the adrenal gland has two sources of cholesterol (see p. 985): (1) it can import cholesterol from circulating cholesterol-containing low-density lipoprotein (LDL) cholesterol by means of LDL receptor–mediated endocytosis (see p. 42), or (2) it can synthesize cholesterol de novo from acetate (see Fig. 46-16). Although both pathways provide the steroid nucleus needed for cortisol and aldosterone synthesis, circulating LDL is quantitatively more important.

In the adrenal gland, cholesterol is metabolized through a series of five reactions to make either cortisol or aldosterone. All relevant enzymes are located in either the mitochondria or smooth endoplasmic reticulum (SER), and except for 3β -hydroxysteroid dehydrogenase (3β -HSD), belong to the family of **cytochrome P-450 oxidases** (Table 50-2).

1. The pathway for cortisol and aldosterone synthesis begins in the mitochondria, where the cytochrome P-450 **side-chain-cleavage (SCC)** enzyme (also called 20,22-desmolase or $P-450_{SCC}$) removes the long

- side chain (carbons 22 to 27) from the carbon at position 20 of the **cholesterol** molecule (27 carbon atoms). This enzyme, or the supply of substrate to it, appears to be the rate-limiting step for the overall process of steroid hormone synthesis.
- The product of the SCC-catalyzed reaction is **pregnenolone** (21 carbon atoms), which exits the mitochondrion. The SER enzyme 3 β -HSD (*not* a P-450 enzyme) oxidizes the hydroxyl group at position 3 of the A ring to a ketone to form **progesterone**.
 - A P-450 enzyme in the SER, 17 α -hydroxylase (P-450_{c17}), then adds a hydroxyl group at position 17 to form **17 α -hydroxyprogesterone**. However, as shown in [Figure 50-2](#), an alternative path to 17 α -hydroxyprogesterone exists: the 17 α -hydroxylase might first add a hydroxyl group at position 17 of *pregnenolone* and form **17 α -hydroxypregnenolone**, which the aforementioned 3 β -HSD can then convert to 17 α -hydroxyprogesterone.
 - In the SER, 21 α -hydroxylase (P-450_{c21}) adds a hydroxyl at carbon 21 to produce **11-deoxycortisol**.
 - In the mitochondria, 11 β -hydroxylase (P-450_{c11}) adds yet another hydroxyl, this time at position 11, to produce **cortisol**.

TABLE 50-2
Cytochrome P-450 Enzymes Involved in Steroidogenesis*

ENZYME	SYNONYM	GENE
Cholesterol side-chain cleavage	P-450 _{SCC}	<i>CYP11A1</i>
11 β -hydroxylase	P-450 _{c11}	<i>CYP11B1</i>
17 α -hydroxylase	P-450 _{c17}	<i>CYP17</i>
17,20-desmolase	P-450 _{c17}	<i>CYP17</i>
21 α -hydroxylase	P-450 _{c21}	<i>CYP21A2</i>
Aldosterone synthase	P-450 _{aldo}	<i>CYP11B2</i>
Aromatase*	P-450 _{arom}	<i>CYP19</i>

*P-450_{arom} catalyzes a reaction essential for the production of estrogens (see [p. 1117](#)).

The enzymes represented by the vertical bars in [Figure 50-2](#), as well as SCC, are present in all three cellular layers of the adrenal cortex. However, 17 α -hydroxylase is not substantially present in the glomerulosa layer. Thus, the fasciculata and, to a much lesser extent, the reticularis layers synthesize cortisol.

The cells of the reticularis layers are principally responsible for androgen synthesis. These cells convert 17 α -hydroxypregnenolone and 17 α -hydroxyprogesterone into the *adrenal androgens* **dehydroepiandrosterone** and **androstenedione**. The enzyme that catalyzes this reaction is called 17,20-desmolase; however, it turns out to be the same SER enzyme as the 17 α -hydroxylase that produced the 17 α -hydroxypregnenolone and 17 α -hydroxyprogesterone in the first place. The androgens formed by the adrenal are far less potent than either testosterone or dihydrotestosterone. However, other tissues (e.g., liver, kidney, adipose) can use 17 β -hydroxysteroid dehydrogenase to convert androstenedione to testosterone (see [p. 1097](#)). In this manner, the adrenal can contribute significant amounts of circulating androgen, particularly in women. Increases in adrenal androgen production precede by 1 to 2 years the increases in gonadal steroid production that occur with puberty. This androgen production promotes growth of pubic and axillary hair and is referred to as *adrenarche* (see [pp. 1088–1090](#)).

The cortisol synthesized by the adrenal cortex diffuses out of the cells and into the blood plasma.

There, ~90% of the cortisol is transported bound to **corticosteroid-binding globulin (CBG)**, also known as transcortin, which is made in the liver. Transcortin is a 383–amino-acid glycoprotein whose affinity for cortisol is ~30-fold higher than that for aldosterone. An additional ~7% of the circulating cortisol is bound to albumin. Thus, only 3% to 4% of the circulating cortisol is free.

The clearance of cortisol from the body depends principally on the liver and kidney. An early step is the formation of an inactive metabolite, cortisone, by the action of either of two **11 β -hydroxysteroid dehydrogenases (11 β -HSDs)**. 11 β -HSD1 is highly expressed in certain glucocorticoid *target tissues*, including liver and both subcutaneous and visceral adipose tissue. The enzymatic reaction is *reversible*. Indeed, when glucocorticoids were first developed as pharmaceutical agents, it was cortisone that was used to treat patients with a variety of inflammatory disorders (e.g., rheumatoid arthritis). For some time, investigators thought that cortisone was the active principle. Only later did it become apparent that the body must convert cortisone to cortisol, which is the biologically active agent. Because excess cortisol produces insulin resistance and many features of metabolic syndrome (e.g., glucose intolerance, hypertension, dyslipidemia; see [Box 51-5](#))—and 11 β -HSD1 is expressed abundantly in adipose tissue—an interesting hypothesis is that increased 11 β -HSD1 activity in adipose tissue locally produces cortisol and thus promotes the development of insulin resistance.

The second **11 β -HSD isozyme (11 β -HSD2)** is expressed in the adrenal cortex (see [Fig. 50-2](#); [Box 50-2](#)), although the adrenal gland does not normally make a significant contribution to the formation of cortisone. 11 β -HSD2 is highly expressed in the renal distal tubule and collecting duct (see [Fig. 35-13C](#)), where it catalyzes an essentially *irreversible* conversion of cortisol to cortisone. This breakdown of cortisol allows aldosterone to regulate the relatively nonspecific mineralocorticoid receptor (MR) without interference from cortisol.

Box 50-2

21 α -Hydroxylase Deficiency

Mutations can affect one or more of the enzyme steps in steroid hormone synthesis and can produce unique clinical syndromes that are a direct result of failure to manufacture a particular hormone, accumulation of excessive amounts of precursor steroids, or both. The most common of these enzymatic disorders is 21 α -hydroxylase deficiency. From [Figure 50-2](#) we would predict that deficiency of this enzyme would lead to inadequate production of both glucocorticoid and mineralocorticoid hormones, which is indeed what occurs. Affected infants are ill with symptoms of “salt losing” (hypotension, dehydration) and glucocorticoid deficiency (hypoglycemia). The natural reaction of the body is to attempt to overcome this deficiency by increasing the secretion of ACTH, which stimulates the synthesis of cortisol and aldosterone. ACTH also causes growth of the adrenal gland. However, if the mutant enzyme is totally inactive, no cortisol or aldosterone synthesis will occur, although all other enzymes of the pathway involved in glucocorticoid and mineralocorticoid synthesis will be expressed in increased amounts. The result is greater than normal activity of SCC, 3 β -HSD, 17 α -hydroxylase, and 11 β -hydroxylase, and the net effect is increased synthesis of both precursor molecules and adrenal androgens. The combination of inadequate production of glucocorticoids and mineralocorticoids, excessive production of androgens, and enhanced growth of the adrenal gland is the classical clinical syndrome of salt-losing, virilizing congenital adrenal hyperplasia. In female infants, the presence of excessive adrenal androgen in utero results in ambiguous genitalia at birth, a condition that should alert the pediatrician to the potential diagnosis. No such clue occurs in the male infant, in whom dehydration, hypotension, and hyperkalemia are the major manifestations.

Cortisol binds to a cytoplasmic receptor that translocates to the nucleus and modulates transcription in multiple tissues

The multiple hydroxylation reactions that convert cholesterol to cortisol result in a hydrophilic compound that, unlike cholesterol, is soluble in plasma, yet lipophilic enough to cross the plasma membrane of target tissue without requiring a membrane transporter. Cortisol, like all steroid hormones, binds to intracellular receptors within target cells (see [pp. 71–72](#)). Virtually all nucleated tissues in the body contain receptors for glucocorticoids. The glucocorticoid receptor (GR) is primarily located in the cytoplasm, where in its unbound form it is complexed to a chaperone protein (i.e., the heat shock protein hsp90, among others; see [Fig. 4-15A](#)). Binding of cortisol causes the chaperone to dissociate from the GR and this allows the cortisol-GR complex to translocate to the nucleus. There, the cortisol-receptor complex associates with **glucocorticoid response elements (GREs)** on the 5' untranslated region of multiple genes to either enhance or diminish gene expression (see [p. 90](#)).

GRs are structurally similar to the receptors for mineralocorticoids, sex steroids, vitamin D, vitamin A, and thyroid hormone. These receptors, either homodimers or heterodimers, belong to the superfamily of nuclear receptors that contains domains A through F (see [Fig. 3-14](#)). Activity of the glucocorticoid-receptor complex requires dimerization of two identical receptor complexes (i.e., the GR functions as a *homodimer*) at the near-palindromic nucleotide site of the GRE on the chromatin. Glucocorticoids mainly act by modulating gene transcription. One exception is the acute feedback effect of cortisol to block the release of preformed **adrenocorticotrophic hormone (ACTH)** in the secretory granules of pituitary corticotrophs. This glucocorticoid effect is demonstrable within seconds to minutes and may relate to an as-yet undefined effect of glucocorticoid on membrane trafficking.

Although glucocorticoids are named for their ability to increase hepatic glucose and glycogen synthesis, they affect many somatic tissues. In **liver**, cortisol induces the synthesis of enzymes involved in gluconeogenesis and amino-acid metabolism in support of gluconeogenesis, thus enhancing hepatic glucose production. In **muscle**, cortisol stimulates the breakdown of muscle protein, which releases amino acids for uptake by the liver. Similarly, cortisol promotes lipolysis in **adipose tissue**. The fatty acids thus released provide an alternative fuel to glucose, whereas the accompanying glycerol provides another substrate for gluconeogenesis, thereby increasing the availability of glucose. For unknown reasons, although fat is mobilized from the extremities, some is also deposited centrally (see description of moon facies in [Box 50-3](#)).

Box 50-3

Therapy with Glucocorticoids

The variety of glucocorticoid actions on body tissues is well illustrated by considering some of the clinically observed effects of hypercortisolism in patients receiving glucocorticoid drugs. Most strikingly, the entire body habitus changes. Body fat redistributes from the extremities to the face and trunk, producing (1) increased supraclavicular and dorsal interscapular fat (buffalo hump), (2) a rounded abdomen, and (3) a rounding of the face called **moon facies**, caused by increased subcutaneous fat in the cheeks and submandibular region. Conversely, the wasting of fat (and some supporting tissues) in the extremities produces thinning of the skin and fragility of cutaneous blood vessels. In bone, glucocorticoids reduce mineral density (osteopenia), which can lead to osteoporosis and bone fractures. The interference with normal immune function increases both the frequency and severity of infections.

Rare malignancies can develop. Wasting of muscle tissue leads to a generalized weakness that is usually most prominent in the proximal muscles of the lower extremities. Finally, as would be expected from a glucocorticoid, patients become insulin resistant and even glucose intolerant (see p. 1038) or frankly diabetic (see Box 51-5). When cortisol is overproduced endogenously (from tumors producing either ACTH or cortisol), hypertension is common. The hypertension most likely results from the weak mineralocorticoid action of cortisol. Exogenous synthetic glucocorticoid therapy rarely produces hypertension because most of these drugs lack the mineralocorticoid activity of the endogenous hormone.

Cortisol has effects unrelated to its glucocorticoid actions that lead to its extensive clinical use in disorders like vasculitis, arthritis, malignancies, and in prevention of organ transplant rejection. Glucocorticoids also act on the cellular elements of trabecular bone (see pp. 1068–1069), decreasing the ability of osteoblasts to synthesize new bone. They also interfere with absorption of Ca^{2+} from the gastrointestinal tract. As a result, long-term glucocorticoid use causes osteoporosis. In addition, glucocorticoids act on the CNS and can cause a variety of effects, including alterations in mood and cognition.

Corticotropin-releasing hormone from the hypothalamus stimulates anterior pituitary corticotrophs to secrete ACTH, which stimulates the adrenal cortex to synthesize and secrete cortisol

As summarized in Figure 50-3, regulation of the synthesis and secretion of cortisol begins with the release of **corticotropin-releasing hormone (CRH)** from hypothalamic neurons as part of either a normal daily circadian rhythm or a centrally driven stress response. CRH stimulates the release of ACTH, also called corticotropin, from the anterior pituitary. ACTH directly stimulates the adrenal fasciculata layers to synthesize and secrete cortisol. Circulating cortisol exerts negative-feedback control on the release of both ACTH and CRH.

FIGURE 50-3 Hypothalamic-pituitary-adrenocortical axis. Small-bodied neurons in the paraventricular nucleus of the hypothalamus secrete CRH, a 41-amino-acid peptide that reaches the corticotrophs in the anterior pituitary via the long portal veins. CRH binds to a GPCR on the corticotroph membrane, triggering the adenylyl cyclase (AC)–cAMP–PKA pathway. The activation of L-type Ca^{2+} channels results in an increase in $[\text{Ca}^{2+}]_i$ that rapidly leads to the release of preformed ACTH. CRH also increases gene transcription and synthesis of the ACTH precursor, POMC. After its release by corticotrophs, ACTH binds to **melanocortin-2 receptors** on the cell membranes in all three layers of the adrenal cortex. This receptor triggers the AC–cAMP–PKA pathway, rapidly enhancing the conversion of cholesterol to pregnenolone and more slowly increasing the synthesis of several proteins that are needed for cortisol synthesis. The cerebral cortex can stimulate the hypothalamic neurons to increase their secretion of CRH. Cortisol exerts negative feedback at the level of both the pituitary and hypothalamus. In addition, ACTH produced by the corticotrophs negatively feeds back on the hypothalamic neurons in a “short loop.”

Corticotropin-Releasing Hormone

Small-bodied neurons in the paraventricular nucleus of the **hypothalamus** (see Fig. 47-3) secrete CRH, a 41-amino-acid neuropeptide. The structure of CRH is highly conserved among species. In humans, CRH is also present in several tissues, including the pancreas and testes, as well as throughout the CNS, where it serves as a neurotransmitter. The hypothalamic neurons synthesize and release CRH via the classic secretory pathway (see pp. 34–35). Neurons store CRH in secretory vesicles located in synaptic terminals in the median eminence of the hypothalamus and can release CRH acutely in the absence of new synthesis. After release into the interstitial fluid of the median eminence, CRH enters the hypophyseal portal venous plexus (see p. 978) and travels to the anterior pituitary.

CRH Receptor

CRH arriving in the anterior pituitary binds to CRH-R1, a G protein–coupled receptor (GPCR) on the cell membrane of corticotroph cells. Hormone binding activates $\text{G}\alpha_s$, which in turn stimulates adenylyl cyclase and raises $[\text{cAMP}]_i$ (see p. 53). Subsequent stimulation of protein kinase A (PKA) activates L-type Ca^{2+} channels, leading to an increase in $[\text{Ca}^{2+}]_i$, which stimulates the exocytosis of preformed ACTH. Over a much longer time, CRH receptor activation also leads to increased gene transcription and synthesis of the ACTH precursor (discussed later).

Arginine Vasopressin

Although CRH is the major regulator of ACTH secretion, the paraventricular nuclei also make another hormone, arginine vasopressin (AVP; see Fig. 40-8). AVP is also a potent ACTH secretagogue and probably plays a physiological role in the regulation of ACTH secretion during stresses like dehydration or trauma.

Adrenocorticotrophic Hormone

A 39-amino-acid peptide hormone secreted by the corticotroph cells of the anterior pituitary, **ACTH** can also be produced by ectopic sources, particularly by small-cell carcinomas of the lung. Pituitary corticotrophs synthesize ACTH by complex post-translational processing of a large precursor protein (i.e., a prehormone) called **pro-opiomelanocortin (POMC)**. POMC is the precursor not only for ACTH but also for a variety of peptide hormones (Fig. 50-4). In the anterior pituitary, POMC yields a long N-terminal peptide, a joining (J) peptide, ACTH, and **β -lipotropin (β -LPH)**. During fetal life and pregnancy, the intermediate pituitary lobe—a small wedge of tissue between the more familiar anterior

and posterior lobes—processes the same POMC in a very different manner to yield a different array of peptides: a short N-terminal peptide, **γ -melanocyte-stimulating hormone (γ -MSH)**, J peptide, **α -MSH**, corticotropin-like intermediate-lobe peptide (CLIP), γ -LPH, and β endorphin. Other cells—such as the appetite-controlling POMC neurons in the hypothalamus (see [p. 1002](#))—can also synthesize POMC.

FIGURE 50-4 Processing of POMC. The primary gene transcript is a prehormone called pro-opiomelanocortin (POMC). The processing of POMC yields a variety of peptide hormones. This processing is different in the anterior and intermediate lobes of the pituitary. In the anterior pituitary, POMC yields a long N-terminal peptide, a joining (J) peptide, ACTH, and β -LPH. In the intermediate pituitary, the same POMC yields a short N-terminal peptide, γ -MSH, J peptide, α -MSH, CLIP, γ -LPH and β -endorphin. Metabolism by the intermediate lobe is important only during fetal life and pregnancy. (Data from Wilson JD, et al (eds): *Williams Textbook of Endocrinology*. Philadelphia, WB Saunders, 1998.)

The **melanocortins** include ACTH as well as α -, β -, and γ -MSH and bind to a family of five GPCRs, the **melanocortin receptors** (MC1R to MC5R). α -MSH, γ -MSH, and ACTH act on MC1R receptors in melanocytes to increase the dispersion of pigment granules. In some patients who greatly overproduce ACTH, hyperpigmentation is a prominent clinical finding. Whether this hyperpigmentation is the result of increased production of MSH, increased production of β -LPH (which also has MSH activity), or the melanotropic action of ACTH per se remains uncertain. **β -LPH** and **γ -LPH** mobilize lipids from adipocytes in animals, although their physiological role in humans is unclear. **β endorphin** has potent opioid actions in the CNS (see [p. 315](#)), but its physiological actions (if any) in the systemic circulation are not known.

ACTH Receptor

In the adrenal cortex, ACTH binds to **MC2R** on the plasma membranes of all three steroid-secreting cell types. However, because only the cells in the fasciculata and reticularis layers have the 17α -hydroxylase needed for synthesizing cortisol (see [Fig. 50-2](#)), these cells are the only ones that secrete cortisol in response to ACTH. ACTH appears to have few other actions at physiological concentrations. MC2R is coupled to a heterotrimeric G protein and stimulates adenylyl cyclase (see [p. 53](#)). The resulting increase in $[cAMP]_i$ activates PKA, which phosphorylates a variety of proteins. A rapid effect of ACTH is to stimulate the rate-limiting step in cortisol formation; that is, the conversion of cholesterol to pregnenolone via the SCC enzyme. In addition, ACTH—over a longer time frame—increases the synthesis of several proteins needed for cortisol synthesis: (1) each of the P-450 enzymes involved in cortisol synthesis (see [Fig. 50-2](#)), (2) the LDL receptor required for the uptake of cholesterol from blood (see [p. 42](#)), and (3) the

3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase that is the rate-limiting enzyme for cholesterol synthesis by the adrenal (see [p. 968](#)).

Thus, ACTH promotes the acute synthesis of cortisol—and, as discussed later, aldosterone to a lesser extent—by the adrenal and increases the content of adrenal enzymes involved in steroidogenesis. In the absence of pituitary ACTH, the fasciculata and reticularis layers of the adrenal cortex atrophy. The glomerulosa layer does not atrophy under these conditions because in addition to ACTH, angiotensin II (ANG II) and high levels of K^+ are trophic factors that act on the glomerulosa layer. The atrophy of the fasciculata and reticularis layers occurs routinely in people treated with glucocorticoid drugs and leaves the person with an iatrogenic form of adrenal insufficiency when use of the drug is abruptly discontinued. Conversely, chronic stimulation of the adrenals by ACTH, such as can occur with pituitary tumors (Cushing disease) or with the simple physiological ACTH excess that can occur with chronic stress, can increase the weight of the adrenals several-fold.

Cortisol exerts negative feedback on CRH and ACTH secretion, whereas stress acts through higher CNS centers to stimulate the axis

Cortisol exerts negative-feedback control on the very axis that stimulates its secretion (see [Fig. 50-3](#)), and it does so at the level of both the anterior pituitary and hypothalamus.

Feedback to the Anterior Pituitary

In the corticotrophs of the anterior pituitary, cortisol acts by binding to a cytosolic receptor, which then moves to the nucleus where it binds to GREs and modulates gene expression and thus inhibits the synthesis of both the CRH receptor and ACTH. Even though, as seen above, the POMC gene yields multiple secretory products, *cortisol* is the main regulator of the transcription of POMC. In addition, elevated levels of cortisol in plasma inhibit the release of presynthesized ACTH stored in vesicles.

Feedback to the Hypothalamus

The negative feedback of cortisol on the CRH-secreting neurons of the hypothalamus is less important than that on the corticotrophs discussed above. Plasma cortisol decreases the mRNA and peptide levels of CRH in paraventricular hypothalamic neurons. Cortisol also inhibits the release of presynthesized CRH. Synthetic glucocorticoids have a similar action.

Control by a Higher CNS Center

CRH-secreting neurons in the hypothalamus are under higher CNS control, as illustrated by two important features of the hypothalamic-pituitary-adrenocortical axis: (1) the circadian and pulsatile nature of ACTH and cortisol secretion, and (2) integration of signals from higher cortical centers that modulate the body's responses to a variety of stressors.

The pituitary secretes ACTH with a **circadian rhythm**. The suprachiasmatic nucleus of the hypothalamus, which lies above the optic chiasm and receives input from the retina, controls the circadian rhythms of the body. Indeed, blind people lose their circadian rhythms. Input from hypothalamic nuclei to the corticotrophs—via both CRH and AVP—appears to modulate the circadian secretion of ACTH and thus the circadian secretion of cortisol as well. As is the case for other hypothalamic releasing hormones,

CRH is released in pulses. As a result, superimposed on the circadian rhythm of ACTH is the **pulsatile secretion** of ACTH, as shown in [Figure 50-5](#). ACTH secretory activity is greatest in the early morning and diminishes late in the afternoon and early evening. The mechanism by which hypothalamic neurons generate pulses of secretory activity is not understood.

FIGURE 50-5 Rhythm of ACTH and cortisol release. The corticotrophs release ACTH in a circadian rhythm, more in the early morning hours and less late in the afternoon and early evening. Superimposed on the circadian rhythm is the effect on the corticotrophs of the pulsatile secretion of CRH by the hypothalamus. Thus, ACTH levels exhibit both circadian and pulsatile behavior. Notice that, although both ACTH and cortisol are secreted episodically, the duration of the ACTH bursts is briefer, which reflects the shorter half-life of ACTH in plasma. (Data from Wilson JD, et al (eds): Williams Textbook of Endocrinology, Philadelphia, WB Saunders, 1998.)

Other evidence of higher CNS control is the enhanced CRH secretion—and thus the enhanced ACTH secretion—that occurs in response to physical, psychological, and biochemical stress. An example of biochemical stress is hypoglycemia, which stimulates the secretion of both CRH and ACTH and thus leads to an increased release of cortisol that tends to raise blood glucose levels.

The increase in ACTH secretion that occurs nocturnally and with stress appears to result from an increased amplitude of the secretory CRH burst rather than an increased frequency of secretion episodes. Because the half-life of cortisol is much longer than that of ACTH, the period of the pulsatile changes in cortisol is longer and the magnitude of the excursions is damped in comparison with those of ACTH.

The Adrenal Cortex: Aldosterone

The mineralocorticoid aldosterone is the primary regulator of salt balance and extracellular volume

Aldosterone determines extracellular volume by controlling the extent to which the kidney excretes or reabsorbs the Na^+ filtered at the renal glomerulus. Na^+ in the extracellular space retains water—it is the primary osmotically active particle in the extracellular space—and thus the *amount* of Na^+ that is present determines the volume of extracellular fluid (see pp. 135–136). The extracellular volume is itself a prime determinant of arterial blood pressure (see pp. 554–555), and therefore aldosterone plays an important role in the maintenance of blood pressure.

The effects of aldosterone on salt balance determine the extracellular volume and should not be confused with the effects of AVP (also known as antidiuretic hormone, or ADH). AVP regulates the *free-water* balance of the body (see p. 844). Water freely passes across cell membranes and thus affects the *concentration* of Na^+ and other solutes throughout the body (see pp. 135–136). Unlike aldosterone, AVP makes only a small contribution to the maintenance of extracellular volume; instead, AVP regulates serum osmolality and hence the Na^+ concentration. Thus, to a first approximation, one can think of aldosterone as the primary regulator of extracellular volume because of its effect on renal Na^+ reabsorption, and AVP as the primary regulator of plasma osmolality because of its effect on free-water balance.

The glomerulosa cells of the adrenal cortex synthesize aldosterone from cholesterol via progesterone

As is the case for cortisol, the adrenal cortex synthesizes aldosterone from cholesterol by using P-450 enzymes in a series of five steps. The initial steps in the synthesis of aldosterone from cholesterol follow the same synthetic pathway that cortisol-secreting cells use to generate **progesterone** (see Fig. 50-2). Because glomerulosa cells are the only ones that contain aldosterone synthase, these cells are the exclusive site of aldosterone synthesis.

1. The cytochrome P-450 **SCC enzyme** ($\text{P-450}_{\text{SCC}}$) produces pregnenolone from cholesterol. This enzyme—or the supply of substrate to it—appears to be the rate-limiting step for the overall process of steroid hormone synthesis.
2. The SER enzyme 3β -HSD, which is not a P-450 enzyme, oxidizes pregnenolone to form **progesterone**.
3. Because glomerulosa cells have minimal 17α -hydroxylase ($\text{P-450}_{\text{c17}}$), they do not convert progesterone to 17α -hydroxyprogesterone. Instead, glomerulosa cells use a 21α -hydroxylase ($\text{P-450}_{\text{c21}}$) in the SER to further hydroxylate the progesterone at position 21 and to produce **11-deoxycorticosterone (DOC)**.
4. In the mitochondria, 11β -hydroxylase ($\text{P-450}_{\text{c11}}$) adds an $-\text{OH}$ at position 11 to produce **corticosterone**. This pair of hydroxylations in steps 3 and 4 are catalyzed by the same two enzymes that produce cortisol from 17α -hydroxyprogesterone.
5. The glomerulosa cells—but not the fasciculata and reticularis cells—also have aldosterone synthase

(P-450_{aldo}), which first adds an –OH group to the methyl at position 18 and then oxidizes this hydroxyl to an *aldehyde* group, hence the name **aldosterone**. This mitochondrial P-450 enzyme, also called 18-methyloxidase, is an isoform of the same 11 β -hydroxylase (P-450_{c11}) that catalyzes the DOC-to-corticosterone step. In fact, aldosterone synthase can catalyze all three steps between DOC and aldosterone: 11 β -hydroxylation, 18-methyl hydroxylation, and 18-methyl oxidation.

As with cortisol, no storage pool of presynthesized aldosterone is available in the glomerulosa cell for rapid secretion. Thus, secretion of aldosterone by the adrenal is limited by the rate at which the glomerulosa cells can synthesize the hormone. Although ACTH also stimulates the production of aldosterone in the glomerulosa cell, increases in extracellular [K⁺] and the peptide hormone ANG II are physiologically more important secretagogues. These secretagogues enhance secretion by increasing the activity of enzymes acting at rate-limiting steps in aldosterone synthesis. These enzymes include the SCC enzyme, which is common to all steroid-producing cells, and aldosterone synthase, which is unique to glomerulosa cells and is responsible for formation of the C-18 aldehyde.

Once secreted, ~37% of circulating aldosterone remains free in plasma. The rest weakly binds to CBG (~21%) or albumin (~42%).

Aldosterone stimulates Na⁺ reabsorption and K⁺ excretion by the renal tubule

The major action of aldosterone is to stimulate the kidney to reabsorb Na⁺ and water and enhance K⁺ secretion. Aldosterone has similar actions on salt and water transport in the colon, salivary glands, and sweat glands. MRs are also present in the myocardium, liver, brain, and other tissues, but the physiological role of mineralocorticoids in these latter tissues is unclear.

Aldosterone, like cortisol and all the other steroid hormones, acts principally by modulating gene transcription (see pp. 90–92). In the kidney, aldosterone binds to both low- and high-affinity receptors. The low-affinity receptor appears to be identical to the **GR**. The high-affinity receptor is a distinct **MR**; it has homology to the GR, particularly in the zinc-finger region involved in DNA binding. Surprisingly, MR in the kidney has a similar affinity for aldosterone and cortisol. Because cortisol normally circulates at much higher concentrations than does aldosterone (5 to 20 μ g/dL versus 2 to 8 ng/dL), the biological effect of aldosterone on any potential target would be expected to be greatly overshadowed by that of cortisol. (Conversely, aldosterone has essentially no significant glucocorticoid action because aldosterone binds only weakly to its low-affinity receptor—that is, the GR.)

How then do the renal-tubule cells avoid sensing cortisol as a *mineralocorticoid*? As noted on page 1021, the cells that are targets for aldosterone—particularly in the initial collecting tubule and cortical collecting tubule of the kidney (see p. 766)—contain 11 β -HSD2, which converts cortisol to cortisone, a steroid with a very low affinity for MR (see Fig. 35-13C). Unlike 11 β -HSD1, which reversibly interconverts cortisone and cortisol, 11 β -HSD2 cannot convert cortisone back to cortisol. As a result, locally within the target cell, the cortisol-to-aldosterone ratio is much smaller than the cortisol dominance seen in plasma. In fact, 11 β -HSD2 is so effective at removing cortisol from the cytosol of aldosterone target tissues that cortisol behaves as only a weak mineralocorticoid despite the high affinity of cortisol for the so-called MR. Thus, the presence of 11 β -HSD2 effectively confers aldosterone specificity on the MR.

In the target cells of the renal tubule, aldosterone increases the activity of several key proteins involved in Na⁺ transport (see pp. 765–766). It increases transcription of the Na-K pump, thus augmenting distal

Na⁺ reabsorption. Aldosterone also raises the expression of apical Na⁺ channels and of an Na/K/Cl cotransporter. The net effect of these actions is to increase Na⁺ reabsorption and K⁺ secretion. The enhanced K⁺ secretion (see [p. 799](#)) appears to occur as a secondary effect to the enhanced Na⁺ reabsorption. However, the stoichiometry between Na⁺ reabsorption and K⁺ secretion in the distal tubule is not fixed.

Aldosterone regulates only that small fraction of renal Na⁺ reabsorption that occurs in the distal tubule and collecting duct. Although most Na⁺ reabsorption occurs in the proximal tubule by aldosterone-independent mechanisms, loss of aldosterone-mediated Na⁺ reabsorption can result in significant electrolyte abnormalities, including life-threatening hyperkalemia and, in the absence of other compensatory mechanisms, hypotension. Conversely, excess aldosterone secretion produces hypokalemia and hypertension (see [p. 1030](#)).

In addition to acting via MR, aldosterone also can exert rapid, nongenomic effects by binding to the GPCR known as GPR30 (see [p. 989](#)).

Angiotensin II, K⁺, and ACTH all stimulate aldosterone secretion

Three secretagogues control aldosterone synthesis by the glomerulosa cells of the adrenal cortex. The most important is ANG II, which is a product of the renin-angiotensin cascade. An increase in plasma [K⁺] is also a powerful stimulus for aldosterone secretion and augments the response to ANG II. Third, just as ACTH promotes cortisol secretion, it also promotes the secretion of aldosterone, although this effect is weak.

Angiotensin II

We introduced the renin-angiotensin-aldosterone axis on [pages 841–842](#). The liver synthesizes and secretes a very large protein called **angiotensinogen**, which is an α_2 -globulin ([Fig. 50-6](#)). **Renin**, which is synthesized by the granular (or juxtaglomerular) cells of the juxtaglomerular apparatus (JGA) in the kidney (see [p. 727](#)), is the enzyme that cleaves this angiotensinogen to form **ANG I**, a decapeptide. Finally, angiotensin-converting enzyme (ACE) cleaves ANG I to form the octapeptide **ANG II**. ACE is present in both the vascular endothelium of the lung (~40%) and elsewhere (~60%). In addition to acting as a potent secretagogue for aldosterone, ANG II exerts powerful vasoconstrictor actions on vascular smooth muscle (see [Table 20-8](#)). ANG II has a short half-life (<1 minute) because plasma aminopeptidases further cleave it to the heptapeptide ANG III. 🍷[N50-2](#)

FIGURE 50-6 Control of aldosterone secretion. Three pathways (shown in three different colors) stimulate the glomerulosa cells of the adrenal cortex to secrete aldosterone.

Metabolism of the Angiotensins

Contributed by Emile Boulpaep, Walter Boron

The liver synthesizes and releases into the blood the α_2 -globulin **angiotensinogen (Agt)**, which is a plasma glycoprotein that consists of 452 amino acids. Its molecular weight ranges from 52 to 60 kDa, depending on the degree of glycosylation. Angiotensinogen belongs to the **serpin** (serine protease inhibitor) superfamily of proteins, which also includes antithrombin III (see p. 446 as well as Tables 18-4 and 18-5). The liver contains only small stores of angiotensinogen, which it constitutively secretes. Production by the liver is greatly increased during the acute-phase response (see Box 18-1). Angiotensinogen is synthesized in several tissues other than liver. In addition to the 52- to 60-kDa form of angiotensinogen, a high-molecular-weight (HMW) angiotensinogen complex of 450 to 500 kDa is also present in plasma. Polymorphisms within the angiotensinogen gene may contribute to normal variations in arterial blood pressure and a tendency to develop hypertension.

The juxtaglomerular cells of the kidney—also called granular cells (see p. 727)—are specialized smooth-muscle cells of the afferent arteriole that synthesize and release both the glycoprotein **renin** (molecular weight 37 to 40 kDa)—pronounced *ree-nin*—and its inactive precursor **prorenin**, which is the major circulating form. Prorenin-activating enzymes on endothelial cells convert this prorenin to renin. The kidney is the major source of circulating prorenin/renin, and the liver is responsible for removing renin from the circulation. The half-life of renin in plasma is 10 to 20 minutes. Renin is an aspartyl proteinase that cleaves a leucine-valine bond near the amino (N) terminus of angiotensinogen to release a decapeptide called **angiotensin I (ANG I)**, which is not biologically active. By an alternative pathway, nonrenin proteases can also produce ANG I. The full sequence of ANG I is **Asp-Arg-Val-Tyr-Ile-His-Pro-Phe-His-Leu**:

Angiotensin-converting enzyme (ACE; molecular weight ~200 kDa) is produced by and attached to endothelial cells. ACE is a dipeptidyl carboxypeptidase (a zinc peptidase) that cleaves ANG I by removing the carboxy-terminal (C-terminal) dipeptide histidine-leucine and producing the octapeptide **angiotensin II (ANG II)**. The ACE cleavage site is a phenylalanine-histidine bond. The sequence of ANG II is **Asp-Arg-Val-Tyr-Ile-His-Pro-Phe**:

ANG I: N-Asp-Arg-Val-Tyr-Ile-His-Pro-Phe-His-Leu-C

↓ ACE

ANG II: N-Asp-Arg-Val-Tyr-Ile-His-Pro-Phe-C

ANG II has a half-life in blood of 1 to 3 minutes, indicating that a large fraction is removed in a single pass through the circulation. ANG II acts on G protein–coupled receptors known as **AT₁** and **AT₂**. In addition, two other receptors are less well characterized: **AT₃** and **AT₄**. ANG IV (see below) can bind to **AT₄** receptors.

By an alternative pathway, non-ACE proteases can also convert ANG I to ANG II. Conversely, note that ANG I is not a specific substrate for ACE, which can cleave other peptides, including bradykinin (see pp. 553–554), enkephalins, and substance P.

Aminopeptidase A (also called angiotensinase A, or glutamyl aminopeptidase) further cleaves the aspartate-arginine bond on ANG II to produce the heptapeptide **angiotensin III** (ANG III, also called ANG-(2-8)), which has the sequence **Arg-Val-Tyr-Ile-His-Pro-Phe**. ANG III, like ANG II, can also bind to AT receptors.

Aminopeptidase B (also called angiotensinase B, or arginyl aminopeptidase) finally cleaves an arginine-valine bond on ANG III to produce the hexapeptide **angiotensin IV** (ANG IV, also called ANG-(3-8)). The sequence of ANG IV is **Val-Tyr-Ile-His-Pro-Phe**. This metabolite is inactive.

Finally, another ANG metabolite has received attention in recent years. **ANG-(1-7)** consists only of the first seven amino acids of ANG I*: **Asp-Arg-Val-Tyr-Ile-His-Pro**. This heptapeptide can arise from ANG I by at least three routes:

Note that, by the above nomenclature, ANG I is ANG-(1-10), and ANG II is ANG-(1-8). The first and third pathways involve a new enzyme called **ACE2**. The second is catalyzed by any in a family of enzymes called **neutral endopeptidases (NEPs)**. ANG-(1-7) can bind to a G protein–coupled receptor called the **Mas receptor** and—when acting on the cardiovascular system—can elicit effects opposite those of ANG II.

* ANG-(1-7) is not to be confused with another heptapeptide metabolite of ANG II, namely, **ANG III**—also known as ANG-(2-8). ANG III has actions similar to those of ANG II, but is weaker (see pp. 553–554).

On the plasma membrane of the glomerulosa cell, ANG II binds to the **AT₁ receptor** (type 1 ANG II receptor), which couples through the G α_q -mediated pathway to phospholipase C (PLC). Stimulation of PLC leads to the formation of diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP₃; see p. 58). DAG activates protein kinase C (PKC). IP₃ triggers the release of Ca²⁺ from intracellular stores, thus causing a rise in [Ca²⁺]_i, which activates Ca²⁺-dependent enzymes such as PKC and Ca²⁺-calmodulin-dependent protein kinases. These changes lead to depolarization of the glomerulosa cell's plasma membrane, opening of voltage-activated Ca²⁺ channels, and a *sustained* increase in Ca²⁺ influx from the extracellular space. This rise in [Ca²⁺]_i is primarily responsible for triggering the synthesis (i.e., secretion) of aldosterone. Aldosterone secretion increases because the rise in [Ca²⁺]_i facilitates the production of pregnenolone either by directly increasing the activity of SCC or by enhancing the delivery of cholesterol to the SCC enzyme in the mitochondria (see Fig. 50-2). In addition, increased [Ca²⁺]_i also stimulates aldosterone synthase and in this manner enhances the conversion of corticosterone to aldosterone.

Potassium

An increase in extracellular K⁺ ([K⁺]_o) has a direct action on the glomerulosa cell (see Fig. 50-6). Several K⁺ channels maintain the normal resting potential of these cells.  **N50-3** Thus, high [K⁺]_o depolarizes the plasma membrane and opens voltage-gated Ca²⁺ channels. The result is an influx of Ca²⁺ and a rise in [Ca²⁺]_i that stimulates the same two steps as ANG II—production of pregnenolone from cholesterol and conversion of corticosterone to aldosterone. Unlike the situation for ANG II, the [Ca²⁺]_i increase induced by high [K⁺]_o does not require activation of PLC or release of Ca²⁺ from the intracellular stores. Because increased [K⁺]_o and ANG II both act by raising [Ca²⁺]_i, they can act synergistically on glomerulosa cells.

N50-3

K⁺ Channel Mutations in Primary Hyperaldosteronism

Contributed by Emile Boulpaep, Walter Boron

Adrenal adenomas that produce aldosterone (from glomerulosa-like cells) can lead to severe “primary” hypertension. In a study by Choi and colleagues, 8 of 22 **aldosterone-producing, unilateral adenomas** had mutations in a G protein-activated, inwardly rectifying K⁺ channel called GIRK4 or KCNJ5 (see Table 6-2, family No. 2). The tissue samples were from the adenomas; the other cells in the body may not have had these mutations.

The authors also looked at a second group: a subset of patients with severe hypertension. Choi and colleagues found somatic mutations of KCNJ5—similar to the mutations in the adenomas—in people with bilateral adrenal hyperplasia and primary hyperaldosteronism. Thus, this is a form of **hereditary**

hypertension.

These mutations in the two diseases cause a loss of selectivity for K^+ over Na^+ in the KCNJ5 channels. The resulting Na^+ conductance depolarizes the glomerulosa cell, activating voltage-gated Ca^{2+} channels; this channel activation produces increased Ca^{2+} entry, a rise in $[Ca^{2+}]_i$, and thus an increase in constitutive aldosterone secretion. This cascade explains the primary hypertension. The presence of hyperplasia or neoplasia is consistent with the idea that KCNJ5 may play a role in cell proliferation.

Adrenocorticotrophic Hormone

ACTH stimulates aldosterone secretion by a pathway that is distinct from that of ANG II or high $[K^+]_o$ (see Fig. 50-6), but has only a minor effect. As noted for fasciculata and reticularis cells on page 1023, in glomerulosa cells MC2R is coupled via a heterotrimeric G protein to adenylyl cyclase. Increases in ACTH raise $[cAMP]_i$ and activate PKA, which phosphorylates large numbers of cytosolic proteins. At some as-yet undefined level, these changes stimulate Ca^{2+} influx across the plasma membrane and enhance the synthesis and secretion of aldosterone. ACTH also enhances mineralocorticoid activity by a second mechanism: stimulation of the fasciculata cells to secrete cortisol, corticosterone, and DOC, all of which have weak mineralocorticoid activity. The hypertension seen in individuals who oversecrete ACTH appears to be mediated by the excess synthesis of these weak mineralocorticoids. Neither ANG II nor hyperkalemia affects the cAMP pathway triggered by ACTH (Box 50-4).

Box 50-4

Treating Hypertension by Attacking the Renin-Angiotensin-Aldosterone Axis

Because the renin-angiotensin-aldosterone axis plays an important role in maintaining extracellular volume and arterial pressure, pharmacologists have sought ways to disrupt this system to treat hypertension. Several agents acting on different parts of the axis are available. The **aldosterone antagonists** spironolactone and eplerenone are diuretics that block the action of aldosterone at the level of the MR. They are weak diuretics but are particularly useful in patients with treatment-resistant hypertension. For patients with resistant hypertension or congestive heart failure, aldosterone antagonists are usually added to one of the more common thiazide diuretics (see Box 40-3) to prevent K^+ wasting.

ACE inhibitors have been available for a number of years and are among the safest and best-tolerated of all antihypertensive medications. These drugs also improve the quality of life and survival of patients with heart failure. Another class of drugs, the **ARBs**, specifically antagonize the AT_1 receptor. These drugs offer a good alternative for those patients who cannot tolerate ACE inhibitors. Quite recently, **inhibitors of renin activity** have also become available, targeting yet another site within the renin-angiotensin system to treat hypertension.

Aldosterone exerts indirect negative feedback on the renin-angiotensin axis by increasing effective circulating volume and by lowering plasma $[K^+]$

The feedback regulation exerted by aldosterone is indirect and occurs through its effects of both increasing salt retention (i.e., extracellular volume) and decreasing $[K^+]_o$.

Renin-Angiotensin Axis

As discussed beginning on [page 841](#), a decrease in effective circulating volume stimulates the granular cells of the JGA of the kidney to increase their synthesis and release of renin, which increases the generation of ANG II and, therefore, aldosterone (see [Fig. 50-6](#)). The **JGA** is located at the glomerular pole of the nephron, between the afferent and efferent arterioles, where the early distal tubule comes in close proximity to its own glomerulus ([Fig. 50-7](#)). Histologically, the JGA comprises specialized epithelial cells of the distal tubule called macula densa cells, as well as specialized smooth-muscle cells of the *afferent* arteriole, which are called granular cells or juxtaglomerular cells. Macula densa cells and granular cells communicate by means of an extracellular matrix.

FIGURE 50-7 Structure of the JGA.

Decreases in effective circulating volume—or the associated decreases in systemic arterial pressure—stimulate renin release from the **granular cells** of the JGA in three ways discussed on [page 841](#). Enhanced renin release leads to increased levels of ANG II and aldosterone. ANG II negatively feeds back on renin release *directly* by inhibiting renin release by granular cells (short-loop feedback). ANG II also negatively feeds back on renin release *indirectly* by acutely increasing systemic arterial pressure (see [p. 553](#)), thereby reducing the stimuli to release renin (see [p. 841](#)). Finally, aldosterone negatively feeds back on renin release more slowly by enhancing renal Na^+ reabsorption (see [p. 766](#)) and thus increasing effective circulating blood volume and blood pressure. Therefore, ANG II and aldosterone complete the regulatory feedback circuit that governs the secretion of aldosterone.

Potassium

High plasma $[K^+]$ stimulates the glomerulosa cell in the adrenal cortex to synthesize and release aldosterone, which in turn stimulates the principal cells of the renal collecting duct to reabsorb more Na^+ and excrete more K^+ (see Fig. 50-6). This excretion of K^+ causes plasma $[K^+]$ to fall toward normal. As a result, stimulation of glomerulosa cells declines, aldosterone secretion falls, and the negative-feedback loop is completed. This sequence of events (i.e., hyperkalemia \rightarrow aldosterone secretion \rightarrow K^+ excretion) probably plays a vital role in preventing wide swings in plasma $[K^+]$ in response to episodic dietary intake of large K^+ loads.

Role of Aldosterone in Normal Physiology

What, then, is the role of aldosterone in normal physiology? Presumably, the salt- and water-retaining properties of aldosterone are of greatest value in meeting the environmental stresses associated with limited availability of salt, water, or both. Such conditions are not prevalent in most Western societies, but they still exist in many developing countries and were probably universal in previous periods of human evolutionary history. In healthy, normotensive humans, blockade of aldosterone generation with ACE-inhibiting drugs reduces ANG II production and markedly decreases plasma aldosterone, but it causes only slight decreases in total-body Na^+ and blood pressure. Redundant mechanisms for maintaining blood pressure probably prevent a larger blood pressure decrease. The reason for the mild effect on Na^+ balance is probably an adaptive increase in salt intake; indeed, patients with adrenal cortical insufficiency frequently crave dietary salt. In contrast to the minor effects of low aldosterone on blood pressure and Na^+ balance in physiologically normal people, the effects of blocking aldosterone production can be catastrophic for K^+ balance; low aldosterone levels can result in life-threatening hyperkalemia. Potassium levels are carefully followed in patients receiving aldosterone antagonists, ACE inhibitors, angiotensin receptor blockers (ARBs), and renin inhibitors (see Box 50-4).

Role of Aldosterone in Disease

Aldosterone does play important roles in several pathological conditions. For example, in many patients with *hypertension*, ACE inhibitors or ARBs are effective in reducing blood pressure (see Box 50-4), a finding implying that their renin-angiotensin-aldosterone axis was overactive. In *hypotension*, as occurs with hemorrhage or dehydration, aldosterone secretion increases, thus raising effective circulating volume and blood pressure.

Aldosterone secretion also increases in congestive heart failure. However, the increased salt retention in this setting is inappropriate because it results in worsening edema formation. In this case, the increase in circulating aldosterone occurs *despite* pre-existing volume overload. The problem in congestive heart failure is that the JGA does not perceive the very real volume overload as an increase in *effective* circulating volume. Indeed, the reduced cardiac output in heart failure diminishes renal glomerular filtration, partly because of decreased arterial blood pressure and partly because of enhanced sympathetic nervous system activity, which constricts the afferent arterioles of the kidney. As a result, the kidney inappropriately assumes that the extracellular volume is decreased and stimulates the renin-angiotensin-aldosterone system.

Hyperaldosteronism was long thought to be an uncommon cause of hypertension. Now we recognize that hyperaldosteronism is responsible for $\sim 10\%$ of hypertension and for an even greater fraction of treatment-resistant hypertension. **Primary hyperaldosteronism** can result from either an isolated adrenal adenoma or bilateral adrenal hyperplasia; even more rarely, adrenal carcinoma can produce excess

aldosterone. **N50-4** In patients with adenomas of the glomerulosa cell, the disorder is called **Conn syndrome**. Hypertension and hypokalemia frequently develop in these patients. As would be expected from feedback regulation of the renin-angiotensin-aldosterone system, the plasma renin concentration is characteristically suppressed in this form of hypertension.

N50-4

Licorice as a Cause of Apparent Mineralocorticoid Excess

Contributed by Emile Boulpaep, Walter Boron

Glycyrrhizic acid is a chemical that consists of **glycyrrhetic acid** (3- β -hydroxy-11-oxoolean-12-en-30-oic acid) conjugated to two glucuronic acid moieties. Glycyrrhizic acid is 150-fold sweeter than sucrose. It is naturally produced by the plant *Glycyrrhiza glabra* (*Leguminosae*) and is also present in European licorice. American licorice manufacturers generally substitute anise for glycyrrhizic acid.

Glycyrrhetic acid and the glycyrrhetic acid moiety of glycyrrhizic acid have the curious property that they inhibit the enzyme **11 β -hydroxysteroid dehydrogenase (11 β HSD)**. This enzyme converts cortisol into cortisone. **N50-7** Because cortisol has a much higher affinity for the MR than does the breakdown product cortisone, inhibition of 11 β HSD produces the same symptoms as a bona fide excess of mineralocorticoids. As described on page 766, this excess leads to Na⁺ retention and hypertension.

These compounds also inhibit **15-hydroxyprostaglandin dehydrogenase** in the surface cells of the stomach and thereby increase levels of prostaglandins that protect the stomach from acid damage. This same action may also promote the release of mucus in the airway, which is why the active compounds of licorice have been used as expectorants.

True licorice has long been used as an herbal medicine.

Reaction Catalyzed by 11 β -Hydroxysteroid Dehydrogenase

Contributed by Eugene Barrett

Refer to Figure 50-2, specifically the **cortisol** molecule (4-pregnen-11 β ,17 α ,21-triol-3,20-dione), which has two highlighted hydroxyl groups—one on the C ring at position 11 and another on the D ring at position 17. The enzyme 11 β -hydroxysteroid dehydrogenase (11 β -HSD) removes one H from the hydroxyl group at position 11 and another H from the same carbon, yielding a ketone group (O=C) at position 11. The product of this reaction is **cortisone** (4-pregnen-17 α ,21-diol-3,11,20-trione). Thus, the enzyme converts a triol (three hydroxyl groups)/dione (two ketone groups) to a diol (two hydroxyl groups)/trione (three ketone groups).

The Adrenal Medulla

The adrenal medulla bridges the endocrine and sympathetic nervous systems

On [page 978](#), we describe cells of the hypothalamus as *neuroendocrine* because they are part of the CNS and appear anatomically as neural tissue, yet they release peptide hormones (e.g., CRH) into the blood that act downstream on the pituitary—a classic endocrine function. The adrenal medulla is similar in many ways. The cells of the medulla, termed **chromaffin cells** because the catecholamines that they contain stain avidly with chromium salts, derive from neural crest cells (see [p. 261](#)) and migrate into the center of the adrenal cortex, which is derived from the mesoderm. The adrenomedullary cells synthesize and secrete epinephrine and—to a lesser extent—norepinephrine. Norepinephrine is the neurotransmitter of the sympathetic division of the autonomic nervous system (see [pp. 342–343](#)). Both the norepinephrine and epinephrine made in the adrenal medulla enter the circulation and act on distal tissues just like other hormones.

Chromaffin cells are the structural and functional equivalents of the **postganglionic** neurons in the sympathetic nervous system (see [p. 343](#)). The preganglionic sympathetic fibers of the splanchnic nerves, which release acetylcholine (ACh), are the principal regulators of adrenomedullary hormone secretion.

The vascular supply to the adrenal medulla is also unusual. The medulla receives vascular input from vessels that begin in a subcapsular plexus of the adrenal cortex. The vessels then branch into a capillary network in the cortex only to merge into small venous vessels that branch into a second capillary network within the medulla. This **portal blood supply** (originating at the entrance to the adrenal) exposes the adrenal medulla to the highest concentrations of glucocorticoids and mineralocorticoids of all somatic tissues.

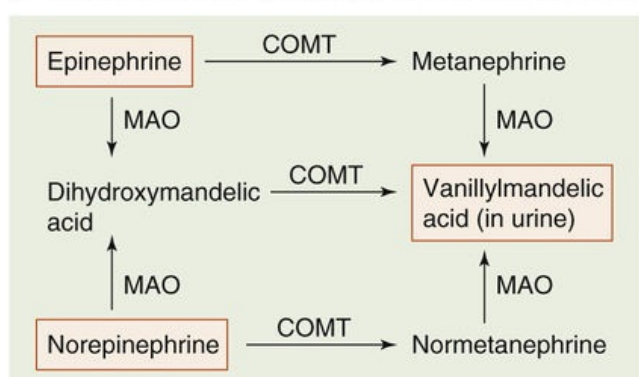

Only chromaffin cells of the adrenal medulla have the enzyme for epinephrine synthesis

It was first appreciated nearly a century ago that extracts of the adrenal medulla have a powerful pressor effect. Subsequent work showed that **catecholamines** ([Fig. 50-8A](#))—L-dopa, dopamine, norepinephrine, and epinephrine—are all made in the adrenal medulla. **Norepinephrine** is found in many other somatic tissues in amounts that roughly parallel the extent of sympathetic innervation of the tissue. In other words, the norepinephrine in these other tissues is not made there but is derived from the sympathetic nerve endings in them. Virtually all the circulating **epinephrine**, the principal product of the adrenal medulla, comes from the adrenal medulla.

A CATECHOLAMINE SYNTHESIS

B DEGRADATIVE METABOLISM OF CATECHOLAMINES

Dopamine, norepinephrine, and epinephrine are all synthesized from the amino acid tyrosine. [Figure 50-8A](#) summarizes the reactions involved in the synthesis of epinephrine. [Figure 50-9](#) illustrates the cellular localization of the four enzymatic reactions, as well as the three critical transport steps that shuttle the reactants and products to their proper location.

1. The activity of the first enzyme in the pathway, **tyrosine hydroxylase**, which converts tyrosine to **L-dopa**, is rate limiting for overall synthesis. This enzyme is located within the *cytosol* of adrenal medullary cells as well as in sympathetic nerve terminals and in specific cells within the CNS.
2. The *cytosolic* enzyme **amino-acid decarboxylase** converts L-dopa to **dopamine** in numerous tissues, including the adrenal medulla.
3. A catecholamine-H⁺ exchanger (vesicular monoamine transporter 1, or VMAT1) moves the dopamine into membrane-enclosed dense-core vesicles called **chromaffin granules**.
4. **Dopamine β-hydroxylase** converts dopamine to norepinephrine by hydroxylating the β carbon. This β-hydroxylase is localized to the inner surface of the membrane of granules within the adrenal medulla and sympathetic nerves. In the nerve terminals of postganglionic sympathetic neurons, the synthetic pathway terminates at this step, and the granules store the norepinephrine for later secretion. However, the cells of the adrenal medulla convert the norepinephrine to epinephrine in three final steps.
5. Norepinephrine formed in the secretory granules moves out into the cytosol.
6. The cytosolic enzyme **phenylethanolamine-N-methyltransferase (PNMT)** transfers a methyl group from S-adenosylmethionine to norepinephrine, thus creating epinephrine. Substantial amounts of this enzyme are present only in the cytosol of adrenal chromaffin cells. [N50-5](#)
7. The secretory granules in the adrenal medulla take up the newly synthesized epinephrine. The same VMAT1 catecholamine-H⁺ exchanger noted in step 3 appears to mediate this uptake of epinephrine. The proton gradient is maintained by an H pump (i.e., a vacuolar-type H-ATPase; see [pp. 118–119](#)) within the secretory vesicle membrane. Thus, in the adrenal medulla, the secretory granules store both epinephrine and norepinephrine before secretion.

FIGURE 50-9 Cellular view of catecholamine synthesis. The chromaffin cell synthesizes and stores epinephrine in a sequence of four enzymatic and three transport steps. AADC, amino-acid decarboxylase; DA, dopamine; DBH, dopamine β -hydroxylase; Epi, epinephrine; NE, norepinephrine; TH, tyrosine hydroxylase.

N50-5

Phenylethanolamine-*N*-Methyltransferase

Contributed by Gene Barrett

PNMT is the enzyme that catalyzes the last step—the addition of a methyl group—in the synthesis of epinephrine. PNMT is also present in very small amounts in the ganglion cells within the heart and in the CNS.

In addition, the kidney also has an enzyme that is an *N*-methyltransferase—but this enzyme is distinct from PNMT. The renal form of *N*-methyltransferase is also present in liver (perhaps along with a small amount of PNMT).

Epinephrine synthesis is under the control of the CRH-ACTH-cortisol axis at two levels. First, ACTH stimulates the synthesis of L-dopa and norepinephrine. Second, cortisol transported from the adrenal cortex by the portal circulation to the medulla upregulates PNMT in chromaffin cells. The result is synergy between the CRH-ACTH-cortisol axis and the sympathetic-epinephrine axis. Thus, the stress that is sensed and propagated by the CRH-ACTH-cortisol axis sustains the epinephrine response.

Similar to the secretory granules that are present in the postganglionic sympathetic neurons, the

secretory granules of the adrenal medulla contain very high concentrations of catecholamines (as high as 0.5 M). These catecholamines—along with ATP and Ca^{2+} —bind to granular proteins called **chromogranins** and thus are not osmotically active in these storage vesicles. Chromogranins are what make dense-core vesicles dense. In humans, the dominant chromogranin is chromogranin B. The release of catecholamines is initiated by CNS control. ACh released from preganglionic neurons in the splanchnic nerves acts on nicotinic ACh receptors to depolarize the postganglionic chromaffin cells. This depolarization triggers the opening of voltage-gated Ca^{2+} channels, a process that raises $[\text{Ca}^{2+}]_i$ and triggers the exocytotic release of epinephrine. The secretion of adrenal catecholamines is accompanied by the release of ATP and the granule proteins. The release of chromogranin A has been used as a marker of adrenal medullary activity. In the circulation, the catecholamines dissociate from the binding complex and are free to act on target tissues.

The early description of the fight-or-flight response to stress (see [p. 347](#)) exemplifies the central control of adrenomedullary function. An organism faced with a severe external threat responds with centrally driven release of adrenal hormones, as well as activation of other aspects of the sympathetic nervous system. This response includes increases in heart rate and contractility, mobilization of fuel stores from muscle and fat, piloerection, pupillary dilatation, and increased sphincter tone of the bowel and bladder. Each response is in some way adapted to deal with the perceived threat successfully. This combined neuroendocrine response is activated within seconds. The secreted catecholamines act very quickly after reaching their target tissues.

The biological actions of catecholamines are very brief, lasting only ~10 seconds in the case of epinephrine. Circulating catecholamines are degraded first by the enzyme **catechol-O-methyltransferase (COMT)**, which is present in high concentrations in endothelial cells and the heart, liver, and kidneys (see [Fig. 50-8B](#)). COMT converts epinephrine to metanephrine, as well as norepinephrine to normetanephrine. A second enzyme, **monoamine oxidase**, converts these metabolites to vanillylmandelic acid (VMA). The liver and also the gut then conjugate these compounds to sulfate (see [p. 955](#)) or glucuronide (see [p. 955](#)) to form derivatives that the kidney excretes in the urine. Determination of the concentration of catecholamines, metanephrines, and VMA in the urine provides a measure of the total adrenal catecholamine production by both the adrenal medulla and the sympathetic system.

Catecholamines bind to α and β adrenoceptors on the cell surface and act through heterotrimeric G proteins

Many of the hormones already discussed have a unique receptor on the cell surface (e.g., insulin, parathyroid hormone, growth hormone, thyroid-stimulating hormone) or within the cell (e.g., thyroid hormones or cortisol). Other hormones (e.g., AVP) and neurotransmitters (e.g., ACh and glutamate) may bind to more than one type of receptor, each acting via a different signal-transduction process. The situation for the catecholamines is even more complex. Epinephrine and norepinephrine can each bind to more than one type of adrenergic receptor, or **adrenoceptor**, all of which are GPCRs. Conversely, individual adrenoceptors can generally bind both epinephrine and norepinephrine—albeit with different affinities. For their work on GPCRs, including adrenoceptors, Robert J. Lefkowitz and Brian K. Kobilka shared the 2012 Nobel Prize in Chemistry. 🏆[N50-6](#)

Robert J. Lefkowitz and Brian K. Kobilka

For more information about Robert Lefkowitz and Brian Kobilka and the work that led to their Nobel Prize, visit http://www.nobelprize.org/nobel_prizes/chemistry/laureates/2012/ (accessed September 2014).

In the late 1940s, Raymond Ahlquist found that epinephrine and epinephrine analogs could produce both excitatory and inhibitory effects, depending on the tissue. This property led to the designation of α -adrenergic receptors (mostly associated with stimulation) and β -adrenergic receptors (mostly associated with inhibition). Moreover, certain drugs could selectively block the α and β effects. This dichotomy proved to be too simple when it was observed that the actions of some drugs that have pure α or pure β activity could be blocked in some tissues but not in others; this variability in response suggested that the tissue response is determined by a *subtype* of α or β receptor.

It is now clear that at least three types of β and two types of α receptors exist (see [Table 14-2](#)), as well as subtypes within these major classes. These receptors differ in primary structure and in the types of G proteins that associate with the receptor. The several β receptors are coupled to stimulatory heterotrimeric G proteins (G_{α_s}) that *stimulate* adenylyl cyclase and thus increase levels of cAMP (see [p. 53](#)), the principal intracellular mediator of β activation. The α_2 adrenoceptors are coupled to other G proteins (G_{α_i}) that *inhibit* adenylyl cyclase and thus lower $[cAMP]_i$ in target tissues. The α_1 receptors are coupled to yet another heterotrimeric G protein (G_{α_q}) that activates PLC (see [p. 58](#)) and thereby increases $[IP_3]_i$ and $[Ca^{2+}]_i$ in target tissues.

Recognition of the diversity of adrenoceptor subtypes has led to a panoply of pharmacological agents that block or stimulate one or the other of these receptor subtypes. Some drugs are nonspecific and affect several receptor subtypes; others specifically block only a single subtype. The clinical value of a particular drug depends on its spectrum of activity. Thus, for example, an agent that selectively blocks the vasoconstrictor response to norepinephrine could be a very useful antihypertensive agent, but its utility would be compromised if it also blocked the ability of bladder smooth muscle to contract.

The CNS-epinephrine axis provides integrated control of multiple functions

The actions of the sympathetic nervous system (see [Chapter 14](#)) in the control of blood pressure (see [p. 539](#)), heart rate (see [p. 539](#)), sweating (see [p. 1218](#)), micturition (see [p. 736](#)), and airway resistance (see [p. 620](#)) are discussed in more detail in other chapters, as indicated. Here, we mention only some of the unique actions attributed to adrenal catecholamine release that integrate several bodily functions as part of the stress response. These adrenal-mediated activities do not occur in isolation but are usually accompanied by generalized noradrenergic sympathetic discharge.

In response to the stress of simple **exercise** (see [pp. 583](#) and [1210](#)), blood flow to muscle is increased; circulating epinephrine appears to be important in this response. Circulating epinephrine also relaxes bronchial smooth muscle to meet the demand for increased ventilation and, when combined with the increased blood flow, increases oxygen delivery to the exercising muscle. Similarly, to sustain muscular activity, particularly early in exercise, epinephrine acting via the β adrenoceptor activates the degradation of muscle glycogen to provide a ready fuel source for the contracting muscle (see [p. 1182](#)). Epinephrine also activates lipolysis in adipose tissue (see [p. 1182](#)) to furnish fatty acids for more sustained muscular

activity if needed. In liver, as in muscle, epinephrine activates glycogenolysis, so that the supply of glucose is maintained in the blood.

In addition to enhancing blood flow and ventilation, the integrated response to exercise increases fuel availability by decreasing insulin levels. Circulating epinephrine, acting through a β adrenoceptor, *stimulates* the secretion of insulin (see [p. 1041](#)). However, during exercise, local autonomic innervation, acting by means of an α adrenoceptor of the pancreas, *inhibits* this effect so that insulin levels fall. The net effects are to promote glycogenolysis and to allow muscle to increase its work while maintaining glycemia so that brain function is not impaired. The fleeing human must not only run, but know *where* to run!

Unlike in other glandular tissue, no endocrine feedback loop governs the secretion of adrenal medullary hormones. Control of catecholamine secretion resides within the CNS. This principle can be illustrated by the changes in epinephrine secretion that occur with even mild **hypoglycemia**. Decreases in blood glucose concentration to less than ~ 3.5 mM (normal concentration, ~ 5.5 mM) are sensed by the CNS, which triggers a central sympathetic response that increases the firing of preganglionic fibers in the celiac plexus. This sympathetic outflow suppresses endogenous insulin secretion by the α -adrenergic mechanism noted above, thus promoting an increase in plasma [glucose]. This sympathetic outflow to the adrenal medulla also triggers a major release of epinephrine that, through β adrenoceptors in the liver, stimulates increased hepatic glycogenolysis. This response helps to restore plasma [glucose] to normal. Restoration of normoglycemia diminishes central sympathetic outflow ([Box 50-5](#)).

Box 50-5

Pheochromocytoma

The dramatic biological effects of catecholamines are well illustrated by patients with pheochromocytoma. A **pheochromocytoma** is a relatively uncommon tumor caused by hyperplasia or more rarely neoplasia of either adrenal medullary tissue or extra-adrenal chromaffin tissue that failed to involute after birth. These tumors, which can be benign or malignant, make catecholamines, just like the normal medulla, except in an unregulated fashion. Patients with pheochromocytomas typically have a plethora of symptoms, as would be expected from such a wide-ranging hormonal system. Paroxysmal (sudden) hypertension, tachycardia, headache, episodes of sweating, anxiousness, tremor, and glucose intolerance usually dominate the clinical findings. The key to the diagnosis of this disorder is a careful history taking, evidence on physical examination of excessive adrenergic tone, and laboratory detection of increased amounts of serum and urinary catecholamines and their metabolites. When chemical evaluation of the metabolites confirms the presence of a pheochromocytoma, it is often possible to localize the tumor to one or the other adrenal gland and resect the tumor. Rarely, both glands are affected, necessitating bilateral adrenalectomy. Such patients must subsequently receive glucocorticoid and mineralocorticoid replacement. No therapy is routinely given to replace the adrenal *medullary* function. It is not clear whether these individuals react less well to external stimuli that would trigger the fight-or-flight response.

CHAPTER 51

The Endocrine Pancreas

Eugene J. Barrett

The islets of Langerhans are endocrine and paracrine tissue

The pancreas contains two types of glands: (1) exocrine glands, which secrete digestive enzymes (see [p. 882](#)) and HCO_3^- (see [pp. 885–886](#)) into the intestinal lumen; and (2) endocrine glands, called the *islets of Langerhans*. The islets are spread throughout the pancreas and in aggregate comprise only 1% to 2% of its tissue mass.

The normal human pancreas contains between 500,000 and several million islets. Islets can be oval or spherical and measure between 50 and 300 μm in diameter. Islets contain at least four types of secretory cells— α cells, β cells, δ cells, and F cells—in addition to various vascular and neural elements ([Fig. 51-1](#) and [Table 51-1](#)). **β cells** secrete insulin, proinsulin, C peptide, and a newly described protein, amylin (or IAPP for islet amyloid polypeptide). β cells are the most numerous type of secretory cell within the islets; they are located throughout the islet but are particularly numerous in the center. **α cells** principally secrete glucagon, **δ cells** secrete somatostatin, and **F cells** (also called pancreatic polypeptide cells) secrete pancreatic polypeptide.

FIGURE 51-1 Islet of Langerhans. The distribution of cell types is representative of islets from ~90% of the human pancreas, which arises embryologically from the dorsal pancreatic bud. In the other islets (not shown), F cells dominate.

TABLE 51-1
Products of Pancreatic Islet Cells

CELL TYPE	PRODUCT
α	Glucagon
β	Insulin Proinsulin C peptide Amylin
δ	Somatostatin
F	Pancreatic polypeptide

The islets are richly perfused (blood flow per gram of tissue is >5 times that of the myocardium) and receive both sympathetic and parasympathetic innervation. These cells also can communicate with each other and influence each other's secretion. We can group these communication links into three categories:

- Humoral communication.** The blood supply of the islet courses outward from the center of the islet toward the periphery, carrying glucose and other secretagogues. In the rat—and less strikingly in humans— β cells are more abundant in the center of the islet, whereas α and δ cells are more abundant in the periphery. Cells within a given islet can influence the secretion of other cells as the blood supply courses outward through the islet carrying the secreted hormonal product of each cell type with it. For example, glucagon is a potent insulin secretagogue, insulin modestly inhibits glucagon release, and somatostatin potently inhibits the secretion of both insulin and glucagon (as well as the secretion of growth hormone and other non-islet hormones).
- Cell-cell communication.** Both gap and tight junctional structures connect islet cells with one another. Cells within an islet communicate via gap junctions, which may be important for the regulation of both insulin and glucagon secretion.
- Neural communication.** Both the sympathetic and parasympathetic divisions of the autonomic nervous system (ANS) regulate islet secretion. Cholinergic stimulation augments insulin secretion. Adrenergic stimulation can have either a stimulatory or inhibitory effect, depending on whether β -adrenergic (stimulatory) or α -adrenergic (inhibitory) stimulation dominates (see [p. 1033](#)).  **N51-1**

N51-1

Antagonistic Effects of α - and β -Adrenergic Receptors on Insulin Secretion

Contributed by Emile Boulpaep, Walter Boron

On page 1033, we noted that the general rule for α - and β -adrenergic receptors—first noted by Raymond Ahlquist—is that α activation leads to stimulation, whereas β activation leads to inhibition. The pattern in pancreatic islets is just the opposite, as noted in the text.

These three communication mechanisms allow for a tight control over the synthesis and secretion of islet hormones.

Insulin

The discovery of insulin was among the most exciting and dramatic events in the history of endocrine physiology and therapy. In the United States and Europe, insulin-dependent diabetes mellitus (IDDM), or type 1 diabetes, develops in ~1 in every 600 children. However, the prevalence is only ~1 in 10,000 in eastern Asia. Before 1922, all children with diabetes died within 1 or 2 years of diagnosis. It was an agonizing illness; the children lost weight despite eating well, became progressively weaker and cachectic, were soon plagued by infections, and eventually died of overwhelming acidosis. No effective therapy was available, and few prospects were on the horizon. It was known that the blood sugar level was elevated in this disease, but beyond that, there was little understanding of its pathogenesis.

In 1889, Minkowski and von Mering demonstrated that removing the pancreas from dogs caused hyperglycemia, excess urination, thirst, weight loss, and death—in short, a syndrome closely resembling type 1 diabetes. Following this lead, a group of investigators in the Department of Physiology at the University of Toronto prepared extracts of pancreas and tested the ability of these extracts to lower plasma [glucose] in pancreatectomized dogs. Despite months of failures, these investigators persisted in their belief that such extracts could be beneficial. Finally, by the winter of 1921, Frederick Banting (a surgeon) and Charles Best (at the time, a medical student) were able to demonstrate that an aqueous extract of pancreas could lower blood glucose level and prolong survival in a pancreatectomized dog.  **N51-2** Within 2 months, a more purified extract was shown to lower blood glucose level in a young man with diabetes. By the end of 1923, insulin (as the islet hormone was named) was being prepared from beef and pork pancreas on an industrial scale, and patients around the world were receiving effective treatment of their diabetes. For the discovery of insulin, Frederick Banting and John Macleod received the 1923 Nobel Prize in Physiology or Medicine.  **N51-3**

N51-2

Frederick Banting and Charles Best

Contributed by Emile Boulpaep, Walter Boron

In 1923, just 2 years after Frederick Banting (a young faculty member just 5 years out of medical school) and Charles Best (a 22-year-old medical student working in Banting's laboratory) discovered insulin at the University of Toronto, the Nobel Prize in Physiology or Medicine was awarded to Frederick Banting and the head of the research team and chairman of Banting's department, John Macleod. The short delay between the discovery and the award of the prize indicates the enormous significance of the discovery.

It is interesting that Frederick Banting protested the award of the Nobel Prize to John Macleod and gave half of his portion of the monetary award to Charles Best.

Since that time, the physiology of the synthesis, secretion, and action of insulin has been studied more extensively than that of any other hormone. Now, nearly a century later, much is known about the metabolic pathways through which insulin regulates carbohydrate, lipid, and protein metabolism in its major targets: the liver, muscle, and adipose tissue. However, the sequence of intracellular signals that triggers insulin secretion by pancreatic β cells, as well as the signal-transduction process triggered when insulin binds to a plasma membrane receptor on target tissues, remain areas of intense study.

Insulin replenishes fuel reserves in muscle, liver, and adipose tissue

What does insulin do? Succinctly put, insulin efficiently integrates body fuel metabolism both during periods of fasting and during feeding (Table 51-2). When an individual is *fasting*, the β cell secretes less insulin. When insulin levels decrease, lipids are mobilized from adipose tissue and amino acids are mobilized from body protein stores within muscle and other tissues. These lipids and amino acids provide fuel for oxidation and serve as precursors for hepatic ketogenesis and gluconeogenesis, respectively. During *feeding*, insulin secretion increases promptly, which diminishes the mobilization of endogenous fuel stores and stimulates the uptake of carbohydrates, lipids, and amino acids by insulin-sensitive target tissues. In this manner, insulin directs tissues to replenish the fuel reserves depleted during periods of fasting.

TABLE 51-2
Effects of Nutritional States

PARAMETER	AFTER A 24-hr FAST	2 hr AFTER A MIXED MEAL
Plasma [glucose], mg/dL	60–80	100–140
mM	3.3–4.4	5.6–7.8
Plasma [insulin], μ U/mL	3–8	50–150
Plasma [glucagon], pg/mL	40–80	80–200
Liver	\uparrow Glycogenolysis \uparrow Gluconeogenesis	\downarrow Glycogenolysis \downarrow Gluconeogenesis \uparrow Glycogen synthesis
Adipose tissue	Lipids mobilized for fuel	Lipids synthesized
Muscle	Lipids metabolized Protein degraded and amino acids exported	Glucose oxidized or stored as glycogen Protein preserved

As a result of its ability to regulate the mobilization and storage of fuels, insulin maintains plasma [glucose] within narrow limits. Such regulation provides the central nervous system (CNS) with a constant supply of glucose needed to fuel cortical function. In higher organisms, if plasma [glucose] (normally \cong 5 mM) declines to <2 to 3 mM (hypoglycemia; Box 51-1) for even a brief period, confusion, seizures, and coma may result. Conversely, persistent elevations of plasma [glucose] are characteristic of the diabetic state. Severe *hyperglycemia* (plasma glucose levels > 15 mM) produces an osmotic diuresis (see Box 35-1) that, when severe, can lead to dehydration, hypotension, and vascular collapse.

Clinical Manifestations of Hypoglycemia and Hyperglycemia

Hypoglycemia N51-4

Early symptoms are principally autonomic and include palpitations, tachycardia, diaphoresis, anxiety, hyperventilation, shakiness, weakness, and hunger. More severe hypoglycemia manifests principally as *neuroglycopenia*, with confusion, aberrant behavior, hallucinations, seizures, hypothermia, focal neurological deficits, and coma.

Hyperglycemia

Early manifestations include weakness, polyuria, polydipsia, altered vision, weight loss, and mild dehydration. For prolonged or severe hyperglycemia (accompanied by metabolic acidosis or diabetic ketoacidosis), manifestations include Kussmaul hyperventilation (deep, rapid breathing; see p. 716), stupor, coma, hypotension, and cardiac arrhythmias.

N51-4

Hypoglycemia

Contributed by Eugene Barrett

Hypoglycemia, which can be viewed most simply as the opposite of diabetes mellitus, has many causes. Perhaps the most frequent setting is a patient with type 1 diabetes who skips a meal or fails to adjust the insulin dose when exercising. Many diabetic patients who seek to maintain tight control over their blood sugar experience frequent hypoglycemic reactions, which they quickly learn to abort with a carbohydrate snack. Patients with type 2 diabetes who take an excessive dose of sulfonylureas are subject to severe hypoglycemia, which may require continuous treatment for several days because the half-life of some of these drugs is quite long.

We saw in Chapter 50 that epinephrine—acting as a β -adrenergic agonist—is a hyperglycemic agent; that is, it promotes glycogenolysis in liver and muscle (see p. 1033). Thus, **β blockers** rarely cause hypoglycemia in healthy individuals because these people can appropriately regulate their insulin secretion. However, because β blockers can mask the early adrenergic response to mild hypoglycemia (sweating, tachycardia, tremulousness), diabetic patients taking both insulin and β blockers commonly progress to severe hypoglycemia without warning. Another drug that can induce hypoglycemia is **pentamidine**, an agent used to treat *Pneumocystis jiroveci* pneumonia. Pentamidine is a β -cell toxin that leads to an acute, excessive release of insulin, which can be followed by hypoglycemia.

Alcoholic patients are at great risk of hypoglycemia. Ethanol suppresses gluconeogenesis, and hepatic glycogen stores may already be low because of poor nutrition. Other severe illnesses that can produce persistent hypoglycemia include liver disease, renal failure, and some large tumors that produce a hypoglycemia-inducing peptide, usually IGF-2. Rarely, an **insulinoma** may develop, which is an islet cell tumor (usually benign) that releases high and unregulated concentrations of insulin into the bloodstream.

Many individuals complain of postprandial hypoglycemia, frequently called *reactive hypoglycemia*. Despite long years of skepticism, investigators now believe that at least some of these patients do indeed experience true symptoms of hypoglycemia within a few hours of eating. There is no absolute glucose

level at which symptoms occur; many people can tolerate extremely low levels of glucose without any problems. However, a rather high *rate* of decline in the plasma glucose level after a meal may cause symptoms. One cause of postprandial hypoglycemia may be a delay in the timing of insulin release after a meal. Thus, the β cells release too much insulin too late after a meal, so the blood glucose level initially rises markedly and then falls rapidly. In some patients, this defect may herald the development of diabetes mellitus.

β cells synthesize and secrete insulin

The Insulin Gene

Circulating insulin comes only from the β cells of the pancreatic islet. It is encoded by a single gene on the short arm of chromosome 11. Exposing islets to glucose stimulates insulin synthesis and secretion. Though the process is not completely understood, this stimulation requires that the glucose be metabolized.

Insulin Synthesis

Transcription of the insulin gene product and subsequent processing produces full-length messenger RNA (mRNA) that encodes **preproinsulin**. Starting from its 5' end, this mRNA encodes a leader sequence and then peptide domains B, C, and A. Insulin is a *secretory protein* (see [pp. 34–35](#)). As the preprohormone is synthesized, the leader sequence of ~24 amino acids is cleaved from the nascent peptide as it enters the rough endoplasmic reticulum. The result is **proinsulin** ([Fig. 51-2](#)), which consists of domains B, C, and A. As the *trans* Golgi packages the proinsulin and creates secretory granules, proteases slowly begin to cleave the proinsulin molecule at two spots and thus excise the 31-amino-acid C peptide. The resulting insulin molecule has two peptide chains, designated the **A and B chains**, that are joined by two disulfide linkages. The mature insulin molecule has a total of 51 amino acids, 21 on the A chain and 30 on the B chain. In the secretory granule, the insulin associates with zinc. The secretory vesicle contains this insulin, as well as proinsulin and C peptide. All three are released into the portal blood when glucose stimulates the β cell.

FIGURE 51-2 Synthesis and processing of the insulin molecule. The mature mRNA of the insulin gene

product contains a 5' untranslated region (UTR); nucleotide sequences that encode a 24–amino-acid leader sequence, as well as B, C, and A peptide domains; and a 3' UTR. Together, the leader plus the B, C, and A domains constitute preproinsulin. During translation of the mRNA, the leader sequence is cleaved in the lumen of the rough endoplasmic reticulum (ER). What remains is proinsulin, which consists of the B, C, and A domains. Beginning in the *trans* Golgi, proteases cleave the proinsulin at two sites, releasing the C peptide as well as the mature insulin molecule, which consists of the B and A chains that are connected by two disulfide bonds. The secretory granule contains equimolar amounts of insulin and the C peptide, as well as a small amount of proinsulin. These components all are released into the extracellular space during secretion.

Secretion of Insulin, Proinsulin, and C Peptide

C peptide has no established biological action. Yet because it is secreted in a 1 : 1 molar ratio with insulin, it is a useful marker for insulin secretion. Proinsulin does have modest insulin-like activities; it is $\sim \frac{1}{20}$ th as potent as insulin on a molar basis. However, the β cell secretes only $\sim 5\%$ as much proinsulin as insulin. As a result, proinsulin does not play a major role in the regulation of blood glucose.

Most of the insulin ($\sim 60\%$) that is secreted into the portal blood is removed in a first pass through the liver. In contrast, C peptide is not extracted by the liver at all. As a result, whereas measurements of the insulin concentration in systemic blood do not quantitatively mimic the secretion of insulin, measurements of C peptide do. C peptide is eventually excreted in the urine, and the quantity of C peptide excreted in a 24-hour period is a rough measure of the amount of insulin released during that time.

Glucose is the major regulator of insulin secretion

In healthy individuals, the **plasma glucose concentration** remains within a remarkably narrow range. After an overnight fast, it typically averages between 4 and 5 mM; the plasma [glucose] rises after a meal, but even with a very large meal it does not exceed 10 mM. Modest increases in plasma [glucose] provoke marked increases in the secretion of insulin and C peptide and hence raise plasma [insulin], as illustrated by the results of an **oral glucose tolerance test (OGTT)** as shown in [Figure 51-3A](#). Conversely, a decline in plasma [glucose] of only 20% markedly lowers plasma [insulin]. The change in the concentration of plasma glucose that occurs in response to feeding or fasting is the main determinant of insulin secretion. In a patient with type 1 diabetes mellitus caused by destruction of pancreatic islets, an oral glucose challenge evokes either no response or a much smaller insulin response, but a much larger increment in plasma [glucose] that lasts for a much longer time (see [Fig. 51-3B](#)).

A NORMAL SUBJECT UNDERGOING SAME CHANGES IN PLASMA [GLUCOSE] FOLLOWING ORAL VS. IV GLUCOSE CHALLENGES

B DIABETIC SUBJECT RECEIVING ORAL GLUCOSE

C NORMAL SUBJECT RECEIVING A HIGHER DOSE OF IV GLUCOSE THAN IN PANEL A

FIGURE 51-3 Glucose tolerance test results. **A**, When a person ingests a glucose meal (75 g), plasma [glucose] (*green curve*) rises slowly, reflecting intestinal uptake of glucose. As a result, plasma [insulin] (*solid red curve*) rises sharply. When a lower glucose dose is given intravenously (IV) over time—in a manner that reproduces the green curve—plasma [insulin] rises only modestly (*dashed red curve*). The difference between the insulin responses indicated by the solid and dashed red lines is due to the “incretin effect” of oral glucose ingestion. **B**, In a patient with type 1 diabetes, the same oral glucose load as that in **A** causes plasma [glucose] to rise to a higher level and to remain high for a longer time. The diagnosis of diabetes is made if the plasma glucose level is above 200 mg/dL at the second hour. **C**, If a large IV glucose challenge (0.5 g glucose/kg body weight given as a 25% glucose solution) is administered as a bolus, plasma [glucose] rises much more rapidly than it does with an oral glucose load. Sensing a rapid rise in [glucose], the β cells first secrete some of their stores of presynthesized insulin. Following this “acute phase,” the cells secrete both presynthesized and newly manufactured insulin in the “chronic phase.”

A glucose challenge of 0.5 g/kg body weight given *as an intravenous bolus* raises the plasma glucose concentration more rapidly than glucose given *orally*. Such a rapid rise in plasma glucose concentration leads to two distinct phases of insulin secretion (see [Fig. 51-3C](#)). The acute-phase or first-phase insulin response lasts only 2 to 5 minutes, whereas the second-phase insulin response persists as long as the blood glucose level remains elevated. The insulin released during the acute-phase insulin response to intravenous glucose arises from preformed insulin that had been packaged in secretory vesicles docked at, or residing near, the β -cell plasma membrane. The second-phase insulin response also comes from preformed insulin within the vesicles with some contribution from newly synthesized insulin. One of the earliest detectable metabolic defects that occurs in both type 1 and type 2 diabetes is loss of the first phase of insulin secretion, as determined by an **intravenous glucose tolerance test**. If a subject consumes glucose or a mixed meal, plasma [glucose] rises much more slowly—as in [Figure 51-3A](#)—because the appearance of glucose in plasma depends on gastric emptying and intestinal absorption. Given that plasma [glucose] rises so slowly, the acute-phase insulin response can no longer be distinguished from the chronic response, and only a single phase of insulin secretion is apparent. However, the total insulin response to an oral glucose challenge exceeds the response observed when comparable changes in plasma [glucose] are produced by intravenously administered glucose (see [Fig. 51-3A](#)). This difference is referred to as the *incretin effect* ([Box 51-2](#)).

Box 51-2

Nonhuman and Mutant Insulin

Cloning of the insulin gene has led to an important therapeutic advance, namely, the use of recombinant human insulin for the treatment of diabetes. Human insulin was the first recombinant protein available for routine clinical use. Before the availability of human insulin, either pork or beef insulin was used to treat diabetes. Pork and beef insulin differ from human insulin by one and three amino acids, respectively. The difference, although small, is sufficient to be recognized by the immune system, and antibodies to the injected insulin develop in most patients treated with beef or pork insulin; occasionally, the reaction is severe enough to cause a frank allergy to the insulin. This problem is largely avoided by using human insulin.

Sequencing of the insulin gene has not led to a major understanding of the genesis of the common forms of human diabetes. However, rare patients with diabetes make a mutant insulin molecule with a single amino-acid substitution in either the A or B chain. In each case that has been described, these changes lead to a less-active insulin molecule (typically only ~1% as potent as insulin on a molar basis). These patients have either glucose intolerance or frank diabetes, but very high concentrations of

immunoreactive insulin in their plasma. In these individuals, the immunoreactivity of insulin is not affected to the same extent as the bioactivity.

In addition to revealing these mutant types of insulin, sequencing of the insulin gene has allowed identification of a flanking polymorphic site upstream of the insulin gene that contains one of several common alleles. In some populations, certain polymorphisms are associated with an increased risk of development of type 1 diabetes mellitus.

Metabolism of glucose by the β cell triggers insulin secretion

The pancreatic β cells take up and metabolize glucose, galactose, and mannose, and each can provoke insulin secretion by the islet. Other hexoses that are transported into the β cell but that cannot be metabolized (e.g., 3-O-methylglucose or 2-deoxyglucose) do not stimulate insulin secretion. Although glucose itself is the best secretagogue, some amino acids (especially arginine and leucine) and small keto acids (e.g., α -ketoisocaproate, α -ketoglutarate), as well as ketohexoses (fructose), can also weakly stimulate insulin secretion. The amino acids and keto acids do not share any metabolic pathway with hexoses other than *oxidation via the citric acid cycle* (see [p. 1185](#)). These observations have led to the suggestion that the ATP generated from the metabolism of these varied substances may be involved in insulin secretion. In the laboratory, depolarizing the islet cell membrane by raising extracellular $[K^+]$ provokes insulin secretion.

From these data has emerged a relatively unified picture of how various secretagogues trigger insulin secretion. Key to this picture is the presence in the islet of an ATP-sensitive K^+ channel and a **voltage-gated Ca^{2+} channel** in the plasma membrane ([Fig. 51-4](#)). The **K^+ channel (K_{ATP})** (see [p. 198](#)) is an octamer of four Kir6.2 channels (see [p. 196](#)) and four **sulfonylurea receptors (SURs)** (see [p. 199](#); [Box 51-3](#)). Glucose triggers insulin release in a seven-step process:

Step 1: Glucose enters the β cell via the GLUT2 glucose transporter by facilitated diffusion (see [p. 114](#)). Amino acids enter through a different set of transporters.

Step 2: In the presence of glucokinase (the rate-limiting enzyme in glycolysis), the entering glucose undergoes glycolysis as well as oxidation via the citric acid cycle (see [p. 1185](#)), phosphorylating ADP and raising $[ATP]_i$. Some amino acids also enter the citric acid cycle. In both cases, the following ratios increase: $[ATP]_i/[ADP]_i$, $[NADH]_i/[NAD^+]_i$, and $[NADPH]_i/[NADP^+]_i$ ($NADH$ and NAD^+ are the reduced and oxidized forms of nicotinamide adenine dinucleotide $[NAD]$, and $NADPH$ and $NADP^+$ are the reduced and oxidized forms of NAD phosphate) [N51-5](#)

Step 3: The increase in the ratio $[ATP]_i/[ADP]_i$, or $[NADH]_i/[NAD^+]_i$, or $[NADPH]_i/[NADP^+]_i$ causes K_{ATP} channels (see [p. 198](#)) to close.

Step 4: Reducing the K^+ conductance of the cell membrane causes the β cell to depolarize (i.e., the membrane potential is less negative).

Step 5: This depolarization activates voltage-gated Ca^{2+} channels (see [pp. 190–191](#)).

Step 6: The increased Ca^{2+} permeability leads to increased Ca^{2+} influx and increased intracellular free Ca^{2+} . This rise in $[Ca^{2+}]_i$ additionally triggers Ca^{2+} -induced Ca^{2+} release (see [pp. 242–243](#)).

Step 7: The increased $[\text{Ca}^{2+}]_i$, perhaps by activation of a Ca^{2+} -calmodulin phosphorylation cascade, ultimately leads to insulin release.

FIGURE 51-4 Mechanism of insulin secretion by the pancreatic β cell. Increased levels of extracellular glucose trigger the β cell to secrete insulin in the seven steps outlined in this figure. Metabolizable sugars (e.g., galactose and mannose) and certain amino acids (e.g., arginine and leucine) can also stimulate the fusion of vesicles that contain previously synthesized insulin. In addition to these fuel sources, certain hormones (e.g., glucagon, somatostatin, cholecystokinin [CCK]) can also modulate insulin secretion. ER, endoplasmic reticulum; IP_3 , inositol 1,4,5-trisphosphate; PLC, phospholipase C.

Sulfonylureas

An entire class of drugs—the sulfonylurea agents—is used in the treatment of patients with type 2 diabetes, or non-insulin-dependent diabetes mellitus (NIDDM). Type 2 diabetes arises from two defects: (1) β cells are still capable of making insulin but do not respond adequately to increased blood [glucose], and (2) insulin target tissues are less sensitive or “resistant” to insulin.

The sulfonylurea agents were discovered accidentally. During the development of sulfonamide antibiotics after the Second World War, investigators noticed that the chemically related sulfonylurea agents produced hypoglycemia in laboratory animals. These drugs turned out to have no value as antibiotics, but they did prove effective in treating the hyperglycemia of type 2 diabetes. The sulfonylureas enhance insulin secretion by binding to the SUR subunits (see p. 199) of K_{ATP} channels, thereby decreasing the likelihood that these channels will be open. This action enhances glucose-stimulated insulin secretion (see Fig. 51-4). By increasing insulin secretion, sulfonylureas overcome insulin resistance and decrease blood glucose in these patients.

Unlike insulin, which must be injected, sulfonylureas can be taken orally and are therefore preferred by many patients. However, they have a therapeutic role only in type 2 diabetes; the β cells in patients with type 1 diabetes are nearly all destroyed, and these patients must be treated with insulin replacement therapy.

N51-5

The Pentose Phosphate Pathway (or Hexose Monophosphate Shunt)

Contributed by Emile Boulpaep, Walter Boron

Figure 58-1 mentions that glucose-6-phosphate can have three major fates. The *anabolic* series of reactions summarized in this figure convert glucose-6-phosphate to glycogen. The glycolytic pathway summarized in Figure 58-6A is a *catabolic* pathway that converts glucose-6-phosphate to pyruvate. The third fate—the **pentose phosphate pathway**—is another catabolic series of reactions that converts glucose-6-phosphate to ribose-5-phosphate.

The pentose phosphate pathway has two major products, NADPH and ribose-5-phosphate. The cell can use the reducing equivalents in **NADPH** (i.e., energy “currency”) to reduce double bonds in the energy-consuming synthesis of fatty acids and steroids. These reactions are particularly important in such tissues as liver, adipose tissue, mammary gland, and adrenal cortex. Note that the cell cannot use NADH to create NADPH. Thus, the pentose phosphate pathway is critical. The second product of the pathway, **ribose-5-phosphate**, is important for the synthesis of ribonucleotides, which is particularly important in growing and regenerating tissues. The pentose phosphate pathway involves four reactions, the first and third of which involve the conversion of $NADP^+$ to NADPH and H^+ .

If the cell does not use the ribose-5-phosphate to generate ribonucleotides, the cell can use a complex series of reactions to convert the ribose-5-phosphate to **fructose-6-phosphate**. This sequence of reactions (i.e., from glucose-6-phosphate to ribose-5-phosphate to fructose-6-phosphate) bypasses or “shunts” the conversion of glucose-6-phosphate to fructose-6-phosphate, which would otherwise be catalyzed by phosphoglucose isomerase (see Fig. 58-6A). For this reason, the pentose phosphate pathway is also called the **hexose monophosphate shunt**.^{*} However, the reader should be reassured that the shunt does not permit the cell to generate two NADPH molecules for free. Three glucose-6-phosphate

molecules ($3 \times 6 = 18$ carbons) must traverse the hexose monophosphate shunt to generate six NADPH molecules ($3 \times 2 = 6$) plus two fructose-6-phosphate ($2 \times 6 = 12$ carbons) molecules, a single glyceraldehyde-3-phosphate ($1 \times 3 = 3$ carbons), and three CO_2 molecules that arise from a decarboxylation reaction in the pentose phosphate pathway ($3 \times 1 = 3$ carbons). If those three glucose molecules had gone through the classical glycolytic pathway, they would have generated $3 \times 2 = 6$ net ATPs and 6 NADHs (see Table 58-3). However, if those same three glucose molecules all go through the pentose phosphate pathway, the net result is only five ATPs, only five NADHs, but six NADPHs. Thus, the cell gives up only one ATP and one NADH for the sake of generating six NADPHs—not a bad deal for the cell!

- Voet D, Voet JG. *Biochemistry*. 2nd ed. Wiley: New York; 1995.

*Note that the term *shunt* is a bit of a misnomer, inasmuch as the “shunt” is not a *shortcut* from glucose-6-phosphate to fructose-6-phosphate (normally catalyzed in one step by phosphoglucose isomerase), but rather a *lengthy* detour!

Other secretagogues can also modulate insulin secretion via the phospholipase C pathway (see [p. 58](#)) or via the adenylyl cyclase pathway (see [p. 53](#)) in addition to the pathway just outlined. For example, glucagon, which stimulates insulin release, may bypass part or all of the glucose/ $[\text{Ca}^{2+}]_i$ pathway by stimulating adenylyl cyclase, thus raising cAMP levels and activating protein kinase A (PKA). Conversely, somatostatin, which inhibits insulin release, may act by inhibiting adenylyl cyclase.

Neural and humoral factors modulate insulin secretion

The islet is richly innervated by both the sympathetic and the parasympathetic divisions of the ANS. Neural signals appear to play an important role in the β -cell response in several settings. **β -adrenergic** stimulation augments islet insulin secretion, whereas **α -adrenergic** stimulation inhibits it (see [Fig. 51-4](#)). Isoproterenol, a synthetic catecholamine that is a specific agonist for the β -adrenergic receptor, potently stimulates insulin release. In contrast, norepinephrine and synthetic α -adrenergic agonists suppress insulin release both basally and in response to hyperglycemia. Because the postsynaptic sympathetic neurons of the pancreas release norepinephrine, which stimulates α more than β adrenoceptors, sympathetic stimulation via the celiac nerves inhibits insulin secretion. In contrast to α -adrenergic stimulation, **parasympathetic** stimulation via the vagus nerve, which releases acetylcholine, causes an increase in insulin release.

Exercise

The effect of sympathetic regulation on insulin secretion may be particularly important during exercise, when adrenergic stimulation of the islet increases. The major role for α -adrenergic *inhibition* of insulin secretion during exercise is to prevent hypoglycemia. Exercising muscle tissue uses glucose even when plasma [insulin] is low. If insulin levels were to rise, glucose use by the muscle would increase even

further and promote hypoglycemia. Furthermore, an increase in [insulin] would inhibit lipolysis and fatty-acid release from adipocytes and would thus diminish the availability of fatty acids, which the muscle can use as an alternative fuel to glucose (see [p. 1211](#)). Finally, a rise in [insulin] would decrease glucose production by the liver. Suppression of insulin secretion during exercise may thus serve to prevent excessive glucose uptake by muscle, which, if it were to exceed the ability of the liver to produce glucose, would lead to severe hypoglycemia, compromise the brain, and abruptly end any exercise!

Feeding

Another important setting in which neural and humoral factors regulate insulin secretion is during feeding. Food ingestion triggers a complex series of neural, endocrine, and nutritional signals to many body tissues. The *cephalic phase* (see [pp. 871](#) and [890](#)) of eating, which occurs before food is ingested, results in stimulation of gastric acid secretion and a small rise in plasma insulin level. This response appears to be mediated by the vagus nerve in both cases. If no food is forthcoming, blood [glucose] declines slightly and insulin secretion is again suppressed. If food ingestion does occur, the acetylcholine released by postganglionic vagal fibers in the islet augments the insulin response of the β cell to glucose.

As already discussed, after a subject drinks a glucose solution, the total amount of insulin secreted is greater than when the same amount of glucose is administered intravenously (see [Fig. 51-3A](#)). This observation has led to a search for enteric factors or **incretins** that augment the islet β -cell response to an oral glucose stimulus. Currently, we know of three peptides released by intestinal cells in response to feeding that enhance insulin secretion: **cholecystokinin** from I cells, **glucagon-like peptide 1 (GLP-1)** from L cells, and **gastric inhibitory polypeptide (GIP**, also called glucose-dependent insulintropic peptide) from K cells. GLP-1 (see [p. 1051](#)), perhaps the most important incretin yet discovered, has a very short half-life in plasma (<2 min), which precludes its therapeutic use. A peptide analog of GLP-1, called exendin-4, is found in the saliva of the Gila monster. A long-lasting synthetic derivative of exendin-4 (exenatide) is approved for use in treating diabetic patients to enhance insulin secretion and to ameliorate hyperglycemia. Because it is a peptide, exenatide cannot be given orally but is effective by subcutaneous injection. Orally available agents have been developed that inhibit the enzyme dipeptidyl-peptidase 4, which breaks down native GLP-1; these *gliptins* are now available to treat type 2 diabetes.

In the laboratory, incretins stimulate insulin secretion by isolated islets of Langerhans, and glucose increases this secretion even further. The presence of these incretins in the gut mucosa gives the islets advance notice that nutrients are being absorbed and “primes” the β cells to amplify their response to glucose. In addition, vagal stimulation of the β cells primes the islets for an amplified response.

The insulin receptor is a receptor tyrosine kinase

Once insulin is secreted into the portal blood, it first travels to the liver, where more than half is bound and removed from the circulation. The insulin that escapes the liver is available to stimulate insulin-sensitive processes in other tissues. At each target tissue, the first action of insulin is to bind to a specific receptor tyrosine kinase (see [pp. 68–70](#)) on the plasma membrane ([Fig. 51-5](#)).

FIGURE 51-5 Insulin receptor. The insulin receptor is a heterotetramer that consists of two extracellular α chains and two membrane-spanning β chains. Insulin binding takes place on the cysteine-rich region of the α chains.

The insulin receptor—as well as the closely related insulin-like growth factor 1 (IGF-1) receptor—is a heterotetramer, with two identical α chains and two identical β chains. **N51-6** The α and β chains are synthesized as a single polypeptide that is subsequently cleaved. The two chains are joined by disulfide linkage (reminiscent of the synthesis of the A and B chains of insulin itself) in the sequence β - α - α - β . The insulin receptor shares considerable structural similarity with the IGF-1 receptor (see [p. 996](#)). The overall sequence homology is ~50%, and this figure rises to >80% in the tyrosine kinase region. This similarity is sufficient that very high concentrations of insulin can stimulate the IGF-1 receptor and, conversely, high levels of IGF-1 can stimulate the insulin receptor.

N51-6

Insulin and IGF-1 Receptors

Contributed by Emile Boulpaep, Walter Boron

Activation of the **insulin** and **IGF-1** receptors (see Fig. 51-5) occurs by somewhat different mechanisms, as we discuss on pages 1041–1042 for the insulin receptor and on page 996 for IGF-1 receptor. In brief, these receptors are tetrameric; they are composed of two α and two β subunits. The α subunit contains a cysteine-rich region and functions in ligand binding. The β subunit is a single-pass transmembrane protein with a cytoplasmic tyrosine kinase domain. The α and β subunits are held together by disulfide bonds (as are the two α subunits), forming a heterotetramer. Ligand binding produces conformational changes that appear to cause allosteric interactions between the two α and β pairs, as opposed to the

dimerization characteristic of the first class of receptor tyrosine kinases (see Fig. 3-12C). Thus, insulin binding results in the autophosphorylation of tyrosine residues in the catalytic domains of the β subunits. The activated insulin receptor also phosphorylates cytoplasmic substrates such as **IRS-1** (see Fig. 51-6), which, once phosphorylated, serves as a docking site for additional signaling proteins.

The insulin receptor's extracellular α chains have multiple *N*-glycosylation sites. The β chains have an extracellular, a membrane-spanning, and an intracellular portion. The β subunit of the receptor is glycosylated on its extracellular domains; receptor glycosylation is required for insulin binding and action. The intracellular domain of the β chain possesses tyrosine kinase activity, which increases markedly when insulin binds to sites on the α chains of the receptor. The insulin receptor can phosphorylate both itself and other intracellular substrates at tyrosine residues (see pp. 68–70). The targets of tyrosine phosphorylation (beyond the receptor itself) include a family of cytosolic proteins known as **insulin-receptor substrates (IRS-1, IRS-2, IRS-3, and IRS-4)** as well as **Src homology C terminus (SHC)**, as illustrated in Figure 51-6. This phosphorylation mechanism appears to be the major one by which insulin transmits its signal across the plasma membrane of insulin target tissues.

FIGURE 51-6 Insulin signal-transduction system. When insulin binds to its receptor—which is a receptor tyrosine kinase (RTK)—tyrosine kinase domains on the intracellular portion of the β chains become active.

The activated receptor transduces its signals to downstream effectors by phosphorylating at tyrosine residues on the receptor itself, the IRS family (IRS-1, IRS-2, IRS-3, IRS-4), and other cytosolic proteins (e.g., SHC). SH2-containing proteins dock onto certain phosphorylated tyrosine groups on the IRSs and thus become activated. Not all of the signaling pathways are active in all of insulin's target cells. For example, the liver cell does not rely on the GLUT4 transporter to move glucose in and out of the cell. Likewise, the liver is a very important target for regulation of the gluconeogenic enzymes by insulin,

whereas muscle and adipose tissue are not. GS, glycogen synthase; GSK-3, glycogen synthase kinase 3; IF, initiation factor; PDK, phosphatidylinositol-dependent kinase.

The IRS proteins are *docking proteins* to which various downstream effector proteins bind and thus become activated. IRS-1 has at least eight tyrosines within specific motifs that generally bind proteins containing SH2 (Src homology domain 2) domains (see [p. 58](#)), so that a single IRS molecule simultaneously activates multiple pathways. The IGF-1 receptor, which is closely related to the insulin receptor, also acts through IRS proteins.

[Figure 51-6](#) illustrates three major signaling pathways triggered by the aforementioned tyrosine phosphorylations. [N51-7](#) The first begins when **phosphatidylinositol 3-kinase (PI3K)** binds to phosphorylated IRS and becomes activated. PI3K phosphorylates a membrane lipid phosphatidylinositol 4,5-bisphosphate (PIP₂) to form phosphatidylinositol 3,4,5-trisphosphate (PIP₃), and it leads to major changes in glucose and protein metabolism.

N51-7

Insulin Signal Transduction

Contributed by Eugene Barrett, Emile Boulpaep, Walter Boron

[Figure 51-6](#) shows three major pathways. In the first pathway, activation of phosphatidylinositol 3-kinase (**PI3K**) phosphorylates phosphatidylinositol 4,5-bisphosphate (PIP₂) to form phosphatidylinositol 3,4,5-trisphosphate (PIP₃; see [p. 58](#)), which in turn activates phosphatidylinositol-dependent kinase (**PDK**). This serine/threonine kinase then activates protein kinase B (PKB), which leads to the insertion of GLUT4 glucose transporters into the plasma membrane. PDK also phosphorylates and thus inactivates glycogen synthase kinase 3 (**GSK-3**); the net effect is reduced inactivation of glycogen synthase (GS) and enhanced glycogen synthesis. Finally PDK activates **mTOR** (target of rapamycin), a serine/threonine kinase that phosphorylates the binding protein PHAS-1 and thus releases an active initiation factor (IF), promoting translation of mRNA into protein. mTOR also phosphorylates p70-S6 kinase, which phosphorylates the ribosomal S6 protein.

In the second pathway, the insulin receptor phosphorylates SHC (which stands for Src *homology*, C terminus) at tyrosine residues, stimulating SOS. In addition, activation of GRB2 also stimulates SOS. The stimulated SOS activates the Ras pathway, as described in [Figure 3-13](#). The activated Raf-1, which is itself a MEK kinase, activates not only MEK but also other MEK kinases, which in turn activate JNK (a kinase) and p38 kinase. MAPK activates both a transcription factor and p90-S6 kinase. The activated p90-S6 kinase phosphorylates a variety of nuclear proteins as well as phosphoprotein phosphatase 1 (PP1); the latter leads to activation of glycogen synthase.

In the third pathway, SH2-containing proteins (shown in blue in [Fig. 51-6](#))—other than PI3K and GRB2, already discussed—bind to specific phosphotyrosine groups on either the insulin receptor or IRS proteins. These SH2-containing proteins have a variety of effects, for example, on enzymes involved in lipid metabolism.

The second signaling pathway begins in one of two ways: (1) the insulin receptor phosphorylates SHC or (2) growth factor receptor-bound protein 2 (GRB2; see [p. 69](#)) binds to an IRS and becomes activated. As illustrated in [Figure 51-6](#), both phosphorylated SHC and activated GRB2 trigger the Ras signaling pathway, leading through mitogen-activated protein kinase kinase (MEK) and mitogen-activated protein

kinase (MAPK; see pp. 68–69) to increased gene expression and growth. Gene-deletion studies in mice show that IRS-1 deletion does not cause diabetes but results in small mice. In contrast, IRS-2 deletion does cause diabetes, in part because of *impaired insulin secretion* by the pancreatic β cell!

The third signaling pathway begins with the binding of SH2-containing proteins—other than PI3K and GRB2, already discussed—to specific phosphotyrosine groups on either the insulin receptor or IRS proteins. This binding activates the SH2-containing protein (Box 51-4).

Box 51-4

The Insulin Receptor and Rare Forms of Diabetes

The ability of insulin to act on a target cell depends on three things: the number of receptors present on the target cell, the receptor's affinity for insulin, and the receptor's ability to transduce the insulin signal.

Several disorders have been described in which a mutation of the insulin receptor blunts or prevents insulin's actions. One such mutation markedly affects growth in utero, as well as after birth. This rare disorder is called **leprechaunism**, and it is generally lethal within the first year of life. Other mutations of the receptor have less devastating consequences.

Some individuals make antibodies to their own insulin receptors. Insulin, produced either endogenously or administered to these patients, does not work well because it must compete with these antibodies for sites on the receptor; as a result, the patient is hyperglycemic. Interestingly, other antibodies can be “insulin mimetic”; that is, not only do the antibodies bind to the receptor, but they also actually mimic insulin's action. This mimicry causes severe *hypoglycemia* in affected individuals.

Neither receptor mutations nor antireceptor antibodies appear to be responsible for any of the common forms of diabetes seen clinically. However, abnormal insulin-receptor signaling may be involved in many patients with type 2 diabetes. Indeed, activation of inflammatory pathways involving the p38 subset of MAPKs (see p. 69) and nuclear factor κ B (see pp. 86–87) can lead to phosphorylation of the insulin receptor (and of IRS proteins), principally at *serine* residues. This serine phosphorylation occurs commonly in animal models of insulin resistance and type 2 diabetes as well as in human diabetes, and can interfere with the normal metabolic actions of insulin.

High levels of insulin lead to downregulation of insulin receptors

The number of insulin receptors expressed on the cell surface is far greater than that needed for the maximal biological response to insulin. For example, in the adipocyte, the glucose response to insulin is maximal when only ~5% of the receptors are occupied; that is, the target cells have many “spare” receptors for insulin.

The number of insulin receptors present on the membrane of a target cell is determined by the balance among three factors: (1) receptor synthesis, (2) endocytosis of receptors followed by recycling of receptors back to the cell surface, and (3) endocytosis followed by degradation of receptors. Cells chronically exposed to high concentrations of insulin have fewer surface receptors than do those exposed to lower concentrations. This dynamic ability of cells to decrease the number of specific receptors on their surface is called *downregulation*. Insulin downregulates insulin receptors by decreasing receptor synthesis and increasing degradation. Such downregulation is one mechanism by which target tissues modulate their response to hormones. Downregulation of insulin receptors results in a decrease in the

sensitivity of the target tissue to insulin without diminishing insulin's maximal effect.

One example of how downregulation can affect insulin's action is shown in [Figure 51-7](#), which illustrates the effect of increases in insulin concentration on glucose uptake in adipocytes from normal individuals and individuals with type 2 diabetes. Adipocytes from patients with type 2 diabetes ([Box 51-5](#)) have fewer insulin receptors per unit of surface area than do adipocytes from normal individuals. The markedly lower glucose transport across the entire physiological range of insulin concentrations in diabetic adipocytes is characteristic of *insulin resistance*. In healthy control adipocytes, glucose transport is maximal when only a few (~5%) of the receptors are occupied. In diabetic adipocytes, a much higher concentration of insulin is required, and a larger *fraction* of the insulin receptors is occupied. However, the major effects in type 2 diabetes apparently are not the result of a decrease in receptor number, but rather are caused by impairment in signaling downstream from the receptor. This impairment includes diminished activity of the insulin receptor tyrosine kinase, PI3K activity, and perhaps other steps along the pathway to GLUT4 recruitment to the plasma membrane (see [Fig. 51-6](#)). It is the summation of these multiple defects, only some of which have been identified, that leads to insulin resistance.

FIGURE 51-7 Response to insulin of normal and downregulated adipocytes.

Box 51-5

Diabetes Mellitus

Diabetes is the most common serious metabolic disease in humans. The hallmark of diabetes is an elevated blood glucose concentration, but this abnormality is just one of many biochemical and physiological alterations. Diabetes is not one disorder, but can arise as a result of numerous defects in regulation of the synthesis, secretion, and action of insulin. The type of diabetes that most commonly affects children is called type 1 **IDDM**. The diabetes that generally begins in adulthood and is

particularly common in obese individuals is called type 2 or **NIDDM**.

Type 1 Diabetes N51-4

Type 1 diabetes is caused by an immune-mediated selective destruction of the β cells of the pancreas. The other cell types present in the islet are spared. The consequence of the loss of insulin, with the preservation of glucagon, can be viewed as an accelerated form of fasting or starvation. A healthy person who is fasting for several days continues to secrete insulin at a low rate that is sufficient to balance the action of glucagon in modulating the production of glucose and ketones by the liver. However, in type 1 diabetes, insulin deficiency is severe, and glucose and ketone production by the liver occur at a rate that greatly exceeds the rate at which they are being used. As a result, the concentration of these substances in blood begins to rise. Even when glucose concentrations reach levels 5 to 10 times normal, no insulin is secreted because β cells are absent. The increased glucose and ketones provide an immense solute load to the kidney that causes osmotic diuresis. In addition, the keto acids that are produced are moderately strong organic acids ($pK < 4.0$), and their increased production causes severe metabolic acidosis (see p. 635). If these patients are not treated with insulin, the acidosis and dehydration lead to death from **diabetic ketoacidosis**.

With appropriate diagnosis and the availability of insulin as an effective treatment, persons with type 1 diabetes can lead full, productive lives. Indeed, some patients have been taking insulin successfully for treatment of type 1 diabetes for >75 years. As technology has improved, patients have been able to monitor their blood glucose levels themselves and adjust their insulin dosages accordingly, using specifically designed insulin analogs that have either short or very long half-lives, or insulin pumps that continuously deliver insulin via a subcutaneous catheter. Thus, individuals with type 1 diabetes can avoid not only severe, life-threatening episodes of ketoacidosis but also the long-term consequences of diabetes—namely, blood vessel injury that can lead to blindness, kidney failure, and accelerated atherosclerosis.

Type 2 Diabetes

In type 2 diabetes, the cause of hyperglycemia is more complex. These individuals continue to make insulin. β cells not only are present but also are frequently hyperplastic (at least early in the course of the disease). For reasons still being defined, the β cells do not respond normally to increases in plasma glucose level by increasing insulin secretion. However, altered insulin secretion is only part of the problem. If we administered identical doses of insulin to the liver, muscle, and adipose tissue of a person with type 2 diabetes and a healthy control, we would find that the patient with type 2 diabetes is resistant to the action of insulin. Thus, both the secretion of insulin and the metabolism of glucose in response to insulin are abnormal in type 2 diabetes. Which problem—decreased insulin release or insulin resistance—is more important in provoking development of the diabetic state likely varies among individuals. Usually, these patients make enough insulin—and it is sufficiently active—that the severe ketoacidosis described above in patients with type 1 diabetes does not develop.

The insulin resistance seen in individuals with type 2 diabetes appears to bring with it an increase in the prevalence of hypertension, obesity, and a specific dyslipidemia characterized by elevated TAGs and depressed high-density lipoproteins (see Fig. 46-15). Insulin resistance (along with one or more of these other metabolic abnormalities) is frequently found in individuals before the development of type 2 diabetes and is referred to as **metabolic syndrome**. This constellation of abnormalities is estimated to affect >45 million individuals in the United States alone. Because each component of this syndrome has adverse effects on blood vessels, these individuals are at particularly increased risk of early atherosclerosis.

Tight control of glucose concentrations in both type 1 and type 2 diabetes, together with careful management of blood pressure and plasma lipids, can retard the development of many of the long-term complications of diabetes.

In liver, insulin promotes conversion of glucose to glycogen stores or to triacylglycerols

Insulin's actions on cellular targets frequently involve numerous tissue-specific enzymatic and structural processes. As we will see in this and the next two sections, the three principal targets for insulin action are liver, muscle, and adipose tissue.

Because the pancreatic veins drain into the portal venous system, all hormones secreted by the pancreas must traverse the liver before entering the systemic circulation. For insulin, the liver is both a target tissue for hormone action and a major site of degradation.

The concentration of insulin in portal venous blood before extraction by the liver is three to four times greater than its concentration in the systemic circulation. The hepatocyte is therefore bathed in a relatively high concentration of insulin and is thus well positioned to respond acutely to changes in plasma [insulin].

After feeding, the plasma [insulin] rises, triggered by glucose and by neural and incretin stimulation of β cells. In the liver, this insulin rise acts on four main processes involved in fuel metabolism. These divergent effects of insulin entail the use of multiple enzymatic control mechanisms, indicated by numbered boxes in [Figure 51-8](#).

FIGURE 51-8 Effect of insulin on hepatocytes. Insulin has four major effects on liver cells. First, insulin promotes glycogen synthesis from glucose by enhancing the transcription of glucokinase (1) and by activating glycogen synthase (2). Additionally, insulin together with glucose inhibits glycogen breakdown to glucose by diminishing the activity of G6Pase (4). Glucose also inhibits glycogen phosphorylase (3). Second, insulin promotes glycolysis and carbohydrate oxidation by increasing the activity of glucokinase (1), phosphofructokinase (5), and pyruvate kinase (6). Insulin also promotes glucose metabolism via the hexose monophosphate shunt (7). Finally, insulin promotes the oxidation of pyruvate by stimulating pyruvate dehydrogenase (8). Insulin also inhibits gluconeogenesis by inhibiting the activity of PEPCK (9), fructose-1,6-bisphosphatase (10), and G6Pase (4). Third, insulin promotes the synthesis and storage of fats by increasing the activity of acetyl CoA carboxylase (11) and fatty-acid synthase (12) as well as the synthesis of several apoproteins packaged with VLDL. Insulin also indirectly inhibits fat oxidation because the increased levels of malonyl CoA inhibit CAT I (13). The inhibition of fat oxidation helps shunt fatty acids to esterification as TAGs and storage as VLDL or lipid droplets. Fourth, by mechanisms that are not well understood, insulin promotes protein synthesis (14) and inhibits protein breakdown (15).

Glycogen Synthesis and Glycogenolysis

Physiological increases in plasma [insulin] decrease the breakdown and utilization of glycogen and—conversely—promote the formation of glycogen from plasma glucose. Although moderately increased levels of insulin allow gluconeogenesis to persist, the hepatocytes store the gluconeogenic product—glucose-6-phosphate—as glycogen rather than releasing it as glucose into the bloodstream. At high concentrations, insulin can inhibit the gluconeogenic conversion of lactate/pyruvate and amino acids to glucose-6-phosphate.

Glucose enters the hepatocyte from the blood via GLUT2, which mediates the facilitated diffusion of glucose. GLUT2 is present in abundance in the liver plasma membrane, even in the absence of insulin, and its activity is not influenced by insulin. Insulin stimulates glycogen synthesis from glucose by activating **glucokinase** (numbered box 1 in Fig. 51-8) and **glycogen synthase** (box 2). The latter enzyme contains multiple serine phosphorylation sites. Insulin causes a net dephosphorylation of the protein, thus increasing the enzyme's activity. At the same time that glycogen synthase is being activated, increases in both insulin and glucose diminish the activity of **glycogen phosphorylase** (box 3). This enzyme is rate limiting for the breakdown of glycogen. The same enzyme that dephosphorylates (and thus *activates*) glycogen synthase also dephosphorylates (and thus *inhibits*) phosphorylase. Thus, insulin has opposite effects on the opposing enzymes, with the net effect that it promotes glycogen formation. Insulin also inhibits **glucose-6-phosphatase (G6Pase; box 4)**, which otherwise converts glucose-6-phosphate (derived either from glycogenolysis or gluconeogenesis) to glucose. Glycogen is an important storage form of carbohydrate in both liver and muscle. The glycogen stored during the postprandial period is then available for use many hours later as a source of glucose.

Glycolysis and Gluconeogenesis

Insulin promotes the conversion of some of the glucose taken up by the liver into pyruvate and—conversely—diminishes the use of pyruvate and other three-carbon compounds for gluconeogenesis. Insulin induces transcription of the **glucokinase** gene (numbered box 1 in Fig. 51-8) and thus results in increased synthesis of this enzyme, which is responsible for phosphorylating glucose to glucose-6-phosphate and initiating the metabolism of glucose. In acting to promote glycolysis and diminish gluconeogenesis, insulin induces the synthesis of a glucose metabolite, fructose-2,6-bisphosphate. This compound is a potent allosteric activator of **phosphofructokinase** (box 5), a key regulatory enzyme in glycolysis. Insulin also stimulates **pyruvate kinase** (box 6), which forms pyruvate, and stimulates **pyruvate dehydrogenase** (box 8), which catalyzes the first step in pyruvate oxidation. Finally, insulin promotes glucose metabolism by the **hexose monophosphate shunt** (box 7).  N51-5

In addition, insulin also inhibits gluconeogenesis at several steps. Insulin diminishes transcription of the gene encoding **phosphoenolpyruvate carboxykinase (PEPCK; numbered box 9 in Fig. 51-8)**, thus reducing the synthesis of a key regulatory enzyme required to form phosphoenolpyruvate from oxaloacetate early in the gluconeogenic pathway. The increased levels of fructose-2,6-bisphosphate also inhibit the activity of **fructose-1,6-bisphosphatase** (box 10), which is also part of the gluconeogenic pathway.

Lipogenesis

Insulin promotes the storage of fats and inhibits the oxidation of fatty acids (see Fig. 58-10) through allosteric and covalent modification of key regulatory enzymes, as well as by transcription of new enzymes (numbered boxes in Fig. 51-8). The pyruvate that is now available from glycolysis can be used to synthesize fatty acids. Insulin promotes dephosphorylation of **acetyl coenzyme A (CoA) carboxylase**

2 (**ACC2**; box 11), the first committed step in fatty-acid synthesis in the liver. This dephosphorylation leads to increased synthesis of malonyl CoA, which allosterically inhibits **carnitine acyltransferase I (CAT I**; box 13). This enzyme converts acyl CoA and carnitine to acylcarnitine, a reaction necessary for long-chain fatty acids to cross the inner mitochondrial membrane, where they can be oxidized. Thus, malonyl CoA inhibits fatty-acid transport and fat oxidation. At the same time, insulin stimulates **fatty-acid synthase** (box 12), which generates fatty acids. Thus, because insulin promotes the formation of malonyl CoA and fatty acids but inhibits fatty-acid oxidation, this hormone favors esterification of the fatty acids with glycerol within the liver to form **triacylglycerols (TAGs)**. The liver can either store these TAGs in lipid droplets or export them as very-low-density lipoprotein (VLDL) particles (see [p. 968](#)). Insulin also induces the synthesis of several of the **apoproteins** that are packaged with the VLDL particle. The hepatocyte then releases these VLDLs, which leave the liver via the hepatic vein. Muscle and adipose tissue subsequently take up the lipids in these VLDL particles and either store them or oxidize them for fuel. Thus, by regulation of transcription, by allosteric activation, and by regulation of protein phosphorylation, insulin acts to promote the synthesis and storage of fat and diminish its oxidation in liver.  **N51-8**

N51-8

Nonalcoholic Fatty Liver Disease

Contributed by Fred Suchy

There are differences in the hepatic metabolism of glucose and fructose of importance to human health. Hepatic glucose metabolism is tightly regulated by phosphofructokinase, which is inhibited by ATP and citrate. Thus, when energy status is sufficient, hepatic uptake of dietary glucose is inhibited and much of the consumed glucose will bypass the liver and reach the systemic circulation. In contrast, dietary fructose is metabolized to fructose-1-phosphate by fructokinase, which is not regulated by hepatic energy status and the inhibitory effects of high ATP and citrate levels. Thus, fructose uptake and metabolism by the liver is unregulated, and relatively little of ingested fructose reaches the systemic circulation. In the liver, the large fructose load can result in increased de novo lipogenesis and inhibition of fatty-acid oxidation. This process contributes to the development of hepatic insulin resistance and **nonalcoholic fatty liver disease (NAFLD)**. Owing to the current epidemic of obesity, NAFLD is now the most common liver disorder in adults and children.

Protein Metabolism

Insulin stimulates the synthesis of protein and simultaneously reduces the degradation of protein within the liver (numbered boxes in [Fig. 51-8](#)). The general mechanisms by which insulin stimulates protein synthesis (box 14) and restrains proteolysis (box 15) by the liver are complex and are less well understood than the mechanisms regulating carbohydrate and lipid metabolism.

In summary, insulin modulates the activity of multiple regulatory enzymes, which are responsible for the hepatic metabolism of carbohydrates, fat, and protein. Insulin causes the liver to take up glucose from the blood and either store the glucose as glycogen or break it down into pyruvate. The pyruvate provides the building blocks for storage of the glucose carbon atoms as fat. Insulin also diminishes the oxidation of fat, which normally supplies much of the ATP used by the liver. As a result, insulin causes the liver, as well as other body tissues, to burn carbohydrates preferentially.

In muscle, insulin promotes the uptake of glucose and its storage as glycogen

Muscle is a major insulin-sensitive tissue and the principal site of insulin-mediated glucose disposal. Insulin has four major effects on muscle.

First, in muscle, unlike in the liver, glucose crosses the plasma membrane principally via **GLUT4**, an *insulin-sensitive* glucose transporter. GLUT4, which is found virtually exclusively in striated muscle and adipose tissue, belongs to a family of proteins that mediate the facilitated diffusion of glucose (see [p. 114](#)). Insulin markedly stimulates GLUT4 in both muscle ([Fig. 51-9](#)) and fat (see below) by a process involving recruitment of preformed transporters from a membranous compartment in the cell cytosol out to the plasma membrane. Recruitment places additional glucose transporters in the plasma membrane, thereby increasing the V_{\max} of glucose transport into muscle and increasing the flow of glucose from the interstitial fluid to the cytosol. As discussed above, a different glucose transporter, GLUT2, mediates glucose transport into hepatocytes (see [Fig. 51-8](#)) and β cells, and insulin does *not* increase the activity of that transporter.

FIGURE 51-9 Effect of insulin on muscle. Insulin has four major effects on muscle cells. First, insulin promotes glucose uptake by recruiting GLUT4 transporters to the plasma membrane. Second, insulin promotes glycogen synthesis from glucose by enhancing the transcription of hexokinase (1) and by activating glycogen synthase (2). Third, insulin promotes glycolysis and carbohydrate oxidation by increasing the activity of hexokinase (1), phosphofructokinase (3), and pyruvate dehydrogenase (4). These actions are similar to those in liver; note that there is little or no gluconeogenesis in muscle. Fourth, insulin promotes protein synthesis (5) and inhibits protein breakdown (6).

The *enzymatic* steps regulated by insulin are indicated by numbered boxes in [Figure 51-9](#).

The second effect of insulin on muscle is to enhance the conversion of glucose to glycogen by activating **hexokinase** (numbered box 1 in [Fig. 51-9](#))—different from the glucokinase in liver—and **glycogen synthase** (box 2).

Third, insulin increases glycolysis and oxidation by increasing the activity of **phosphofructokinase**

(box 3) and **pyruvate dehydrogenase** (box 4).

Fourth, insulin also stimulates the synthesis of protein in skeletal muscle (box 5) and slows the degradation of existing proteins (box 6). The result is preservation of muscle protein mass, which has obvious beneficial effects in preserving strength and locomotion. The insulin-induced increase in glucose utilization permits the muscle to diminish fat utilization and allows it to store as TAGs some of the fatty acid that it removes from the circulation. The stored TAGs and glycogen are a major sources of energy that muscle can use later when called on to exercise or generate heat.

Exercise and insulin have some interesting parallel effects on skeletal muscle. Both increase the recruitment of GLUT4 transporters to the sarcolemma and both increase glucose oxidation; therefore, both increase glucose uptake by muscle. Additionally, exercise and insulin appear to have synergistic effects on the above processes. Clinically, this synergism is manifest as a marked increase in insulin sensitivity induced by exercise and is exploited as part of the treatment of patients with diabetes mellitus.

In muscle, as in the liver, insulin directs the overall pattern of cellular fuel metabolism by acting at multiple sites. In both tissues, insulin increases the oxidation of carbohydrate, thus preserving body protein and fat stores. Carbohydrate ingested in excess of that used immediately as an oxidative fuel is either stored as glycogen in liver and muscle or is converted to lipid in the liver and exported to adipose tissue and muscle.

In adipocytes, insulin promotes glucose uptake and conversion to TAGs for storage

Adipose tissue is the third major insulin-sensitive tissue involved in the regulation of body fuel. Again, insulin has several sites of action in adipocytes. All begin with the same receptor-mediated action of insulin to stimulate several cellular effector pathways. Insulin has four major actions on adipocytes.

First, like muscle, adipose tissue contains the insulin-sensitive GLUT4 glucose transporter. In insulin-stimulated cells, preformed transporters are recruited from an intracellular compartment to the cell membrane, which markedly accelerates the entry of glucose into the cell.

Second, insulin promotes the breakdown of glucose to metabolites that will eventually be used to synthesize TAGs. Unlike in muscle or liver, little of the glucose taken up is stored as glycogen. Instead, the adipocyte glycolytically metabolizes much of the glucose to α -glycerol phosphate, which it uses to esterify long-chain fatty acids into TAGs. The glucose not used for esterification goes on to form acetyl CoA and then malonyl CoA and fatty acids. Insulin enhances this flow of glucose to fatty acids by stimulating **pyruvate dehydrogenase** (numbered box 1 in [Fig. 51-10](#)) and **acetyl CoA carboxylase** (box 2).

FIGURE 51-10 Effect of insulin on adipocytes. Insulin has four major effects on adipocytes. First, insulin promotes glucose uptake by recruiting GLUT4 transporters to the plasma membrane. Second, insulin promotes glycolysis, which leads to the formation of α -glycerol phosphate. Insulin also promotes the conversion of pyruvate to fatty acids by stimulating pyruvate dehydrogenase (1) and acetyl CoA carboxylase (2). Third, insulin promotes the esterification of α -glycerol phosphate with fatty acids to form TAGs, which the adipocyte stores in fat droplets. Conversely, insulin inhibits HSL (3), which would otherwise break the TAGs down into glycerol and fatty acids. Fourth, insulin promotes the synthesis of LPL in the adipocyte. The adipocyte then exports this enzyme to the endothelial cell, where it breaks down the TAGs contained in chylomicrons and VLDL, yielding fatty acids. These fatty acids then enter the adipocyte for esterification and storage in fat droplets as TAGs.

Third, insulin promotes the formation of TAGs by simple mass action; the increased levels of α -glycerol phosphate increase its esterification with fatty acids (principally C-16 and C-18) to yield TAGs.

Some of the fatty acids are a result of the glucose metabolism noted above. Most of the fatty acids, however, enter the adipocyte from chylomicrons and VLDLs (see [Table 46-4](#)) in the blood. The cell sequesters these TAGs in lipid droplets, which form most of the mass of the adipose cell. Conversely, insulin restrains the activity of **adipose triacylglycerol lipase (ATGL)**; see [p. 1182](#)), which converts TAGs to diacylglycerols (DAGs), and **hormone-sensitive lipase (HSL)**, which converts DAGs to monoacylglycerols (MAGs). In fat, these enzymes (numbered box 3 in [Fig. 51-10](#)) mediate the conversion of stored TAGs to fatty acids and glycerol for export to other tissues.

Fourth, insulin induces the synthesis of a different enzyme—**lipoprotein lipase (LPL)**. This lipase does not act on the lipid stored within the adipose cell. Rather, the adipocyte exports the LPL to the endothelial cell, where it resides on the extracellular surface of the endothelial cell, facing the blood and anchored to the plasma membrane. In this location, the LPL acts on TAGs in chylomicrons and VLDLs and cleaves them into glycerol and fatty acids. These fatty acids are then available for uptake by nearby adipocytes, which esterify them with glycerol phosphate to form TAGs. This mechanism provides an efficient means by which insulin can promote the storage of lipid in adipose tissue.

Glucagon

Glucagon is the other major pancreatic islet hormone that is involved in the regulation of body fuel metabolism. Ingestion of protein appears to be the major physiological stimulus for secretion of glucagon. Glucagon's principal target tissue is the liver. Like insulin, glucagon is secreted first into the portal blood and is therefore anatomically well positioned to regulate hepatic metabolism.

Although the *amino acids* released by digestion of a protein meal appear to be the major glucagon secretagogue, glucagon's main actions on the liver appear to involve the regulation of *carbohydrate* and *lipid* metabolism. Glucagon is particularly important in stimulating glycogenolysis, gluconeogenesis, and ketogenesis. Glucagon does not act solely on the liver but also has glycogenolytic action on cardiac and skeletal muscle, lipolytic action on adipose tissue, and proteolytic actions on several tissues. However, these extrahepatic effects appear to be more prominent at pharmacological concentrations of glucagon. At more physiological concentrations, the liver is the major target tissue.

In many circumstances, glucagon's actions on liver antagonize those of insulin, and the mechanism of glucagon action is understood in considerable detail.

Pancreatic α cells secrete glucagon in response to ingested protein

Glucagon is a 31–amino-acid peptide (molecular weight, ~3500 Da) synthesized by α cells in the islets of Langerhans. In humans, the glucagon gene is located on chromosome 2. The initial gene product is the mRNA encoding preproglucagon. As is the case for insulin, a peptidase removes the signal sequence of preproglucagon during translation of the mRNA in the rough endoplasmic reticulum to yield proglucagon. Proteases in the α cells subsequently cleave the proglucagon (molecular weight, ~9000 Da) into the mature glucagon molecule and several biologically active peptides ([Fig. 51-11](#)). Neuroendocrine cells (i.e., L cells) within the gut process the proglucagon differently to yield not glucagon but GLP-1—a potent incretin—and other peptides.

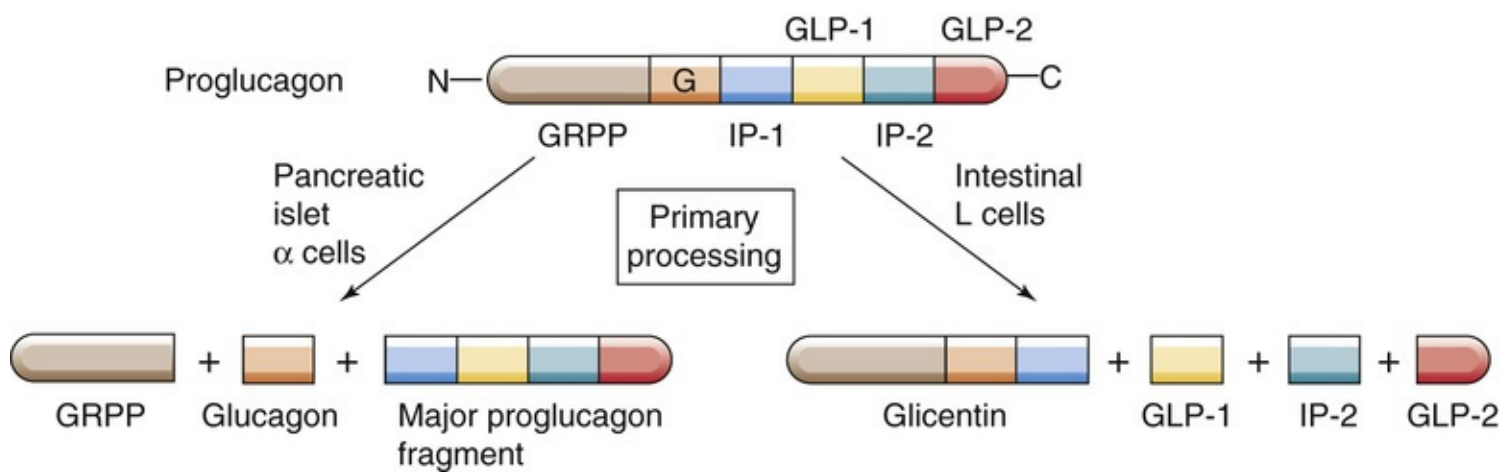

FIGURE 51-11 Synthesis of the glucagon molecule. The proglucagon molecule includes amino-acid sequences that, depending on how the peptide chain is cleaved, can yield glucagon-related polypeptide (GRPP), glucagon, intervening peptide 1 (IP-1), GLP-1, IP-2, and GLP-2. Proteases in the pancreatic α cells cleave proglucagon at points that yield GRPP, glucagon, and a C-terminal fragment. Proteases in neuroendocrine cells in the intestine cleave proglucagon to yield glicentin, GLP-1, IP-2, and GLP-2.

Pancreatic α Cells

The mature glucagon molecule is the major secretory product of the α cell. As with insulin, the fully processed glucagon molecule is stored in secretory vesicles within the cell's cytosol. Although amino acids are the major secretagogues, the concentrations of amino acids required to provoke secretion of glucagon *in vitro* are higher than those generated *in vivo*. This observation suggests that other neural or humoral factors amplify the response *in vivo*, in a manner analogous to the effects of incretin on insulin secretion. However, the best studied incretin (GLP-1) *inhibits* glucagon secretion. Whereas both glucose and several amino acids stimulate insulin secretion by β cells, only amino acids stimulate glucagon secretion by α cells; glucose inhibits glucagon secretion. The signaling mechanism by which α cells recognize either amino acids or glucose is not known.

Glucagon, like the incretins, is a potent insulin secretagogue. However, because most of the α cells are located downstream from the β cells (recall that the circulation of blood proceeds from the β cells and then out past the α cells), it is unlikely that glucagon exerts an important paracrine effect on insulin secretion.

Intestinal L Cells

Proteases in neuroendocrine cells in the intestine process proglucagon differently than do α cells (see Fig. 51-11). L cells produce four peptide fragments: glicentin, GLP-1, intervening peptide 2 (IP-2), and GLP-2. **Glicentin** contains the amino-acid sequence of glucagon but does not bind to glucagon receptors. Both GLP-1 and GLP-2 are glucagon-like in that they cross-react with some antisera directed to glucagon, but GLP-1 and GLP-2 have very weak biological activity as glucagon analogs. However, GLP-1—released by the gut into the circulation in response to carbohydrate or protein ingestion—is one of the most potent incretins, stimulating insulin secretion. GLP-2 is not an incretin, and its biological actions are not known.

Glucagon, acting through cAMP, promotes the synthesis of glucose by the liver

Glucagon is an important regulator of hepatic glucose production and ketogenesis in the liver. As shown

in [Figure 51-12](#), glucagon binds to a receptor that activates the heterotrimeric G protein $G\alpha_s$, which stimulates membrane-bound adenylyl cyclase (see [p. 53](#)). The cAMP formed by the cyclase in turn activates PKA, which phosphorylates numerous regulatory enzymes and other protein substrates, thus altering glucose and fat metabolism in the liver. Whereas insulin leads to the dephosphorylation of certain key enzymes (i.e., glycogen synthase, acetyl CoA carboxylase, phosphorylase), glucagon leads to their phosphorylation.

FIGURE 51-12 Glucagon signal transduction. Glucagon generally antagonizes the effects of insulin in the liver. Glucagon binds to a $G\alpha_s$ -coupled receptor, activating the adenylyl cyclase–cAMP–PKA cascade.

Glucagon has three major effects on liver cells. First, glucagon promotes net glycogen breakdown. Glucagon inhibits glycogen synthesis by reducing the activity of glucokinase (1) and glycogen synthase (2). However, glucagon promotes glycogen breakdown by activating glycogen phosphorylase (3) and G6Pase (4). Second, glucagon promotes net gluconeogenesis. The hormone inhibits glycolysis and carbohydrate oxidation by reducing the activity of glucokinase (1), phosphofructokinase (5), and pyruvate kinase (6). Glucagon also stimulates gluconeogenesis by increasing the transcription of PEPCK (9), fructose-1,6-bisphosphatase (10), and G6Pase (4). Third, glucagon promotes the oxidation of fats. The hormone inhibits the activity of acetyl CoA carboxylase (11). Glucagon indirectly stimulates fat oxidation because the decreased levels of malonyl CoA relieve the inhibition of malonyl CoA on CAT (13). The numbering scheme for these reactions is the same as that in Figure 51-8.

A particularly clear example of the opposing actions of insulin and glucagon involves the activation of **glycogenolysis** (see p. 1182). PKA phosphorylates the enzyme **phosphorylase kinase** (see Fig. 58-9), thus increasing the activity of phosphorylase kinase and allowing it to increase the phosphorylation of its substrate, **glycogen phosphorylase b**. The addition of a single phosphate residue to phosphorylase b

converts it to phosphorylase *a*. Liver phosphorylase *b* has little activity in breaking the one to four glycosidic linkages of glycogen, but phosphorylase *a* is very active. In addition to converting phosphorylase *b* to the active phosphorylase *a* form, PKA also phosphorylates a peptide called **inhibitor 1** (see [Fig. 3-7](#)). In its phosphorylated form, inhibitor I decreases the activity of phosphoprotein phosphatase 1 (PP1), which otherwise would dephosphorylate both phosphorylase kinase and phosphorylase *a* (converting them to their *inactive* forms). PP1 also activates glycogen synthase. Thus, via inhibitor I, glucagon modulates several of the enzymes involved in hepatic glycogen metabolism to provoke *net glycogen breakdown*. As a result of similar actions on the pathways of gluconeogenesis and lipid oxidation, glucagon also stimulates these processes. Conversely, glucagon restrains glycogen synthesis, glycolysis, and lipid storage.

Glucagon also enhances gluconeogenesis by genomic effects, acting synergistically with glucocorticoids (see [p. 1022](#)). The genomic effects of glucagon occur as PKA phosphorylates the transcription factor cAMP response element-binding protein (CREB; see [p. 89](#)), which interacts with the cAMP response elements (CREs; see [p. 89](#)), increasing the expression of key gluconeogenic enzymes (e.g., G6Pase and PEPCK). Phosphorylated CREB also increases the expression of peroxisome proliferator-activated receptor- γ coactivator-1 α (PGC-1 α), which also enhances the expression of key gluconeogenic enzymes. Insulin restrains the transcription of these two enzymes in two ways, both via the PI3K/Akt pathway (see [Fig. 51-6](#)). First, insulin increases the release of the transcription-factor domain of sterol regulatory element-binding protein 1 (SREBP-1; see [pp. 87–88](#)), which antagonizes the transcription of mRNA encoding the two enzymes. Second, insulin increases the phosphorylation of the transcription factor FOXO1, thereby promoting its movement out of the nucleus and subsequent degradation; this action prevents FOXO1 from binding to the promoter regions of G6Pase and PEPCK.

These actions of glucagon can be integrated with our understanding of insulin's action on the liver in certain physiological circumstances. For example, after an overnight fast, when insulin concentrations are low, glucagon stimulates the liver to produce the glucose that is required by the brain and other tissues for their ongoing function. **N51-9** With ingestion of a protein meal, absorbed amino acids provoke insulin secretion, which can inhibit hepatic glucose production and promote glucose storage by liver and muscle (see above). If the meal lacked carbohydrate, the secreted insulin could cause hypoglycemia. However, glucagon secreted in response to a protein meal balances insulin's action on the liver and thus maintains glucose production and avoids hypoglycemia.

N51-9

Maintaining Plasma Glucose Levels during Starvation

Contributed by Fred Suchy

Hepatic gluconeogenesis is critical to maintaining normal plasma glucose levels during starvation. Glucagon and glucocorticoids positively regulate gluconeogenesis through synergistic signaling pathways.

Glucagon promotes the interaction of cAMP response element-binding protein (CREB; see [p. 89](#)) with CREB-binding protein (CBP; see [p. 84](#)) and CREB-regulated transcription coactivator 2 (CRTC2). Both CBP and CRTC2 facilitate the binding of CREB to cAMP response elements (CREs).

The hepatocyte nuclear factors **forkhead O box (FOXO)** and peroxisome proliferator-activated receptor- γ (PPAR γ) coactivator 1 α (PGC-1 α) also acts synergistically to increase transcription of gluconeogenic genes.

The response to **glucocorticoids** is mediated by the glucocorticoid receptor, which binds to glucocorticoid response elements (GREs) in the promoters of gluconeogenic genes.

Sirtuin 1, an NAD-dependent deacetylase, is another energy sensor and modifier of the transcriptional activity of some of these transcription factors. For example, it deacetylates and affects the activity of PGC-1 α . In contrast, insulin secreted postprandially represses transcription of gluconeogenic enzymes through activation of the Akt signaling pathway.

Glucagon promotes oxidation of fat in the liver, which can lead to ketogenesis

Glucagon plays a major regulatory role in hepatic lipid metabolism. As we saw in our discussion of insulin (see [Fig. 51-8](#)), the liver can esterify fatty acids with glycerol to form TAGs, which it can store or export as VLDL particles. Alternatively, the liver can partially oxidize fatty acids—and form **ketone bodies** (see [p. 1185](#))—or fully oxidize them to CO₂. Whereas fatty-acid esterification and storage occur in the liver cytosol, oxidation and ketogenesis occur within the mitochondria.

Glucagon stimulates fat oxidation indirectly by increasing the activity of **CAT I** (see [pp. 1183–1185](#)), which mediates the transfer of fatty acids across the outer mitochondrial membrane. Glucagon produces this stimulation by inhibiting acetyl CoA carboxylase, which generates malonyl CoA, the first committed intermediate in the synthesis of fatty acids by the liver. Malonyl CoA is also an inhibitor of the CAT system. By inhibiting acetyl CoA carboxylase, glucagon lowers the concentration of malonyl CoA, releases the inhibition of CAT I, and allows fatty acids to be transferred into the mitochondria. These fatty acids are oxidized to furnish ATP to the liver cell. If the rate of fatty-acid transport into the mitochondria exceeds the need of the liver to phosphorylate ADP, the fatty acids will be only *partially oxidized*; the result is the accumulation of the keto acids **β -hydroxybutyric acid** and **acetoacetic acid**, which are two of the three ketone bodies. These keto acids can exit the mitochondria and the liver to be used by other tissues as oxidative fuel.

During fasting, the decline in insulin and the increase in glucagon promote ketogenesis (see [pp. 1185–1187](#)); this process is of vital importance to the CNS, which can use keto acids but not fatty acids as fuel. In the adaptation to fasting, glucagon therefore plays the important role of stimulating the conversion of fatty acids to ketones and provides the brain with the fuel that is needed to allow continued function during a fast. We discuss fasting in more depth beginning on [pages 1188–1192](#). 🍌[N51-10](#)

N51-10

Fasting

Contributed by Eugene Barrett

During fasting, falling insulin levels and rising glucagon levels promote the conversion of stored fat to ketone bodies and promote gluconeogenesis from muscle protein.

Insulin and glucagon are the principal regulators of body fuel metabolism. The integrated secretion and action of insulin and glucagon are vital to fuel homeostasis. In humans, after an overnight fast, plasma [insulin] is low. The low [insulin] and the availability of glucagon result in the production of glucose by the liver from the breakdown of endogenous glycogen as well as from the conversion of noncarbohydrate substrates into glucose (i.e., gluconeogenesis). These processes are highly regulated so that the rate at which glucose is produced by the liver matches the rate at which it is used by tissues, especially by the

CNS. If the amount of glucose being provided by the liver is inadequate, plasma [glucose] will decline. The β cell, sensing this decrease, reduces the amount of insulin being secreted, whereas the α cell increases glucagon secretion. These two changes will increase glucose production by the liver and correct the plasma [glucose] toward normal. Conversely, if glucose is being overproduced and plasma [glucose] rises, insulin secretion increases and glucagon secretion is suppressed. Hepatic glucose production therefore declines and plasma [glucose] returns toward normal.

If fasting continues for several more days, insulin secretion continues to decline and glucagon secretion increases. The decline in insulin concentration allows an increased rate of proteolysis in muscle and mobilization of fatty acids from adipose tissue. The amino acids released by muscle serve as a substrate for hepatic gluconeogenesis. This response is particularly important after the first several days of fasting, when hepatic glycogen stores have been depleted and gluconeogenesis is the major pathway of hepatic glucose production. At the same time, the increased glucagon concentration stimulates ketogenesis in the liver and provides ketone bodies for the CNS. Ketones provide an alternative fuel source for the brain that allows the brain to decrease its use of glucose. Because most of the glucose comes from gluconeogenesis—and because the building blocks for gluconeogenesis come from accelerated proteolysis—the availability of ketone bodies allows the body to use the energy stored in fat and spare body protein. Because much of this body protein comes from the structural proteins in skeletal muscle and because catabolism of these proteins impairs muscle function (such as strength and mobility), it is a clear survival advantage to have the brain burn fat and not protein for fuel.

We discuss fasting beginning on pages 1188–1192.

In addition to its effects on hepatic glucose and lipid metabolism, glucagon also has the extrahepatic actions of accelerating **lipolysis** in adipose tissue and **proteolysis** in muscle. However, these effects are generally demonstrable only with high concentrations of glucagon, and although they may be important in certain pathological situations associated with greatly elevated glucagon concentrations (e.g., ketoacidosis or sepsis), they appear less important in the day-to-day actions of glucagon.

Somatostatin

Somatostatin inhibits the secretion of growth hormone, insulin, and other hormones

Somatostatin is made in the δ cells of the pancreatic islets (see [Fig. 51-1](#)), as well as in the D cells of the gastrointestinal tract (see [pp. 868–870](#)), in the hypothalamus, and in several other sites in the CNS (see [pp. 993–994](#)). Somatostatin was first described as a hypothalamic peptide that *suppresses* the release of growth hormone; growth hormone had also been called somatotropin, which accounts for the name somatostatin. In both pancreatic δ cells and the hypothalamus, somatostatin exists as both 14- and 28-amino-acid peptides. In the hypothalamus, the 14-amino-acid form is predominant, whereas in the gastrointestinal tract (including the δ cells), the 28-amino-acid form predominates. The 14-amino-acid form is the C-terminal portion of the 28-amino-acid form. The biological activity of somatostatin resides in these 14 amino acids.

Somatostatin inhibits the secretion of multiple hormones, including growth hormone, insulin, glucagon, gastrin, vasoactive intestinal peptide (VIP), and thyroid-stimulating hormone. This property has led to therapeutic use of a long-acting somatostatin analog (octreotide) in some difficult-to-treat endocrine tumors, including those that produce growth hormone (acromegaly), insulin (insulinoma), or serotonin (carcinoid), among others. The concentration of somatostatin found in pancreatic venous drainage is sufficiently high to inhibit basal insulin secretion. Recall that blood flows from the center of each islet—which is where the bulk of the β cells are—to the periphery of the islet—which is where the δ cells tend to be located (see [Fig. 51-1](#)). This spatial arrangement minimizes the effect of somatostatin on the islet from which it is secreted. Whether somatostatin has important paracrine actions on some β cells or on α cells remains controversial.

The islet cells also make other peptides; for example, **pancreatic polypeptide** is made in the F cells of the pancreas. As with insulin and glucagon, secretion of pancreatic polypeptide is altered by dietary intake of nutrients. However, whether pancreatic polypeptide has any actions in mammalian fuel metabolism is not clearly understood.

Occasionally, islet cell tumors may develop and secrete gastrin, VIP, growth hormone–releasing factor, or other hormones. Although these individual instances prove that these peptides can be made by islet tissue, they have no known normal function in the islet.

The Parathyroid Glands and Vitamin D

Eugene J. Barrett, Paula Q. Barrett

Calcium and Phosphate Balance

Calcium plays a critical role in many cellular processes, including hormone secretion, muscle contraction, nerve conduction, exocytosis, and the activation and inactivation of many enzymes. As described in [Chapter 3](#), calcium also serves as an intracellular second messenger by carrying information from the cell membrane into the interior of the cell. It is therefore not surprising that the body very carefully regulates the plasma concentration of free ionized calcium, the physiologically active form of the ion, and maintains plasma ionized calcium concentration within a narrow range.

Phosphate is no less important. Because it is part of the ATP molecule, phosphate plays a critical role in cellular energy metabolism. It also plays crucial roles in the activation and deactivation of enzymes. However, unlike calcium, the plasma phosphate concentration is not strictly regulated, and its levels fluctuate throughout the day, particularly after meals.

Calcium and phosphate homeostasis are intimately tied to each other for two reasons. First, calcium and phosphate are the principal components of hydroxyapatite crystals $[\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2]$, which by far constitute the major portion of the mineral phase of bone. Second, they are regulated by the same hormones, primarily parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D (calcitriol) and, to a lesser extent, the hormone calcitonin. These hormones act on three organ systems—bone, kidneys, and gastrointestinal (GI) tract—to control the levels of calcium and phosphate in plasma. However, the actions of these hormones on calcium and phosphate are typically opposed in that a particular hormone may elevate the level of one ion while lowering that of the other. [Figures 52-1](#) and [52-2](#) depict the overall daily balance of calcium and phosphate for an individual in a steady state.

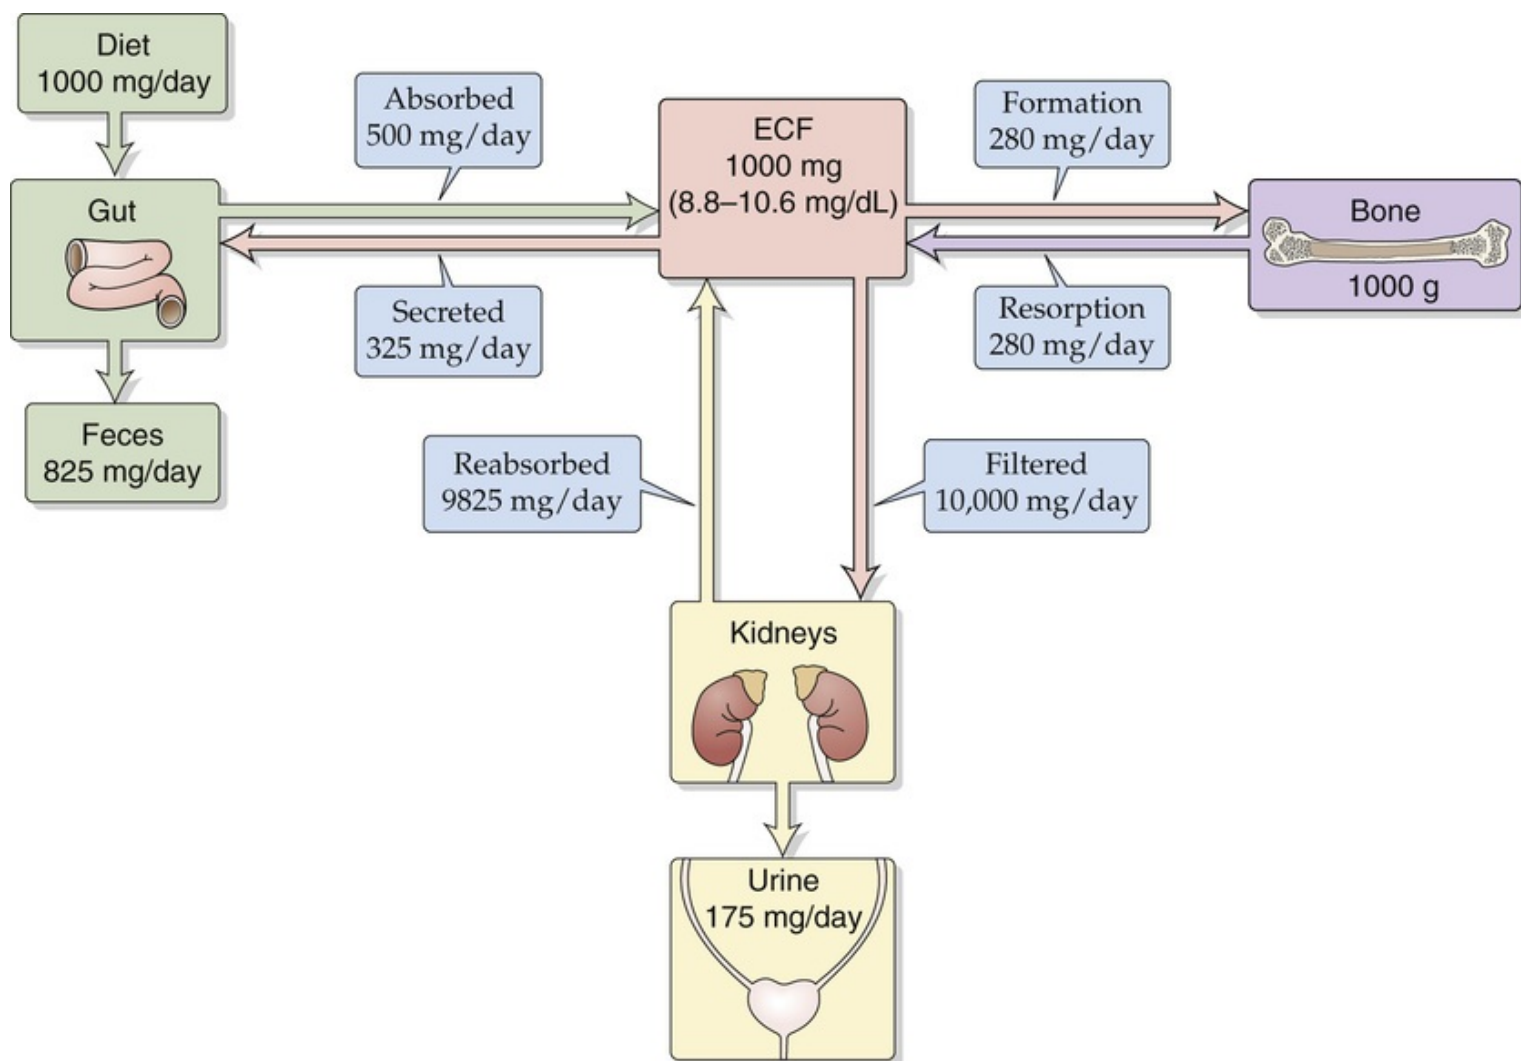

FIGURE 52-1 Calcium distribution and balance. Note that all values are examples for a 70-kg human, expressed in terms of elemental calcium. These values can vary depending on factors such as diet.

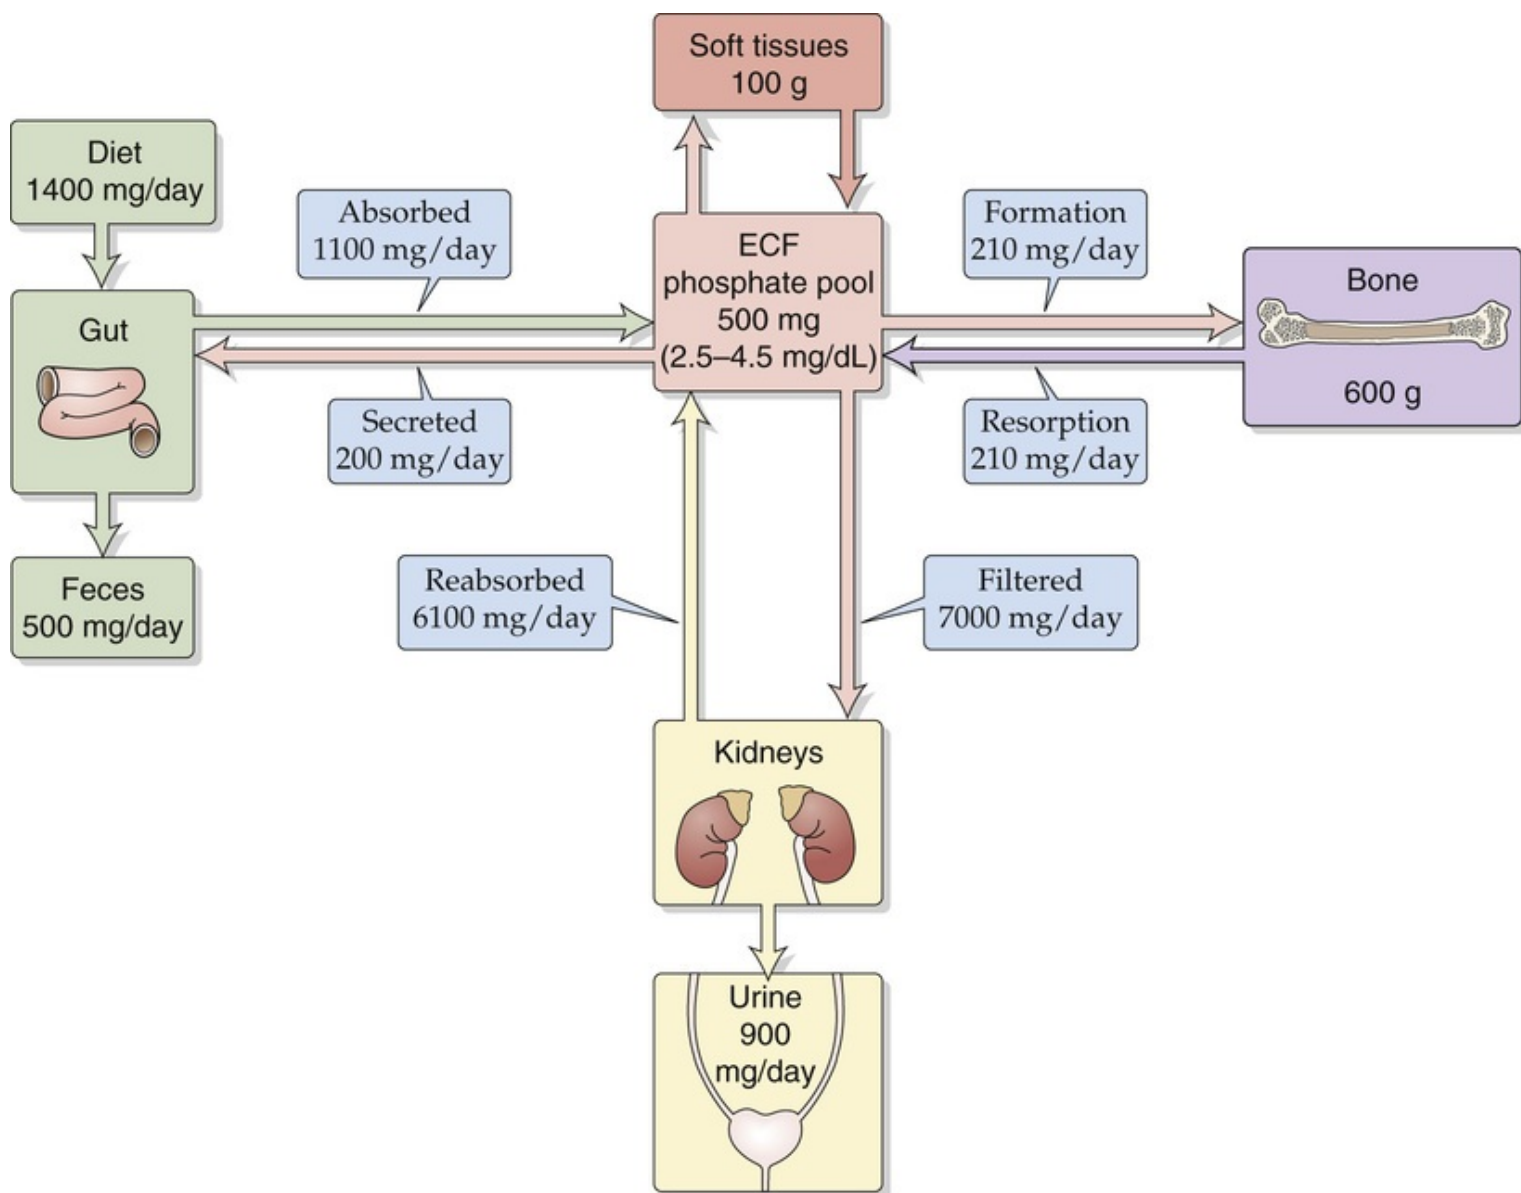

FIGURE 52-2 Phosphate distribution and balance. Note that all values are examples for a 70-kg human, expressed in elemental phosphorus. These values can vary depending on factors such as diet.

The gut, kidneys, and bone regulate calcium balance

In plasma, calcium exists in three physicochemical forms: (1) as a free ionized species (Ca^{2+}), (2) bound to (more accurately, associated with) anionic sites on serum proteins (especially albumin), and (3) complexed with low-molecular-weight organic anions (e.g., phosphate, citrate, and oxalate). The **total concentration** of all three forms in the plasma is normally 2.2 to 2.6 mM (8.8 to 10.6 mg/dL). In healthy individuals, ~45% of calcium is free, 45% is bound to protein, and 10% is bound to small anions. The body tightly regulates the ionized form of Ca^{2+} between 1.0 and 1.3 mM (4.0 and 5.2 mg/dL). The ionized form is the most important with regard to regulating the secretion of PTH and is involved in most of the biological actions of calcium.

Most total-body calcium is located within bone, ~1 kg (see Fig. 52-1). The total amount of calcium in the extracellular pool is only a tiny fraction of this amount, ~1 g or 1000 mg. The typical daily dietary intake of calcium is ~800 to 1200 mg. Dairy products are the major dietary source of calcium. Although the intestines absorb approximately one half the dietary calcium (~500 mg/day), they also secrete calcium for removal from the body (~325 mg/day), and therefore, the *net* intestinal uptake of calcium is only ~175 mg/day. The second major organ governing calcium homeostasis is bone, which in the steady state

deposits ~280 mg/day of calcium and resorbs an equal amount. The third organ system involved, the kidney, filters ~10 times the total extracellular pool of calcium per day, ~10,000 mg/day. The kidneys reabsorb ~99% of this Ca^{2+} , so that the net renal excretion of Ca^{2+} is ~1% of the filtered load (see [Fig. 36-16](#)). In a person in Ca^{2+} balance, urinary excretion (~175 mg/day) matches net absorption by the GI tract.

The gut, kidneys, and bone also regulate phosphate balance

The concentration of total phosphate in adult plasma—predominantly inorganic phosphate in the form of H_2PO_4^- and HPO_4^{2-} —ranges from 0.8 to 1.5 mM, a variation of 80%. It is ~50% higher in children. Laboratories report total plasma phosphate concentration as elemental phosphorus (range in adults, 2.5 to 4.5 mg/dL). Between 85% and 90% of the circulating inorganic phosphate is filterable by the kidneys, either ionized (50%) or complexed to Na^+ , Ca^{2+} , or Mg^{2+} (40%); only a small proportion (10% to 15%) is protein bound.

Like calcium, most total-body phosphate is present in bone, which contains ~0.6 kg of elemental phosphorus (see [Fig. 52-2](#)). A smaller amount of phosphorus (0.1 kg) resides in the soft tissues, mainly as organic phosphates, such as phospholipids, phosphoproteins, nucleic acids, and nucleotides. An even smaller amount (~500 mg) is present in the extracellular fluid (ECF) as inorganic phosphate. The daily dietary intake of phosphorus is typically 1400 mg, mostly as inorganic phosphate. Again, dairy products are the major source. The net absorption of phosphate by the intestines is ~900 mg/day. In the steady state, bone has relatively small phosphate turnover, ~210 mg/day. The kidneys filter ~14 times the total extracellular pool of phosphate per day (~7000 mg/day) and reabsorb ~6100 mg/day. Hence, the net renal excretion of phosphorus is ~900 mg/day, the same as the net absorption by the GI tract.

Physiology of Bone

Dense cortical bone and the more reticulated trabecular bone are the two major bone types

Bone consists largely of an extracellular matrix composed of proteins and hydroxyapatite crystals, in addition to a small population of cells. The matrix provides strength and stability. The cellular elements continually remodel bone to accommodate growth and allow bone to reshape itself in response to varying loading stresses. Basically, bone has three types of bone cells. **Osteoblasts** promote bone formation. Osteoblasts and preosteoblasts are the principal target cells for PTH's action to stimulate bone growth. **Osteoclasts** promote bone resorption and are found on the growth surfaces of bone. Their activity is increased by cytokines, with RANK ligand being particularly important. **Osteocytes** are found within the bony matrix and are derived from osteoblasts that have encased themselves within bone. In response to mechanical loading, osteocytes produced both stimulatory and inhibitory cues. These cells stimulate the bone-forming activities of osteoblasts and lining cells by secreting growth factors such as osteocalcin and Wnt ligands. Osteocytes inhibit osteoblast activity by secreting antagonists of Wnt signaling, including sclerostin and dickkopf1. Osteocytes also appear to play a role in the transfer of mineral from the interior of bone to the growth surfaces. Bone remodeling consists of a carefully coordinated interplay of osteoblastic, osteocytic, and osteoclastic activities.

As shown in [Figure 52-3](#), bone consists of two types of bone tissue. **Cortical** (also called **compact** or **lamellar**) bone represents ~80% of the total bone mass. Cortical bone is the outer layer (the cortex) of all bones and forms the bulk of the long bones of the body. It is a dense tissue composed mostly of bone mineral and extracellular matrix elements, interrupted only by penetrating blood vessels and a sparse population of osteocytes nested within the bone. These osteocytes are interconnected with one another and with the osteoblasts on the surface of the bone by canaliculi, through which the osteocytes extend cellular processes. These connections permit the transfer of Ca^{2+} from the interior of the bone to the surface, a process called *osteocytic osteolysis*. Dense cortical bone provides much of the strength for weight bearing by the long bones.

FIGURE 52-3 Cortical and trabecular bone. Under the periosteum is a layer of compact cortical bone that surrounds the more reticulated trabecular bone. The fundamental unit of cortical bone is the osteon, a tube-like structure that consists of a haversian canal surrounded by ring-like lamellae. The inset shows a cross section through an osteon. The superficial lining cells surround the osteoblasts, which secrete osteoid, a matrix of proteins that are the organic part of bone. The lining cells are formed from osteoblasts that become quiescent. Osteocytes are osteoblasts that have become surrounded by matrix. Canaliculi allow the cellular processes of osteocytes to communicate, via gap junctions, with each other and with osteoblasts on the surface. Trabecular bone has both osteoblasts and osteoclasts on its surface; this is where most bone remodeling takes place.

Trabecular (or **cancellous** or **medullary**) bone constitutes ~20% of the total bone mass. It is found in the interior of bones and is especially prominent within the vertebral bodies. It is composed of thin spicules of bone that extend from the cortex into the medullary cavity (see Fig. 52-3, inset). The lacework of bone spicules is lined in many areas by osteoblasts and osteoclasts, the cells involved in bone remodeling. Trabecular bone is constantly being synthesized and resorbed by these cellular elements. Bone turnover also occurs in cortical bone, but the fractional rate of turnover is much lower. When the rate of bone resorption exceeds that of synthesis over time, the loss of bone mineral produces the disease osteoporosis.

The extracellular matrix forms the nidus for the nucleation of hydroxyapatite crystals

Collagen and the other extracellular matrix proteins that form the protein matrix of bone are called

osteoid. **Osteoid** provides sites for the nucleation of hydroxyapatite crystals, the mineral component of bone. Osteoid is not a single compound, but a highly organized matrix of proteins synthesized principally by osteoblasts. Type I collagen accounts for ~90% of the protein mass of osteoid. It comprises a triple helix of two $\alpha 1$ monomers and one $\alpha 2$ collagen monomer. While still within the osteoblast, monomers self-associate into helical structures. After secretion from the osteoblast, helices associate into collagen fibers; cross-linking of collagen occurs both within a fiber and between fibers. Collagen fibers are arranged in the osteoid in a highly ordered manner. The organization of collagen fibers is important for the tensile strength (i.e., the ability to resist stretch or bending) of bone. In addition to providing tensile strength, collagen also acts as a nidus for nucleation of bone mineralization. Within the collagen fibers, the crystals of hydroxyapatite are arranged with their long axis aligned with the long axis of the collagen fibers.

Several other osteoblast-derived proteins are important to the mineralization process, including osteocalcin and osteonectin. **Osteocalcin** is a 6-kDa protein synthesized by osteoblasts at sites of new bone formation. 1,25-Dihydroxyvitamin D induces the synthesis of osteocalcin. Osteocalcin has an unusual structure: it possesses three γ -carboxylated glutamic acid residues. These residues are formed by post-translational modification of glutamic acid by vitamin K–dependent enzymes. Like other proteins with γ -carboxylated glutamic acid, osteocalcin binds Ca^{2+} avidly. It binds hydroxyapatite, the crystalline mineral of bone, with even greater avidity. This observation has led to the suggestion that osteocalcin participates in the nucleation of bone mineralization at the crystal surface. **Osteonectin**, a 35-kDa protein, is another osteoblast product that binds to hydroxyapatite. It also binds to collagen fibers and facilitates the mineralization of collagen fibers in vitro. Additional proteins have been identified that appear to participate in the mineralization process. For instance, extracellular glycoproteins present in bone may inhibit mineralization and their removal may be necessary for mineralization to occur.

Bone remodeling depends on the closely coupled activities of osteoblasts and osteoclasts

In addition to providing the proteins in osteoid, osteoblasts promote mineralization by exporting Ca^{2+} and PO_4^{3-} from intracellular vesicles that have accumulated these minerals. Exocytosis of Ca^{2+} and PO_4^{3-} raises the local extracellular concentration of these ions around the osteoblast to levels that are higher than in the bulk ECF, which promotes crystal **nucleation** and growth (Fig. 52-4). Bone formation along spicules of trabecular bone occurs predominantly at sites of previous resorption by osteoclasts. The processes of bone resorption and synthesis are thus spatially coupled within an active **basic multicellular unit (BMU)**. In adults, 1 to 2 million BMUs actively remodel bone.

FIGURE 52-4 Bone formation and resorption. PTH and vitamin D stimulate osteoblastic cells to secrete agents that induce stem cells to differentiate into osteoclast precursors, mononuclear osteoclasts, and finally mature, multinucleated osteoclasts. Thus, PTH *indirectly* promotes bone resorption. Osteoblasts also secrete Ca²⁺ and inorganic phosphate (P_i), which nucleate on the surface of bone. IL-6R, interleukin-6 receptor.

Vitamin D and PTH stimulate osteoblastic cells to secrete factors—such as macrophage colony-stimulating factor (M-CSF; see [p. 431](#))—that cause osteoclast precursors to proliferate (see [Fig. 52-4](#)). These precursors differentiate into mononuclear osteoclasts and then, with further stimulation by RANK ligand (also released by PTH-stimulated osteoblasts), fuse to become multinucleated osteoclasts. **Osteoclasts** resorb bone in discrete areas in contact with the “ruffled border” of the cell ([Fig. 52-5](#)). The osteoclast closely attaches to the bone matrix when integrins on its membrane attach to vitronectin in the bone matrix. The osteoclast—in reality a one-cell epithelium—then secretes acid and proteases across its ruffled border membrane into a confined resorption space (the lacuna). The acid secretion is mediated by a V-type H pump (see [pp. 118–119](#)) and the ClC-7 Cl[−] channel at the ruffled border membrane. Abundant intracellular carbonic anhydrase provides the H⁺. Cl-HCO₃ exchangers, located in the membrane that faces the blood, remove the HCO₃[−] formed as a byproduct by the carbonic anhydrase. The acidic environment beneath the osteoclast dissolves bone mineral and allows acid proteases to hydrolyze the

exposed matrix proteins. Having reabsorbed some of the bone in a very localized area, the osteoclast moves away from the pit or trough in the bone that it has created. Osteoblastic cells replace the osteoclast and now build new bone matrix and promote its mineralization.

FIGURE 52-5 Bone resorption by the osteoclast. The osteoclast moves along the surface of bone and settles down, sealing itself to the bone via integrins that bind to vitronectins on the bone surface. The osteoclast reabsorbs bone by secreting H⁺ and acid proteases into the lacuna. Thus, the osteoclast behaves as a one-cell epithelium. The acid secretion is mediated by a V-type H pump and ClC7 Cl⁻ channel at the ruffled border membrane facing the lacuna. Carbonic anhydrase (CA) in the cytosol supplies the H⁺ to the H pump and also produces HCO₃⁻ as a byproduct. Cl-HCO₃ exchangers—located on the membrane opposite the ruffled border—remove this HCO₃⁻. AC, adenylyl cyclase; IL-6R, interleukin-6 receptor; PKA, protein kinase A; TRAP, tartrate-resistant acid phosphatase.

RANK ligand (RANKL), previously called osteoprotegerin ligand, appears to be a major stimulator of both the differentiation of preosteoclasts to osteoclasts (see Fig. 52-4) and the activity of mature osteoclasts (see Fig. 52-5). RANKL is a member of the tumor necrosis factor (TNF) cytokine family and exists both as a membrane-bound form (mRANKL) on the surface of stromal cells and osteoblasts, and as a soluble protein (sRANKL) secreted by these same cells. RANKL binds to and stimulates a membrane-bound receptor of the osteoclast called **RANK** (receptor for activation of nuclear factor κ B), a member of the TNF receptor family. The interaction is essential for the formation of mature osteoclasts.

The activity of RANKL is under the control of a soluble member of the TNF receptor family called

osteoprotegerin (OPG; from the Latin *osteo* [bone] + *protegere* [to protect]). Like RANKL, OPG is produced by osteoblastic and stromal cells (see [Fig. 52-4](#)). By scavenging RANKL, OPG limits osteoclastogenesis, thereby protecting bone from osteoclastic activity. The precise role of RANKL, RANK, and OPG in the development of various forms of osteoporosis (diminished bone density) and osteopetrosis (increased bone density) is only beginning to be understood. However, the balance between OPG and RANKL production by the osteoblast/stromal cell appears to be a very important factor in the development of osteoporosis from either estrogen deficiency or glucocorticoid excess. In both cases, RANKL production rises and OPG production falls. In 2010, the U.S. Food and Drug Administration approved **denosumab**, a humanized monoclonal antibody against RANKL, for the treatment of postmenopausal osteoporosis.

In rare human monogenic syndromes, defects of the Wnt signaling system are associated with marked increases or decreases in bone mass. Moreover, targeted disruption of specific Wnt antagonists in mice reveals the major role of Wnt in osteoblastogenesis and in modulation of the activity of both osteoblasts and osteocytes. Wnt increases the differentiation of mesenchymal stem cells and preosteoblasts, thereby increasing bone-forming capacity. In addition, Wnt increases the production of OPG, which competes with RANKL and thereby decreases osteoclastogenesis. New therapies to treat or prevent bone loss based on manipulation of Wnt signaling offer substantial promise.

Parathyroid Hormone

Plasma Ca^{2+} regulates the synthesis and secretion of PTH

Humans have four parathyroid glands, two located on the posterior surface of the left lobe of the thyroid and two more on the right. Combined, these four glands weigh <500 mg. They are composed largely of **chief cells**, which are responsible for the synthesis and secretion of PTH. These cells, like cells that secrete other peptide hormones, are highly specialized to synthesize, process, and secrete their product. The major regulator of PTH secretion is ionized plasma Ca^{2+} , although vitamin D also plays a role. Both inhibit the synthesis or release of PTH. In contrast, an increase in plasma phosphorus concentration stimulates PTH release.

PTH Synthesis and Vitamin D

The PTH gene possesses upstream regulatory elements in the 5' region, including response elements for both vitamins D and A (see [p. 90](#)). The vitamin D response element binds a **vitamin D receptor (VDR)** when the receptor is occupied by a vitamin D metabolite, usually 1,25-dihydroxyvitamin D. The VDR is a member of the family of nuclear receptors, like the steroid hormone and thyroid hormone receptors. Like the thyroid hormone receptor, VDR forms a heterodimer with the retinoid X receptor (RXR) and acts as a transcription factor (see [Table 3-6](#)). The receptor has a very high affinity for the 1,25-dihydroxylated form of vitamin D ($K_D \cong 10^{-10} \text{ M}$), less affinity for the 25-hydroxy form ($K_D \cong 10^{-7} \text{ M}$), and little affinity for the parent vitamin (either D_2 or D_3 , see below). Binding of the vitamin D–VDR complex to the VDR response element *decreases* the rate of PTH transcription.

Processing of PTH

After transport of the mature PTH messenger RNA (mRNA) to the cytosol, PTH is synthesized on ribosomes of the rough endoplasmic reticulum (RER) and begins its journey through the secretory pathway (see [pp. 34–35](#)). PTH is transcribed as a prepro-PTH of 115 amino acids ([Fig. 52-6](#)). The 25–amino-acid “pre” fragment targets PTH for transport into the lumen of the RER. This signal sequence (see [p. 28](#)) appears to be cleaved as PTH enters the RER. During transit through the secretory pathway, the 90–amino-acid pro-PTH is further processed to the mature, active, 84–amino-acid PTH. This cleavage appears quite efficient, and no pro-PTH appears in the storage granules. Conversely, the breakdown of 1–84 PTH or “intact” PTH into its N- and C-terminal fragments—as discussed below—already starts in the secretory granules.

FIGURE 52-6 PTH synthesis. The synthesis of PTH begins with the production of prepro-PTH (115 amino acids) in the RER. Cleavage of the signal sequence in the ER lumen yields pro-PTH (90 amino acids). During transit through the secretory pathway, enzymes in the Golgi cleave the “pro” sequence, yielding the mature or “intact” PTH (84 amino acids), which is stored in secretory granules. Beginning in the secretory granule, enzymes cleave PTH into two fragments. The N-terminal fragment is either 33 or 36 amino acids in length and contains all of the biological activity.

Metabolism of PTH

Once secreted, PTH circulates free in plasma and is rapidly metabolized; the half-life of 1-84 PTH is ~4 minutes. Beginning in the secretory granules inside the parathyroid chief cells and continuing in the circulation—predominantly in the liver—PTH is cleaved into two principal fragments, a 33- or 36-amino-acid N-terminal peptide and a larger C-terminal peptide (see Fig. 52-6). Virtually all the known biological activity of PTH resides in the N-terminal fragment, which is rapidly hydrolyzed, especially in the kidney. However, the half-life of the C-terminal fragment is much longer than that of either the N-terminal peptide or the intact 84-amino-acid PTH molecule. An estimated 70% to 80% of the PTH-derived peptide in the circulation is represented by the biologically inactive C-terminal fragment. The presence of a significant amount of antigenically recognized but biologically inactive C-terminal fragments in the circulation has complicated the use of the usual radioimmunoassay methods for measuring PTH in both clinical and experimental settings. This problem has been solved by the development of sensitive enzyme-linked immunosorbent assays (ELISAs) that use two antibodies that react with two distinct sites on the PTH molecule and measure only the **intact PTH hormone** (i.e., 84 amino acids). These assays are invaluable in the diagnosis of disorders of PTH secretion, particularly when kidney function is impaired (a circumstance that further prolongs the half-life of the inactive C-terminal metabolites). **N52-1**

N52-1

Historical Assays for PTH

Contributed by Eugene Barrett

On pages 1059–1060, we discuss the modern methods for assaying intact PTH. In the past, clinicians exploited the effects of PTH on renal phosphate transport and renal cAMP production to assay biologically active PTH levels. Both the renal threshold (T_m) for phosphate (see p. 786 and Fig. 36-15) and the rate of urinary excretion of cAMP are readily determined in humans and are indirect measures of plasma PTH levels. In the case of cAMP, one actually measures the excretion of “nephrogenous” cAMP; that is, the total urinary cAMP minus the amount of cAMP filtered in the glomeruli.

With the advent of the newer PTH assays, these tests have largely been discarded in clinical settings.

High plasma $[Ca^{2+}]$ inhibits the synthesis and release of PTH

To a first approximation, and ignoring the contributions of vitamin D that are discussed below, regulation of PTH secretion by plasma Ca^{2+} appears to be a simple negative-feedback loop. The major stimulus for PTH secretion is a *decline* in the concentration of Ca^{2+} in the blood (hypocalcemia) and ECF. Hypocalcemia also stimulates synthesis of new PTH, which is necessary because the parathyroid gland contains only enough PTH to maintain a stimulated secretory response for several hours.

Using cultured parathyroid chief cells (which like the parathyroids *in vivo* respond to very small decreases in the concentration of ionized Ca^{2+}), investigators identified a **Ca^{2+} -sensing receptor (CaSR)** that resides in the plasma membrane of the parathyroid cell (Fig. 52-7A). This receptor binds Ca^{2+} in a saturable manner, with an affinity profile that is similar to the concentration dependence for PTH secretion. CaSR is a member of the **G protein-coupled receptor (GPCR)** family (see pp. 51–66). Coupling of this Ca^{2+} receptor to $G\alpha_q$ activates phospholipase C, which generates inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG) and results in the release of Ca^{2+} from internal stores and the activation of protein kinase C (PKC; see pp. 60–61). Unlike most endocrine tissues, in which activation of these signaling systems promotes a secretory response, in the parathyroid the rise in $[Ca^{2+}]_i$ and activation of PKC *inhibit* hormone secretion. (Another example is the granular cell of the juxtaglomerular apparatus, in which an increase in $[Ca^{2+}]_i$ inhibits secretion of renin; see p. 842). Thus, increasing levels of plasma $[Ca^{2+}]$ decrease PTH secretion (see Fig. 52-7B).

A PARATHYROID Ca^{2+} RECEPTOR

B RESPONSE OF PARATHYROID GLAND TO CHANGES IN PLASMA $[\text{Ca}^{2+}]$

FIGURE 52-7 PTH secretion and its dependence on ionized Ca^{2+} in the plasma. **A**, Four parathyroid glands lie on the posterior side of the thyroid. The chief cells synthesize, store, and secrete PTH. Increases in extracellular $[\text{Ca}^{2+}]$ inhibit PTH secretion in the following manner: Ca^{2+} binds to a receptor that is coupled to a heterotrimeric G protein, $\text{G}\alpha_q$, which activates phospholipase C (PLC). This enzyme converts phosphoinositides (phosphatidylinositol 4,5-bisphosphate, or PIP_2) to IP_3 and DAGs. The IP_3 causes the release of Ca^{2+} from internal stores, whereas the DAG stimulates PKC. Paradoxically, both the elevated $[\text{Ca}^{2+}]_i$ and the stimulated PKC inhibit release of granules containing PTH. Increased $[\text{Ca}^{2+}]_o$ also inhibits PTH synthesis. Thus, increased levels of plasma Ca^{2+} lower PTH release and therefore tend to lower plasma $[\text{Ca}^{2+}]$. **B**, Small decreases in free plasma $[\text{Ca}^{2+}]$ greatly increase the rate of PTH release. About half of the total plasma Ca^{2+} is free. In patients with familial hypocalciuric hypercalcemia (FHH), the curve is shifted to the right; that is, plasma $[\text{Ca}^{2+}]$ must rise to higher levels before inhibiting PTH secretion. As a result, these patients have normal PTH levels, but elevated plasma $[\text{Ca}^{2+}]$. ER, endoplasmic reticulum.

The PTH receptor couples via G proteins to either adenylyl cyclase or phospholipase C

The action of PTH to regulate plasma $[\text{Ca}^{2+}]$ is secondary to its binding to the **PTH 1R receptor (PTH1R)**. A second PTH receptor, PTH2R, has been identified. However, its role, if any, in the regulation of plasma $[\text{Ca}^{2+}]$ is uncertain. Kidney and bone have the greatest abundance of PTH1R. Within the kidney, PTH1R is most abundant in the proximal and distal convoluted tubules. In bone, the preosteoblast and osteoblast appear to be the major target cells. PTH1R is a GPCR (see pp. 51–66) that binds some N-terminal fragments of PTH, the biologically active 1-34 peptide, as well as the 1-84 intact PTH molecule (see Fig. 52-6). PTH1R also binds PTH-related protein (PTHrP), which is discussed below. In contrast, PTH2R is selectively activated by PTH.

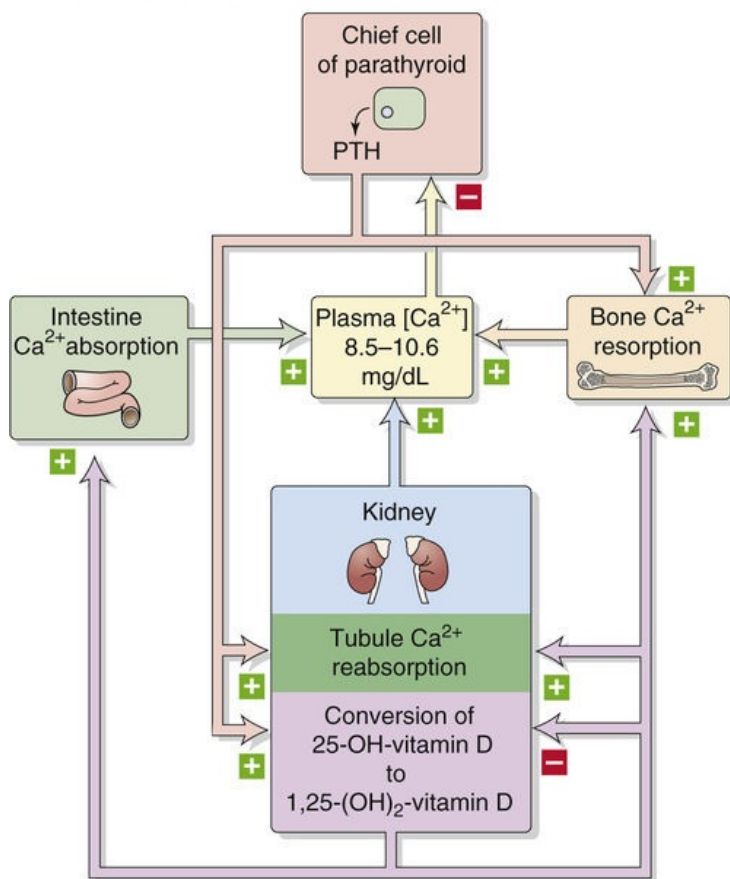

PTH1R appears to be coupled to two heterotrimeric G proteins and thus to two signal-transduction systems. Binding of PTH to the receptor stimulates $\text{G}\alpha_s$, which in turn activates **adenylyl cyclase** and thus releases cAMP and stimulates protein kinase A (see pp. 56–57). The activated PTH receptor also stimulates $\text{G}\alpha_q$, which in turn stimulates **phospholipase C** (see p. 58) to generate IP_3 and DAG. The IP_3 releases Ca^{2+} from internal stores, thus increasing $[\text{Ca}^{2+}]_i$ and activating Ca^{2+} -dependent kinases. In humans, the bone PTH receptor on osteoblastic cells is identical to that present in renal cortical cells.

As discussed in the next two sections, the net effects of PTH on the kidney and bone are to increase plasma $[\text{Ca}^{2+}]$ and to lower plasma [phosphate].

In the kidney, PTH promotes Ca^{2+} reabsorption, phosphate loss, and 1-hydroxylation of 25-hydroxyvitamin D

PTH exerts a spectrum of actions on target cells in the kidney and bone, as illustrated for Ca^{2+} in Figure 52-8A and for phosphate in Figure 52-8B. In renal tubules, PTH receptors are located on the basolateral membrane. Binding of PTH to its receptors activates dual intracellular signaling systems and in this manner modifies transepithelial transport.

A CONTROL OF PLASMA CALCIUM

B CONTROL OF PLASMA PHOSPHATE

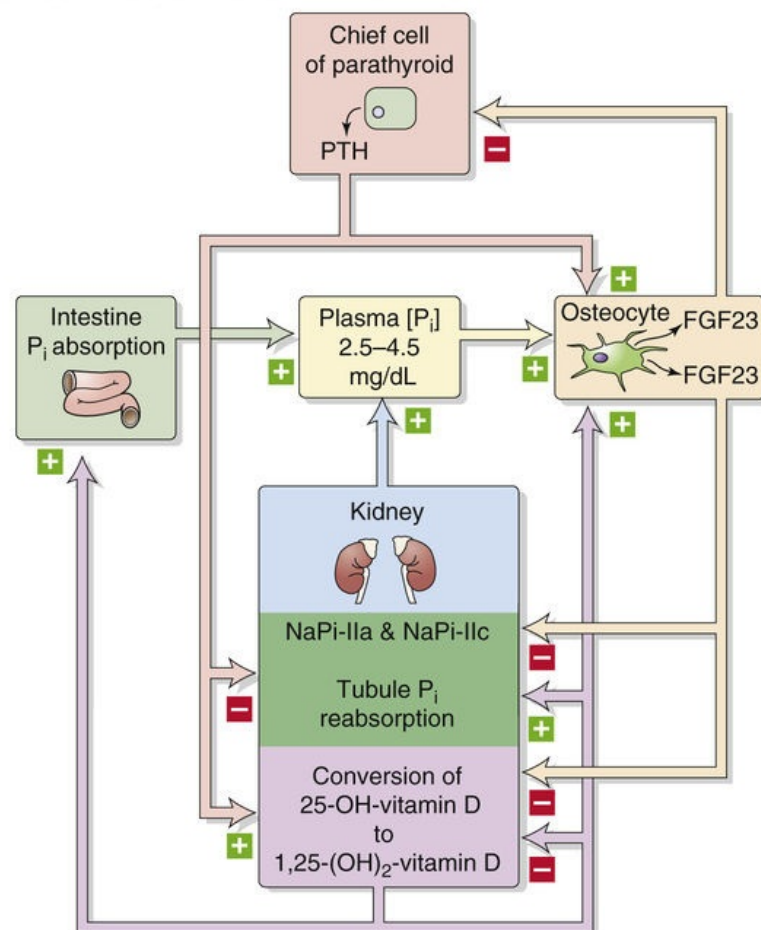

FIGURE 52-8 Feedback loops in the control of plasma calcium and phosphate levels. The three major regulators are PTH released by parathyroid chief cells; 1,25-dihydroxyvitamin D released by renal proximal-tubule cells; and, in the case of phosphate, FGF23 released by osteocytes. Plasma Ca^{2+} concentration feeds back on the parathyroid glands, whereas plasma inorganic phosphate (P_i) concentration feeds back on osteocytes.

Stimulation of Ca^{2+} Reabsorption

A key action of PTH is to promote the reabsorption of Ca^{2+} in the thick ascending limb (TAL) and distal convoluted tubule (DCT) of the kidney (see [p. 789](#)). Most of the ~ 25 mmol of Ca^{2+} filtered each day is reabsorbed in the proximal tubule ($\sim 65\%$) and TAL ($\sim 25\%$). The distal nephron is responsible for reabsorbing an additional 5% to 10% of the filtered load of Ca^{2+} , with $\sim 0.5\%$ of the filtered load left in the urine. Thus, when PTH stimulates distal Ca^{2+} reabsorption, it greatly decreases the amount of Ca^{2+} excreted in the urine (usually 4 to 5 mmol/day) and tends to raise plasma $[\text{Ca}^{2+}]$ (see [Fig. 52-8A](#)).

Greater fractional Ca^{2+} excretion occurs when Ca^{2+} reabsorption in the proximal tubule, TAL, or DCT is impaired, as occurs with osmotic or loop diuretics or hypoparathyroidism. As discussed below, vitamin D has a synergistic action to promote Ca^{2+} reabsorption in the DCT.

Inhibition of Phosphate Reabsorption

PTH reduces phosphate reabsorption in the proximal tubule, producing a characteristic phosphaturia and decreasing plasma phosphate levels (see [Fig. 52-8B](#)). This phosphaturia results from a PTH-induced redistribution of **Na/phosphate cotransporters (NaPi-IIa and NaPi-IIc; see pp. 785–786)** away from the apical membrane of the renal proximal tubule and into a pool of subapical vesicles (see [pp. 786–787](#)). Note that fibroblast growth factor 23 (FGF23; see [p. 787](#)), released by osteocytes in response to high

plasma $[P_i]$, also inhibits NaPi-IIa and NaPi-IIc and thus phosphate reabsorption (see Fig. 52-8B). Conversely, a PTH-induced decrease in plasma $[P_i]$ inhibits the release of FGF23, which in turn promotes P_i reabsorption, countering the action of PTH.

As discussed below, PTH stimulates bone to resorb calcium and phosphate from the hydroxyapatite crystals of bone mineral. Thus, PTH stimulates both steps in the movement of phosphate from bone to blood to urine. Elimination of phosphate via the urine plays an important role when elevated levels of PTH liberate Ca^{2+} and phosphate from bone. At normal plasma Ca^{2+} and phosphorus concentrations, the $Ca \times PO_4$ ion product approaches the solubility product. Clinically, this product is measured as total plasma calcium (in mg/dL) \times plasma elemental phosphorus (in mg/dL). Further, PTH-induced increases in $[Ca^{2+}]$ —if accompanied by a rise in phosphate levels—would cause calcium phosphate salts to precipitate out of the soluble phase, at least partly negating the action of PTH to raise plasma $[Ca^{2+}]$. Thus, PTH-induced phosphaturia diminishes the $Ca \times PO_4$ ion product and prevents precipitation when Ca^{2+} mobilization is needed. The body tightly regulates plasma $[Ca^{2+}]$ but allows plasma levels of phosphate to vary more widely.

In addition to affecting phosphate reabsorption, PTH decreases the proximal-tubule reabsorption of HCO_3^- (see p. 829) and of several amino acids. These actions appear to play a relatively minor role in whole-body acid-base and nitrogen metabolism, respectively.

Stimulation of the Last Step of Synthesis of 1,25-Dihydroxyvitamin D

A third important renal action of PTH is to stimulate the 1-hydroxylation of 25-hydroxyvitamin D in the mitochondria of the proximal tubule. The resulting 1,25-dihydroxyvitamin D is the most biologically active metabolite of dietary or endogenously produced vitamin D. Its synthesis by the kidney is highly regulated, and PTH is the primary stimulus to increase 1-hydroxylation. Note that *hyperphosphatemia* elevates plasma FGF23, which inhibit this hydroxylation (see Fig. 52-8B). Conversely, *hypophosphatemia*, either spontaneous or induced by the phosphaturic action of PTH, also promotes the production of 1,25-dihydroxyvitamin D. As discussed on pages 1065–1067, the 1,25-dihydroxyvitamin D formed in the proximal tubule has three major actions: (1) enhancement of renal Ca^{2+} reabsorption, (2) enhancement of Ca^{2+} absorption by the small intestine, and (3) modulation of the movement of Ca^{2+} and phosphate in and out of bone (Box 52-1).

Box 52-1

Familial Hypocalciuric Hypercalcemia

The Ca^{2+} receptor on the parathyroid cell is mutated in patients with the disorder **familial hypocalciuric hypercalcemia (FHH)**. Plasma Ca^{2+} level in these patients is typically elevated 10% to 30% above the normal range. These patients generally tolerate this elevated plasma $[Ca^{2+}]$ very well. The finding of a total plasma Ca^{2+} of 3.0 to 3.3 mM (12 to 13 mg/dL)—the normal range is 2.2 to 2.6 mM (8.8 to 10.6 mg/dL)—is frequently more alarming to the physician than to the patient. Despite having a plasma $[Ca^{2+}]$ that would make most people symptomatic with kidney stones, fatigue, or loss of mental concentration, these patients have remarkably few symptoms, presumably because they have adapted to the hypercalcemia since birth. The amount of Ca^{2+} present in their urine is typically less than normal (hence the designation *hypocalciuric*) and much lower than that encountered in persons with hypercalcemia due to other causes. Despite the high plasma $[Ca^{2+}]$, the plasma [PTH] in FHH patients is

typically normal. The normal [PTH] suggests that regulation of PTH secretion is intact but the set-point at which the Ca^{2+} turns off PTH secretion is shifted toward a higher plasma $[\text{Ca}^{2+}]$ (see Fig. 52-7B).

FHH is an autosomal dominant disorder, and several different point mutations have been identified in different families. *Heterozygotes* express both normal and mutated Ca^{2+} receptors. Rarely, infants are born with the *homozygous* disorder (i.e., both copies of the receptor are defective). These infants have very severe hypercalcemia (>15 mg/dL) and severe hyperparathyroidism. The condition is life threatening and is characterized by markedly elevated plasma $[\text{Ca}^{2+}]$, neuronal malfunction, demineralization of bone, and calcification of soft tissues. These infants die unless the inappropriately regulated parathyroid glands are removed.

Like the parathyroid gland, the renal TAL and DCT have abundant plasma-membrane Ca^{2+} receptors on their basolateral membranes. These receptors respond to changes in plasma Ca^{2+} and inhibit Ca^{2+} reabsorption (see p. 789). Thus, with a mutated receptor, renal Ca^{2+} reabsorption may not be inhibited until plasma $[\text{Ca}^{2+}]$ rises to abnormally high levels. The result would be the increased Ca^{2+} reabsorption and the hypocalciuria characteristic of FHH.

The discovery of CaSR led to the development of a CaSR agonist that mimics Ca^{2+} (a *calcimimetic*). This drug has now come into clinical use for treating patients with parathyroid cancer or hyperparathyroidism secondary to chronic renal disease. Calcimimetics decrease the secretion of PTH and secondarily decrease plasma $[\text{Ca}^{2+}]$.

In bone, PTH can promote net resorption or net deposition

The second major target tissue for PTH is bone, in which PTH promotes both bone resorption and bone synthesis.

Bone Resorption by Indirect Stimulation of Osteoclasts

The net effect of *persistent* increases of PTH on bone is to stimulate bone *resorption*, thus increasing plasma $[\text{Ca}^{2+}]$. Osteoblasts express abundant surface receptors for PTH; osteoclasts do not. Because osteoclasts lack PTH receptors, PTH by itself cannot regulate the coupling between osteoblasts and osteoclasts. Rather, PTH acts on osteoblasts and osteoclast precursors to induce the production of several cytokines that increase both the number and the activity of bone-resorbing osteoclasts. PTH causes osteoblasts to release agents such as M-CSF and stimulates the expression of RANKL, actions that promote the development of osteoclasts (see Fig. 52-4). In addition, PTH and vitamin D stimulate osteoblasts to release interleukin-6 (IL-6), which stimulates existing osteoclasts to resorb bone (see Fig. 52-5).

One of the initial clues that cytokines are important mediators of osteoclastic bone resorption came from observations on patients with multiple myeloma—a malignancy of plasma cells, which are of B-lymphocyte lineage. The tumor cells produce several proteins that activate osteoclasts and enhance bone resorption. These proteins were initially called *osteoclast-activating factors*. We now know that certain lymphocyte-derived proteins strongly activate osteoclastic bone resorption, including RANKL, lymphotoxin, IL-1, and TNF- α .

Bone Resorption by Reduction in Bone Matrix

PTH also changes the behavior of osteoblasts in a manner that can promote net loss of bone matrix. For example, PTH inhibits collagen synthesis by osteoblasts and also promotes the production of proteases

that digest bone matrix. Digestion of matrix is important because osteoclasts do not easily reabsorb bone mineral if the bone has an overlying layer of unmineralized osteoid.

Bone Deposition

Whereas persistent increases in PTH favor net resorption, *intermittent* increases in plasma [PTH] have predominately bone-synthetic effects, inducing higher rates of bone formation and mineral apposition. PTH promotes bone synthesis by three mechanisms. First, PTH promotes bone synthesis *directly* by activating Ca^{2+} channels in osteocytes, a process that leads to a net transfer of Ca^{2+} from bone fluid to the osteocyte. The osteocyte then transfers this Ca^{2+} via gap junctions to the osteoblasts at the bone surface. This process is called *osteocytic osteolysis*. The osteoblasts then pump this Ca^{2+} into the extracellular matrix, which contributes to mineralization. Second, PTH decreases the production of sclerostin by osteocytes. Lower levels of plasma sclerostin and dickkopf1 promote osteoblastic differentiation and also inhibit osteoblastic apoptosis. Third, PTH stimulates bone synthesis *indirectly* in that osteoclastic bone resorption leads to the release of growth factors trapped within the matrix; these include insulin-like growth factor 1 (IGF-1), IGF-2, fibroblast growth factor 2 (FGF2), and transforming growth factor- β . Finally, PTH stimulates osteoblasts to produce OPG and thereby interfere with RANKL activation of osteoclasts.

The PTH 1-34 peptide is now available as a pharmacological agent for the treatment of osteoporosis. Clinical data show marked increases in bone density—particularly within the axial skeleton—in response to injections of PTH 1-34 once or twice daily. The effects on trabecular bone are striking, with less positive responses seen in cortical bone—particularly in the limbs.

Vitamin D

The active form of vitamin D is its 1,25-dihydroxy metabolite

By the 1920s, investigators recognized that dietary deficiency of a fat-soluble vitamin was responsible for the childhood disease **rickets** (Box 52-2). This disorder is characterized clinically by hypocalcemia and multiple skeletal abnormalities. Dietary replacement of vitamin D corrects this disorder and has led to the practice of adding vitamin D to milk, bread, and other products. This practice has greatly reduced the prevalence of this previously common disorder.

Box 52-2

Rickets and Osteomalacia

Deficiency of vitamin D in *children* produces the disease **rickets**, in which bone has abnormal amounts of unmineralized osteoid. Both cortical and trabecular bone are involved. The lack of mineralization diminishes bone rigidity and leads to a characteristic *bowing* of the long bones of the legs of affected children. In *adults*, vitamin D deficiency produces a disorder called **osteomalacia**. Microscopically, the bone looks very much the same in adult and childhood vitamin D deficiency. However, because the longitudinal growth of the long bones has been completed in adults, bowing of weight-bearing bones does not occur. Instead, the increased unmineralized osteoid content of bone causes a decline in bone strength. Affected individuals are more prone to the development of bone fractures. These fractures may be very small and difficult to see radiographically. As more and more of the bone surface is covered by osteoid and as recruitment of new osteoclasts is diminished, osteoclastic bone resorption is impaired and hypocalcemia develops. Hypocalcemia causes nerves to become more sensitive to depolarization. In sensory nerves, this effect leads to sensations of numbness, tingling, or burning; in motor nerves, it leads to increased spontaneous contractions, or tetany.

Although rickets and osteomalacia are very uncommon in developed countries because of vitamin D supplementation, milder degrees of vitamin D deficiency are recognized increasingly in the elderly population, in whom milk consumption and sunlight exposure are frequently inadequate. The resulting fall in plasma $[Ca^{2+}]$ can lead to mild secondary hyperparathyroidism. Such *continuous* elevations of PTH can lead to further bone resorption and worsening osteoporosis.

Rickets or osteomalacia also can occur with impaired ability of the kidney to 1-hydroxylate the 25-hydroxyvitamin D previously synthesized in the liver. An acquired impairment is seen in many patients with chronic renal failure, in which the activity of 1α -hydroxylase is reduced. The genetic form of the 1α -hydroxylase deficiency is a rare autosomal recessive disorder. Either form is called vitamin D–dependent rickets because it can be successfully treated with either 1,25-dihydroxyvitamin D or doses of dietary vitamin D₂ or D₃ that are higher (by ~10- to 100-fold) than the 400 U/day used to prevent nutritional rickets.

Vitamin D exists in the body in two forms, vitamin D₃ and vitamin D₂ (Fig. 52-9). **N52-2 Vitamin D₃** can be synthesized from the 7-dehydrocholesterol that is present in the skin, provided sufficient ultraviolet light is absorbed. This observation explains why nutritional rickets was more prevalent in northern

countries, where people have reduced skin exposure to sunlight. Vitamin D₃ is also available from several natural sources, including cod and halibut liver, eggs, and fortified milk. **Vitamin D₂** is obtained only from the diet, largely from vegetables. Vitamin D₃ (see [Fig. 52-9A](#)) and vitamin D₂ (see [Fig. 52-9B](#)) differ only in the side chains of ring D. The side chain in vitamin D₃ (cholecalciferol) is characteristic of cholesterol, whereas that of vitamin D₂ (ergocalciferol) is characteristic of plant sterols.

A METABOLISM OF VITAMIN D₃

B VITAMIN D₂

N52-2

Metabolism of Vitamin D₃ and D₂*Contributed by Eugene Barrett*Vitamin D₃

Vitamin D₃—or cholecalciferol—actually can be thought of as a hormone because it can arise entirely from the metabolism of an endogenous source (7-dehydroxycholesterol) and because it acts through a specific receptor. Ultraviolet light triggers the cleavage in the skin of the B ring of 7-dehydroxycholesterol, creating an unstable intermediate that—over a period of about 2 days—rearranges to form cholecalciferol (vitamin D₃). Vitamin D₃ can also come from animal sources in the diet. However, vitamin D₃ is not active as such. In the liver, a P-450 enzyme hydroxylates vitamin D₃ at the 25 position, creating 25-hydroxyvitamin D₃. Then in the proximal-tubule cells of the kidney, another P-450 enzyme hydroxylates 25-hydroxyvitamin D₃ at position 1, forming 1,25-dihydroxyvitamin D₃, the active form of vitamin D₃.

Vitamin D₂

Vitamin D₂, which comes exclusively from dietary *plant* sources, differs from vitamin D₃ only in the side chain off carbon 17 in ring D. Like vitamin D₃, vitamin D₂ undergoes 25-hydroxylation in the liver and 1-hydroxylation in the kidney. Also like vitamin D₃, the 1,25-dihydroxylated metabolite of vitamin D₂ is about 1000-fold more active than the 25-monohydroxylated form.

Vitamin D (i.e., either D₂ or D₃) is fat soluble, but water insoluble. Its absorption from the intestine depends on its solubilization by bile salts (see [p. 933](#)). In the circulation, vitamin D is found either solubilized with chylomicrons (see [pp. 932–933](#)) or associated with a **vitamin D-binding protein**. Most of the body stores of vitamin D are located in body fat. The body's pools of vitamin D are large, and only 1% to 2% of the body's vitamin D is turned over each day. Therefore, several years of very low dietary intake (as well as diminished endogenous synthesis) are required before the endogenous pools are depleted and deficiency develops.

The principal active form of vitamin D is not vitamin D₂ or D₃, but rather a dihydroxylated metabolite of either. Hydroxylation of vitamin D proceeds in two steps (see [Fig. 52-9A](#)). When circulating levels of 25-hydroxyvitamin D are low, adipocytes release vitamin D into the blood plasma. A cytochrome P-450 mixed-function oxidase, principally in the liver, creates the first hydroxyl group at carbon 25. The 25-hydroxylation of vitamin D does not appear to be highly regulated, but rather it depends on the availability of vitamin D₂ or D₃. The second hydroxylation reaction occurs in the renal proximal tubule under the tight control of PTH, vitamin D itself, and FGF23 (see [p. 787](#)). PTH stimulates this 1-hydroxylation, whereas FGF23 and 1,25-dihydroxyvitamin D (the reaction product) both inhibit the process (see [Fig. 52-8](#)).

In addition to vitamins D₂ and D₃ and their respective 25-hydroxy and 1,25-dihydroxy metabolites, >15 other metabolites of vitamin D have been identified in plasma. However, the specific physiological

function of these metabolites, if any, is unclear.

Although considered a vitamin because of its dietary requirement, vitamin D can also be considered a hormone, both because it is endogenously synthesized and because even the fraction that arises from the diet must be metabolized to a biologically active form.

Vitamin D and its metabolites, like the steroid hormones, circulate bound to a globulin, in this case a 52-kDa vitamin D-binding protein. This binding protein appears particularly important for carriage of vitamins D₂ and D₃ in plasma because they are less soluble than their hydroxylated metabolites. Vitamin D and its metabolites arrive at target tissues and, once in the cytosol, associate with the VDR, a transcription factor that is in the family of nuclear receptors (see pp. 71–72). Like the thyroid hormone receptor (see Table 3-6), VDR forms a heterodimer with RXR. The VDR specifically recognizes the 1,25-dihydroxyvitamin D with an affinity that is three orders of magnitude higher than that for 25-hydroxyvitamin D. However, because the circulating concentration of 25-hydroxyvitamin D is ~1000-fold higher than that of 1,25-dihydroxyvitamin D, both species probably contribute to the biological actions of the hormone.

The biological actions of 1,25-dihydroxyvitamin D appear to be expressed principally, but not exclusively, via regulation of the transcription of a variety of proteins. The VDR/RXR complex associates with a regulatory site in the promoter region of the genes coding for certain vitamin D-regulated proteins. Thus, the occupied VDR alters the synthesis of these vitamin D-dependent proteins. An example is PTH, which stimulates the formation of 1,25-dihydroxyvitamin D. The 5' regulatory region of the PTH gene has a VDR consensus sequence; when occupied by the VDR complex, this element *diminishes* transcription of the PTH gene.

Vitamin D, by acting on the small intestine and kidney, raises plasma [Ca²⁺] and thus promotes bone mineralization

The actions of vitamin D can be grouped into two categories: actions on classic target tissues involved in regulating body mineral and skeletal homeostasis, and a more general action that regulates cell growth. The actions of vitamin D on the small intestine, bone, and kidney serve to prevent any abnormal decline or rise in plasma [Ca²⁺].

Small Intestine

In the duodenum, 1,25-dihydroxyvitamin D increases the production of several proteins that enhance Ca²⁺ absorption. Figure 52-10A summarizes the intestinal absorption of Ca²⁺, which moves from the intestinal lumen to the blood by both paracellular and transcellular routes (see p. 938). In the paracellular route, which occurs throughout the small intestine, Ca²⁺ moves *passively* from the lumen to the blood; 1,25-dihydroxyvitamin D does *not* regulate this pathway. The transcellular route, which occurs only in the duodenum, involves three steps. First, Ca²⁺ enters the cell across the apical membrane via TRPV6 Ca²⁺ channels (see p. 938). Second, the entering Ca²⁺ binds to several high-affinity binding proteins, particularly **calbindin**. These proteins, together with the exchangeable Ca²⁺ pools in the RER and mitochondria, effectively buffer the cytosolic Ca²⁺ and maintain a favorable gradient for Ca²⁺ entry across the apical membrane of the enterocyte. Thus, the intestinal cell solves the problem of absorbing relatively large amounts of Ca²⁺ while keeping its free cytosolic [Ca²⁺] low. Third, the enterocyte extrudes Ca²⁺ across the basolateral membrane by means of both a Ca pump and an Na-Ca exchanger.

A INTESTINAL Ca^{2+} ABSORPTION

B INTESTINAL PHOSPHATE ABSORPTION

FIGURE 52-10 Intestinal absorption of Ca^{2+} and phosphate. **A**, The small intestine absorbs Ca^{2+} by two

mechanisms. Passive paracellular absorption of Ca^{2+} occurs throughout the small intestine. This pathway is the predominant one but is not under the control of vitamin D. The second mechanism—active transcellular absorption of Ca^{2+} —occurs only in the duodenum. Ca^{2+} enters the cell across the apical membrane via TRPV6 Ca^{2+} channels. Inside the cell, the Ca^{2+} is buffered by binding proteins, such as calbindin, and is also taken up into intracellular organelles, such as the ER. The enterocyte then extrudes Ca^{2+} across the basolateral membrane via a Ca pump and an Na-Ca exchanger. Thus, the net effect is Ca^{2+} absorption. The active form of vitamin D—1,25-dihydroxyvitamin D—stimulates all three steps of transcellular Ca^{2+} absorption. **B**, Inorganic phosphate (P_i) enters the enterocyte across the apical membrane via an Na/P_i cotransporter (NaPi). Once inside the cell, the P_i is extruded across the basolateral membrane. Thus, the net effect is P_i absorption.

Vitamin D promotes intestinal Ca^{2+} absorption primarily by genomic effects that involve induction of the synthesis of epithelial Ca^{2+} channels and pumps and Ca^{2+} -binding proteins, as well as other proteins (e.g., alkaline phosphatase).

The effect of PTH to stimulate intestinal Ca^{2+} absorption is thought to be entirely indirect and mediated by PTH's action to increase the renal formation of 1,25-dihydroxyvitamin D (see Fig. 52-8), which then enhances intestinal Ca^{2+} absorption.

Vitamin D also stimulates phosphate absorption by the small intestine (see Fig. 52-10B). The initial step—as in the renal proximal tubule (see pp. 785–786)—is mediated by the NaPi cotransporter and appears to be rate limiting for transepithelial transport and subsequent delivery of phosphate to the circulation. 1,25-Dihydroxyvitamin D stimulates the synthesis of this transport protein and thus promotes phosphate entry into the mucosal cell.

Kidney

In the kidney, vitamin D appears to act synergistically with PTH to enhance Ca^{2+} *reabsorption* in the DCT (see p. 789). High-affinity Ca^{2+} -binding proteins, similar to those found in the intestinal mucosa, have been specifically localized to this region of the kidney. It appears that PTH is a more potent regulator of Ca^{2+} reabsorption than is vitamin D (see Fig. 52-8). Indeed, parathyroidectomy increases the fractional excretion of Ca^{2+} , and even high doses of vitamin D cannot correct this effect. In addition, as in the intestine, vitamin D promotes phosphate *reabsorption* in the kidney. The effects of vitamin D on phosphate reabsorption, like its effects on Ca^{2+} , are less dramatic than those of PTH. Finally, 1,25-dihydroxyvitamin D directly inhibits the *1-hydroxylation* of vitamin D, establishing a negative-feedback loop.

Bone

The actions of vitamin D on bone are complex and are the result of both indirect and direct actions. The overall effect of vitamin D replacement in animals with diet-induced vitamin D deficiency is to increase the flux of Ca^{2+} into bone. However, as we see below, the major effects of vitamin D on bone are *indirect*: the action of vitamin D on both the small intestine and the kidneys makes more Ca^{2+} available to mineralize previously unmineralized osteoid. The *direct* effect of vitamin D on bone is via both osteoblasts and osteoclast precursor cells, both of which have VDRs. Vitamin D increases both osteoblastic and osteoclastic differentiation; when these activities are balanced, vitamin D simply increases bone turnover. However, when vitamin D is present in excess, it favors bone resorption because osteoblasts produce certain proteins with matrix-destroying properties (e.g., alkaline phosphatase, collagenase, plasminogen activator) as well as proteins that favor osteoclastogenesis (e.g., RANKL rather than OPG; see Fig. 52-4). Thus, because vitamin D can directly increase the number of mature

osteoclasts, supplying vitamin D to bone obtained from vitamin D–deficient animals in in vitro experiments mobilizes Ca^{2+} from bone into the medium. Additional evidence that vitamin D directly promotes bone resorption comes from experiments on rachitic animals who are maintained on a calcium-deficient diet. Treating these animals with vitamin D causes plasma $[\text{Ca}^{2+}]$ to rise, an indication of net bone resorption. At the same time, however, the elevated plasma $[\text{Ca}^{2+}]$ promotes the mineralization of previously unmineralized osteoid—at the expense of bone resorption from other sites.

In summary, the antirachitic action of vitamin D is both indirect and direct. By enhancing the absorption of Ca^{2+} and phosphate from the intestine and by enhancing the reabsorption of Ca^{2+} and phosphate from the renal tubules, vitamin D raises the concentrations of both Ca^{2+} and phosphate in the blood and ECF. This increase in the $\text{Ca} \times \text{PO}_4$ ion product, along with more differentiated osteoblasts, results—*indirectly*—in net bone mineralization. On the other hand, when vitamin D is in excess, the *direct* effect of vitamin D predominates, increasing bone mobilization.

Calcium ingestion lowers—whereas phosphate ingestion raises—levels of both PTH and 1,25-dihydroxyvitamin D

Calcium Ingestion

When an individual ingests a meal containing calcium, the ensuing rise in plasma $[\text{Ca}^{2+}]$ inhibits PTH secretion. The decline in PTH causes a decrease in the resorption of $\text{Ca}^{\text{protein } 2+}$ and phosphorus from bone, thus limiting the postprandial increase in plasma Ca^{2+} and phosphate levels. In addition, the decrease in PTH diminishes Ca^{2+} reabsorption in the kidney and thus facilitates a calciuric response. If dietary Ca^{2+} intake remains high, the lower PTH will result in decreased 1-hydroxylation of 25-hydroxyvitamin D, which will eventually diminish the fractional absorption of Ca^{2+} from the GI tract.

If dietary Ca^{2+} intake is deficient, the body will attempt to restore Ca^{2+} toward normal by increasing plasma [PTH]. This response will help to mobilize Ca^{2+} from bone, to promote renal Ca^{2+} retention, and, over time, to increase the level of 1,25-dihydroxyvitamin D, which will enhance gut absorption of Ca^{2+} .

Phosphate Ingestion

If one ingests phosphorus much in excess of Ca^{2+} , the rise in plasma [phosphate] will increase the plasma $\text{Ca} \times \text{PO}_4$ ion product, thereby promoting deposition of mineral in bone and lowering plasma $[\text{Ca}^{2+}]$. The low plasma $[\text{Ca}^{2+}]$, in turn, increases PTH secretion, provoking a phosphaturia and thus a fall of plasma [phosphate] toward normal. In addition, the PTH mobilizes Ca^{2+} and phosphate from bone by its action. Over longer periods, the action of PTH to modulate the 1-hydroxylation of 25-hydroxyvitamin D plays an increasingly important role in defending the plasma $[\text{Ca}^{2+}]$ by increasing intestinal Ca^{2+} absorption.

The plasma [phosphate] is thus largely maintained *indirectly* through the actions of PTH in response to $[\text{Ca}^{2+}]$. Another regulator of plasma [phosphate] is the protein **fibroblast growth factor 23 (FGF23; see p. 787)**, secreted by osteocytes and osteoblasts in response to high plasma [phosphate]. FGF23 acts on the intestine to decrease phosphate absorption and on the kidney to limit phosphate reabsorption. Excessive FGF23 production causes an autosomal form of hereditary hypophosphatemia rickets by impairing bone mineralization, secondary to phosphate deficiency. Conversely, FGF23 deficiency can lead to hyperphosphatemia and ectopic calcification.

Calcitonin and Other Hormones

Calcitonin inhibits osteoclasts, but its effects are transitory

Calcitonin is a 32–amino-acid peptide hormone made by the clear or C cells of the thyroid gland. C cells (also called parafollicular cells) are derived from neural crest cells of the fifth branchial pouch, which in humans migrate into the evolving thyroid gland. Although it is located within the thyroid, calcitonin's major, if not sole, biological action relates to the regulation of mineral metabolism and bone turnover. The incidental nature of its relationship with the major functions of the thyroid is emphasized by the finding that, in many nonhuman species, C cells are found in a body called the ultimobranchial gland and not in the thyroid at all.

Calcitonin is synthesized in the secretory pathway (see [pp. 34–35](#)) by post-translational processing of a large procalcitonin. As illustrated in [Figure 52-11](#), alternative splicing of the calcitonin gene product gives rise to several biologically active peptides. In the C cells, calcitonin is the only peptide made in biologically significant amounts. Within the central nervous system, calcitonin gene–related peptide (CGRP) is the principal gene product, and it appears to act as a neurotransmitter in peptidergic neurons (see [Table 13-1](#)). Calcitonin is stored in secretory vesicles within the C cells, and its release is triggered by a rise in the extracellular $[\text{Ca}^{2+}]$ above normal. Conversely, a lowering of the extracellular $[\text{Ca}^{2+}]$ diminishes calcitonin secretion. The threshold $[\text{Ca}^{2+}]$ for enhancing calcitonin secretion is in the midphysiological range. In principle, this secretory profile would leave calcitonin well poised to regulate body Ca^{2+} homeostasis.

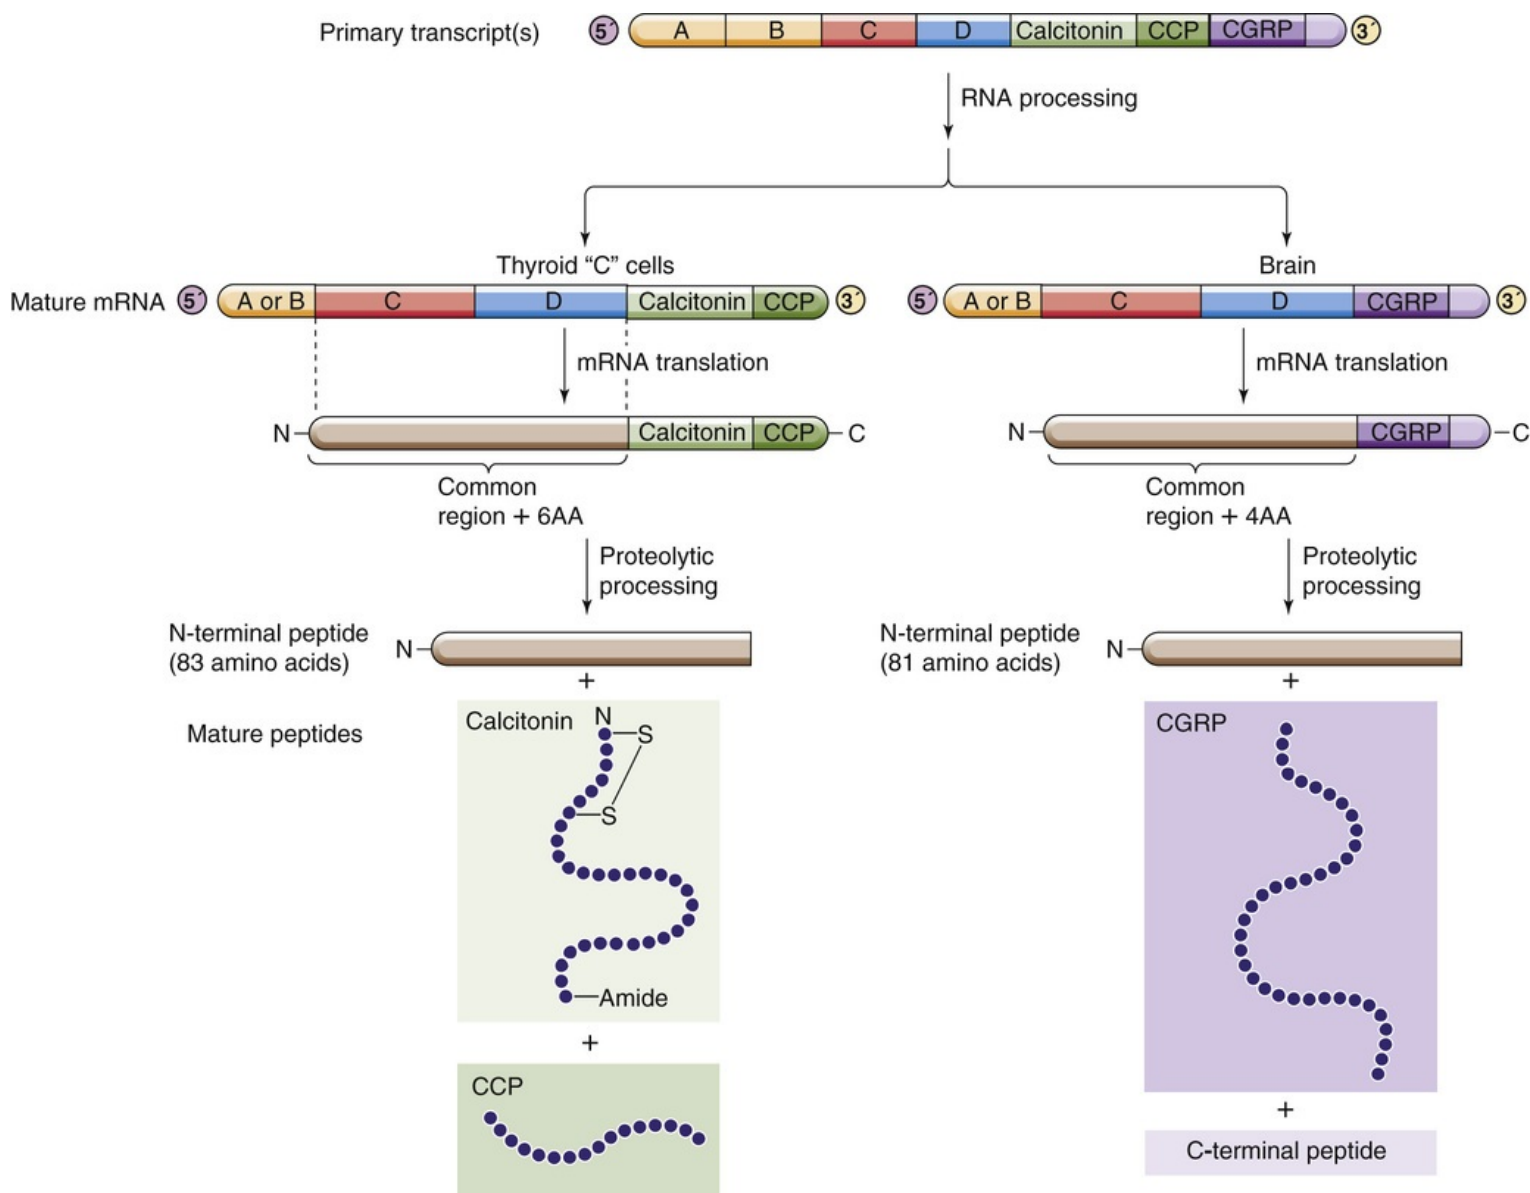

FIGURE 52-11 Synthesis of calcitonin and CGRP. A common primary RNA transcript gives rise to both calcitonin and CGRP. In the thyroid gland, C cells produce a mature mRNA that they translate to procalcitonin. They then process this precursor to produce an N-terminal peptide, calcitonin (a 32–amino-acid peptide), and calcitonin C-terminal peptide (CCP). In the brain, neurons produce a different mature mRNA and a different “pro” hormone. They process the peptide to produce an N-terminal peptide, CGRP, and a C-terminal peptide. AA, amino acids.

The precise role of calcitonin in body Ca^{2+} homeostasis has been difficult to define. This difficulty was first apparent from the simple clinical observation that, after complete thyroidectomy with removal of all calcitonin-secreting tissue, plasma $[\text{Ca}^{2+}]$ remains normal (provided the parathyroid glands are not injured). Conversely, patients with a rare calcitonin-secreting tumor of the C cells frequently have plasma calcitonin concentrations that are 50 to 100 times normal, yet they maintain normal plasma levels of Ca^{2+} , vitamin D, and PTH. Nevertheless, several lines of evidence suggest that calcitonin does have biologically important actions. First, although calcitonin appears to have a minimal role in the minute-to-minute regulation of plasma $[\text{Ca}^{2+}]$ in humans, it does play an important role in many nonmammalian species. This role is particularly clear for teleost fish. The $[\text{Ca}^{2+}]$ in seawater (and therefore in food) is relatively high, and calcitonin, secreted in response to a rise in plasma $[\text{Ca}^{2+}]$, decreases bone resorption, thus returning the plasma $[\text{Ca}^{2+}]$ toward normal. Salmon calcitonin, which differs from human calcitonin in 14 of its 32 amino-acid residues, is roughly 10-fold more potent on a molar basis in inhibiting human osteoclast function than is the human hormone.

The second line of evidence that calcitonin may have biologically important actions is the presence of calcitonin receptors. Like PTH receptors, the **calcitonin receptor** is a GPCR that, depending on the target cell, may activate either adenylyl cyclase (see [p. 53](#)) or phospholipase C (see [pp. 53–56](#)). Within bone, the osteoclast—which lacks PTH receptors—appears to be the principal target of calcitonin. Indeed, the presence of calcitonin receptors may be one of the most reliable methods of identifying osteoclasts. In the osteoclast, calcitonin raises $[cAMP]_i$, which activates effectors such as protein kinases. Calcitonin inhibits the resorptive activity of the osteoclast, thus slowing the rate of bone turnover. It also diminishes osteocytic osteolysis, and this action—together with its effect on the osteoclast—is responsible for the hypocalcemic effect after the acute administration of pharmacological doses of calcitonin. The hypocalcemic action of calcitonin is particularly effective in circumstances in which bone turnover is accelerated, as occurs in rapidly growing young animals and in humans with hyperparathyroidism. The antiosteoclastic activity of calcitonin is also useful in treating Paget disease of bone ([Box 52-3](#)). However, within hours of exposure to high concentrations of calcitonin, osteoclasts desensitize. This “escape” from the hypocalcemic effect of calcitonin has limited the use of calcitonin in the clinical treatment of hypercalcemia. The transitory nature of the action of calcitonin appears to result, in part, from rapid downregulation of calcitonin receptors.

Box 52-3

Osteoporosis

Approximately 25 million Americans, mostly postmenopausal women, are affected by **osteoporosis**, and every year between 1 and 2 million of these individuals experience a fracture related to osteoporosis. The cost in economic and human terms is immense. Hip fractures are responsible for much of the morbidity associated with osteoporosis, but even more concerning is the observation that as many as 20% of women with osteoporotic hip fracture will die within 1 year of their fracture.

The major risk factor for osteoporosis is the postmenopausal decline in estrogen levels in aging women. Rarely, other endocrine disorders such as hyperthyroidism, hyperparathyroidism, androgen deficiency, and Cushing disease (hypercortisolism) are responsible. Other risk factors include inadequate dietary Ca^{2+} intake, alcoholism, cigarette smoking, and a sedentary lifestyle.

Strategies to prevent the development of osteoporosis begin in the premenopausal years. High Ca^{2+} intake and a consistent program of weight-bearing exercises are widely recommended.

Pharmacological agents are now available for preventing or at least retarding the development of osteoporosis and for treating the disease once it has become established. These agents can be broadly classified into two groups: antiresorptive drugs and anabolic drugs that stimulate bone formation.

Among the antiresorptive drugs, **estrogen** is the most widely used. It is most effective when started at the onset of menopause, although it may offer benefits even in patients who are 20 or more years past menopause. However, possible increased risk of breast and endometrial cancer from postmenopausal estrogen limit use of this treatment. Another class of drugs—the **bisphosphonates**—are effective inhibitors of bone resorption and have become a mainstay for the treatment of osteoporosis in both men and women. The newer bisphosphonates, which have a much greater potency, can be given either orally or as a once-a-year intravenous treatment.

Agents that can stimulate bone formation include **vitamin D**—often given as 1,25-dihydroxyvitamin D (calcitriol)—which is combined with Ca^{2+} therapy to increase the fractional absorption of Ca^{2+} and to stimulate the activity of osteoblasts. **PTH** is also now available as an injectable treatment for

osteoporosis (see p. 1063), and when given intermittently, it potently stimulates osteoblast formation and increases bone mass. PTH also appears to decrease the rate of vertebral fractures. As mentioned on pages 1057–1058, denosumab—a monoclonal antibody to RANKL—is another antiresorptive therapy. It is also being used in some cases of bone resorption associated with metastatic disease. Now in clinical trials are agents that promote Wnt signaling by interfering with either sclerostin or dickkopf1; the hope is that these agents will have both prosynthetic and antiresorptive actions.

Calcitonin and the bisphosphonates have also been used successfully to treat **Paget disease of bone**, a disorder characterized by localized regions of bone resorption and reactive sclerosis. The level of bone turnover at sites of active Paget disease can be extremely high. Although it remains asymptomatic in many individuals, the disease can cause pain, deformity, fractures, and (if bony overgrowth occurs in the region of the eighth cranial nerve) vertigo and hearing loss. The cause of Paget disease is not known.

In the kidney, calcitonin, like PTH, causes a mild phosphaturia by inhibiting proximal-tubule phosphate transport. Calcitonin also causes a mild natriuresis and calciuresis. These actions may contribute to the acute hypocalcemic and hypophosphatemic actions of calcitonin. However, these renal effects are of short duration and do not appear to be important in the overall renal handling of Ca^{2+} , phosphate, or Na^{+} .

Sex steroid hormones promote bone deposition, whereas glucocorticoids promote resorption

Although PTH and 1,25-dihydroxyvitamin D are the principal hormones involved in modulating bone turnover, other hormones participate in this process. For example, the sex steroids **testosterone** and **estradiol** are needed for maintaining normal bone mass in males and females, respectively. The decline in estradiol that occurs postmenopausally exposes women to the risk of **osteoporosis**; that is, a decreased mass of both cortical and trabecular bone caused by a decrease in bone matrix (see [Box 52-3](#)). Osteoporosis is less common in men because their skeletal mass tends to be greater throughout adult life and because testosterone levels in men decline slowly with age, unlike the abrupt menopausal decline of estradiol in women.

Glucocorticoids also modulate bone mass. This action is most evident in circumstances of glucocorticoid excess, which leads to osteoporosis, as suggested by the effects of glucocorticoids on the production of OPG (see [pp. 1057–1058](#)) and RANKL (see [p. 1057](#)).

The precise cellular mechanisms that mediate the action of androgens, estrogens, or glucocorticoids on bone have not been well defined. Despite the loss of bone that occurs with androgen or estrogen deficiency or glucocorticoid excess, in each case the coupling of bone synthesis to degradation is *qualitatively* preserved. Synthesis of new bone continues to occur at sites of previous bone resorption, and no excess of unmineralized osteoid is present. Presumably, the decline in bone mass reflects a *quantitative* shift in which the amount of new bone formed at any site is less than what was resorbed. Because this shift occurs at multiple sites, the result is a decline in overall bone mass.

PTHrP, encoded by a gene that is entirely distinct from that for PTH, can cause hypercalcemia in certain malignancies

Unlike PTH, which is synthesized exclusively by the parathyroid gland, a peptide called **PTH-related protein (PTHrP)** is made in many different normal and malignant tissues. The PTH1R receptor (see [p.](#)

1061) in kidney and bone recognizes PTHrP with an affinity similar to that for intact PTH. PTHrP mimics each of the actions of PTH on kidney and bone. Thus, when present in sufficient concentrations, PTHrP causes hypercalcemia. PTHrP exists in three alternatively spliced isoforms of a single gene product. The gene encoding PTHrP is completely distinct from that for PTH. The similar actions of PTHrP and PTH arise from homology within the first 13 amino acids of PTHrP and native PTH. Only weak homology exists between amino acids 14 and 34 (three amino acids are identical), and essentially none beyond amino acid 34. This situation is an unusual example of mimicry among peptides that are structurally quite diverse.

The normal physiological roles of PTHrP are largely in regulating endochondral bone and mammary-gland development. The lactating breast also secretes PTHrP, and this hormone is present in very high concentrations in milk. PTHrP may promote the mobilization of Ca^{2+} from maternal bone during milk production. In nonlactating humans, the plasma PTHrP concentration is very low, and PTHrP does not appear to be involved in the day-to-day regulation of plasma $[\text{Ca}^{2+}]$. It appears likely that under most circumstances, PTHrP acts in a paracrine or autocrine, rather than in an endocrine, regulatory fashion.

Many tumors are capable of manufacturing and secreting PTHrP, among them the following: squamous cell tumors of the lung, head, and neck; renal and bladder carcinomas; adenocarcinomas; and lymphomas. Patients with any of these tumors are subject to severe hypercalcemia of fairly abrupt onset. 🍷N52-3

N52-3

Parathyroid Hormone–Related Protein

Contributed by Emile Boulpaep, Walter Boron

PTHrP was discovered at Yale University as the factor responsible for humeral hypercalcemia of malignancy (HHM). Andrew Stewart, Karl Insogna, Arthur Broadus, and their colleagues first demonstrated that this factor stimulates adenyl cyclase activity. They later showed that this activity was inhibited by PTH antagonists and finally identified the 17-kDa protein.

Sexual Differentiation

Sam Mesiano, Ervin E. Jones

Reproduction is a fundamental process of life. All living organisms must reproduce either asexually (e.g., bacteria) or sexually (e.g., mammals). **Asexual reproduction** is highly efficient and produces large numbers of genetically identical offspring in a relative short amount of time. This strategy, however, is vulnerable to environmental changes because genetic and phenotypic variation between individual progeny is minimal and consequently the probability of producing progeny that have beneficial traits in a hostile environment is relatively low. In contrast, **sexual reproduction** is less efficient but produces progeny with markedly increased genetic and phenotypic variation, which increases the probability of producing individuals with characteristics that may be adaptive to environmental changes. In this context, natural selection favors sexual reproduction, and consequently most extant animals and flowering plants reproduce sexually.

In sexual reproduction a new individual is created by combining the genetic material of two individuals. Sexual reproduction involves the evolution of two sexually dissimilar individuals belonging to the same species, one male and one female, and each equipped with its own specific attributes necessary for its particular contribution to the process of procreation. Each sex produces its own type of sex cell or **gamete**, and the union of male and female gametes generates species-specific progeny. In addition, mechanisms—some simple, some complex—have evolved to ensure the proximity and union of the sex cells, known as **syngamy**. Thus, within each species, the relevant sexual characteristics of each partner have adapted differently to achieve the most efficient union of these progenitor cells. These differences between the sexes of one species are called **sexual dimorphism**. For example, oviparous species such as frogs release their eggs into a liquid medium only when they are in relative proximity to sperm. As effective as this approach is, it also typifies the wastefulness of reproduction among higher species inasmuch as most gametes go unfertilized.

Even among species that normally reproduce sexually, sexual dimorphism is not universal. For example, monoecious (i.e., hermaphroditic) species, such as cestodes and nematodes, have the capacity to produce both sperm and eggs. By definition, the ability to produce just one kind of gamete depends on sexually dimorphic differentiation.

Organisms that reproduce sexually normally have a single pair of **sex chromosomes** that are morphologically distinguishable from other chromosomes, the **autosomes**. Each of the sex chromosomes carries genetic information that determines the primary and secondary sexual characteristics of an individual; that is, whether the individual functions and appears as male or female. It has become abundantly clear that genes determine sexual differentiation and sexual expression and, as a result, mechanisms and patterns of reproduction.

The sex of the gonad is genetically programmed: Will a female gonad (ovary) or a male gonad (testis) develop? Although germ cells of the early embryonic gonad are totipotent, these cells develop into female gametes or **ova** if the gonad becomes an ovary, but they develop into male gametes or **sperm** if the gonad becomes a testis. These two anatomically and functionally distinct gonads determine either “maleness” or “femaleness” and dictate the development of both primary and secondary sexual characteristics.

Endocrine and paracrine modulators that are specific for either the ovary or the testis are primarily responsible for female or male sexual differentiation and behavior and therefore the individual's role in procreation. 🍌N53-1

N53-1

Definitions of Sex and Gender

Contributed by Ervin Jones

Gender—or, more accurately, gender identification—refers to the concept held by the individual (or by those raising the individual) that the individual is male, female, or ambivalent.

Sex refers to biological characteristics that distinguish female from male. The distinction may be made on the basis of chromosomes, gonads, internal and external morphology, and hormonal status.

Genetic Aspects of Sexual Differentiation

Meiosis occurs only in germ cells and gives rise to male and female gametes

Gametes derive from a specialized lineage of embryonic cells—the **germline**—known as **germ cells**. They are the only cells that can divide by mitosis and meiosis and differentiate into sperm or ova. Germ cells are therefore the critical link between generations. The process by which cells decide between becoming somatic cells of the body or germ cells occurs in the early embryo and involves factors and processes that prevent the somatic fate and induce germline differentiation. Studies in experimental model systems are beginning to unravel the complex process of germline determination, which involves germline-specific transcription factors (see [pp. 81–88](#)) and small noncoding RNAs (see [pp. 99–100](#)) and DNA methylation (see [pp. 95–96](#)) to control expression of specific genes. The process by which germ cells develop into either sperm or ova is referred to as gametogenesis and involves **meiosis**.

Except for the gametes, all other nucleated cells in the human body—**somatic cells**—have a **diploid** number ($2N$) of chromosomes. Human diploid cells have 22 autosome pairs consisting of two homologous chromosomes, one contributed by the father and one by the mother. Diploid cells also contain a single pair of sex chromosomes comprising either XX or XY. Each somatic cell in human females has 44 autosomes (i.e., 22 pairs) plus two X chromosomes, and each somatic cell in males has 44 autosomes plus one X and one Y chromosome. The **karyotype** is the total number of chromosomes and the sex chromosome combination, and thus in normal females is designated 46,XX, and in normal males, 46,XY ([Fig. 53-1](#)). Gametes have a **haploid** number (N) of chromosomes and contain either an X or Y sex chromosome.

FIGURE 53-1 Normal human karyotype. The normal human has 22 pairs of autosomal chromosomes (autosomes) as well as a pair of sex chromosomes. Females have two X chromosomes, whereas males have one X and one Y chromosome. 🟡N53-7

N53-7

Karyotype

Contributed by Emile Boulpaep, Walter Boron

The representation in Figure 53-1 is obtained by taking photomicrographs of chromosomes and then rearranging them as shown. The chromosomes are numbered according to size, the largest chromosomes having the smallest number. Pairs of homologous chromosomes are identified on the basis of size, patterns of banding, and the placement of centromeres.

In the case of humans, one generally uses leukocytes (white blood cells) that have been treated with a hypotonic solution to cause swelling and thus help disperse the chromosomes, and with colchicine to arrest mitosis in metaphase. A dye is then applied to visualize the chromosomes better.

Mitosis is the only kind of cell division that occurs in somatic cells. Mitosis results in the formation of two identical daughter cells (Fig. 53-2A), each having the same number of chromosomes (i.e., 46 in humans) and the same DNA content as the original cell. After **interphase**, during which nuclear DNA in

the form of chromatin replicates, mitosis proceeds in a continuum of five phases:

1. **Prophase.** The replicated chromatin condenses into 46 chromosomes that comprise two identical sister chromatids bound together at the centromere.
2. **Metaphase.** The nuclear envelope breaks down, the chromosomes align along the midplane of the cell known as the metaphase plate, and microtubules enter the nuclear space and attach to the centromere of each chromosome.
3. **Anaphase.** The centromeres dissolve and the microtubules pull apart the sister chromatids toward opposite poles of the cell.
4. **Telophase.** A new nuclear membrane envelopes each cluster of chromatids, which decondense back into chromatin.
5. **Cytokinesis.** The cell divides into two genetically identical daughter cells, each containing one of the nuclei.

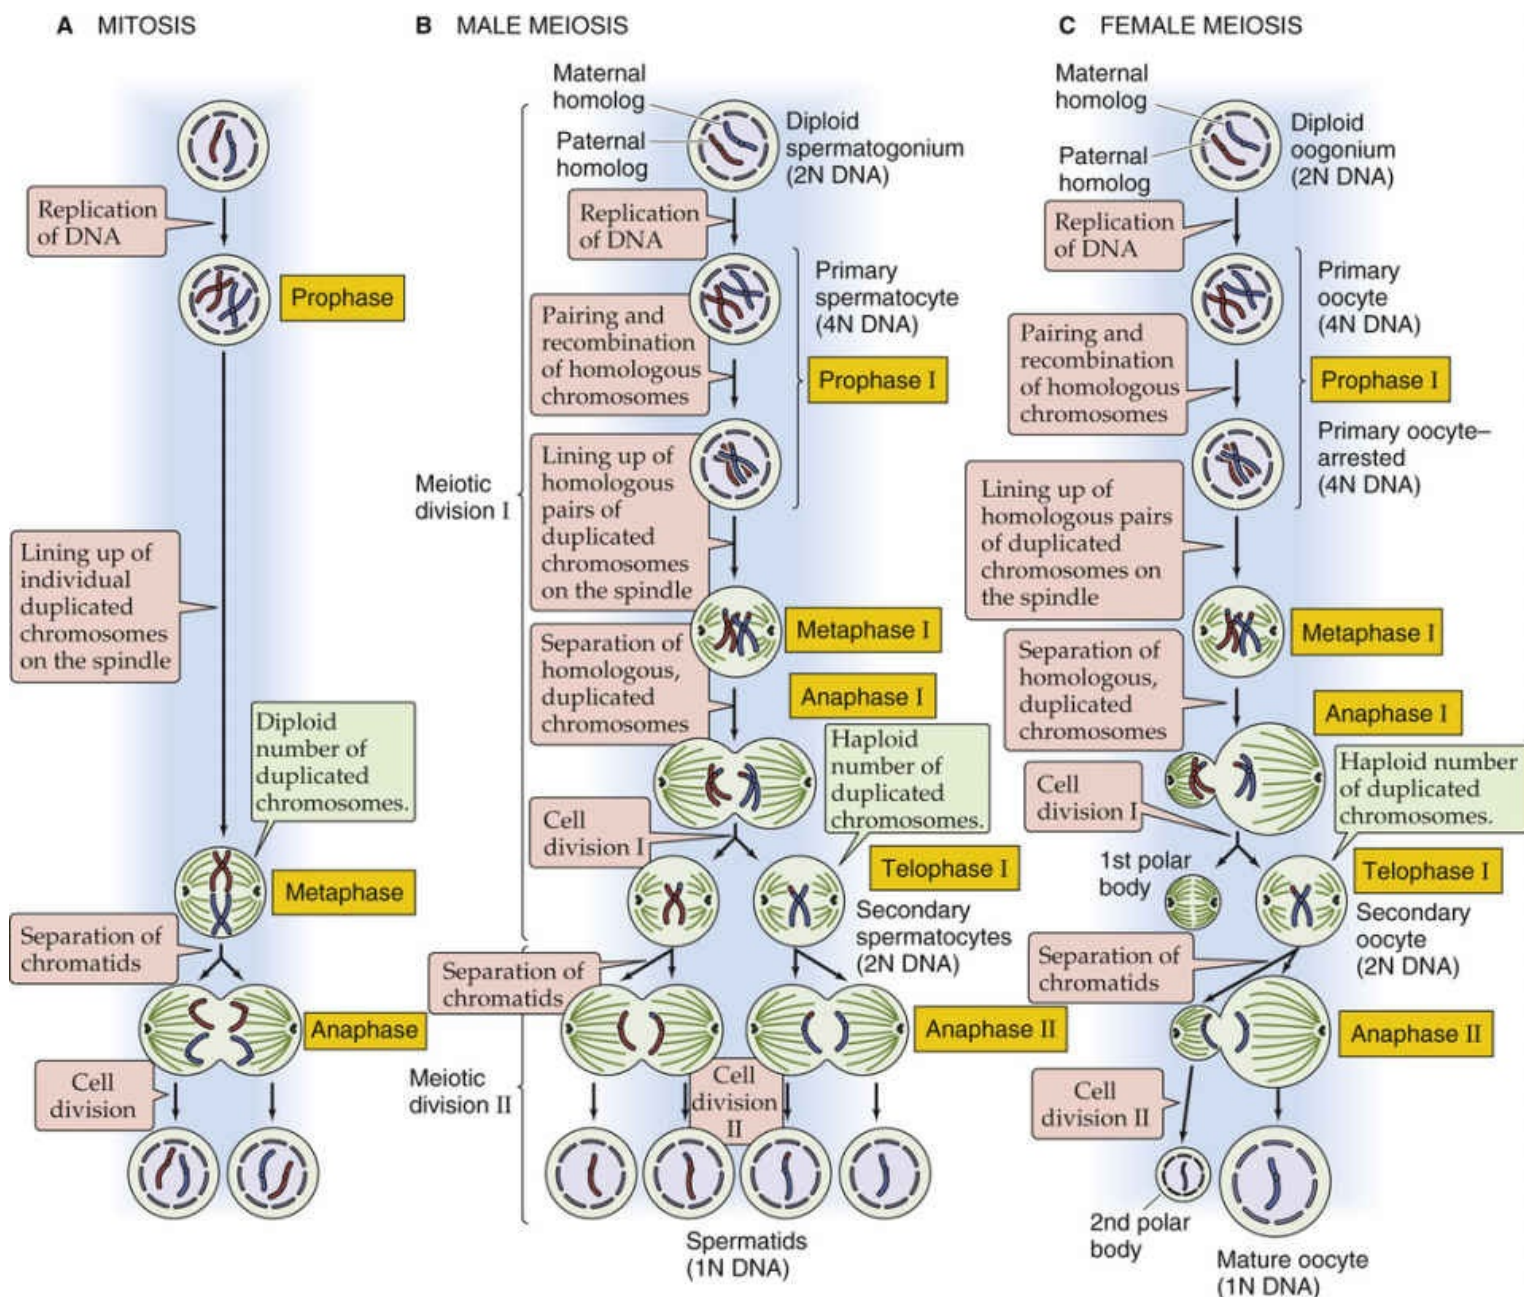

FIGURE 53-2 Mitosis and meiosis. **A**, In mitosis, the two daughter cells are genetically identical to the mother cell. **B**, In male meiosis, the four daughter cells are haploid. Cell division I produces both recombination (i.e., crossing over of genetic material between homologous chromosomes) and reduction to the haploid number of chromosomes. Cell division II separates the chromatids of each chromosome, just as in mitosis. **C**, Female meiosis is similar to male meiosis. A major difference is that instead of producing four mature gametes, female meiosis produces only *one* mature gamete and two polar bodies (or, if the first polar body divides, *three* polar bodies). **N53-8**

N53-8

Meiosis in Males versus Females

Contributed by Emile Boulpaep, Walter Boron

Figure 53-2B in the text shows meiosis in the male, whereas Figure 53-2C shows meiosis in the female.

In both males and females, the **primordial germ cell (PGC)** enters the gonad and undergoes many rounds of mitotic divisions. At some point, both a **spermatogonium** (in the case of males) and an **oogonium** (in the case of females) enter the first of two meiotic divisions (top cell in Fig. 53-2B, C).

In the case of males (see Fig. 53-2B), one **primary spermatocyte** (diploid 4N DNA)—a cell that has

just entered prophase I—ultimately gives rise to two **secondary spermatocytes** (haploid 2N DNA) at the completion of the first meiotic division, and four **spermatids** (haploid 1N DNA) at the completion of the second meiotic division. Thus, one primary spermatocyte yields four mature gametes.

In the case of females (see Fig. 53-2C), one **primary oocyte** (diploid 4N DNA)—a cell that is arrested in prophase I until shortly before ovulation—ultimately gives rise to one **secondary oocyte** (haploid 2N DNA) and one diminutive **first polar body** (haploid 2N DNA) at the completion of the first meiotic division. The polar body is equivalent to one of the two cells at telophase I in Figure 53-2B. In the second meiotic division, which the cell completes at the time of fertilization, the secondary oocyte gives rise to one mature oocyte (haploid 1N DNA) and a diminutive **second polar body** (haploid 1N DNA). Thus, unlike the situation in males, one primary oocyte yields one mature gamete—equivalent to one of the four cells at the bottom of Figure 53-2B.

Note that the *first polar body* sometimes divides during meiosis II, thereby yielding a total of three polar bodies and one oocyte. This is the same amount of DNA produced in spermatogenesis (i.e., four spermatids from one spermatogonium).

Daughter cells produced by mitosis are genetically identical because there is no exchange of genetic material between homologous chromosomes and the sister chromatids of each chromosome split, one going to each daughter cell during anaphase of the single mitotic division.

Meiosis occurs only in germ cells—**spermatogonia** in males and **oogonia** in females—still with a complement of 2N DNA ($N = 23$). Germ cells initially multiply by mitosis and then enter meiosis when they begin to differentiate into sperm (see Fig. 53-2B) or ova (see Fig. 53-2C). **Gametogenesis** reduces the number of chromosomes by half, so that each gamete contains one chromosome from each of the original 23 pairs. This reduction in genetic material from the diploid (2N) to the haploid (N) number involves two divisions referred to as **meiosis I** and **meiosis II**. Because of this halving of the diploid number of chromosomes, meiosis is often referred to as a *reduction division*.

Meiosis is a continuum composed of two phases: the homologous *chromosomes* separate during meiosis I, and the *chromatids* separate during meiosis II. Prior to the start of meiosis I, the chromosomes duplicate so that the cells have 23 pairs of duplicated chromosomes (i.e., each chromosome has two chromatids)—or 4N DNA. During prophase of the first meiotic division, homologous pairs of chromosomes—22 pairs of autosomal chromosomes (autosomes) plus a pair of sex chromosomes—exchange genetic material through a process known as **recombination** or **crossing over** at attachment points known as **chiasmata**. This results in a random, but balanced, exchange of chromatid segments between the homologous maternal and paternal chromatids to produce recombinant homologous chromosomes comprising a mix of maternal and paternal DNA. At the completion of meiosis I, the daughter cells have a haploid number (23) of duplicated, crossed-over chromosomes—or 2N DNA.

During meiosis II, no additional duplication of DNA takes place. The chromatids simply separate so that each daughter receives a haploid number of unduplicated chromosomes—1N DNA. Gametes produced by this process are genetically different from each other and from either parent. The genetic diversity that arises from recombination during meiosis and the combining of gametes from different parental lineages causes significant phenotypic variation within the population, providing an efficient mechanism for adaptation and natural selection.

A major difference between male and female gametogenesis is that one spermatogonium yields four spermatids (see Fig. 53-2B), whereas one oogonium yields one mature oocyte and two or three polar bodies (see Fig. 53-2C). We discuss the details regarding timing and process for spermatogenesis on [page 1100](#), and for oogenesis on [page 1120](#).

Fertilization of an oocyte by an X- or Y-bearing sperm establishes the zygote's genotypic sex

Fusion of two haploid gametes, a mature spermatozoan from the father and a mature oocyte from the mother—referred to as **fertilization**—produces a new diploid cell with 2N DNA, a zygote, that will become a new individual.

The sex chromosomes that the parents contribute to the offspring determine the **genotypic sex** of that individual. The genotypic sex determines the **gonadal sex**, which in turn determines the **phenotypic sex** that becomes fully established at puberty. Thus, sex-determining mechanisms established at fertilization direct all later ontogenetic processes (processes that lead to the development of an organism) involved in male-female differentiation.

Fusion of a sperm and an egg—two haploid germ cells—results in a **zygote**, which is a diploid cell containing 46 chromosomes (see Fig. 53-1): 22 pairs of somatic chromosomes (autosomes) and a single pair of sex chromosomes. In females, these sex chromosomes are both X chromosomes, whereas males have one X and one Y chromosome.

When the karyotypes of normal females and males are compared, two differences are apparent. First, among the 23 pairs of chromosomes in females, 8 pairs—including the 2 X chromosomes—are of similar size, whereas males have only $7\frac{1}{2}$ such pairs. Second, instead of a second X chromosome, males have a Y chromosome that is small and acrocentric (i.e., the centromere is located at one end of the chromosome): this chromosome is the only such chromosome that is not present in females.

In the offspring, 23 of the chromosomes—including 1 of the sex chromosomes—are from the mother, and 23—including the other sex chromosome—come from the father. Thus, the potential offspring has a unique complement of chromosomes differing from those of both the mother and the father. The ovum provided by the mother (XX) always provides an X chromosome. Because the male is the heterogametic (XY) sex, half the spermatozoa are X bearing whereas the other half are Y bearing. Thus, the type of sperm that fertilizes the ovum determines the sex of the zygote. X-bearing sperm produce XX zygotes that develop into females with a 46,XX karyotype, whereas Y-bearing sperm produce XY zygotes that develop into males with a 46,XY karyotype. The genotypic sex of an individual is determined at the time of fertilization. The Y chromosome appears to be the fundamental determinant of sexual development. When a Y chromosome is present, the individual develops as a male; when the Y chromosome is absent, the individual develops as a female. In embryos with abnormal sex chromosome complexes, the number of X chromosomes is apparently of little significance.

Genotypic sex determines differentiation of the indifferent gonad into either an ovary or a testis

The **indifferent gonad** is composed of an outer cortex and an inner medulla. In embryos with an XY sex chromosome complement (i.e., 46,XY), the medulla differentiates into a testis and the cortex regresses. On the other hand, in embryos with an XX sex chromosome complement (i.e., 46,XX), the cortex develops into an ovary and the medulla regresses. Thus, the Y chromosome exerts a powerful testis-determining effect on the indifferent gonad. In the absence of a Y chromosome, the indifferent gonad develops into an ovary.

Interestingly, two X chromosomes are necessary for normal ovarian development. In individuals with the karyotype 45,XO—**Turner syndrome**—the ovaries fail to develop fully and appear as streaks on the

pelvic sidewall ([Box 53-1](#)). Even the absence of only some genetic material from one X chromosome in XX individuals (e.g., due to chromosome breakage or deletion) may cause abnormal gonadal differentiation. However, a complete Y chromosome is necessary for development of the testes. Indeed, individuals with the karyotype 47,XXY—**Klinefelter syndrome**—are not phenotypic females (based on the presence of two X chromosomes) but *males*. Taken together, the data on 45,XO and 47,XXY individuals tell us that the absence of a Y chromosome causes female phenotypic development.

Box 53-1

Gonadal Dysgenesis

The best-known example of gonadal dysgenesis is a syndrome referred to as **Turner syndrome**, a disorder of the female sex characterized by short stature, primary amenorrhea, sexual infantilism, and certain other congenital abnormalities. Cells in these individuals have a 45,XO karyotype (i.e., they lack one of the X chromosomes). The gonads of individuals with Turner syndrome appear as firm, flat, glistening streaks (referred to as streak gonads) lying below the fallopian tubes with no evidence of either germinal or secretory elements. Instead, they are largely composed of connective tissue arranged in whorls suggestive of ovarian stroma. Individuals with Turner syndrome have normal female differentiation of both the internal and external genitalia, although these genitalia are usually small and immature.

Turner syndrome can also be caused by **partial deletion of the X chromosome**, particularly if the entire short arm of the X chromosome is missing, or by formation of an **X-chromosome ring** that develops as a result of a deletion and subsequent joining of the two free ends of the chromosome.

In at least half of affected individuals, Turner syndrome is caused by the total absence of one X chromosome. In others, the lesion is structural (i.e., partial deletion or ring chromosome). In at least a third of cases, the genetic lesion appears as part of a mosaicism; that is, *some* of the cells carry the aberrant or absent chromosome, whereas the rest are normal.

We have just seen that the absence of a Y chromosome and the presence of two complete X chromosomes lead to normal ovarian development. Why? The X chromosome is far larger than the Y chromosome (see [Fig. 53-1](#)) and contains nearly 10% of the human genome compared to <100 genes on the Y chromosome. Thus, the large number of X-linked diseases—affecting such processes as blood clotting and color vision—is hardly surprising. Compared with males, females have a double dose of X-chromosome genes. To avoid an overdosage of X-derived gene products, each somatic 46,XX cell at the blastocyst stage separately and randomly inactivates either the maternal or paternal X chromosome in a process called **lyonization**. Once inactivated, that X chromosome remains inactivated for the life of the cell and all of its descendants. The inactivated X chromosome is visible at interphase as a small dark dot of condensed chromatin in the nucleus known as the **Barr body**. Presence of a Barr body can be used to determine the genotypic sex of a cell. If one X chromosome is normally inactivated in females, then why are two X chromosomes necessary for normal ovarian development, as evidenced by the deficiencies in 45,XO individuals? The answer is that many genes on the inactivated X chromosome somehow are not silenced and are necessary for normal ovarian development.

The testis-determining gene is located on the Y chromosome

With rare exceptions (see below), a Y chromosome ([Fig. 53-3A](#)) is necessary for normal testicular

development. Thus, it stands to reason that the gene that determines organogenesis of the testis is normally located on the Y chromosome. This so-called **testis-determining factor (TDF)** has been mapped to the short arm of the Y chromosome and indeed turns out to be a single gene called *SRY* (for *sex-determining region Y*). The ***SRY* gene** encodes a transcription factor that belongs to the high-mobility group (HMG) superfamily of transcription factors. The family to which *SRY* belongs is evolutionarily ancient. One portion of the *SRY* protein, the 80–amino-acid HMG box, which actually binds to the DNA—is highly conserved among members of the family.

FIGURE 53-3 Location of the testis-determining region of the Y chromosome and an example of translocation. **A**, The Y chromosome is much smaller than the X chromosome. Giemsa staining of the chromosome results in alternating light and dark bands, some of which are shown here. The short or “p” arm of the Y chromosome is located above the centromere, whereas the long or “q” arm is located below. The numbers to the left of the chromosome indicate the position of bands. The *TDF* is the *SRY* gene. **B**, Crossing-over events between normal X and Y chromosomes of the father can generate an X chromatid that contains a substantial portion of the *TDF* region and a Y chromatid that lacks its *TDF*. The figure shows both an equal and an unequal recombination event. If a sperm cell bearing an X chromosome with a translocated *TDF* fertilizes an ovum, the result is a male with a 46,XX karyotype, because one of the X chromosomes contains the *TDF*. Conversely, if the sperm cell carries a Y chromosome lacking its *TDF*, the result can be a 46,XY individual that appears to be female.

Rarely, the TDF may also be found translocated on other chromosomes. One example is a 46,XX male

(see Fig. 53-3B), an individual whose sex chromosome complement is XX but whose phenotype is male. During normal male meiosis, human X and Y chromosomes pair and recombine at the distal end of their short arms. It appears that most 46,XX males arise as a result of an aberrant exchange of paternal genetic material between X and Y chromosomes during spermatogenesis. In such cases, the TDF is transferred from a Y chromatid to an X chromatid. If the sperm cell that fertilizes the ovum contains such an X chromosome with a TDF, the resultant individual will be a 46,XX male.

Endocrine and paracrine messengers modulate phenotypic differentiation

Just as an individual's genes determine whether the indifferent gonad develops into an ovary or a testis, so does the sex of the gonad dictate the gonad's endocrine and paracrine functions. Normally, chemical messengers—both endocrine and paracrine—produced by the gonad determine the primary and secondary sexual phenotypes of the individual. However, if the gonads fail to produce the proper messengers, if other organs (e.g., the adrenal glands) produce abnormal levels of sex steroids, or if the mother is exposed to chemical agents (e.g., synthetic progestins, testosterone) during pregnancy, sexual development of the fetus may deviate from that programmed by the genotype. Therefore, genetic determination of sexual differentiation is not irrevocable; numerous internal and external influences during development may modify or completely reverse the phenotype of the individual, whatever the genotypic sex (Box 53-2).

Box 53-2

Discordance Between Genotype and Gonadal Phenotype

Discordance between genotypic and phenotypic sex are referred to as **disorders of sex development (DSD)**, a term that describes congenital conditions in which development of chromosomal, gonadal, or anatomical sex is atypical. The term DSD avoids gender labeling in the diagnosis as well as names with negative social connotation (e.g., hermaphrodite, pseudohermaphrodite, intersex) that some patients and parents may perceive to be harmful.

Most DSD conditions are caused by aberrant expression of *SRY*. For example, a number of patients have no recognizable Y chromosome but do have testes. Some of these individuals are 46,XX and possess both male and female sex organs. Others have **mixed gonadal dysgenesis**—a testis in addition to a streak ovary—and a 45,XO karyotype. Some affected individuals have only one type of gonadal tissue but morphological characteristics of both sexes. All these patterns can result from mosaicisms (e.g., 46,XY/46,XX) or from translocation of the *SRY* gene (see Fig. 53-3B)—which normally resides on the Y chromosome—to either an X chromosome or an autosome. A “normal” testis in the absence of a Y chromosome has never been reported.

Another group of individuals with a karyotype of 46,XY has **pure gonadal dysgenesis**—streak gonads, but no somatic features of XO. In the past investigators assumed that these individuals possessed an abnormal Y chromosome. Perhaps the *SRY* gene is absent or its expression is somehow blocked.

Differentiation of the Gonads

The primary sex organs of an individual are the gonads: testes in males and ovaries in females. During embryonic development, the gonads originate as bilateral swellings in the intermediate mesoderm (coelomic epithelium and the underlying urogenital mesenchyme) adjacent to the developing kidneys. Early on (approximately fifth week in humans; [Fig. 53-4A](#)), these gonadal ridges are identical in the two sexes and are referred to as the indifferent gonads (see [Fig. 53-4B](#)). They are composed of an outer cortex and an inner medulla (see [Fig. 53-4C](#)) and capable of becoming either testis (see [Fig. 53-4D](#)) or ovary (see [Fig. 53-4E](#)). The products of genes on the sex chromosomes determine whether each indifferent gonad differentiates into a testis or an ovary. Thus, genotypic sex determines gonadal sex.

A EARLY EMBRYO (FIFTH WEEK)

B MIGRATION OF GERM CELLS TO GONADAL RIDGES

C INDIFFERENT OR PRIMORDIAL GONAD

E DEVELOPING OVARY

D DEVELOPING TESTIS

FIGURE 53-4 Early gonad and germ cell migration. **A**, The PGCs originate in the endodermal endothelium of the yolk sac. **B**, The PGCs migrate along the mesentery of the hindgut and reach the region of the urogenital ridge called the gonadal ridge. **C**, The indifferent gonad consists of an outer cortex and an inner medulla. **D**, The testis develops from the medulla of the indifferent gonad; the cortex regresses. **E**, The ovary develops from the cortex of the indifferent gonad; the medulla regresses.

Primordial germ cells migrate from the yolk sac to the primordial gonad

Germ cells—cells that give rise to gametes—play a key role in sexual differentiation by affecting gonad development. The **primordial germ cells (PGCs)** do not originate in the gonad; instead, they migrate to the gonad from the yolk sac along the mesentery of the hindgut at about the fifth week of embryo development (see Fig. 53-4A, B). The PGCs of humans are first found in the endodermal epithelium of the yolk sac in the vicinity of the allantoic stalk, and from there the germ cells migrate into the adjoining

mesenchyme. During their journey they divide by mitosis. They eventually take up their position embedded in the gonadal ridges. Gonadal development fails to progress normally in the absence of germ cells. Thus, any event that interferes with germ cell migration may cause abnormal gonadal differentiation.

The gonad forms from a portion of the coelomic epithelium, the underlying mesenchyme, and the PGCs that migrate from the yolk sac. At 5 weeks' development, a thickened area of coelomic epithelium develops on the medial aspect of the urogenital ridge as a result of proliferation of both the coelomic epithelium and cells of the underlying mesenchyme. This prominence, which forms on the medial aspect of the mesonephros, is known as the **gonadal ridge** (see [Fig. 53-4B, C](#)).

Migration of the PGCs to the gonadal ridge establishes the *anlagen* for the primordial gonad. The primordial gonad at this early stage of development consists of both a peripheral cortex and a central medulla (see [Fig. 53-4C](#)) and has the capacity to develop into either an ovary or a testis. The cortex and medulla have different fates in males and females. The genotypic sex of the embryo directs the sexual development of the gonads. In an embryo with a 46,XY karyotype, the medullary portion of the gonad develops to become a testis and the cortex regresses. Conversely, 46,XX germ cells stimulate development of the cortex of the early gonad to become an ovary and the medulla regresses.

The primitive testis develops from the medulla of the primordial gonad

In male embryos, PGCs migrate from the cortex of the gonad, in which they were originally embedded, into the primitive sex cords of the medulla. There the PGCs induce maturation of primitive sex cord structures, which become hollowed out (see [Fig. 53-4D](#)) and develop into the **seminiferous tubules**, including the Sertoli cells. The PGCs also give rise to spermatogonia (see [p. 1100](#)), the first cells in the pathway to mature sperm. Remnants of the primitive sex cords also form the **rete testis**, a system of thin, interconnected tubules that develop in the dorsal part of the gonad; they drain the seminiferous tubules into the **efferent ductules**, which develop from the adjoining tubules of the mesonephros (see [pp. 1079–1080](#)). These tubular structures establish a pathway from the male gonad to the mesonephric duct, which evolves into the outlet for sperm. At the same time, the cortex regresses to form a thin epithelial layer covering the coelomic surface of the testis, and mesenchymal cells take up residence among the sex cords and eventually become the **Leydig cells** of the testis. At around the 10th week of development, the Leydig cells respond to fetal pituitary and placental hormones (mainly human chorionic gonadotropin; see [p. 1111](#)) by producing testosterone, which influences the differentiation of the external genitalia.

The main cell types within the seminiferous tubules are **Sertoli** cells and **spermatogonia**, which continue to divide by mitosis (albeit slowly) until puberty. At puberty the rate of spermatogonia division increases and a subgroup of spermatogonia begin meiosis and enter the process of spermatogenesis to produce mature sperm. A stem-cell population of spermatogonia is maintained by mitosis throughout the life of the male.

The primitive ovary develops from the cortex of the primordial gonad

In female embryos, the medulla of the gonad regresses, the primary sex cords are resorbed, and the interior of the gonad is filled with a loose mesenchyme that is highly permeated by blood vessels. However, the cortex greatly increases in thickness, due to the investment of mitotically dividing PGCs,

which remain embedded within it and give rise to **oogonia** (see [Fig. 53-4E](#)). By the eighth week the developing ovaries contain around 600,000 oogonia and that number increases to 6 to 7 million by week 20. A large number of oogonia die and become resorbed; the remainder become surrounded by a single layer of granulosa cells to form **primordial follicles** and enter meiosis to become **primary oocytes** (see [pp. 1120–1121](#)). Unlike spermatogonia, the entire investment of oogonia (surviving PGCs) in the developing ovary is irreversibly committed to meiosis by the 20th week of development. At this stage, the oocytes are arrested at prophase I of meiosis and remain in that state until the follicle is selected for maturation or death later in life. At birth, each ovary holds around 1 million primordial follicles, each containing one primary oocyte arrested at prophase I. Because all the oogonia are depleted at midgestation (they either die or become oocytes), the number of primordial follicles formed at that time is all that will be available for reproduction for the rest of the female's life. This process is distinct from spermatogenesis, which occurs continually after puberty due to the replenishment of spermatogonia by mitosis.

Development of the Accessory Sex Organs

The embryonic gonad determines the development of the internal genitalia and the external sexual phenotype

Higher vertebrates, including humans, have evolved elaborate systems of glands and ducts—collectively referred to as the **accessory sex organs**—for storing and transporting gametes. Together the gonads and accessory sex organs constitute the **primary sex characteristics**. The accessory sex organs can be divided into the external and internal components. In males the external organs are the penis and scrotum. Although they are outside the abdominal cavity, the testicles, contained in the scrotum, are usually considered internal organs. Other internal organs are the epididymis, vas deferens, seminal vesicles, ejaculatory ducts, prostate, and bulbourethral glands. In females the external organs include the vulva, labia, and clitoris; the internal organs are the vagina, uterus, and fallopian tubes.

Secondary sex characteristics are external specializations that are not essential for the production and movement of gametes; instead, they are primarily concerned with sex behavior and with the birth and nutrition of offspring. Examples include pubic hair and breasts. Not only do the sex steroids produced by the gonads affect the accessory sex organs, they also modulate the physiological state of the secondary sex characteristics toward “maleness” in the case of the testes and “femaleness” in the case of the ovaries.

Embryos of both sexes have a double set of embryonic genital ducts

The internal genital ducts and accessory sex organs are derived from embryonic duct systems—the **wolffian ducts** (or mesonephric ducts) and the **müllerian ducts** (or paramesonephric ducts)—and the urogenital sinus ([Fig. 53-5A](#)). The genital ducts are an essential part of the genital organs and form the pathway by which the sex cells—ova and spermatozoa—move to the location of fertilization.

A SEXUALLY INDIFFERENT DUCT SYSTEM

B MALE DEVELOPMENT

C FEMALE DEVELOPMENT

FIGURE 53-5 Transformation of the genital ducts. **A**, At the time that the gonad is still indifferent, it is closely associated with the mesonephros as well as the excretory duct (mesonephric or wolffian duct) that leads from the mesonephros to the urogenital sinus. Parallel to the wolffian ducts are the paramesonephric or müllerian ducts, which merge caudally to form the uterovaginal primordium. **B**, In males, the mesonephros develops into the epididymis. The wolffian duct develops into the vas deferens, seminal vesicles, and ejaculatory duct. The müllerian ducts degenerate. **C**, In females, the mesonephros as well as the wolffian (mesonephric) ducts degenerate. The paramesonephric or müllerian ducts develop into the fallopian tubes, the uterus, the cervix, and the upper one third of the vagina.

It is worth recalling that during mammalian embryogenesis, three sets of kidneys develop, two of which are transient. The **pronephric kidney**, which develops first, is so rudimentary that it never functions.

However, the duct that connects the pronephric kidney to the urogenital sinus—the pronephric duct—eventually serves the same purpose for the second kidney, the **mesonephric kidney** or mesonephros, as it develops embryologically. Unlike the pronephric kidney, the mesonephros functions transiently as a kidney. It has glomeruli and renal tubules; these tubules empty into the wolffian duct (see [Fig. 53-5A](#)), which in turn carry fluid to the urogenital sinus. As discussed below, the mesonephros and its wolffian ducts will—depending on the sex of the developing embryo—either degenerate or develop into other reproductive structures. In addition to the wolffian ducts, a second pair of genital ducts, the müllerian ducts, will develop as invaginations of the coelomic epithelium on the lateral aspects of the mesonephros. The müllerian ducts run caudally and parallel to the wolffian ducts. In the caudal region, they cross ventral to the wolffian ducts and fuse to form a cylindrical structure, the uterovaginal canal. The third or **metanephric kidney** becomes the permanent mammalian kidney. Its excretory duct is the ureter. Early in development (<7 weeks) embryos of both sexes have wolffian and müllerian ducts (see [Fig. 53-4C](#) and [Fig. 53-5A](#)). However, later in gestation (by the 10th week) only one of the duct systems survives in each sex: wolffian ducts in males and müllerian ducts in females.

In males, the wolffian ducts become the epididymis, vas deferens, seminal vesicles, and ejaculatory duct

During development, the **mesonephros** ceases to be an excretory organ in both sexes and disappears entirely in females. As the mesonephros degenerates in males, caudal mesonephric tubules develop into many parallel **efferent ductules** that connect the upstream rete testis to the head of the epididymis, which serves as a reservoir for sperm.

In male embryos, the müllerian ducts regress and the **wolffian ducts** develop into the channels through which the spermatozoa pass from the testis to the urethra (see [Fig. 53-5B](#)). The most proximal portion of the wolffian duct becomes the head, the body, and the tail of the epididymis. The tail of the epididymis connects to the **vas deferens**, which also arises from the wolffian duct. A lateral outgrowth from the distal end of the mesonephric duct forms the **seminal vesicle**. The portion of the mesonephric duct between the seminal vesicle and the point where the mesonephric duct joins the urethra becomes the **ejaculatory duct**. At about the level where the ejaculatory duct joins with the urethra, multiple outgrowths of the urethra grow into the underlying mesenchyme and form the **prostate gland**. The mesenchyme of the prostate gives rise to the stroma of the prostate, whereas the prostatic glands develop from endodermal cells of the prostatic urethra.

In females, the müllerian ducts become the fallopian tubes, the uterus, and the upper third of the vagina

In female embryos, the mesonephros and the wolffian ducts degenerate. The müllerian ducts persist and establish three functional regions (see [Fig. 53-5C](#)). The cranial portions of the müllerian ducts remain separate and give rise to the fallopian tubes. The upper end of the duct develops a fringe, which will become the **fimbriae**, by adding a series of minor pits or müllerian tunnels. The midportions of the left and right müllerian ducts fuse and give rise to the fundus and corpus of the **uterus**. The most distal portions of the fused bilateral müllerian ducts form the **uterovaginal primordium** that gives rise to the cervix and the upper third of the vagina. The lower two thirds of the vagina and external female genitalia are derived from the urogenital sinus.

In males, development of the wolffian ducts requires testosterone

As already noted, the developing embryo has two precursor duct systems ([Fig. 53-6A](#)). In a normal male embryo (see [Fig. 53-6B](#)), the wolffian ducts develop whereas the müllerian ducts regress. In a normal female embryo (see [Fig. 53-6C](#)), the müllerian ducts develop whereas the wolffian ducts regress. It appears that maturation of one of these systems and degeneration of the other depend on local factors produced by the developing gonad.

FIGURE 53-6 Jost experiments. **A**, Very early in development, both the wolffian (mesonephric) and the müllerian (paramesonephric) ducts are present in parallel. **B**, In the normal male, the wolffian duct develops into the vas deferens, the seminal vesicles, and the ejaculatory duct. The müllerian ducts degenerate. **C**, In the normal female, the müllerian ducts develop into the fallopian tubes, the uterus, the cervix, and the upper one third of the vagina. The wolffian ducts degenerate. **D**, Bilateral removal of the testes deprives the embryo of both antimüllerian hormone (AMH) and testosterone. Absence of AMH causes the müllerian ducts to follow the female pattern of development. In the absence of testosterone, the wolffian ducts degenerate. Thus, the genetically male fetus develops female internal and external genitalia. **E**, After bilateral removal of the ovaries, müllerian development continues along normal female lines. Thus, the ovary is not required for female duct development. **F**, Unilateral removal of a testis results in female duct development on the same (ipsilateral) side as the castration. Duct development follows the male pattern on the side with the remaining testis. Virilization of the external genitalia proceeds normally. **G**, In the absence of both testes, administering testosterone preserves development of the wolffian ducts. However, because of the absence of AMH, there is no müllerian regression. **H**, In the presence of both ovaries, administration of testosterone promotes development of the wolffian ducts. Because there are no testes—and thus no AMH—the müllerian ducts develop normally.

A classic series of experiments performed by Alfred Jost in 1953 revealed that male sexual differentiation requires factors produced by fetal testicular tissue. The experimental approach was to castrate rabbit fetuses at various stages of development and allow the pregnancies to continue. Castrating a male fetus before maturation of the wolffian ducts causes the wolffian ducts to regress and the müllerian ducts to persist (i.e., fail to regress), which induces the development of female internal and external genitalia (see [Fig. 53-6D](#)). However, castrating female fetuses at a comparable stage in development has no appreciable effect, and müllerian development continues along normal female lines (see [Fig. 53-6E](#)). Thus, although normal male development requires the testes, development of the fallopian tubes and

uterus does *not* require the ovaries.

Unilateral removal of the testis resulted in female duct development on the same (ipsilateral) side as the castration, but virilization of the external genitalia proceeded normally (see [Fig. 53-6F](#)). Removing *both* testes—and administering testosterone—resulted in essentially normal development of the wolffian ducts, but no müllerian regression was seen (see [Fig. 53-6G](#)). Thus, although testosterone can support wolffian development, it is unable to cause müllerian regression. It became clear that a testicular product other than testosterone is necessary for regression of the müllerian ducts. Thus, one would predict that treating a normal female with testosterone would lead to preservation of the wolffian ducts, as well as the müllerian ducts. This pattern of dual ducts is indeed observed (see [Fig. 53-6H](#)).

In males, antimüllerian hormone causes regression of the müllerian ducts

After Jost, other investigators performed experiments indicating that the Sertoli cells of the testis produce a nonsteroid macromolecule—**antimüllerian hormone (AMH)** or **müllerian-inhibiting substance (MIS)**—that causes müllerian degeneration in the male fetus. AMH, a growth-inhibitory glycoprotein, is a member of the transforming growth factor- β (TGF- β) superfamily of glycoproteins involved in the regulation of growth and differentiation (see [p. 68](#)). Besides TGF- β , this gene superfamily includes the inhibins and activins, which also play key regulatory roles in the reproductive system (see [pp. 1095 and 1113–1115](#)). The proteins produced by this gene family are all synthesized as dimeric precursors and undergo post-translational processing for activation. AMH is glycosylated and is secreted as a 140-kDa dimer consisting of two identical disulfide-linked subunits. The antimitogenic activity and müllerian duct bioactivity of AMH reside primarily in its C-terminal domain.

The human AMH gene is located on chromosome 19, and AMH is one of the earliest sexually dimorphic genes expressed during development. The transcription factor SRY, which represents the TDF, may be involved in initiating the transcription of AMH. The sequential timing of SRY and AMH expression is consistent with activation of AMH by SRY, a series of events that may control sexual dimorphism.

Although the exact mechanism of AMH action has not been completely clarified, it is thought to involve receptor-mediated *dephosphorylation*. AMH appears to act directly on mesenchymal cells of the müllerian duct and indirectly, through the mesenchyme, on müllerian duct epithelial cells. AMH binding has been localized to the mesenchymal cells surrounding the müllerian duct and to the developing oocytes in preantral follicles.

During embryogenesis in males, AMH—which is secreted by the Sertoli cells in the testis—causes involution of the müllerian ducts, whereas testosterone—which is secreted by the Leydig cells of the testis—stimulates differentiation of the wolffian ducts. In females, the müllerian ducts differentiate spontaneously in the absence of AMH, and the wolffian ducts involute spontaneously in the absence of testosterone.

Differentiation of the External Genitalia

The urogenital sinus develops into the urinary bladder, the urethra, and, in females, the vestibule of the vagina

Early in embryological development, a tubular structure called the cloaca is the common termination of the urogenital and gastrointestinal systems ([Fig. 53-7A](#)). The cloacal membrane separates the cloaca from the amniotic fluid. Eventually, a wedge of mesenchymal tissue separates the cloaca into a dorsal and a ventral cavity (see [Fig. 53-7B](#)). The dorsal cavity is the rectum. The ventral compartment is the **urogenital sinus**. Both the wolffian and the müllerian ducts empty into this urogenital sinus (see [Fig. 53-5A](#)).

A PARTITIONING OF CLOACA

B INDIFFERENT UROGENITAL SINUS

C MALE DEVELOPMENT

D FEMALE DEVELOPMENT

FIGURE 53-7 Differentiation of the urogenital sinus. **A**, The urorectal septum begins to separate the rectum (dorsal) from the urogenital sinus (ventral). The urogenital sinus is divided into a vesicle (i.e.,

urinary bladder) part, a pelvic part, and a phallic part. The common space into which the rectum and urogenital sinus empty, the cloaca, is closed by the cloacal membrane. **B**, At this stage, the rectum and the urogenital sinus are fully separated. The urogenital membrane separates the urogenital sinus from the outside of the embryo. **C**, The male has a common opening for the reproductive and urinary tracts. The prostatic utricle, which is the male homolog of the vagina, empties into the prostatic urethra. **D**, A solid core of tissue called the *vaginal plate* grows caudally from the posterior wall of the urogenital sinus. The lumen of the vagina forms as the center of this plate resorbs. Thus, the female has separate openings for the urinary and reproductive systems.

The urogenital sinus can be divided into three regions: vesicle, pelvic, and phallic. In males (see [Fig. 53-7C](#)), the vesicle region becomes the urinary bladder, the pelvic region becomes the prostatic part of the urethra, and the phallic region becomes the initial portion of the penile urethra.

In females (see [Fig. 53-7D](#)), the vesicle region of the urogenital sinus also develops into the urinary bladder. The pelvic region becomes the entire female urethra. The phallic region of the urogenital sinus develops into the vestibule of the vagina; into this vestibule empty the urethra, the vagina, and the ducts of the greater vestibular glands of Bartholin.

As noted above, fusion of the caudal portion of the müllerian ducts produces the uterovaginal primordium. Contact of this primordium with the dorsal wall of the urogenital sinus induces the development of paired sinovaginal bulbs, which grow into the urogenital sinus and then fuse to form a solid core of tissue called the **vaginal plate**. This plate grows caudally to the phallic portion of the urogenital sinus. Resorption of the center of the vaginal plate creates the vaginal lumen. The remaining cells of the vaginal plate form the vaginal epithelium. During early fetal development, a thin membrane, the **hymen**, separates the lumen of the vagina from the cavity of the urogenital sinus. Usually, the hymen partially opens during the prenatal period. Occasionally, the hymen persists completely, does not allow escape of the menstrual effluvium at menarche, and gives rise to a condition known clinically as hematocolpos.

In males, the vagina disappears when the müllerian ducts are resorbed. However, remnants of the vagina sometimes persist as a prostatic utricle.

The external genitalia of both sexes develop from common anlagen

Although anatomically separate precursors give rise to the internal sex organs, common anlagen give rise to the external genitalia of the two sexes ([Fig. 53-8A](#)). Knowledge of the common origins of the external genitalia during normal development facilitates understanding of the ambiguities of abnormal sexual development.

A EARLY INDIFFERENT STAGE

B LATE INDIFFERENT STAGE

C MALE DEVELOPMENT

D FEMALE DEVELOPMENT

FIGURE 53-8 Development of the external genitalia. **A**, Genital folds and genital swellings surround the cloacal membrane. **B**, Early in the fourth week of development—in both sexes—the genital tubercle begins to enlarge to form the phallus. **C**, In males, the genital tubercle becomes the glans penis. The urogenital folds fuse to form the shaft of the penis. The labioscrotal swellings become the scrotum. **D**, In females, the genital tubercle becomes the clitoris. The urogenital folds remain separate as the labia minora. The labioscrotal swellings become the labia majora where they remain unfused. Ventrally, the labioscrotal swellings fuse to form the mons pubis. Dorsally they fuse to form the posterior labial commissure.

The **genital tubercle** (see [Fig. 53-8B](#)) develops during the fourth week on the ventral side of the cloacal membrane. As a result of elongation of the genital tubercle, a phallus develops in both sexes. The genital tubercle of the primitive embryo develops into the **glans penis** in males (see [Fig. 53-8C](#)) and the **clitoris** in females (see [Fig. 53-8D](#)). Until about the end of the first trimester of pregnancy, the external genitalia of males and females are anatomically indistinguishable. The phallus undergoes rapid growth in females initially, but its growth slows, and in the absence of androgens, the phallus becomes the relatively small clitoris in females.

The paired **urogenital folds** give rise to the ventral aspect of the penis in males (see [Fig. 53-8C](#)) and the labia minora in females (see [Fig. 53-8D](#)). After formation of the urogenital opening, a groove—the urethral groove—forms on the ventral side of the phallus; this groove is continuous with the urogenital opening. The bilateral urogenital folds fuse over the urethral groove to form an enclosed spongy urethra; the line of fusion is the penile raphé. As the urogenital folds fuse to form the ventral covering of the penis, they do so in a posterior-to-anterior direction, thus displacing the urethral orifice to the tip of the penis. Elongation of the genital tubercle and fusion of the genital folds occur at the 12th to the 14th week of gestation. However, in females, the urogenital folds normally remain separate as the labia minora.

In males, the **genital** or **labioscrotal swellings** fuse to give rise to the scrotum. In females, however, the labioscrotal swellings fuse anteriorly to give rise to the mons pubis and posteriorly to form the posterior labial commissure. The unfused labioscrotal swellings give rise to the labia majora.

Endocrine and Paracrine Control of Sexual Differentiation

The SRY gene triggers development of the testis, which makes the androgens and AMH necessary for male sexual differentiation

As noted above, the female pattern of sexual differentiation is the default program and the male pattern of sexual differentiation is directed by endocrine and paracrine factors produced by the testes. Therefore, we will successively examine the control of testicular development, the development of the male internal system of genital ducts, and the development of the male urogenital sinus and external genitalia.

[Figure 53-9](#) summarizes the regulatory cascade that determines the pathway for sex determination. The indifferent gonad develops into a testis in response to TDF—the product of the *SRY* gene (see [p. 1075](#))—before week 9 of development. If TDF is not present or if TDF is present only after the critical window of 9 weeks has passed, an ovary will develop instead of a testis. Further male-pattern sexual differentiation depends on the presence of three hormones: testosterone, **dihydrotestosterone (DHT)**, and AMH. The testis directly produces both testosterone and AMH. Peripheral tissues convert testosterone to DHT.

FIGURE 53-9 Pathways for the hormonal control of sex determination.

Testosterone Production

Both the fetal and the postnatal testis produce testosterone, the primary male sex steroid (see pp. 1097–1100), and, in lesser amounts, DHT and estradiol. The **Leydig cells** (see p. 1095) are the source of testosterone production in the testes. The early increase in the number of Leydig cells and secretion of

testosterone in humans could depend on either maternal human chorionic gonadotropin (hCG) or fetal luteinizing hormone. The human testis has its greatest abundance of side-chain-cleavage enzyme—which catalyzes the first committed step in steroid synthesis (see [Fig. 50-2](#))—at 14 to 15 weeks of gestation and low values by 26 weeks of gestation. Because hCG follows a similar temporal pattern, it may be hCG that supports *early* testosterone production. Late regulation of testosterone production by fetal luteinizing hormone is supported by the finding that the testes of anencephalic fetuses, which lack a functional pituitary gland (see [Box 10-2](#)) at term, have few Leydig cells.

Androgen Receptor

The androgenic steroid hormones, principally testosterone and DHT, passively move into target cells and act by binding to the **androgen receptor (AR)**, which functions as a ligand-activated transcription factor to modulate the expression of genes whose products affect cell function and phenotype (see [pp. 71–72](#)). ARs are present in cells of the wolffian ducts and urogenital sinus tissues.

Congenital absence or abnormality of AR leads to **androgen insensitivity syndrome**, one kind of testicular feminization in which the external genitalia develop the female phenotype, and the wolffian and müllerian ducts regress ([Box 53-3](#)).

Box 53-3

Impaired Androgen Action in Target Tissues

In the absence of androgens, male embryos follow a typically female pattern of sexual development. Any defect in the mechanisms by which androgens *act* on target tissues—in genotypic males—may lead to a DSD (see [Box 53-2](#)) that had been referred to as **male pseudohermaphroditism**. Affected individuals have a normal male karyotype (46,XY) and unambiguous male gonads but may have ambiguous external genitalia or may phenotypically appear as females. In principle, impaired androgen action could result from a deficiency of the enzyme that converts testosterone to DHT in target tissues, absence of androgen receptors, qualitatively abnormal receptors, a quantitative deficiency in receptor levels, or postreceptor defects. The two major forms that have been identified clinically are defects in the conversion of testosterone to DHT (5 α -reductase deficiency) [N53-5](#) and androgen-receptor defects. [N53-6](#)

A classic example of pseudohermaphroditism is a condition known as **guevedoces** (Dominican Spanish slang for *penis at 12*), first identified in isolated villages of the Dominican Republic in the 1970s. In those communities, ~2% of children who appear as girls at birth and through childhood undergo a remarkable masculinization at puberty. They do not develop breasts or menstruate, but instead become male: the clitoris enlarges to the size of a normal penis and is capable of an erection; the hitherto unrecognized and fully developed testes descend into their labia majora; the individual is capable of ejaculation of mature sperm, albeit through a urethral opening at the base of the enlarged clitoris/penis; and the individuals develop typical male secondary sexual characteristics, including facial hair, increased muscle growth, and a sexual attraction to females. These individuals are actually 46,XY males. At birth they have undescended testes, developed wolffian duct derivatives, no müllerian duct structures, but normal female external genitalia. They appear female at birth and through childhood because they have a 5 α -reductase deficiency and, thus, insufficient androgen to masculinize the tissues of the urogenital sinus. The sudden masculinization at puberty is due to increased testosterone levels, which become high enough to exert androgenic action on the genital tubercle and urogenital sinus. These individuals spend the rest of their lives as men.

5 α -Reductase Deficiency

Contributed by Ervin Jones

The activity of 5 α -reductase, which is necessary for the conversion of testosterone to DHT (see Fig. 54-6), is either low or absent in fibroblasts taken from the genital region and other tissues of individuals with one form of DSD (see Box 53-2). The testosterone concentration is either normal or increased. On the other hand, the concentration of DHT is low, which explains why testosterone-dependent development (e.g., differentiation of the wolffian duct) occurs whereas DHT-dependent development (e.g., male-pattern development of the urogenital sinus and external genitalia) does not. This disorder is transmitted via an autosomal recessive gene that is phenotypically manifested only in genetic males. At birth, these children have ambiguous genitalia, with a blind vaginal pouch and a small phallus that is bound ventrally and covered by a hood; they also have hypospadias (i.e., the urethral orifice is located too low on the undersurface of the penis). Wolffian duct development (which depends on testosterone) occurs, and müllerian regression (which depends on AMH) is normal. These individuals may be raised as females.

At the time of puberty, marked, though selective, virilization occurs. The testes descend from their intra-abdominal position. These individuals also undergo other signs of masculinization, including deepening of the voice, muscular development, and phallic enlargement. The cause of virilization at puberty in these individuals is unknown. However, it may be that the large quantities of testosterone produced at puberty are able to sufficiently stimulate androgen receptors in DHT-dependent tissues or that even relatively low levels of 5 α -reductase activity are able to generate sufficient DHT in the presence of high levels of substrate (i.e., testosterone). However, masculine features that depend on DHT—such as beard growth, acne, and temporal balding—fail to occur.

Androgen-Receptor Defects

Contributed by Ervin Jones

Individuals with **complete androgen resistance** (also known as **androgen insensitivity syndrome** or **testicular feminization**) have normal levels of testosterone and DHT. Moreover, the pathways of testosterone metabolism (see Fig. 54-6) and half-life are normal. However, androgen receptors are defective or absent. As a result, either androgens do not bind to receptors at high levels, or the androgen-receptor complex does not bind properly to DNA. Because target cells behave as though androgens were not present at all, androgen-dependent sexual development does not occur. As a result, the wolffian ducts degenerate, and the urogenital sinus and external genitalia all develop according to the female pattern. However, the normal levels of AMH suppress müllerian development. Although a rudimentary uterus and fallopian tubes are sometimes found, their growth and development have obviously been inhibited.

The term **testicular feminization**, which is no longer used, was introduced by J.M. Morris in 1953 to describe a group of patients with a distinctive form of male pseudohermaphroditism. This X-linked disorder has a prevalence of 1 in 20,000 live male births. These individuals are genetic males—their sex chromosome complex is XY—but phenotypic females. They appear normal at birth with the exception of the presence of an inguinal hernia. The testis is either intra-abdominal, located in an inguinal hernia, or in

the labia majora. They have unambiguous female external genitalia. However, the labia majora are underdeveloped, the vagina is shallow and ends blindly, and the uterus is at most rudimentary. The clitoris is normal or small. Development and growth of individuals with complete androgen resistance usually follow the normal female pattern. At puberty, breast development occurs at the expected time. However, these individuals have a significant deficiency or total lack of pubic and axillary hair and fail to menstruate.

DHT Formation

In certain target tissues, cytoplasmic 5α -reductase converts testosterone to DHT (see Fig. 54-6), which binds to the same AR as does testosterone. However, DHT binds to AR with an affinity that is ~ 100 -fold greater than the binding of testosterone. Moreover, the DHT-AR complex binds to DNA targets more tightly than does the testosterone-receptor complex. Thus, a relatively low circulating level of testosterone—not enough to produce secondary masculinization—can profoundly affect cells of the urogenital sinus that express AR and 5α -reductase. Conversely, a deficiency in 5α -reductase is another cause of testicular feminization (see Box 53-3).  N53-2

N53-2

DHT and Intracrine Control of Hormone Action

Contributed by Sam Mesiano

Steroid hormone activity in some target cells is modified by specific enzymes that convert the incoming steroid to a more or less active form before it interacts with its cognate receptor. This is referred to as **intracrine** control of hormone action. In some androgen-responsive cells the cytoplasmic 5α -reductase enzyme converts testosterone to DHT (see Fig. 54-6), which binds to the same AR as testosterone but with a much higher affinity, ~ 100 -fold greater than testosterone. Moreover, the DHT-AR complex binds to DNA targets more tightly than does the testosterone-AR complex. Thus, androgen target cells have the capacity to markedly increase the potency of testosterone by converting it to DHT. Via this mechanism a relatively low circulating level of testosterone that is not enough to produce secondary masculinization can have a profound effect on cells of the urogenital sinus that express AR and the 5α -reductase enzyme.

Other examples of intracrine effects are the intracellular conversion by 11β -hydroxysteroid dehydrogenase 2 of the active cortisol to the inactive cortisone in principal cells of the cortical collecting duct (see p. 766) and the conversion of the less-active thyroxine (T_4) to the more-active triiodothyronine (T_3) by deiodinase in many targets of thyroid hormones (see pp. 1009–1010).

Antimüllerian Hormone

As noted on page 1080, the Sertoli cells of the testis produce AMH, which promotes the regression of müllerian ducts. The cranial end of the müllerian duct becomes the vestigial appendix testis at the superior pole of the testis. The müllerian ducts are responsive to AMH at around the eighth week of development and undergo apoptosis in a craniocaudal direction. The ducts completely regress within 1 week of exposure to AMH. AMH deficiency in males, which is usually caused by mutations in the genes encoding AMH or its receptor, can lead to **persistent müllerian duct syndrome**. These males have undescended testes and a small rudimentary uterus and other müllerian-duct derivatives. AMH also appears to be involved in the regulation of sex hormone (testosterone and estradiol) production as well as

in puberty and gender-specific behaviors in both sexes via targets in the brain.

Androgens direct the male pattern of sexual differentiation of the internal ducts, the urogenital sinus, and the external genitalia

Androgens play two major roles in male phenotypic differentiation: (1) they trigger conversion of the wolffian ducts to the male ejaculatory system, and (2) they direct the differentiation of the urogenital sinus and external genitalia. The wolffian phase of male sexual differentiation is regulated by testosterone itself and does not require conversion of testosterone to DHT. In contrast, virilization of the urogenital sinus, the prostate, the penile urethra, and the external genitalia during embryogenesis requires DHT, as does sexual maturation at puberty.

Differentiation of the Duct System

Shortly after the Sertoli cells initiate AMH production, the fetal Leydig cells begin producing testosterone. The embryonic mesenchyme contains androgen receptors and is the first site of androgen action during formation of the male urogenital tract. The Sertoli cells also produce a substance referred to as **androgen-binding protein (ABP)**. It is possible that ABP binds and maintains a high concentration of testosterone locally. These high local levels of testosterone stimulate growth and differentiation of the medulla of the gonad into the rete testes, as well as differentiation of the wolffian ducts into the epididymis, the vas deferens, the seminal vesicles, and the ejaculatory duct. Testosterone also promotes development of the prostate from a series of endodermal buds located at the proximal aspect of the urethra. In the absence of testosterone, the wolffian system remains rudimentary, and normal male internal ductal development does not occur. Cells of the wolffian ducts lack 5 α -reductase and therefore cannot convert testosterone to DHT. Thus, the internal male ducts respond to testosterone per se and do not require the conversion of testosterone to DHT.

Differentiation of the Urogenital Sinus and External Genitalia

Development of the male external genitalia and internal derivatives of the urogenital sinus (prostate and bulbourethral glands) commences at around the 9th week of gestation—all under the influence of DHT—soon after maturation of the wolffian ducts and is completed by 13th week of gestation. If androgens are absent (in females, or in males in which androgen production or action is disrupted) the indifferent external genitalia remain unfused and follow the female pattern of differentiation. In female fetuses exposed to abnormally high levels of extragonadal androgens (e.g., in congenital adrenal hyperplasia; [Box 53-4](#)) virilization of the urogenital sinus occurs; the extent of the virilization is more pronounced the earlier in development the exposure occurs. Once the labioscrotal swellings have established the female form, androgen-induced virilization affects mainly the size of the clitoris. However, if androgen exposure occurs earlier in development, partial fusion of the labioscrotal swellings can occur. The cells of the urogenital sinus and external genitalia, unlike those of the wolffian duct, contain 5 α -reductase and are thus capable of converting testosterone to DHT. Indeed, conversion of testosterone to DHT is usually required for normal male development of the external genitalia.

Congenital Adrenal Hyperplasia

Ambiguous genitalia in genotypic females may result from disorders of adrenal function. Several forms of **congenital adrenal hyperplasia** have been described, including the deficiency of several enzymes involved in steroid synthesis (see Fig. 50-2): the side-chain-cleavage enzyme, 17 α -hydroxylase, 21 α -hydroxylase, 11 β -hydroxylase, and 3 β -hydroxysteroid dehydrogenase. Deficiencies in 21 α -hydroxylase, 11 β -hydroxylase, and 3 β -hydroxysteroid dehydrogenase all lead to virilization in females—and thus ambiguous genitalia—as a result of the hypersecretion of adrenal androgens. **21 α -hydroxylase deficiency**, by far the most common, accounts for ~95% of cases. Some of the consequences of this deficiency are discussed in Box 50-2.

As indicated by Figure 50-2, 21 α -hydroxylase deficiency reduces the conversion of progesterone to 11-deoxycorticosterone—which goes on to form aldosterone—and also reduces the conversion of 17 α -hydroxyprogesterone to 11-deoxycortisol—which is the precursor of cortisol. As a result, adrenal steroid precursors are shunted into androgen pathways. Because negative feedback by cortisol to the hypothalamic-pituitary-adrenal axis (see Fig. 50-3) is lacking in the fetus, the adrenal gland experiences high levels of adrenocorticotrophic hormone (ACTH), which induce the production of the weak androgen DHEA by the fetal zone of the adrenal cortex. The abnormally high levels of DHEA interact with the androgen receptor in tissue of the urogenital sinus to induce masculinization. In female infants, the result is sometimes called the adrenogenital syndrome. The external genitalia are difficult to distinguish from male genitalia on visual inspection. The clitoris is enlarged and resembles a penis, and the labioscrotal folds are enlarged and fused and resemble a scrotum. The genitalia thus have a male phenotype in an otherwise normal female infant.

In the presence of high intracellular concentrations of DHT, the genital tubercle, the bipotential predecessor to either a clitoris or a penis, elongates to become the glans penis, the corpus spongiosum, and the two corpora cavernosa. Formation of the penis and scrotum is complete by ~13 weeks of gestation. Congenital absence of 5 α -reductase (see Box 53-3) is associated with normal development of the wolffian duct system but impaired virilization of the external genitalia. Even extremely high concentrations of testosterone after this time fail to cause midline fusion of the urethral groove or scrotum, although the clitoris will enlarge.

In the absence of androgen secretion by the fetal testis—or abnormal extragonadal sources—the indifferent external genitalia remain unfused and follow the female pattern of differentiation (Box 53-5).

Box 53-5

Androgen Dependence of Testicular Descent

In preparation for descent, the testes enlarge. In addition, the mesonephric kidneys and wolffian (mesonephric) ducts atrophy. This process frees the testes for their future move down the posterior abdominal wall and across the abdomen to the deep inguinal rings. Testicular descent occurs in three phases during the last two thirds of gestation. During the first stage of testicular descent, rapid growth of the abdominopelvic region causes *relative* movement of the testes down to the inguinal region (Fig. 53-10A). The role of the gubernaculum—the ligament attaching the inferior part of the testis to the lower segment of the labioscrotal fold—is uncertain. However, the gubernaculum shortens and appears to guide the testis to its place of ultimate functional residence in the scrotum. The second stage of testicular descent is herniation of the abdominal wall adjacent to the gubernaculum (see Fig. 53-10B). This

herniation, which occurs as a result of increasing abdominal pressure, forms the processus vaginalis; the processus vaginalis then folds around the gubernaculum and creates the inguinal canal. In the third stage, the gubernaculum increases to the approximate diameter of the testis. As its proximal portion degenerates, the gubernaculum draws the testis into the scrotum through the processus vaginalis (see Fig. 53-10C).

FIGURE 53-10 Testicular descent.

The testes usually complete their descent by the seventh month of gestation; ~97.5% of full-term infants and 79% of premature infants have fully descended testes at birth. At 9 months of age, only 0.8% of male infants have undescended testes. The incidence of undescended testes in young men is 0.2%.

Testicular descent is an androgen-dependent process, and development of the structures involved in testicular descent depends on testosterone. Thus, in testosterone-deficient states caused by inadequate secretion or disordered androgen action, the testes of genetic males often fail to descend. This abnormality can be seen in individuals with both 5 α -reductase deficiency and complete androgen resistance (i.e., testicular feminization syndrome).

Androgens and estrogens influence sexual differentiation of the brain

Gonadal steroids influence the development of sexually dimorphic nuclei in the diencephalons of rodents and lower primates. However, androgens do not act directly on the hypothalamus and other areas of the brain having to do with sex behavior and control of gonadotropin secretion. Rather, aromatase—which catalyzes the formation of estrone and estradiol (see Fig. 55-8)—converts androgens to estrogens in the brain. Thus, androgens in the brain serve as prohormones for estrogens. Therefore, estrogens are derived from androgens that appear to masculinize sexually dimorphic nuclei directly in the brain. It is not clear why, in females, estrogens do not *masculinize* the brain.

Gonadal steroids affect sex behavior in both males and females. In rodents, lordosis behavior in females and mounting behavior in males is one example of sex behavior. An example of functional sexual dimorphism in the human brain is the manner in which gonadotropin is released. Gonadotropin release has been described as *cyclic* in the female and *tonic* in the male inasmuch as females have midcycle cyclic release of gonadotropin before ovulation whereas males seem to have a continuous tonic pattern of gonadotropin release.

Although controversy continues over the role of prenatal virilization in the determination of sexual dimorphism, sex steroids clearly have an impact on sexual behavior and sexual reference in humans.

Puberty

Although at birth humans have the primary and secondary sex organs necessary for procreation, final sexual maturity occurs only at **puberty**, the transition between the juvenile and adult states when an individual becomes capable of reproducing.

Puberty involves steroid hormones produced by the gonads and the adrenals

Puberty involves two physiological processes: (1) **gonadarche**, the physical and functional maturation of the gonads, such that they produce gametes and sex steroids; and (2) adrenarche, the increased production of the androgenic steroids dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEAS), and androstenedione (A4) by the adrenal cortex (see [Fig. 50-2](#)). **Adrenarche** is peculiar to humans and great apes and occurs in both sexes during the prepubertal period (ages 6 to 8 years). The increased levels of adrenal androgens induce **pubarche**, the growth of pubic hair. The function of adrenarche is unclear, inasmuch as its absence does not prevent gonadarche or the attainment of reproductive competence. The mechanisms that control the timing of adrenarche are also not known.

Gonadarche is induced by increased production of the gonadotropic hormones follicle-stimulating hormone (FSH) and luteinizing hormone (LH) by the anterior pituitary (see [pp. 1094–1095](#) and [1111–1112](#)). Although a surge in levels of the pituitary gonadotropins occurs during intrauterine life and a second peak takes place in the immediately postnatal period, gonadotropin levels decrease at ~4 months of age and thereafter decline further and remain low until just before puberty. At puberty, the marked increase in FSH and LH production by the hypothalamic-pituitary axis induces gonadarche. The gonadal steroids produced in response to FSH and LH induce growth and maturation of the genitals and secondary sex organs and the development of secondary sex characteristics. The gonadal steroids also participate (with growth hormone and insulin-like growth factors) in the adolescent growth spurt. In males gonadarche leads to **spermarche**, the initiation of sperm production by the testes (see [p. 1092](#)), and in females it leads to **folliculogenesis** and **menarche**, the initiation of menstrual cycles, and **thelarche**, development of breasts (see [p. 1108](#)).

Hypothalamic gonadotropin-releasing hormone secretion controls puberty

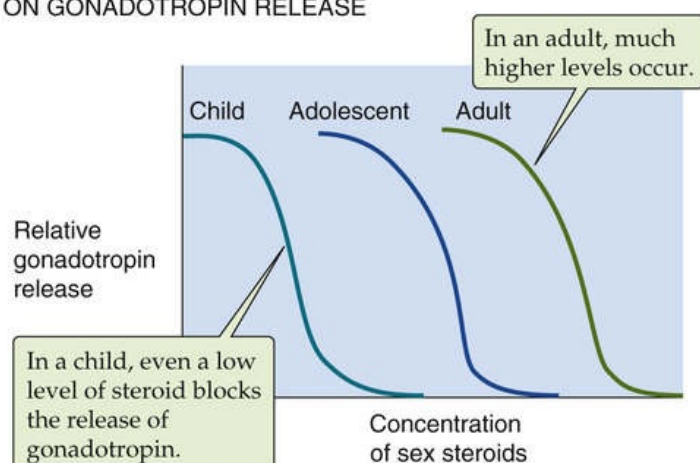

Gonadotropin production by the anterior pituitary is under the control of gonadotropin-releasing hormone (GnRH), produced by neurons in the hypothalamus (see [pp. 1092–1094](#) and [1111](#)). The activity of hypothalamic GnRH neurons is controlled by higher centers in the brain that integrate multiple physiological signals. One of the earliest events of puberty in males and females is the onset of pulsatile release of GnRH from the hypothalamus and, in turn, FSH and LH from the anterior pituitary, during rapid eye movement sleep. These pulses eventually occur throughout the day ([Fig. 53-11A](#)). The appearance of GnRH pulsatility early in puberty is associated with decreased sensitivity of the hypothalamic-pituitary system to circulating sex steroids. The low GnRH and gonadotropin secretion during the prepubertal years appears to be due to high sensitivity of the hypothalamic-pituitary system to negative-feedback inhibition by gonadal steroids (see [Fig. 53-11B](#)). Before puberty, even low levels of sex steroids are

sufficient to feed back on the hypothalamic-pituitary system and block the release of gonadotropins. After puberty, the levels of steroids required to block gonadotropin release progressively increase. Thus, the sensitivity of the hypothalamic-pituitary system to inhibition by sex steroids falls at puberty to reach the low level that is characteristic of the adult (see Fig. 53-11C). The precipitating event that is responsible for initiating pulsatile GnRH release is unknown, although it may reflect the maturation of hypothalamic neurons. Once a pulsatile pattern of gonadotropin secretion is established, it continues throughout reproductive life.

A PATTERNS OF GONADOTROPIN LEVELS THROUGHOUT THE LIFE OF A FEMALE

B NEGATIVE FEEDBACK OF SEX STEROIDS ON GONADOTROPIN RELEASE

C AGE DEPENDENCE OF FEEDBACK SENSITIVITY

FIGURE 53-11 Gonadotropin function during life. **A**, Levels of both LH and FSH peak during fetal life and again during early infancy, before falling to low levels throughout the rest of childhood. At the onset of puberty, LH and FSH levels slowly rise and—in females—begin to oscillate at regular monthly intervals. At menopause, gonadotropin levels rise to very high levels. The four insets show daily changes. **B**, In childhood, even very low sex steroid levels are sufficient to fully suppress gonadotropin output. In adolescence, higher levels—and, in adults, even higher levels—of sex steroids are required to suppress gonadotropin release. **C**, This graph is a plot of age versus the midpoints of curves such as those in **B**.

Multiple factors control the timing of puberty

In girls, adrenarche leading to pubarche occurs between 8 and 13 years of age, and gonadarche leading to menarche and thelarche occurs between 12 and 13 years of age. The earliest physical manifestation of puberty in boys is an increase in testicular volume, which usually occurs between 9 and 14 years of age (Table 53-1).

TABLE 53-1
Tanner Stages in Male and Female Puberty

STAGE	PUBIC HAIR (BO TH SEXES)	MALE GENITAL DEVELO PMENT	FEMALE BREAST AND GENITAL* DEVELO PMENT
1	Preadolescent. No pubic hair is present, only vellus hair, as on the abdomen.	Preadolescent. The penis, scrotum, and testes are the same size—relative to body size—as in a young child.	Preadolescent. Breasts: only papillae are elevated.
2	Pubic hair is sparse, mainly at the base of the penis (boys) or along labia majora (girls).	Scrotum and testes are enlarged.	Breast buds begin to develop. Breasts and papillae are both elevated, and the diameter of the areolae increases.
3	Pubic hair is darker, coarser, and curlier and spreads above the pubis.	Penis is enlarged, predominantly in length. Scrotum and testes are further enlarged.	Breasts and areolae further enlarge. Vagina enlarges and begins producing a discharge. Menstrual periods may begin.
4	Pubic hair is of the adult type, but covers an area smaller than in most adults.	Penis is further enlarged in length and also in diameter. Scrotum and testes are further enlarged.	Areolae and papillae project out beyond the level of the expanding breast tissue. Menstruation and ovulation begin. Periods will most likely be irregular.
5	Adult pattern.	Adult pattern.	With further enlargement of the breast, the areolae are now on the same level as the rest of the breast. Only the papillae project. Adult pattern.

*The official Tanner stages for females include pubic hair and breast development.

The precise cause of the onset of puberty is not completely understood. Multiple intrinsic (genetic) and extrinsic (environmental) factors play a role. Genetic factors appear to be major determinants of pubertal onset. Other factors, such as nutrition, geographic location, and exposure to light, also play a role. Over the last century, the age of girls at menarche in the United States and Europe has gradually decreased. The reason that menarche now occurs at a younger age is incompletely understood. It could be due to improved nutrition. However, better nutritional status alone cannot completely explain the decreased age of pubertal onset. Proximity to the equator and lower altitudes are also associated with early onset of puberty. A loose correlation is also seen between the onset of menarche in the mother and the onset of menarche in the daughter. The onset of puberty is also related to body composition and to fat deposition. Severe obesity and heavy exercise delay puberty.

Androgens and estrogens influence secondary sex characteristics at puberty

Profound alterations in steroid hormone secretion during the peripubertal period cause changes in the primary sex organs and secondary sex characteristics. In both sexes, the process of puberty can be divided into five developmental stages—referred to as the **Tanner stages**—based on the extent of pubic hair growth and genital and breast development. In males and females, Tanner stage 1 is the prepubertal state and Tanner stage 5 is the adult state (Fig. 53-12 and Table 53-1).

A FEMALE PUBERTY (BREAST DEVELOPMENT AND PUBIC HAIR)

B MALE PUBERTY (GENITAL DEVELOPMENT AND PUBIC HAIR)

FIGURE 53-12 Tanner stages of puberty based on pubic hair, genital, and breast development in boys and girls. Pubic hair and genital/breast development may not be synchronous and are usually scored separately. For example, a girl may be at breast stage 3 but pubic hair stage 2. (Data from Carel JC, Léger J: Clinical practice. Precocious puberty. *N Engl J Med* 358:2366, 2008.)

Males

The range of onset of normal male puberty extends from 9 to 14 years. Boys complete pubertal development within 2 to $4\frac{1}{2}$ years. In a normal male, the first sign of puberty (Tanner stage 2) is enlargement of the testes to >2.5 cm (see [Fig. 53-12B](#)). Testicular enlargement is mainly due to growth of the seminiferous tubules with some contribution by Leydig cell growth. **N53-3** In normal boys, pubic hair generally develops 1 to $1\frac{1}{2}$ years after genital development. Pubic hair growth can be due to adrenarche or gonadarche and therefore can occur independently of genital growth.

Testicular Size

Contributed by Ervin Jones

Testicular size is generally determined using a ruler or calipers. It is expected that a length of >2.5 cm is compatible with the onset of normal pubertal development. The **testicular volume index** is defined as the sum of the product of length \times width for the left and right testes. An orchidometer allows direct comparison of the patient's testes with an ovoid of measured volume. A popular method uses the Prader orchidometer, a set of solid or hollow ovoids encompassing the range of sizes from infancy to adulthood (1 to 25 mL). The volumes of the testes are then recorded; a volume of 3 mL closely correlates with the onset of pubertal development.

The male sex steroids, which are known as androgens, affect nearly every tissue in the body, including the brain. The changes that occur in male puberty are induced mainly by testosterone secreted by the testes. Testosterone stimulates adult maturation of the external genitalia and accessory sex organs, including the penis, the scrotum, the prostate, and the seminal vesicles. It also induces the male secondary sexual characteristics, which include deepening of the voice, as well as evolving male patterns of hair growth. **N53-4** Testosterone also has anabolic effects, including stimulation of linear body growth, nitrogen retention, and muscular development in the adolescent and mature male. The biological effects of testosterone and its metabolites can be classified according to their tissue sites of action. Effects that relate to growth of the male reproductive tract or development of secondary sexual characteristics are referred to as **androgenic**, whereas the growth-promoting effects on somatic tissue are called **anabolic**.

N53-4

Male Secondary Sex Characteristics

Voice and Hair Patterns

Contributed by Ervin Jones

Androgens also determine the male secondary sexual characteristics, which include deepening of the voice as well as evolving male patterns of hair growth. The changes in the voice are a result of androgen-dependent effects on the size of the larynx as well as the length and thickness of the vocal cords. In boys, the length of the vocal cords increases by $\sim 50\%$ during puberty, whereas girls have little increase in vocal cord length. The surfaces of the human body that bear secondary sexual hair include the face (particularly the upper lip, chin, and the sideburn areas), the axilla, and the pubic region. Temporal hair recession and male-pattern balding—beginning above the temples (i.e., receding hairline) and at the vertex of the scalp—are also androgen-dependent phenomena.

The pubertal growth spurt, a marked increase in growth rate (total body size), occurs late in puberty in boys. The acceleration of growth appears due to the combined effects of increased secretion of growth hormone and testosterone. In boys, height increases by an average of 28 cm during the pubertal spurt. The 10-cm mean difference in adult stature between men and women is due to a greater pubertal growth spurt in boys and to greater height at the onset of peak pubertal height velocity in boys compared with girls. Before puberty, boys and girls have the same mean body mass, skeletal mass, and body fat. However, men

have 150% of the average woman's lean and skeletal body mass, and women have 200% of the body fat of men. Men have twice the number of muscle cells of women, and 1.5 times the muscle mass.

Females

The first physical sign of puberty in girls is usually the onset of thelarche that begins between 10 and 11 years of age (see [Fig. 53-12A](#)). During the next 3 to 5 years, the breasts continue to develop under the influence of several hormones. Progesterone is primarily responsible for development of the alveoli (see [Fig. 56-11C](#)). Estrogen is the primary stimulus for development of the duct system that connects the alveoli to the exterior. Insulin, growth hormone, glucocorticoids, and thyroxin contribute to breast development, but they are incapable of causing breast growth by themselves.

During puberty, the uterus and cervix enlarge, and their secretory functions increase under the influence of estrogens (mainly estradiol). The uterine glands increase in number and length, and the endometrium and stroma proliferate in response to estrogens. The mucous membranes of the female urogenital tract respond to hormones, particularly estrogens.

Menarche usually occurs around 2 years after the initiation of thelarche. In the United States, most girls experience menarche between the ages of 11 and 13 years, the average age is 12.5 years, and the normal range is between 8 and 16 years. During puberty, a girl's body shape changes in response to rising levels of estradiol. The hips and pelvis widen and the proportion of body fat increases (compared with males) and distributes mainly to the breasts, hips, buttocks, thighs, upper arms, and pubis to produce the typical adult female body shape.

The appearance of secondary sex characteristics at puberty completes sexual differentiation and development

Although at birth humans have the primary and secondary sex organs necessary for procreation, final sexual maturity occurs only at puberty. Profound alterations in hormone secretion during the peripubertal period cause changes in the primary and secondary sex organs. In the following chapters the events occurring in puberty are discussed in more detail for both males (see [Chapter 54](#)) and females (see [Chapter 55](#)).

The Male Reproductive System

Sam Mesiano, Ervin E. Jones

The male reproductive system consists of two essential elements: the *gonads* (in this case the testes) and the complex array of glands and ducts that constitute the sex accessory organs ([Fig. 54-1A, B](#)).

A SAGITTAL SECTION OF THE MALE PELVIS

B URINARY BLADDER (DORSAL VIEW)

C TESTIS

D TESTICULAR LOBULE

E CROSS SECTION OF SEMINIFEROUS TUBULE

FIGURE 54-1 Anatomy of the male internal genitalia and accessory sex organs. **A**, The two major elements of the male sexual anatomy are the gonads (i.e., testes) and the sex accessories (i.e., epididymis, vas deferens, seminal vesicles, ejaculatory duct, prostate, bulbourethral or Cowper's glands, urethra, and penis). Note that the urethra can be subdivided into the prostatic urethra, the bulbous urethra, and the penile urethra. **B**, The vas deferens expands into an ampulla before coursing across the rear of the urinary bladder and merging with the outflow from the seminal vesicle. The merger forms the ejaculatory duct. The left and right ejaculatory ducts penetrate the prostate gland and open into the

prostatic urethra. **C**, The spermatozoa form in the seminiferous tubules and then flow into the rete testis and from there into the efferent ductules, the epididymis, and the vas deferens. **E**, The seminiferous tubule is an epithelium formed by Sertoli cells, with interspersed germ cells. The most immature germ cells (the spermatogonia) are near the periphery of the tubule, whereas the mature germ cells (the spermatozoa) are near the lumen of the tubule. The Leydig cells are interstitial cells that lie between the tubules.

The **testes** are responsible for the production of gametes, the haploid cells—**spermatozoa**, plural of spermatozoon—necessary for sexual reproduction and for the synthesis and secretion of hormones, including the principal male sex hormone, testosterone. These hormones are necessary for functional conditioning of the sex organs, the male **secondary sexual characteristics**, feedback control of gonadotropin secretion, and modulation of sexual behavior.

The testes (see [Fig. 54-1C](#)) are composed mainly of seminiferous tubules (see [Fig. 54-1D, E](#)) and interstitial cells of Leydig, located in the spaces between the tubules. A seminiferous tubule is an epithelium made up of Sertoli cells (see [Fig. 54-1E](#)) and is also the site of **spermatogenesis**—the production of the haploid spermatozoa from the diploid germ cells. The seminiferous epithelium rests on a basement membrane, itself supported by a thin lamina propria externa.

The male **sex accessory organs** include the paired epididymides, the vas deferens, the seminal vesicles, the ejaculatory ducts, the prostate, the bulbourethral glands (Cowper's glands), the urethra, and the penis. The primary role of the male sex accessory glands and ducts is to store and transport spermatozoa to the exterior, and thus enable spermatozoa to reach and fertilize female gametes.

Hypothalamic-Pituitary-Gonadal Axis

The hypothalamic-pituitary-gonadal axis ([Fig. 54-2](#)) controls two primary functions: (1) production of gametes (spermatogenesis in males and oogenesis in females), and (2) gonadal sex steroid biosynthesis (testosterone in males and estradiol and progesterone in females). In both sexes, the hypothalamus produces gonadotropin-releasing hormone (GnRH), which stimulates the gonadotrophs in the anterior pituitary to secrete the two gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Although the names of these hormones reflect their function in the female reproductive system (see [pp. 1111–1112](#)) they play similar roles in controlling gonadal function in both sexes. The hypothalamic-pituitary axis is therefore the central regulator of male and female reproductive systems. In the male, LH and FSH control, respectively, the Leydig and Sertoli cells of the testes.

FIGURE 54-2 Hypothalamic-pituitary-gonadal axis. Small-bodied neurons in the arcuate nucleus and preoptic area of the hypothalamus secrete GnRH, a decapeptide that reaches the gonadotrophs in the anterior pituitary via the long portal veins (see Fig. 47-3). Stimulation by GnRH causes the gonadotrophs to synthesize and release LH, which stimulates Leydig cells, and FSH, which stimulates Sertoli cells.

The hypothalamus secretes GnRH, which acts on gonadotrophs in the anterior pituitary

Gonadotropin-releasing hormone (GnRH), which is synthesized by small-bodied peptidergic neurons in the hypothalamus, stimulates the synthesis, storage, and secretion of gonadotropins by gonadotroph cells in the anterior pituitary. The hypothalamic-pituitary-portal system (see [p. 978](#)) describes the route by which GnRH and other releasing hormones emanating from the hypothalamus reach the anterior pituitary gland. The neurons that synthesize, store, and release GnRH are dispersed throughout the hypothalamus but are principally located in the arcuate nucleus and preoptic area. During embryonic development, GnRH neurons originate in the olfactory placode and migrate to the hypothalamus. Studies involving both rats and primates show that sites of GnRH production other than the hypothalamus (e.g., the limbic system) can also participate in the control of sex behavior. Neuronal systems originating from other areas of the brain impinge on the hypothalamic GnRH-releasing neurons and thus form a functional neuronal network that integrates multiple environmental signals (e.g., diurnal light-dark cycles) and physiological signals (e.g., extent of body fat stores, stress) to control GnRH release and, ultimately, the function of the reproductive system.

GnRH is a decapeptide hormone encoded by a single gene on chromosome 8. Like many other peptide hormones, GnRH is synthesized as a prohormone—69 amino acids long in this case. Cleavage of the prohormone yields the decapeptide GnRH (residues 1 to 10), a 56-amino-acid peptide (residues 14 to 69) referred to as **GnRH-associated peptide (GAP)**, and three amino acids that link the two ([Fig. 54-3](#)). Via the secretory pathway (see [p. 34](#)), the neuron transports both GnRH and GAP down the axon for secretion into the extracellular space. The role of GAP is unknown.

FIGURE 54-3 Map of the GnRH gene. The mature mRNA encodes a preprohormone with 92 amino acids. Removal of the 23-amino-acid signal sequence yields the 69-amino-acid prohormone. Cleavage of this prohormone yields GnRH. AA, amino acid.

GnRH neurons project axons directly to a small swelling on the inferior boundary of the hypothalamus, known as the median eminence, which lies above the pituitary stalk. The axons terminate near portal vessels that carry blood to the anterior pituitary (see [p. 978](#)). Consequently, GnRH secreted at the axon terminals in response to neuron activation enters the portal vasculature and is transported directly to gonadotrophs in the anterior pituitary.

GnRH stimulates the release of both FSH and LH from the gonadotroph cells in the anterior pituitary by interacting with high-affinity membrane receptors on the gonadotroph cell surface (see [Fig. 55-5](#)). The

GnRH receptor (GnRHR) is a G protein–coupled receptor (GPCR; see pp. 51–52) linked to $G\alpha_q$, which activates phospholipase C (PLC; see p. 58). PLC acts on membrane phosphatidylinositol 4,5-bisphosphates (PIP_2) to liberate inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 stimulates the release of Ca^{2+} from internal stores, which triggers exocytosis LH and FSH. DAG stimulates protein kinase C, which indirectly increases expression of genes encoding LH and FSH. The net effect is an increase in the synthesis and release of LH and FSH from the gonadotrophs. Because secretion of GnRH into the portal system is pulsatile, secretion of LH and FSH by the gonadotrophs is also episodic. The frequency of pulsatile LH discharge in men is ~8 to 14 pulses over a 24-hour period. FSH pulses are not as prominent as LH pulses, both because of their lower amplitude and because of the longer half-life of FSH in the circulation.

Upon binding GnRH, the GnRH receptor is internalized and partially degraded in the lysosomes. However, some GnRH receptors are shuttled back to the cell surface, and de novo receptor synthesis continues from GnRH receptor gene expression. Return of the GnRH receptor to the cell membrane is referred to as **receptor replenishment**. A consequence of receptor internalization, however, is that the responsiveness of gonadotrophs to GnRH can be decreased by prolonged exposure to GnRH. Thus, although pulsatile GnRH discharge elicits a corresponding pulsatile release of LH and FSH, *continuous* administration of GnRH—or intermittent administration of high doses of GnRH analogs—suppresses the release of gonadotropins. This effect occurs because continuous (rather than pulsatile) exposure to GnRH causes a decrease in the number of GnRH receptors on the surface of the gonadotroph (i.e., receptor internalization exceeds replenishment). The induced desensitization to GnRH can be used therapeutically to control the reproductive function. A clinical application of this principle is chemical castration in prostatic cancer. Here, the administration of long-acting GnRH analogs desensitize the gonadotrophs to GnRH, which leads to low LH and FSH levels and thereby reduces testosterone production (see Box 55-2).

Under the control of GnRH, gonadotrophs in the anterior pituitary secrete LH and FSH

Luteinizing hormone (LH) and **follicle-stimulating hormone (FSH)** are members of the same family of hormones as human chorionic gonadotropin (hCG; see p. 1139) and thyroid-stimulating hormone (TSH; see p. 1010). These glycoprotein hormones are composed of two polypeptide chains designated α and β , both of which are required for full biological activity. The α subunits of LH and FSH, as well as the α subunits of hCG and TSH, are identical. In humans, the common α subunit has 92 amino acids and a molecular weight of ~20 kDa. The β subunits differ among these four hormones and thus confer specific functional and immunological characteristics to the intact molecules.

Each of the unique β subunits of FSH and LH is 115 amino acids in length. The β subunits of LH and hCG are identical except that the β subunit of hCG has an additional 24 amino acids and additional glycosylation sites at the C terminus. 🟡N54-1 The biological activities of LH and hCG are very similar. Indeed, in most clinical uses (e.g., in an attempt to initiate spermatogenesis in oligospermic men), hCG is substituted for LH because hCG is much more readily available. 🟡N54-2

N54-1

Human Chorionic Gonadotropin

Contributed by Ervin Jones, Walter Boron, Emile Boulpaep

hCG is secreted by the placenta, and some reports have described that small amounts of this substance are made in the testes, pituitary gland, and other nonplacental tissues.

hCG appears in the urine of pregnant women about 12 to 14 days after conception—the basis for pregnancy tests. In former times, hCG was extracted from the urine of pregnant women.

N54-2

Plasma Lifetime of Luteinizing Hormone, Human Chorionic Gonadotropin, and Follicle-Stimulating Hormone

Contributed by Ervin Jones

The disappearance of exogenous **LH** from the circulation is independent of gonadal function and follows a dual exponential time course. The half-life of the fast component is 40 minutes and that of the slow component is 120 minutes. Because of its increased glycosylation, **hCG** has an even longer half-life. **FSH** has a slower turnover rate; its disappearance from the blood is described by two exponentials with half-lives of about 4 hours and 3 days, respectively.

Differential secretion of FSH and LH is affected by several other hormonal mediators, including sex steroids, inhibins, and activins (see [pp. 1113–1115](#)). Thus, depending on the specific hormonal milieu produced by different physiological circumstances, the gonadotroph produces the α and β subunits of FSH and LH at different rates.

The specific gonadotropin and the relative proportions of each gonadotropin released from the anterior pituitary depend on the developmental age. The pituitary gland of the male fetus contains functional gonadotrophs by the end of the first trimester of gestation. Thereafter, gonadotropin secretion rises rapidly and then plateaus. Gonadotropin secretion begins to decline in utero during late fetal life and increases again during the early postnatal period.

Male primates release LH in response to GnRH administration at 1 to 3 months of age, a finding indicative of functional competence of the anterior pituitary gland. Also during this time, a short-lived postnatal surge of LH and testosterone secretion occurs in males. Although the cause of this short-lived surge of gonadotropins remains to be understood, it is clearly independent of sex steroids. The sensitivity of the gonadotrophs to stimulation subsequently diminishes, and the system remains quiescent until just before puberty.

Release of FSH is greater than that of LH during the prepubertal period, a pattern that is reversed after puberty. GnRH preferentially triggers LH release in men. This preferential release of LH may reflect maturation of the testes, which secrete inhibins, a specific inhibitor of FSH secretion at the level of the anterior pituitary gland. Increased sensitivity of the pituitary to increasing gonadal steroid production may also be responsible for the diminished secretion of FSH.

LH stimulates the Leydig cells of the testis to produce testosterone

LH derives its name from effects observed in the female, that is, from the ability to stimulate ovulation and the formation and maintenance of the corpus luteum (see [p. 1116](#)). The comparable substance in the

male was originally referred to as interstitial cell–stimulating hormone (ICSH). Subsequently, investigators realized that LH and ICSH are the same substance, and the common name became LH.

LH stimulates the synthesis of testosterone by the testes. Testosterone production decreases in males after hypophysectomy. Conversely, LH (or hCG) treatment of men increases testosterone levels, but only if the testes are intact and functional. The interstitial **Leydig cells** are the principal targets for LH and the primary source of testosterone production in the male. The plasma membranes of Leydig cells have a high-affinity LH receptor, a GPCR coupled to G_{α_s} (Fig. 54-4). Binding of LH to this receptor activates membrane-bound adenylyl cyclase (see p. 53), which catalyzes the formation of cAMP, which in turn activates protein kinase A (PKA). Activated PKA modulates gene transcription (see Fig. 4-13) and increases the synthesis of enzymes and other proteins necessary for the biosynthesis of testosterone (see pp. 1097–1100).

FIGURE 54-4 Leydig and Sertoli cell physiology. The Leydig cell (*left*) has receptors for LH. The binding of LH increases testosterone synthesis. The Sertoli cell (*right*) has receptors for FSH. (Useful mnemonics: L for LH and Leydig, S for FSH and Sertoli.) FSH promotes the synthesis of androgen-binding protein (ABP), aromatase, growth factors, and inhibin. There is crosstalk between Leydig cells and Sertoli cells. The Leydig cells make testosterone, which acts on Sertoli cells. Conversely, the Sertoli cells convert some of this testosterone to estradiol (because of the presence of aromatase), which can act on the Leydig cells. Sertoli cells also generate growth factors that act on the Leydig cells.

FSH stimulates Sertoli cells to synthesize hormones that influence Leydig cells and spermatogenesis

The Sertoli cells are the primary testicular site of FSH action (see Fig. 54-4). FSH also regulates Leydig cell physiology via effects on Sertoli cells. The signaling events after FSH binding are similar to those described above for LH on the Leydig cell. Thus, binding of FSH to a GPCR activates G_{α_s} , causing stimulation of adenylyl cyclase, an increase in $[cAMP]_i$, stimulation of PKA, transcription of specific genes, and increased protein synthesis. These proteins are important for synthesis and action of steroid

hormones, including the following:

1. **Androgen-binding protein (ABP)**, which is secreted into the luminal space of the seminiferous tubule, near the developing sperm cells. ABP helps to keep local testosterone levels high.
2. **P-450 aromatase (P-450_{arom})**; see [p. 1117](#) and [Table 50-2](#), a key steroidogenic enzyme that converts testosterone, which diffuses from the Leydig cells to the Sertoli cells, into estradiol.
3. **Growth factors** and other products that support sperm cells and spermatogenesis. These substances significantly increase the number of spermatogonia, spermatocytes, and spermatids in the testis. The stimulatory effect of FSH on spermatogenesis is not a direct action of FSH on the spermatogonia; instead, stimulation of spermatogenesis occurs via the action of FSH on Sertoli cells. FSH may also increase the fertility potential of sperm; it appears that this effect of FSH results from stimulation of motility, rather than from an increase in the absolute number of sperm.
4. **Inhibins**, which exert negative feedback on the hypothalamic-pituitary-testicular axis to inhibit FSH secretion (see below). Inhibins are members of the transforming growth factor- β (TGF- β) superfamily, which also includes the activins and antimüllerian hormone (see [p. 1080](#)). Inhibins are glycoprotein heterodimers consisting of one α and one β subunit that are covalently linked. The granulosa cells in the ovary and the Sertoli cells in the testis are the primary sources of inhibins. We discuss the biology of inhibins and activins in more detail on [pages 1113–1115](#). Inhibins are secreted into the seminiferous tubule fluid and into the interstitial fluid of the testicle. In addition to exerting an endocrine effect on the axis, inhibins also have paracrine effects, acting as growth factors on Leydig cells.

Leydig cells and Sertoli cells engage in **crosstalk** (see [Fig. 54-4](#)). For example, the Leydig cells make testosterone, which acts on Sertoli cells. In the rat, β endorphin produced by fetal Leydig cells binds to opiate receptors in Sertoli cells and inhibits their proliferation. Synthesis of β endorphins could represent a local feedback mechanism by which Leydig cells constrain the number of Sertoli cells. Conversely, Sertoli cells affect Leydig cells. For example, Sertoli cells convert testosterone—manufactured by Leydig cells—to estradiol, which decreases the capacity of Leydig cells to produce testosterone in response to LH. In addition, FSH acting on Sertoli cells produces growth factors that may increase the number of LH receptors on Leydig cells during development and thus result in an increase in steroidogenesis (i.e., an increase in testosterone production).

What, then, is required for optimal spermatogenesis to occur? It appears that two testicular cell types (Leydig cells and Sertoli cells) are required, as well as two gonadotropins (LH and FSH) and one androgen (testosterone). First, LH and Leydig cells are required to produce testosterone. Thus, LH, or rather its substitute hCG, is used therapeutically to initiate spermatogenesis in azoospermic or oligospermic men. Second, FSH and Sertoli cells are important for the nursing of developing sperm cells and for the production of inhibin and growth factors, which affect the Leydig cells. Thus, FSH plays a primary role in regulating development of the appropriate number of the Leydig cells so that adequate testosterone levels are available for spermatogenesis and the development of secondary sex characteristics.

During early puberty in boys, both FSH and LH levels increase while, simultaneously, the Leydig cells proliferate and plasma levels of testosterone increase ([Fig. 54-5](#)). [N54-3](#)

Effects of Follicle-Stimulating Hormone on Leydig and Sertoli Cells during Puberty

Contributed by Ervin Jones

As noted in the upper panel of eFigure 54-1, both FSH and LH levels increase during early puberty in boys, while simultaneously the Leydig cells proliferate. As a result, the Leydig cells increase their production of testosterone, and plasma levels of this steroid hormone increase, as shown in the lower panel of eFigure 54-1.

FIGURE 54-1 Plasma levels of FSH, LH, and testosterone from puberty to adulthood. The upper panel shows how plasma levels of biologically active LH and FSH increase during puberty, expressed in terms of both the stages of puberty and bone age. The lower panel shows the concomitant rise in plasma levels of testosterone. LH stimulates Leydig cells to synthesize testosterone. FSH indirectly promotes testosterone synthesis by stimulating the Sertoli cells to produce factors that act on Leydig cells. (*Upper panel*, modified from Reiter EO, Beitins IZ, Ostrea TR, et al: Bioassayable luteinizing hormone during childhood and adolescence and in patients with delayed pubertal development. *J Clin Endocrinol Metab* 54:155–161, 1982; and Beitins IZ, Padmanabhan V, Kasa-Vubu J, et al: Serum bioactive follicle-stimulating hormone concentration from prepuberty to adulthood: A cross-sectional study. *J Clin Endocrinol Metab* 71:1022–1027, 1990; *lower panel*, modified from Grumbach MM, Styne DM: Puberty: Ontogeny, neuroendocrinology, physiology, and disorders. In Wilson JD, Foster DW, Kronenberg HM, Larsen PR [eds]: *Williams Textbook of Endocrinology*, 9th ed. Philadelphia, WB Saunders, 1998, pp 1509–1625.)

The primary target of FSH in the testis is the Sertoli cell (see Fig. 54-4). Via this action on Sertoli cells, FSH indirectly increases the number of **Leydig cells**, which is a key part of pubertal development. In hypogonadotropic-hypogonadal men (i.e., individuals who have decreased levels of both LH and FSH), treating with exogenous FSH stimulates the Sertoli cells to release factors that induce differentiation and maturation of Leydig cells. Subsequent treatment with hCG (i.e., which acts like LH) acts on these Leydig cells to synthesize testosterone and thereby support spermatogenesis.

During puberty, a related change is that **Sertoli cells** become relatively less sensitive to FSH, but at the same time they become more dependent on the testosterone that the Leydig cells produce. Thus, there is a continuum in the development of the Sertoli cells: as proliferation and maturation of the Sertoli cells proceeds during puberty, the responsiveness of the Sertoli cell to FSH declines while its responsiveness to testosterone increases. The mechanism for this switch appears to be that FSH stimulates the synthesis of androgen receptors on Sertoli cells.

The hypothalamic-pituitary-testicular axis is under feedback inhibition by testicular steroids and inhibins

The hypothalamic-pituitary-testicular axis in postpubertal males not only induces production of testosterone and inhibin by the testes but also receives negative feedback from these substances (see Fig. 54-2).

Normal circulating levels of **testosterone** inhibit the pulsatile release of GnRH by the hypothalamus and thereby reduce the frequency and amplitude of the LH- and FSH-secretory pulses. Testosterone also

has negative-feedback action on LH secretion at the level of the pituitary gonadotrophs.

The **inhibins** also feed back on FSH secretion. Evidence for such negative feedback is that plasma FSH concentrations increase in proportion to the loss of germinal elements in the testis. Thus, FSH specifically stimulates the Sertoli cells to produce inhibin, and inhibin “inhibits” FSH secretion. Inhibin appears to diminish FSH secretion by acting at the level of the anterior pituitary rather than the hypothalamus.

The secretion of LH and FSH is under the additional control of neuropeptides, amino acids such as aspartate, corticotropin-releasing hormone (CRH), and endogenous opioids.

Testosterone

Leydig cells convert cholesterol to testosterone

Cholesterol is the obligate precursor for androgens and other testicular steroids. The Leydig cell can synthesize cholesterol *de novo* from acetyl coenzyme A or can take it up as low-density lipoproteins from the extracellular fluid by receptor-mediated endocytosis (see [p. 42](#)). The two sources appear to be equally important in humans.

Preceding the metabolism of cholesterol is the translocation of this precursor to the mitochondrial inner membrane, which requires two proteins. The first is **sterol-carrier protein 2 (SCP-2)**, a 13.5-kDa protein that translocates cholesterol from the plasma or organellar membranes to other organellar membranes, including the outer mitochondrial membrane. The second protein is the **steroidogenic acute regulatory protein (StAR)**, which belongs to a large family of proteins involved in lipid trafficking and metabolism. The 37-kDa **pro-StAR** protein—the precursor to StAR—ferries cholesterol from the endoplasmic reticulum to the outer mitochondrial membrane. The 30-kDa **mature StAR protein** resides in the mitochondrial intermembrane space and extracts cholesterol from the mitochondrial outer membrane and ferries it across to the mitochondrial inner membrane.

The **Leydig cell** uses a series of five enzymes to convert cholesterol to testosterone. Three of these enzymes are **P-450 enzymes** (see [Table 50-2](#)).  **N54-4** As summarized in [Figure 54-6](#), because 3 β -hydroxysteroid dehydrogenase (3 β -HSD) can oxidize the A ring of four intermediates, testosterone synthesis from cholesterol can take four pathways. The following is the “preferred” pathway:

FIGURE 54-6 Biosynthesis of testosterone. This scheme summarizes the synthesis of the androgens from cholesterol. The individual enzymes are shown in the horizontal and vertical boxes; they are located

in either the SER or the mitochondria. The side-chain-cleavage enzyme that produces pregnenolone is also known as 20,22-desmolase. The chemical groups modified by each enzyme are highlighted in the reaction product. There are four possible pathways from pregnenolone to testosterone; the preferred pathway in the human testis appears to be the delta-5 pathway, the one along the left edge of the figure to androstenediol, followed by oxidation of the A ring to testosterone. Some of these pathways are shared in the biosynthesis of the glucocorticoids and mineralocorticoids (see Fig. 50-2) as well as the estrogens (see Fig. 55-8).

N54-4

Cytochrome P-450 Enzymes

Contributed by Emile Boulpaep, Walter Boron

The term cytochrome P-450 enzymes refers to a family of several hundred heme-containing enzymes that are located primarily in the SER. See Table 50-2 for some examples of these enzymes that play a role in steroidogenesis. We discuss the roles of these P-450 enzymes for the adrenal gland on page 1021, for the testis on page 1097, and for the ovary on page 1117. On page 64, we discuss the role of a P-450 enzyme (i.e., epoxxygenase) in the metabolism of arachidonic acid (see also Fig. 3-11).

These enzymes are **monooxygenases**.* That is, they transfer *one atom* of molecular oxygen to an organic substrate RH to form ROH, whereas the *other oxygen atom* accepts two protons from the reduced form of the enzyme to form water:

This monooxygenation reaction is also referred to as a **hydroxylation** reaction because the enzyme hydroxylates RH to form ROH. Note that at the end of the reaction, the P-450 monooxygenase is in its reduced form. Another enzyme—a cytochrome **P-450 reductase**—recycles the P-450 monooxygenase to its reduced form; in the process, this P-450 reductase becomes oxidized. Finally, the oxidized P-450 reductase recycles to its reduced form by oxidizing the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) to NADP^+ or the reduced form of nicotinamide adenine dinucleotide (NADH) to NAD^+ or one of the flavin nucleotides (reduced flavin adenine dinucleotide [FADH_2] or reduced flavin mononucleotide [FMNH_2]).

The P-450 enzymes are so named because when the reduced forms of the enzymes bind carbon monoxide, they absorb light strongly at 450 nm.

Nelson DL, Cox MM. *Lehninger Principles of Biochemistry*. 3rd ed. Worth Publishers: New York; 2000 [pp; 782; 783].

*Enzymes that transfer both oxygen atoms of molecular oxygen to an organic substrate are termed dioxygenases. In contrast, oxidases (e.g., cytochrome oxidase in the electron transport chain of mitochondria) are enzymes that catalyze oxidations in which neither of the atoms

of molecular oxygen becomes part of the oxidized product. Instead, the molecular oxygen acts as an electron acceptor to form a molecule such as H_2O or H_2O_2 .

- 1. Cholesterol conversion to pregnenolone.** The pathway for testosterone synthesis begins in the mitochondrial inner membrane, where the **cytochrome P-450 side-chain-cleavage enzyme (P-450_{scc}**, also called 20,22-desmolase)  **N54-4** removes the long side chain (carbons 22 to 27) from the carbon at position 20 of the cholesterol molecule (27 carbon atoms), yielding **pregnenolone** (21 carbon atoms). This reaction is the rate-limiting step in the biosynthesis of testosterone, as it is for other steroid hormones. LH stimulates this reaction in the Leydig cell in two ways. First, LH increases the affinity of P-450_{scc} for cholesterol. Second, LH has long-term actions of increasing the levels of SCP-2, StAR, and P-450_{scc} via PKA-stimulated gene transcription.
- 2. Pregnenolone conversion to 17 α -hydroxypregnenolone.** In the smooth endoplasmic reticulum (SER), 17 α -hydroxylase (P-450_{c17})  **N54-4** then adds a hydroxyl group at position 17 to form **17 α -hydroxypregnenolone**. P-450_{c17}, a key branch-point enzyme in the steroidogenic pathway, also converts progesterone to 17 α -hydroxyprogesterone (see [Fig. 54-6](#), middle column).
- 3. 17 α -hydroxypregnenolone conversion to dehydroepiandrosterone.** In the SER, the 17,20-desmolase (a different activity of the *same* P-450_{c17} whose 17 α -hydroxylase activity catalyzes the previous step) removes the position-20 side chain from position 17 of 17 α -hydroxypregnenolone, producing a 19-carbon steroid called **dehydroepiandrosterone (DHEA)**. This so-called delta-5 pathway on the left of [Figure 54-6](#) is the preferred route in Leydig cells to yield DHEA, the precursor for all sex steroids.
- 4. DHEA conversion to androstenediol.** In the SER of the Leydig cell, a 17 β -hydroxysteroid dehydrogenase (17 β -HSD, which is *not* a P-450 enzyme) converts the ketone at position 17 of DHEA to a hydroxyl group to form **androstenediol**.
- 5. Androstenediol conversion to testosterone.** Finally, in the SER, 3 β -HSD (*not* a P-450 enzyme) oxidizes the hydroxyl group of androstenediol at position 3 of the A ring to a ketone, forming **testosterone**.  **N54-5**

N54-5

Delta-5 and Delta-4 Steroids

Contributed by Sam Mesiano

Pregnenolone is called P5. Progesterone is P4. This is where the terms delta-5 and delta-4 come from.

3 β -HSD is a major branch-point enzyme in the steroidogenic pathway (see [Fig. 54-6](#)). It converts all delta-5 steroids to delta-4 steroids via an isomerase activity and therefore is essential for the production of mineralocorticoids and glucocorticoids. The competition between **17 α -hydroxylase/17,20-desmolase** (two enzymatic activities mediated in the same protein, also known as P-450_{c17}) and 3 β -HSD for pregnenolone and 17 α -hydroxypregnenolone is a major determinant of whether a steroidogenic cell will produce mineralocorticoids, glucocorticoids, or sex steroids. In the Leydig cell, 17 α -hydroxylase/17,20-desmolase prevails to produce DHEA, which 17 β -HSD1 then converts to androstenediol. DHEA can also undergo conversion, via 3 β -HSD, to androstenedione, which 17 β -HSD1 then converts to

testosterone.

In addition, the testis can also use 5 α -reductase, which is located in the SER, to convert testosterone to dihydrotestosterone (DHT). However, extratesticular tissue is responsible for most of the production of DHT. The conversion of testosterone to DHT is especially important in certain testosterone target cells (see pp. 1097–1099).

The Leydig cells of the testes make ~95% of the circulating testosterone. Although testosterone is the major secretory product, the testes also secretes pregnenolone, progesterone, 17-hydroxyprogesterone, androstenedione, androsterone, and DHT. The conversion of testosterone to DHT by Leydig cells is minor compared with its production in certain testosterone target cells (see p. 1085). Androstenedione is of major importance because it serves as a precursor for extraglandular estrogen formation. In men who are between the ages of 25 and 70 years, the rate of testosterone production remains relatively constant (Table 54-1). Figure 54-5 summarizes the changes in plasma testosterone levels as a function of age in human males. N54-6

TABLE 54-1
Androgen Production and Turnover

STEROID	BLOOD PRODUCTION RATE—HORMONE DELIVERED TO THE BLOOD (µg/day)	PLASMA CONCENTRATION (µg/L)
Testosterone	6500	6.5
Androstenedione	2000–6000	1.5
Dihydrotestosterone	300	0.5

N54-6

Testosterone Secretion and Production Rates

Contributed by Emile Boulpaep, Walter Boron

In the text, we noted that plasma testosterone levels are relatively constant in males between the ages of 25 and 70 years. As for any substance in the blood, the stability of plasma levels of testosterone indicates that the rate of testosterone production is equal to the rate of testosterone removal. However, the stability of plasma testosterone levels says nothing about the individual rates of production and removal.

It is important to distinguish between the secretion rate of a hormone and the production rate. **Secretion** refers to the release of the hormone from a specific organ or gland, and may be determined by selectively catheterizing the artery and vein supplying that tissue and ascertaining the arterial-venous difference in the concentration of that substance. For example, the concentration of testosterone is 400 to 500 µg/L in effluent of the spermatic vein; this level is ~75 times higher than the concentration found in the arterial blood. Thus, if we knew the blood flow out of the spermatic vein, then we could compute the *rate of secretion* of testosterone by the testis.

Production rate refers to the total appearance of the hormone in the circulation as the result of the secretion by all tissues in the body. Thus, the secretion rate for the testes equals the whole-body production rate only when other tissues make no contribution.

In the **steady state**, the amount of testosterone *cleared* from the circulation equals the amount produced. Thus,

$$\frac{\text{PR}}{(\mu\text{g/day})} = \frac{\text{MCR}}{(\text{L/day})} \times \frac{[\text{S}]}{(\mu\text{g/L})} \quad (\text{NE 54-1})$$

Here, PR is the whole-body production rate, MCR is the **metabolic clearance rate**, and [S] is the concentration of the substance in the plasma. MCR is defined in the same way as renal clearances (see Table 33-2). That is, MCR is the virtual number of liters per day that are fully cleared of testosterone. This clearance is due to the metabolism of testosterone, which is discussed on pages 1099–1100. Because the mean metabolic clearance rate for testosterone is ~1000 L/day, and the testosterone concentration is about 6.5 µg/L (range, 3 to 10 µg/L), the production rate must be about 6500 µg/day. Evidence for this high clearance rate is the fact that the plasma half-life of testosterone is only 10 to 20 minutes.

Adipose tissue, skin, and the adrenal cortex also produce testosterone and other androgens

Several tissues besides the testes—including adipose tissue, skin, adrenal cortex, brain, and muscle—produce testosterone and several other androgens. These substances may be synthesized de novo from cholesterol or produced by peripheral conversion of precursors. Moreover, the peripheral organs and tissues may convert sex steroids to less active forms (see Fig. 54-6). Notable sites of extragonadal conversion include adipose tissue and the skin. Androstenedione is converted to testosterone in peripheral tissues. In this case, **androstenedione** is the precursor for the hormone testosterone. Testosterone can be converted to estradiol or DHT or go “backward” by reversible interconversion to androstenedione. Thus, a potent hormone such as testosterone may also serve as a precursor for a weaker hormone (androstenedione), a hormone with different activities (estradiol), or a more potent hormone having similar activities (DHT). This last example may be illustrated by the effects of DHT on hair follicles, sebaceous glands, and the sex accessory organs. In these tissues, the androgenic effects of circulating testosterone are amplified by its conversion by 5α-reductase to DHT, which has a much higher affinity for the **androgen receptor (AR)**; see p. 1085). Some tissues, including the brain, aromatize testosterone to estradiol, and thus the action of this metabolite occurs via the estrogen receptor.

The adrenal cortex (see p. 1021) is another source of androgen production in both males and females. Normal human adrenal glands synthesize and secrete the weak androgens DHEA, conjugated DHEA sulfate, and androstenedione. Essentially, all the DHEA in male plasma is of adrenal origin. However, <1% of the total testosterone in plasma is derived from DHEA. As summarized in Table 54-1, the plasma concentration of androstenedione in males is only ~25% that of testosterone. About 20% of androstenedione is generated by peripheral metabolism of other steroids. Although the adrenal gland contributes significantly to the total androgen milieu in males, it does not appear to have significant effects on stimulation and growth of the male accessory organs (Box 54-1). This occurs primarily as a result of DHT production from circulating testosterone.

Box 54-1

Testosterone and Aging Men

For a long time, the abrupt hormonal alterations that signal the dramatic changes of female menopause were believed to have no correlate in men. We now know that men do experience a gradual decline in

their serum testosterone levels (see Fig. 54-5)  N54-6 and that this decline is closely correlated with many of the changes that accompany aging: decreases in bone formation, muscle mass, growth of facial hair, appetite, and libido. The blood hematocrit also decreases. Testosterone replacement can reverse many of these changes by restoring muscle and bone mass and correcting the anemia.

Although the levels of both total and free testosterone decline with age, levels of LH are frequently not elevated. This finding is believed to indicate that some degree of hypothalamic-pituitary dysfunction accompanies aging.

Testosterone acts on target organs by binding to a nuclear receptor

Most testosterone in the circulation is bound to specific binding proteins. About 45% of plasma testosterone binds to **sex hormone-binding globulin (SHBG)** and ~55% binds to serum albumin and corticosteroid-binding globulin (CBG; see [p. 1021](#)). A small fraction (~2%) of the total circulating testosterone circulates free, or unbound, in plasma. The free form of testosterone enters the cell by passive diffusion and subsequently exerts biological actions or undergoes metabolism by other organs such as the prostate, liver, and intestines (see the next section). The quantity of testosterone entering a cell is determined by the plasma concentration and by the intracellular milieu of enzymes and binding proteins.

Once it diffuses into the cell, testosterone either binds to a high-affinity AR in the nucleus or undergoes conversion to DHT, which also binds to the AR. This receptor functions as a homodimer (AR/AR) and is a member of the family of nuclear receptors (see [Table 3-6](#)) that includes receptors for glucocorticoids, mineralocorticoids, progesterone, estrogens, vitamin D, thyroid hormone, and retinoic acid. The gene coding for the AR is located on the X chromosome. The androgen-AR complex is a transcription factor that binds to hormone response elements on DNA located in the promoter regions of the target genes. Interaction between the androgen-AR complex and nuclear chromatin causes marked increases in transcription, which ultimately lead to the synthesis of specific proteins. As a result of these synthetic processes, specific cell functions ensue, including growth and development. Thus, presence of the AR in a cell or tissue determines whether that tissue responds to androgens.

Whether the active compound in any tissue is DHT or testosterone depends on the presence or absence in that tissue of the microsomal enzyme **5 α -reductase**, which converts testosterone to DHT. The biological activity of DHT is 30 to 50 times higher than that of testosterone. Some tissues, including the brain, aromatize testosterone to estradiol, and thus the action of this metabolite occurs via the estrogen receptor.

Some of the effects of androgens may be nongenomic. For example, androgens may stimulate hepatic microsomal protein synthesis by a mechanism independent of binding to the AR. Other evidence indicates that the action of androgens on the prostate gland may occur via the adenylyl cyclase/PKA system (see [pp. 56–57](#)) and could result in gene activation under some circumstances.

Metabolism of testosterone occurs primarily in the liver and prostate

Only small amounts of testosterone enter the urine without metabolism; this urinary testosterone represents <2% of the daily testosterone production. The large remaining balance of testosterone and other androgens is converted in the liver to 17-ketosteroids and in the prostate to DHT. The degradation

products of testosterone are primarily excreted in the urine and feces as water-soluble conjugates of either sulfuric acid or glucuronic acid.

Biology of Spermatogenesis and Semen

Spermatogenesis includes mitotic divisions of spermatogonia, meiotic divisions of spermatocytes to spermatids, and maturation to spermatozoa 🍌N54-7

N54-7

Definitions

Contributed by Emile Boulpaep, Walter Boron

The following are definitions of four related terms:

Spermatogenesis. As noted on page 1100, spermatogenesis includes the mitotic divisions of spermatogonia, the meiotic divisions of spermatogonia (diploid $2N$ DNA) to haploid spermatids (haploid $1N$ DNA), and the maturation to spermatozoa. This process includes both *spermatocytogenesis* and *spermiogenesis*.

Spermatocytogenesis. This term refers to the meiotic stages of spermatogenesis, in which spermatogonia (diploid $2N$ DNA) develop into primary spermatocytes (diploid $4N$ DNA), and then into secondary spermatocytes (haploid $2N$ DNA), and then finally into spermatids (haploid $1N$ DNA).

Spermiogenesis. This term refers to the maturation of spermatids (haploid $1N$ DNA) to mature spermatozoa. Spermiogenesis involves no cell division.

Spermiation. The release of the spermatozoa from the Sertoli cells is termed spermiation.

The primordial germ cells (see pp. 1076–1077) migrate into the gonad during embryogenesis. In males, these cells become the immature stem-cell population of the germinal cell line, or **spermatogonia**, and reside on the inner basal lamina of the seminiferous tubules (see Fig. 54-1E). Beginning at puberty and continuing thereafter throughout life, these spermatogonia divide mitotically (Fig. 54-7). The spermatogonia have the normal diploid complement of 46 chromosomes ($2N$): 22 pairs of autosomal chromosomes plus one X and one Y chromosome.

N54-12

Spermatogenesis

Contributed by Ervin Jones

Early during embryogenesis, the primordial germ cells migrate to the gonad, where they become type A spermatogonia. Beginning at puberty, the spermatogonia undergo many rounds of mitotic division, with one daughter cell renewing the type A stem-cell population and the other generating type B spermatogonia. After many mitotic divisions, type B spermatogonia (2N DNA) enter the first meiotic division, at which time they are referred to as *primary spermatocytes*. During prophase, each primary spermatocyte has a full complement of duplicated chromosomes (4N DNA). Each primary spermatocyte divides into two secondary spermatocytes, each with a haploid number of duplicated chromosomes (2N DNA). The secondary spermatocyte enters the second meiotic division, producing two spermatids, each of which has a haploid number of unduplicated chromosomes (1N DNA). Further maturation of the spermatids yields the spermatozoa (mature sperm). Note that one primary spermatocyte yields four spermatozoa.

Spermatogonia can be classified into two types: A and B. Type A spermatogonia form the stem-cell population of male germ cells and divide by mitosis. One of the daughter cells renews the stock of type A spermatogonia and the other becomes a type B spermatogonium that undergoes several additional rounds of mitosis before its progeny initiate meiosis and progress through spermatogenesis (see [Fig. 54-7](#)). Type B spermatogonia that enter into the first meiotic division become **primary spermatocytes**. At prophase of meiosis I, the chromosomes undergo crossing over (see [Fig. 53-2B](#)). At this stage, each cell has a duplicated set of 46 chromosomes (4N): 22 pairs of duplicated autosomal chromosomes, a duplicated X chromosome, and a duplicated Y chromosome. After this first meiotic division is completed, the daughter cells become **secondary spermatocytes**, which have a haploid number of duplicated chromosomes (2N): 22 duplicated autosomal chromosomes and either a duplicated X or a duplicated Y chromosome. Secondary spermatocytes enter the second meiotic division almost immediately. This division results in smaller cells called spermatids, which have a *haploid* number of *unduplicated* chromosomes (1N). **Spermatids** form the inner layer of the epithelium and are found in rather discrete aggregates inasmuch as the cells derived from a single spermatogonium tend to remain together—with cytoplasm linked in a syncytium—and differentiate synchronously.

Spermatids transform into **spermatozoa** in a process called **spermiogenesis**,  N54-7 which involves cytoplasmic reduction and differentiation of the body and the tailpieces. Thus, as maturation progresses, developing male gametes decrease in volume. Conversely, maturation leads to an increase in cell number, with each primary spermatocyte producing four spermatozoa, two with an X chromosome and two with a Y chromosome.

As additional generations of type B spermatogonia appear, the cells are displaced toward the lumen of the tubule. Thus, when viewed in cross sections of seminiferous tubules (see [Fig. 54-1E](#)), spermatogonia are located adjacent to the basement membrane, whereas the more differentiated spermatids are located nearest the lumen. Groups of spermatogonia at comparable stages of development undergo mitosis simultaneously. However, spermatogenesis is asynchronous along the seminiferous tubule; different areas

along the tubule are at different stages of spermatogenesis. In a continuous process, a young man produces sperm at a rate of ~1000 per second.

Each stage of spermatogenesis has a specific duration. The time between formation of type B spermatogonia and differentiation of daughter cells into mature sperm is ~64 days. Each cell type has a characteristic life span: 16 to 18 days for type B spermatogonia, 23 days for primary spermatocytes, 1 day for secondary spermatocytes, and ~23 days for spermatids. The rate of spermatogenesis is constant and cannot be accelerated by hormones such as gonadotropins or androgens. Germ cells must move forward in their differentiation. If the environment is unfavorable and makes it impossible for them to pursue their differentiation at the normal rate, they undergo apoptosis (see [p. 1241](#)) and are eliminated in the semen. Healthy 20-year-old men produce sperm at a rate of ~6.5 million sperm per gram of testicular parenchyma per day. The rate falls progressively with age and averages ~3.8 million sperm per gram per day in men 50 to 90 years old. This decrease is probably related to the high rate of apoptosis of germ cells during meiotic prophase. Among fertile men, those aged 51 to 90 years exhibit a significant decrease in the percentage of morphologically normal and motile spermatozoa.

In summary, three processes occur concurrently in the seminiferous epithelium: (1) the production of cells by mitosis, (2) differentiation of spermatogonia to spermatids with a reduction in the number of chromosomes by meiosis, and (3) the conversion of spermatids to mature sperm by spermiogenesis. Thus, spermatogenesis is a regular, ordered, sequential process resulting in the production of mature male gametes.

It is instructive to consider how spermatogenesis in the male differs from oogenesis in the female. The two processes differ in each of the three steps just noted: (1) In the female, the *mitotic* proliferation of germ cells takes place entirely before birth. In the male, spermatogonia proliferate only after puberty and then throughout life. (2) The *meiotic* divisions of a primary oocyte in the female produce only one mature ovum with a large amount of cytoplasm and two to three polar bodies (see [p. 1073](#)). In the male, the meiotic divisions of a primary spermatocyte produce four mature spermatozoa with a minimal amount of cytoplasm.  [N53-8](#) (3) In the female, the second meiotic division is completed only on fertilization (see [p. 1131](#)) and thus no further development of the cell takes place after the completion of meiosis. In the male, the products of meiosis (the spermatids) undergo substantial further differentiation to produce mature spermatozoa.

The Sertoli cells support spermatogenesis

Sertoli cells (also called sustentacular cells) are generally regarded as support or “nurse” cells for the spermatids ([Fig. 54-8](#)). Sertoli cells (1) maintain an environment conducive for spermatogenesis; (2) in response to FSH, secrete substances that promote proliferation of spermatogonia and initiate meiosis; (3) secrete androgen-binding protein, which concentrates testosterone in the proximity of developing gametes; (4) secrete inhibin, which controls pituitary gland production of FSH; (5) phagocytose excess cytoplasm produced by gametes during spermiogenesis; and (6) produce antimüllerian hormone, which represses formation of derivatives of the müllerian duct (see [p. 1080](#)).

FIGURE 54-8 Interaction of Sertoli cells and sperm. This figure is an idealized high-magnification view of a portion of the wall of a seminiferous tubule (see Fig. 54-1C). A single Sertoli cell spans from the basal lamina to the lumen of the seminiferous tubule. Adjacent Sertoli cells are connected by tight junctions and surround developing germ cells. From the basal lamina to the lumen of the tubule, there is a gradual maturation of the germ cells.

The Sertoli cells are large polyhedral cells extending from the basement membrane toward the lumen of the seminiferous tubule. Spermatids are located adjacent to the lumen of the seminiferous tubules during the early stages of spermiogenesis and are surrounded by processes of Sertoli cell cytoplasm. Tight junctions connect the adjacent Sertoli cells, forming a **blood-testis barrier**—analogous to the blood-brain

barrier in both sexes (see [pp. 284–287](#)) and to the blood-oocyte/granulosa barrier in the ovarian follicle of females—that presumably provides a protective environment for developing germ cells. In addition, gap junctions between the Sertoli cells and developing spermatozoa may represent a mechanism for transferring material between these two types of cells. Release of the spermatozoa from the Sertoli cell is called **spermiation**. Spermatids progressively move toward the lumen of the tubule and eventually lose all contact with the Sertoli cell after spermiation ([Box 54-2](#)).

Box 54-2

Sertoli Cell–Only Syndrome

Clinicians have described a group of normally virilized men whose testes are small bilaterally and whose ejaculates contain no sperm cells (azoospermia). In these men, the seminiferous tubules are lined by Sertoli cells but show a complete absence of germ cells. Sertoli cell–only syndrome (or germinal cell aplasia) accounts for 10% to 30% of male infertility secondary to azoospermia and can either be caused by a single-gene defect or be acquired (e.g., as a result of orchitis, alcoholism, or toxic agents). Leydig cell function is usually preserved. Plasma testosterone and LH levels are usually normal, whereas FSH levels are often, but not always, elevated. It is not entirely clear why FSH levels are elevated in these men. This elevation may result from the absence of germ cells or from suboptimal secretion of inhibin by the Sertoli cells, inasmuch as inhibin is a powerful inhibitor of FSH secretion at the level of the anterior pituitary gland. Segments of Sertoli cell–only tubules may be observed in conditions such as orchitis or after exposure to agents that are toxic to the gonads. However, these individuals generally have functional spermatogenesis in the other seminiferous tubules.

Sperm maturation occurs in the epididymis

The seminiferous tubules open into a network of tubules, the **rete testis**, that serves as a reservoir for sperm. The rete testis is connected to the epididymis via the **efferent ductules** (see [p. 1078](#)), which are located near the superior pole of the testicle. The **epididymis** is a highly convoluted single long duct, 4 to 5 m in total length, on the posterior aspect of the testis. The epididymis can be divided anatomically into three regions: the head (the segment closest to the testis), the body, and the tail (see [Fig. 54-1C](#)).

Spermatozoa are essentially immotile on completion of spermiogenesis. Thus, transfer of spermatozoa from the seminiferous tubule to the rete testes is passive. Secretions flow from the testes through the epididymis with assistance by ciliary action of the luminal epithelium and contraction of the smooth-muscle elements of the efferent duct wall. Thus, sperm transport through this ductal system is also primarily passive. After leaving the testes, sperm take 12 to 26 days to travel through the epididymis and appear in the ejaculate. The epididymal transit time for men between the ages of 20 and 80 years does not differ significantly.

Sperm are stored in the epididymis, where they undergo a process of maturation before they are capable of progressive motility and fertilization ([Table 54-2](#)). Spermatozoa released at ejaculation are fully motile and capable of fertilization, whereas spermatozoa obtained directly from the testis are functionally immature insofar as they cannot penetrate an ovum. However, these immature spermatozoa can fertilize if they are injected into an ovum. During maturation in the epididymis, spermatozoa undergo changes in motility, metabolism, and morphology.  **N54-8** Spermatozoa derived from the head (caput) of the epididymis (see [Fig. 54-1C](#)) are often unable to fertilize ova, whereas larger proportions of spermatozoa captured from the body (corpus) are fertile. Spermatozoa obtained from the tail (cauda) of

the epididymis or from the vas deferens are almost always capable of fertilization.

TABLE 54-2
Aspects of Sperm Maturation in the Epididymis

Progressive increase in forward motility
Increased ability to fertilize
Maturation of acrosome
Molecular reorganization of the plasma membrane:
Lipids (stabilization of plasma membrane)
Proteins (shedding as well as acquisition of new proteins)
Ability to bind to zona pellucida
Acquisition of receptors for proteins of the zona pellucida
Increased disulfide bonds between cysteine residues in sperm nucleoproteins
Topographic regionalization of glycosidic residues
Accumulation of mannosylated residues on the periacrosomal plasma membrane
Decreased cytoplasm and cell volume

N54-8
Sperm Maturation

Contributed by Ervin Jones

Most of the changes that occur to the sperm within the epididymis have to do with the acquisition of **motility**. Sperm isolated from the caput of the epididymis exhibit inconsistent patterns of motility, ranging from immotility to highly random movements of the flagellum. As sperm pass through the epididymis, rapid forward progression occurs and random tail flexing is reduced; these changes are first seen in a few spermatozoa obtained from the corpus and comprise the predominant pattern in those obtained from the cauda of the vas deferens. Motility is a prerequisite for fertility; it may be surmised that the acquisition of progressive forward motility is largely a function of maturation of the spermatozoa.

Biochemical changes also occur as sperm pass through the epididymis. It has been suggested that membrane-bound enzymes play a role in modifying the surface of spermatozoa during epididymal transit. Total protein concentrations decrease by more than half in spermatozoa but remain unchanged in epididymal fluid during epididymal transit. Further, it appears that the majority of the testicle-derived proteins are removed from the spermatozoal surface during epididymal maturation, to be replaced by new low-molecular-weight peptides. These new peptides appear almost simultaneously with the development of forward-progressive motility.

Nuclear changes also occur as spermatozoa traverse the epididymis. Nuclear proteins play a role in morphogenesis and in the stabilization of the head of the sperm cell. Protamine staining increases as spermatozoa pass from the rete testes to the corpus of the epididymis and sharply declines thereafter. These observations, taken together, underscore the significance of the epididymis for sperm maturation, a prerequisite for the acquisition of fertilizing capacity.

The epididymis empties into the **vas deferens**, which is responsible for the movement of sperm along the tract. The vas deferens contains well-developed muscle layers that facilitate sperm movement. The vas deferens passes through the inguinal canal, traverses the ureter, and continues medially to the posterior and inferior aspect of the urinary bladder, where it is joined by the duct arising from the **seminal vesicle**; together, they form the ejaculatory duct. The **ejaculatory duct** enters the prostatic portion of the urethra after passing through the prostate. Sperm are stored in the epididymis as well as in the proximal

end of the vas deferens. All these accessory structures depend on androgens secreted by the testis for full functional development.

Spermatozoa are the only independently motile cells in the human body

Spermatozoa are highly specialized cells consisting of a head, midpiece, and tail ([Fig. 54-9](#)). The **head** contains the nucleus and is essentially devoid of cytoplasm, which is lost during spermatogenesis. Within the nucleus, the haploid number of chromosomes are packaged as tightly coiled chromatin fibers. The anterior segment of the head contains the **acrosome**, which lies in front of and around the anterior two thirds of the sperm nucleus, much like a motorcycle helmet fits over one's head. The acrosome is essentially a large secretory vesicle, originating from the Golgi complex in the spermatid and containing enzymes that will facilitate penetration of the ovum. The **midpiece** is the engine of sperm. It consists of multiple mitochondria arranged as spirals around a filamentous core. The energy for sperm motility comes from the metabolism of fructose present in the seminal fluid. The filamentous core in the midpiece forms a drive-shaft connection to the tail. The **tail** is a specialized flagellum, powered by the midpiece, that executes rapid lashing movements, propelling the cell forward.

FIGURE 54-9 Anatomy of a spermatozoon.

The accessory male sex glands—the seminal vesicles, prostate, and bulbourethral glands—produce the seminal plasma

Only 10% of the volume of **semen** (i.e., seminal fluid) is sperm cells. The normal concentration of sperm

cells is >20 million per milliliter and the typical ejaculate volume is >2 mL. The typical ejaculate content varies between 150 and 600 million spermatozoa.

Aside from the sperm cells, the remainder of the semen (i.e., 90%) is **seminal plasma**, the extracellular fluid of semen (Table 54-3). Very little seminal plasma accompanies the spermatozoa as they move through the testes and epididymis. The seminal plasma originates primarily from the accessory glands (the seminal vesicles, prostate gland, and bulbourethral glands). The seminal vesicles contribute ~70% of the volume of semen. Aside from the sperm, the remaining ~20% represents epididymal fluids, as well as secretions of the prostate gland and bulbourethral glands. However, the composition of the fluid exiting the urethral meatus during ejaculation is not uniform. The first fluid to exit is a mixture of prostatic secretions and spermatozoa with epididymal fluid. Subsequent emissions are composed mainly of secretions derived from the seminal vesicles. The first portion of the ejaculate contains the highest density of sperm; it also usually contains a higher percentage of motile sperm cells.

TABLE 54-3
Normal Parameter Values for Semen

PARAMETER	VALUE
Volume of ejaculate	2–6 mL
Viscosity	Liquefaction in 1 hr
pH	7–8
Count	≥20 million/mL
Motility	≥50%
Morphology	60% normal

Seminal plasma is isotonic. The pH in the lumen of the epididymis is relatively acidic (6.5 to 6.8) as the result of H⁺ secretion by clear cells that are analogous to intercalated cells in the nephron (see p. 729). Addition of the relatively alkaline secretions of the seminal vesicles raises the final pH of seminal plasma to between 7.3 and 7.7. Spermatozoa generally tolerate alkalinity better than acidity. A pH near neutrality or slightly higher is optimal for the motility and survival of sperm cells in humans and in other species.

Seminal plasma contains a plethora of sugars and ions. Fructose and citric acid are contributed to the seminal plasma by the accessory glands, and their concentrations vary with the volume of semen ejaculated. The **fructose** is produced in the seminal vesicles. In a man with oligospermia (i.e., a low daily sperm output) and a low ejaculate volume (recall that more than half of the ejaculate comes from the seminal vesicles), the absence of fructose suggests obstruction or atresia of the seminal vesicles. Ascorbic acid and traces of B vitamins are also found in human seminal plasma. The prostate gland releases a factor—which contains sugars, sulfate, and a vitamin E derivative—that acts to prevent the clumping of sperm heads. In addition, human semen also contains high concentrations of choline and spermine, and is also rich in Ca²⁺, Na⁺, Mg²⁺, K⁺, Cl[−], Zn²⁺, and phosphate. Concentrations of Zn²⁺ and Ca²⁺ are higher in semen than in any other fluid and most other tissues. Calcium ions stimulate the motility of immature epididymal spermatozoa, but they inhibit the motility of spermatozoa in ejaculates obtained from humans. It appears that the diminished response of sperm to Ca²⁺ and the acquisition of progressive motility are functions of epididymal maturation.

Semen also contains free amino acids, low-molecular-weight polypeptides, and proteins. The free amino acids, which probably arise from the breakdown of protein after the semen is ejaculated, may protect spermatozoa by binding toxic heavy metals or by preventing the agglutination of proteins.

Human semen coagulates immediately after ejaculation. Coagulation is followed by liquefaction, which is apparently caused by proteolytic enzymes contained in prostatic secretions. Prostatic secretion is rich

in acid phosphatase. The natural substrate for acid phosphatase is phosphorylcholine, which is contributed by the seminal vesicles. Hyaluronidase is also present in human semen, although its functional role remains to be clarified. Hyaluronidase is not a product of the accessory glands; rather, it is contained within the sperm cell cytoplasm and is rapidly released into the seminal plasma. Hyaluronidase may play a role in facilitating penetration of the oocyte by the sperm cell because of its ability to depolymerize hyaluronic acid. [N54-9](#)

N54-9

Congenital and Acquired Ductal Obstruction

Contributed by Ervin Jones

Genital duct obstruction may be congenital and may result from ductal absence or structural abnormality, or it may be acquired as a result of stricture, infection, or vasectomy. Genital duct obstruction is found in ~7% of infertile men. An uncommon cause of male infertility is congenital **absence of the vas deferens**, which accounts for as many as 50% of cases of congenital ductal obstruction. These patients generally have azoospermic ejaculates with low volume. Congenital absence of the vas deferens is common in male patients with cystic fibrosis (CF) and is sometimes the only manifestation of CF.

Epididymal abnormalities range from the presence of an incomplete epididymis to the presence of only small portions of the epididymis; in addition, the seminal vesicles are often absent. Spermatogenesis is thought to be normal inasmuch as testicular biopsy specimens demonstrate germ cells in several stages of development. Obstruction of the epididymis may also occur as a result of gonococcal or tuberculous epididymitis. Smallpox and filariasis are common causes of ductal obstruction in areas where these diseases are endemic. Inspissated secretions may occlude the epididymis in men with Young syndrome or CF.

Elective vasectomy, a simple surgical procedure in which a small segment of the vas deferens is removed to ensure male infertility, is currently the leading cause of ductal obstruction.

Azoospermia in men with normal testes is the hallmark of genital duct obstruction. However, when specimens of testicles from men who have had vasectomies are examined microscopically, interstitial fibrosis is found in as many as 20% of cases. This group exhibits low fertility after elective reversal of their vasectomy. When the seminiferous tubules are examined, increased thickness of the tubule wall, an increase in cross-sectional tubular area, and decreased numbers of Sertoli cells are usually noted. Testosterone and gonadotropin levels are normal in most patients with ductal obstruction.

Male Sex Act

Sex steroids influence the central nervous system, even in utero, and play important roles in determining and regulating complex patterns of sexual behavior. However, reproductive behavior is extraordinarily complex and is influenced by numerous factors other than sex steroids, such as one's genetic constitution, social contacts, and the age at which hormones exert their effects. In this subchapter we describe the neurophysiology of the male sex act.

The sympathetic and parasympathetic divisions of the autonomic nervous system control the male genital system

The testes, epididymis, male accessory glands, and erectile tissue of the penis (corpora cavernosa and corpus spongiosum) receive dual innervation from the sympathetic and parasympathetic branches of the autonomic nervous system (ANS; see pp. 340–341). The penis also receives both somatic efferent (i.e., motor) and afferent (i.e., sensory) innervation via the pudendal nerve (S2 through S4).

Sympathetic Division of the ANS

As described in Chapter 14, the preganglionic **sympathetic neurons** originate in the thoracolumbar segments of the spinal cord (T1 through T12, L1 through L3; see Fig. 14-4). For the lower portion of the sympathetic chain (T5 and below), the preganglionic fibers may pass through the paravertebral sympathetic trunk and then pass via splanchnic nerves to a series of prevertebral plexuses and ganglia (see below). Once within one of these plexuses or ganglia, the preganglionic fiber may either (1) synapse with the postganglionic fiber, or (2) pass on to a more caudal plexus or ganglion without synapsing.

The sympathetic efferent (motor) nerve fibers that are supplied to the male sex organs emanate from five primary prevertebral nerve plexuses (Fig. 54-10): the celiac, superior mesenteric, inferior mesenteric, superior hypogastric, and inferior hypogastric or pelvic plexuses. The **celiac plexus** is of interest in a discussion of male sex organs only because preganglionic sympathetic fibers pass through this plexus on their way to more caudal plexuses. The **superior mesenteric** plexus lies on the ventral aspect of the aorta. Preganglionic fibers from the celiac plexus pass through the superior mesenteric plexus on their way to more caudal plexuses.

A SYMPATHETIC INNERVATION

B SAGITTAL SECTION SHOWING INNERVATION OF MALE GENITAL SYSTEM

FIGURE 54-10 Innervation of the male genital system. **A**, The sympathetic innervation of the male genital system involves a series of prevertebral nerve plexuses and ganglia. **B**, Three motor pathways as well as a sensory pathway are involved in erection. (1) Parasympathetic innervation: Preganglionic parasympathetic fibers arise from the sacral spinal cord and from the pelvic nerve, and they synapse in the pelvic plexus. The postganglionic parasympathetic fibers follow the cavernous nerve to the penile corpora and vasculature. (2) Sympathetic innervation: Preganglionic sympathetic fibers exit the thoracolumbar cord and synapse in one of several prevertebral ganglia. Postganglionic fibers reach the genitalia via the hypogastric nerve, the pelvic plexus, and the cavernous nerves. (3) Somatic innervation: Somatic (i.e., not autonomic) motor fibers originate in the sacral spinal cord, forming the motor branch of the pudendal nerve. The fibers innervate the striated penile muscles. In addition to these three motor pathways, there is also an afferent pathway from the penis. The dorsal nerve of the penis is the main terminus of the sensory pudendal nerve and is the sole identifiable root for tactile sensory information from the penis.

Most of the preganglionic sympathetic fibers pass from the superior mesenteric plexus to the **inferior mesenteric** plexus, although some of the nerves pass directly to the hypogastric plexus. The **superior hypogastric plexus** is a network of nerves located distal to the bifurcation of the aorta. The **inferior hypogastric** or **pelvic plexus** receives sympathetic supply from the hypogastric nerve.

In addition to these five plexuses, two other small ganglia are of interest. The **spermatic ganglion** is located near the origin of the testicular artery from the aorta. The spermatic ganglion receives fibers directly from the lumbar sympathetic nerves and from branches of several other ganglia. The **hypogastric** (or pelvic) **ganglion** is located at the junction of the hypogastric and pelvic nerve trunks.

Parasympathetic Division of the ANS

The preganglionic **parasympathetic neurons** relating to the male reproductive system originate in the sacral segments of the spinal cord (S2 through S4; see Fig. 14-4). These fibers pass via the pelvic nerve to the pelvic plexus, where they synapse with the postganglionic parasympathetic neurons.

Visceral Afferents

Sensory fibers are present in all the nerve tracts described (see Fig. 14-2). These fibers either (1) travel with the pelvic nerves to the dorsal root of the spinal cord, (2) travel with the sacral nerves to the sympathetic trunk and then rise in the sympathetic trunk to the spinal cord, or (3) travel with the hypogastric nerve and ascend to more rostral prevertebral plexuses and then to the spinal cord.

The principal functions of motor innervation to the male accessory glands include control of smooth-muscle contraction, vascular tone, and epithelial secretory activity.

Erection is primarily under parasympathetic control

During erection, relaxation of the smooth muscles of the corpora cavernosa and the corpus spongiosum allows increased inflow of blood to fill the corporal interstices and results in an increase in volume and rigidity. Vascular actions of the smooth muscles of the corpora and the perineal striated muscles are coordinated. For example, contraction of the striated muscles overlying the vascular reservoirs of the penile bulb increases the pressure of the blood in the corpora and promotes increased rigidity.  **N54-10** The three major efferent (i.e., motor) pathways for the regulation of penile erection are parasympathetic (pelvic nerve), sympathetic (hypogastric nerve), and somatic (pudendal nerve). The two corpora cavernosa and the corpus spongiosum are usually coordinated in their erection (i.e., tumescence) and detumescence. However, they may act independently inasmuch as their vascular and neuroeffector systems are relatively independent.

N54-10

Nonvascular Contributions to Erection

Contributed by Ervin Jones

Striated muscle also contributes to erection. The contribution of skeletal muscle varies among species but plays a lesser role in humans, where erections are purely vascular.

Parasympathetic Innervation

The first and most important pathway for erection is the parasympathetic division of the ANS. These fibers derive from the lumbar and sacral portions of the spinal cord and travel via the *pelvic nerve*, the *pelvic plexus*, and the *cavernous nerve* to the penile corpora and vasculature (see [Fig. 54-10](#)). This pathway is almost entirely parasympathetic but apparently also carries some sympathetic fibers (see below). The parasympathetic activity results in vasodilatation of the penile blood vessels, which increases blood flow to the cavernous tissue and engorges the organ with blood. In erectile tissue, parasympathetic postganglionic terminals release acetylcholine (ACh) and nitric oxide (NO), similar to the system discussed in [Figure 14-11](#). First, ACh binds to M_3 muscarinic receptors on endothelial cells. Via $G\alpha_q$, these receptors would then lead to stimulation of PLC, increased $[Ca^{2+}]_i$, activation of NO synthase, and local release of NO (see [p. 66](#)). Second, the nerve terminals may also directly release NO. Regardless of the source of NO, this gas diffuses to the vascular smooth-muscle cell, where it stimulates guanylyl cyclase to generate cGMP, which in turn causes vasodilation (see [Table 20-8](#); [Box 54-3](#)).

Box 54-3

Erectile Dysfunction

Sildenafil (**Viagra**), vardenafil (Levitra), and tadalafil (Cialis) are reasonably well tolerated oral medications used to treat erectile dysfunction. Men with erectile dysfunction experience significant improvement in rigidity and duration of erections after treatment with these medications.

As indicated in the text, the smooth-muscle tone of the human corpus cavernosum is regulated by the synthesis and release of NO, which raises $[cGMP]_i$ in vascular smooth-muscle cells, thereby relaxing the smooth muscle and leading to vasodilatation and erection. Breakdown of cGMP by cGMP-specific phosphodiesterase type 5 limits the degree of vasodilation and, in the case of the penis, limits erection. Sildenafil, vardenafil, and tadalafil are highly selective high-affinity inhibitors of cGMP-specific phosphodiesterase type 5 and thereby raise $[cGMP]_i$ in smooth muscle and improve erection in men with erectile dysfunction.

The new medications are attractive because they are effective and benefit most men with insufficient erection. These medications stimulate erection only during sexual arousal and thus have a rather natural effect. They can be taken as little as 1 hour before planned sexual activity.

One of the side effects of sildenafil is “blue vision,” a consequence of the effect of inhibiting cGMP-specific phosphodiesterase in the retina. In individuals taking other vasodilators, sildenafil can lead to sudden death. In women, sildenafil may improve sexual function by increasing blood flow to the accessory secretory glands (see pp. 1108 and 1127).

Sympathetic Innervation

The second pathway, which is thought to be entirely **sympathetic**, exits the thoracolumbar spinal cord. The preganglionic fibers then course via the least splanchnic nerve, the sympathetic chain, and the inferior mesenteric ganglion. The postganglionic fibers reach the genitalia via the *hypogastric nerve*, the *pelvic plexus*, and the *cavernous nerves* (see above). Tonic sympathetic activity contributes to penile *flaccidity*. During erection, a decrease in this sympathetic tone allows relaxation of the corpora and thus contributes to tumescence.

Somatic Innervation

The third pathway is the motor branch of the pudendal nerve. It has primarily **somatic** (i.e., not autonomic) fibers, originates in the sacral spinal cord, and innervates the striated penile muscles. Contraction of the striated ischiocavernosus muscle during the final phase of erection increases pressure inside the corpora cavernosa to values that are even higher than systemic arterial pressure. Contraction of the striated bulbospongiosus muscle increases engorgement of the corpus spongiosum, and thus the glans penis, by pumping blood up from the penile bulb underlying this muscle. Humans are apparently less dependent on their striated penile muscle for achieving and maintaining erection. However, these muscles are active during ejaculation and contribute to the force of seminal expulsion.

Postganglionic neurons release other so-called nonadrenergic, noncholinergic neurotransmitters (see [p. 543](#))—including NO—that also contribute to the erectile process.

Afferent Innervation

The penis also has an afferent pathway. The dorsal nerve of the penis is the main terminus of the sensory pudendal nerve and is the sole identifiable root for tactile sensory information from the penis.

Emission is primarily under sympathetic control

The term seminal **emission** refers to movement of the ejaculate into the prostatic or proximal part of the urethra. Under some conditions, seminal fluid escapes episodically or continuously from the penile urethra; this action is also referred to as emission. Emission is the result of peristaltic contractions of the ampullary portion of the vas deferens, the seminal vesicles, and the prostatic smooth muscles. These actions are accompanied by constriction of the internal sphincter of the bladder, which is under sympathetic control (see [p. 736](#)); this constriction of the sphincter prevents retrograde ejaculation of sperm into the urinary bladder (see [Box 54-3](#)).

The rhythmic contractions involved in emission result from contraction of smooth muscle. In contrast to those of other visceral organ systems, the smooth-muscle cells of the male ducts and accessory glands fail to establish close contact with one another and show limited electrotonic coupling. In the male accessory glands, individual smooth-muscle cells are directly innervated and have only limited spontaneous activity (i.e., multiunit smooth muscle; see [p. 243](#)). This combination allows a fast, powerful, and coordinated response to neural stimulation.

Motor Activity of the Duct System

A gradation between two forms of smooth-muscle activity occurs along the male duct system. The efferent ducts and proximal regions of the epididymis are sparsely innervated but display spontaneous contractions that can be increased via adrenergic agents acting on α -adrenergic receptors. In contrast, the distal end of the epididymis and the vas deferens are normally quiescent until neural stimulation is received during the ejaculatory process. Contraction of the smooth muscle of the distal epididymis, vas deferens, and accessory sex glands occurs in response to stimulation of the *sympathetic* fibers in the hypogastric nerve and release of norepinephrine. Indeed, an intravenous injection of epinephrine or norepinephrine can induce seminal emission, whereas selective chemical sympathectomy or an adrenergic antagonist can inhibit seminal emission. The role of *parasympathetic* innervation of the musculature of these ducts and accessory glands in the male is not entirely clear. Parasympathetic fibers may be preferentially involved in basal muscular activity during erection (i.e., before ejaculation) and during urination.

Secretory Activity of the Accessory Glands

The effect of autonomic innervation on the secretory activity of the epithelia of the male accessory glands has been studied extensively. Electrical stimulation of the pelvic nerves (parasympathetic) induces copious secretions. The secretory rate depends on the frequency of stimulation and can be blocked with atropine, a competitive inhibitor of muscarinic ACh receptors. Cholinergic drugs induce the formation of copious amounts of secretions when these drugs are administered systemically. Secretions from the bulbourethral glands also contribute to the ejaculate. The bulbourethral glands do not store secretions but produce them during coitus. The secretory activity of the bulbourethral glands also appears to be under cholinergic control inasmuch as administration of atropine causes marked inhibition of secretion from these glands.

Control of the motor activity of the ducts and the secretory activity of the accessory glands is complex and involves both the sympathetic and the parasympathetic divisions of the ANS. The central nervous system initiates and coordinates all these activities ([Box 54-4](#)).

Box 54-4

Retrograde Ejaculation

As noted in the text, emission is normally accompanied by constriction of the internal urethral sphincter. Retrograde ejaculation occurs when this sphincter fails to constrict. As a result, the semen enters the urinary bladder rather than passing down the urethra. Retrograde ejaculation should be suspected in patients who report absent or small-volume ejaculation after orgasm. The presence of >15 sperm per high-power field in urine specimens obtained after ejaculation confirms the occurrence of retrograde ejaculation.

Lack of emission or retrograde ejaculation may result from any process that interferes with innervation of the vas deferens and bladder neck. Several medical illnesses, such as diabetes mellitus (which can cause peripheral neuropathy) and multiple sclerosis, or the use of pharmaceutical agents that interfere with sympathetic tone can lead to retrograde ejaculation. Retrograde ejaculation may also occur as a result of nerve damage associated with certain surgical procedures, including bladder neck surgery, transurethral resection of the prostate, colorectal surgery, and retroperitoneal lymph node dissection. Retrograde ejaculation from causes other than surgery involving the bladder neck may be treated with pharmacological therapy. Sympathomimetic drugs such as phentolamine (an α -adrenergic agonist), ephedrine (which enhances norepinephrine release), and imipramine (which inhibits norepinephrine reuptake by presynaptic terminals) may promote normal (i.e., antegrade) ejaculation by increasing the tone of the vas deferens (propelling the seminal fluid) and the internal sphincter (preventing retrograde movement).

Ejaculation is under the control of a spinal reflex

As discussed, seminal emission transports semen to the proximal (posterior) part of the urethra.

Ejaculation is the forceful expulsion of this semen from the urethra. Ejaculation is normally a reflex reaction triggered by the entry of semen from the prostatic urethra into the bulbous urethra. Thus, emission sets the stage for ejaculation. The ejaculatory process is a spinal cord reflex, although it is also under considerable cerebral control. The afferent (i.e., sensory) impulses reach the sacral spinal cord (S2 through S4) and trigger efferent activity in the somatic motor neurons that travel via the pudendal nerve.

The resulting rhythmic contractions of the striated muscles of the perineal area—including the muscles of the pelvic floor, as well as the ischiocavernosus and bulbospongiosus muscles—forcefully propel the semen via the urethra through the external meatus. In addition, spasmodic contractions of the muscles of the hips and the anal sphincter generally accompany ejaculation.

Orgasm is a term best restricted to the culmination of sexual excitation, as generally applied to both men and women. Orgasm is the cognitive correlation of ejaculation in the human male. Although orgasm, the pleasurable sensation that accompanies ejaculation, is not well understood, clearly it is as much a central phenomenon as it is a peripheral one.  **N54-11**

N54-11

Neuronal Lesions Affecting Erection and Ejaculation

Contributed by Ervin Jones

Erectile dysfunction is often associated with disorders of the central and peripheral nervous systems. Spinal cord disease and peripheral neuropathies are of particular interest, and effects of spinal cord injuries have been studied in some detail. Erectile capacity is usually preserved in men with lesions of the premotor neurons (neurons that project from the brain to the spinal cord; eTable 54-1). In these men, reflexogenic erections occur in 90% to 100% of cases, whereas psychogenic erections do not occur because the pathways from the brain are blocked. Ejaculation is more significantly impaired with upper than with lower motor neuron lesions, presumably because of loss of the psychogenic component.

A clinically important feature of the spinal segmentation of nerve roots (i.e., thoracolumbar and lumbosacral) for generation of erection is that spinal or peripheral nerve damage may affect only one of the effector systems. Because the lumbosacral system also carries most of the penile afferents, erection in response to penile stimulation (reflexogenic) is most affected by damage to the lower spinal cord or the nerves that project there. Evidence from men with spinal injuries in the T10 through T12 region has implicated the sympathetic thoracolumbar pathway in mediation of erections resulting from sexual stimuli received via the cranial nerves or generated within the brain as memories, fantasies, or dreams. In men with lower motor neuron lesions, reflexogenic erections are absent. However, psychogenic erections still occur in most men with incomplete lesions and in about one fourth of men with complete lesions. It remains uncertain whether this sympathetic pathway is normally the principal route for psychogenic erections or whether it just assumes the role when lumbosacral parasympathetic pathways are damaged.

eTABLE 54-1

Effects of Neural Lesions on Erection and Ejaculation

LESION	REFLEXOGENIC ERECTION	PSYCHOGENIC ERECTION	EFFECT ON EJACULATION
Upper motor neuron	Present	Absent	Significantly impaired
Lower motor neuron	Absent	Present	Less impaired

The Female Reproductive System

Sam Mesiano, Ervin E. Jones

The female reproductive system functions to (1) produce haploid gametes—**ova**, (2) facilitate **syngamy**—or fertilization—between an ovum and a spermatozoon, (3) supply a site for **implantation** of the embryo (if syngamy occurs) and the establishment of pregnancy, (4) provide for the physical environment and nutritional needs of the developing fetus and its timely birth, and (5) nurture the neonate.

The system consists of the gonads (the ovaries), the fallopian tubes, the uterus and cervix, the vagina ([Fig. 55-1A](#)), the external genitalia, and the mammary glands, and is controlled by hormones produced in the hypothalamus, pituitary, and ovaries. The principal female sex hormones are estrogens (mainly estradiol) and progesterone, which are produced by the ovaries in a cyclic manner and regulate the growth and function of the female sex accessory structures and the development of secondary sexual characteristics. Function of the female reproductive system is ultimately regulated by hormones produced by the hypothalamic-pituitary-gonadal axis under the control of higher brain centers. The system involves finely tuned neuroendocrine feedback interactions between hormones produced by the hypothalamus and anterior pituitary and hormones produced by the ovaries. The result is the cyclic production of gametes and the preparation of the sex accessory organs for the establishment of pregnancy.

A OBLIQUE VIEW OF THE INTERNAL FEMALE SEX ORGANS

B CROSS SECTION THROUGH AN OVARY

FIGURE 55-1 Anatomy of the female internal genitalia and accessory sex organs.

Female reproductive organs include the ovaries and

accessory sex organs

The ovaries lie on the sides of the pelvic cavity (see [Fig. 55-1A](#)). Covered by a layer of mesothelial cells, each ovary consists of an inner medulla and an outer cortex. The cortex of the ovary in a mature female contains developing follicles and corpora lutea in various stages of development (see [Fig. 55-1B](#)). These elements are interspersed throughout the stroma, which includes connective tissue, interstitial cells, and blood vessels. The **medulla** comprises large blood vessels and other stromal elements.

The female **sex accessory organs** include the fallopian tubes, the uterus, the vagina, and the external genitalia. The **fallopian tubes** provide a pathway for the transport of ova from the ovary to the uterus. The distal end of the fallopian tube expands as the infundibulum, which ends in multiple fimbriae. The fimbriae and the rest of the fallopian tubes are lined with epithelial cells, most of which have cilia that beat toward the uterus. The activity of these cilia and the contractions of the wall of the fallopian tube, particularly around the time of ovulation, facilitate transport of the ovum. Interspersed with ciliated cells are peg cells that secrete fluid and nutrients supporting the ovum and spermatozoa as well as the zygote that may result as fertilization occurs in the fallopian tubes.

The **uterus** is a complex, pear-shaped, muscular organ that is suspended by a series of supporting ligaments. It is composed of a fundus, a corpus, and a narrow caudal portion called the **cervix**. The external surface of the uterus is covered by serosa, whereas the interior, or **endometrium**, of the uterus consists of complex glandular tissue and stroma. The bulk of the uterine wall consists of specialized smooth muscle, **myometrium**, that lies between the endometrium and the uterine serosa. The uterus is continuous with the vagina via the cervical canal. The cervix is composed of dense fibrous connective tissue and smooth-muscle cells. Glands lining the cervical canal produce a sugar-rich secretion, the viscosity of which is conditioned by estrogen and progesterone.

The human **vagina** is ~10 cm in length and is a single, expandable tube. The vagina is lined by stratified epithelium and is surrounded by a thin muscular layer. During development, the lower end of the vagina is covered by the membranous hymen, which is partially perforated during fetal life. In some instances, the hymen remains continuous. The **external genitalia** include the clitoris, the labia majora, and the labia minora, as well as the accessory secretory glands (including the glands of Bartholin), which open into the vestibule. The **clitoris** is an erectile organ that is homologous to the penis (see [p. 1091](#)) and mirrors the cavernous ends of the glans penis.

The breasts can also be considered as part of the female reproductive system. Breast development (thelarche) begins at puberty in response to ovarian steroid hormones. The ductal epithelium of the breast is sensitive to ovarian steroids and especially during pregnancy becomes activated to produce milk (**lactation**) that will sustain the newborn infant.

Reproductive function in the human female is cyclic

In some species (e.g., rabbits), female reproductive function, and specifically **ovulation** (the liberation of fertilizable oocytes), is triggered by mating. However, in most species, the female reproductive system functions in a cyclic manner. In some of these species with cyclic function (e.g., sheep, cattle, horses), females are receptive to males only around the time of ovulation, which maximizes the chances of fertilization and pregnancy. This receptive behavior is known as estrus, and the animals are said to have seasonal estrus cycles, whereby the ovaries are active only at a certain time of the year. Such cyclic reproductive function in females enhances reproductive efficiency by coordinating gamete production with environmental (in seasonal species) and physiological changes that attract males and prepare the

reproductive tract for sperm and ovum transport, fertilization, implantation, and pregnancy. In a small subset of species (e.g., humans, baboons, apes), ovulation occurs in monthly cycles—known as **menstrual cycles**—that are associated with regular episodes of uterine bleeding termed menstruation.

Hypothalamic-Pituitary-Gonadal Axis and Control of the Menstrual Cycle

The human menstrual cycle coordinates changes in both the ovary and endometrium

The human menstrual cycle involves rhythmic changes in two organs: the ovary and the uterus (Fig. 55-2). Although menstrual cycles are generally regular during the reproductive years, the length of the menstrual cycle may be highly variable because of disturbances in neuroendocrine function. Starting with the first day of the menses on day 0, the average menstrual cycle lasts 28 days. However, considerable variation occurs during both the early reproductive years and the premenopausal period, primarily because of the increased frequency of anovulatory cycles (Box 55-1).

FIGURE 55-2 Ovarian and endometrial cycles. The menstrual cycle comprises parallel ovarian and endometrial cycles. The follicular phase of the ovarian cycle and the menses start on day 0. In this idealized example, ovulation occurs on day 14, and the entire cycle lasts 28 days.

Box 55-1

Effect of Energy Stores on Female Fertility

Activity of the hypothalamic GnRH neurons in females is very sensitive to environmental and physiological conditions, as is particularly obvious in species with a seasonal estrus. The evolutionary rationale for this environmental sensitivity is that reproduction is most efficient when resources are available to sustain a pregnancy and nurture the newborn. In addition, pregnancy confers a survival risk to females.

Leptin is produced by adipocytes and its levels in the circulation reflect the amount of energy stores (see pp. 1001–1002). Because leptin promotes the production and release of GnRH by hypothalamic neurons, leptin signals the brain that fat stores are sufficient to support human female reproductive function. Indeed, increased leptin levels are associated with the onset of puberty in both sexes, and normal levels of leptin are needed to maintain menstrual cycles and normal female reproductive function. Low levels of leptin—due to starvation, anorexia, or strenuous exercise—are associated with amenorrhea (cessation of menstrual cycles). Thus, signals to the neuroendocrine reproductive axis are permissive for reproduction if fuel reserves are adequate, but inhibit the system if reserves are low. The practical consequence is to help ensure that reproduction occurs when the female has sufficient energy reserves to sustain a pregnancy and nurture an infant.

The **ovarian cycle** includes four key events: (1) folliculogenesis, (2) ovulation, (3) formation of the corpus luteum, and (4) death (atresia) of the corpus luteum. Temporally, the ovarian cycle includes two major phases: the follicular and luteal phases. The **follicular phase** begins soon after the corpus luteum degenerates, lasts 12 to 14 days, and ends at ovulation. The **luteal phase** begins at ovulation, lasts 12 to 14 days, and ends when the corpus luteum degenerates.

Steroid hormones produced by the ovaries during the follicular and luteal phases induce changes in the endometrial lining of the uterus that constitute the endometrial cycle. The **endometrial cycle** consists of three key events: (1) menstruation, (2) endometrial growth and proliferation, and (3) differentiation of the endometrial epithelium into a glandular secretory phenotype. The endometrial cycle is divided into menses, the **proliferative phase** and the **secretory phase** (see [Fig. 55-2](#)).

Ovarian and endometrial events are integrated into a single sequence as follows.

Follicular/Proliferative Phase

The follicular/proliferative phase begins with the initiation of menstruation and averages ~14 days. The follicular phase of the ovarian cycle varies more in duration than any other phase of the cycle. During this time, **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)** stimulate the growth of a cohort of follicles, all of which (even those destined for atresia) produce **estradiol**. Consequently, circulating estradiol levels gradually increase during the follicular phase. Because estradiol stimulates rapid growth of the endometrium, this period is the proliferative phase of the *endometrial cycle*. Eventually, a single large, dominant preovulatory follicle develops in one of the ovaries. This follicle becomes the principal source of estradiol as the follicular phase progresses.

Ovulation

As we will see below, for most of the follicular phase, estradiol exerts negative feedback on gonadotropin secretion at the level of the hypothalamus and pituitary. However, toward the end of the follicular phase (day 12 to 13), when estradiol levels are maximal, the effect of estradiol on the hypothalamus and pituitary switches from negative to positive feedback. The result is a large transient surge in LH and a small increase in FSH secretion by the gonadotrophs. The LH surge causes the dominant follicle to rupture and releases its oocyte—ovulation.

Luteal/Secretory Phase

After release of the ovum, the remnants of the dominant follicle transform into a **corpus luteum**, which is why the second half of the *ovarian cycle* is called the luteal phase. Luteal cells produce **progesterone** and small amounts of estradiol, which together stimulate the endometrium to develop secretory glands—hence the term secretory phase of the *endometrial cycle*. If embryo implantation does not occur by day 20 to 22 of the cycle (i.e., midway through the luteal phase), the corpus luteum begins to degenerate and its production of progesterone and estradiol rapidly declines. The mechanisms that control the life span of the corpus luteum during a nonfertile cycle are not fully understood. If pregnancy is established, **human chorionic gonadotropin (hCG)** produced by the placenta maintains the corpus luteum. As a result, the corpus luteum maintains support for the endometrium, and menstruation does not occur.

Menses

In the absence of pregnancy, withdrawal of progesterone (and estrogen) due to the demise of the corpus luteum leads to degeneration and shedding of the superficial part of the endometrium known as the

functional layer. Degeneration of the functional layer is due to necrosis caused by the constriction of blood vessels that supply the endometrium. The necrotic tissue then sloughs away from the uterus and, in conjunction with blood from the underlying vessels and other uterine fluids, is shed as menstrual discharge (i.e., the period). Menstruation usually last 4 to 6 days. The first day of the menses (i.e., the first day of the endometrial cycle) is also the first day of the ovarian cycle. Rebuilding of the functional layer resumes when estrogen levels rise as a result of follicle growth during the new follicular phase.

The hypothalamic-pituitary-ovarian axis drives the menstrual cycle

Neurons in the hypothalamus synthesize, store, and release **gonadotropin-releasing hormone (GnRH)**. Long portal vessels carry the GnRH to the anterior pituitary, where the hormone binds to receptors on the surface of gonadotrophs. The results are the synthesis and release of both FSH and LH from the gonadotrophs ([Fig. 55-3](#)). These trophic hormones, LH and FSH, stimulate the ovary to synthesize and secrete the sex steroids **estrogens** and **progestins** as well as to produce mature gametes. The ovaries also produce peptides called **inhibins** and **activins**. Together, these ovarian steroids and peptides exert both negative and positive feedback on both the hypothalamus and the anterior pituitary. This complex interaction is unique among the endocrine systems of the body in that it generates a monthly pattern of hormone fluctuations. Because the cyclic secretion of estrogens and progestins primarily controls endometrial maturation, menstruation reflects these cyclic changes in hormone secretion.

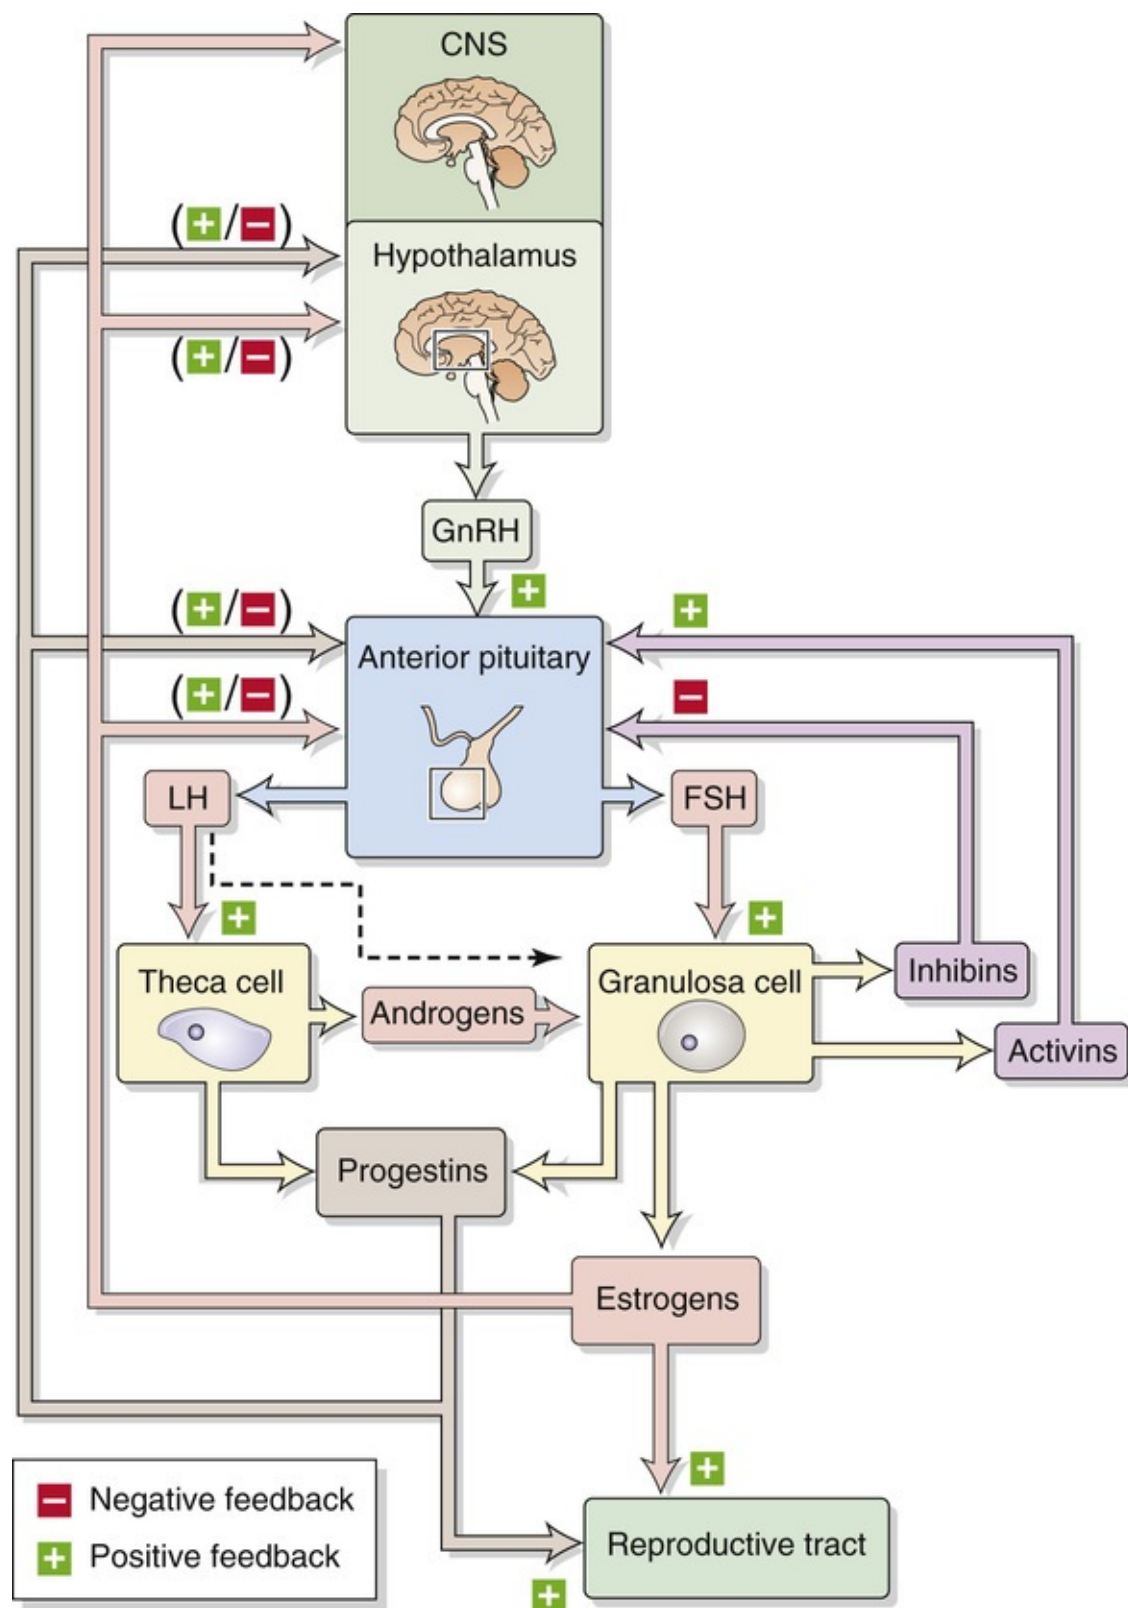

FIGURE 55-3 Hypothalamic-pituitary-ovarian axis. Small-bodied neurons in the arcuate nucleus and the preoptic area of the hypothalamus secrete GnRH, which reaches the gonadotrophs in the anterior pituitary via the long portal veins. GnRH causes the gonadotrophs to synthesize and release two gonadotropins—FSH and LH. LH binds to receptors on theca cells to increase the biosynthesis of progestins and androgens. The androgens enter granulosa cells, which convert the androgens to estrogens. The dashed arrow indicates that the granulosa cells also have LH receptors. FSH binds to receptors on granulosa cells to increase the production of steroidogenic enzymes as well as activins and inhibins. The activins and inhibins act only on the anterior pituitary. The estrogens and progestins act on both the anterior pituitary and the hypothalamic neurons, exerting both positive- and negative-feedback controls. CNS, central nervous system.

Neurons in the hypothalamus release GnRH in a pulsatile fashion

A finely tuned neuroendocrine feedback between hormones produced by the brain and ovaries controls the menstrual cycle. As noted on [pages 1092–1094](#), the process begins in the arcuate nucleus and the preoptic area of the hypothalamus, where neurons synthesize GnRH and transport it to their nerve terminals in the median eminence for storage and subsequent release. Higher centers in the brain trigger the release of GnRH near portal vessels, which carry GnRH to the gonadotrophs in the anterior pituitary. Before puberty, the GnRH neurons are quiescent and thus the reproductive system is inactive. 🧠 **N55-1** After puberty, activity of the neurons increases, triggering release of GnRH in rhythmic pulses, about once per hour. Because the half-life of GnRH in blood is only 2 to 4 minutes, these hourly bursts of GnRH cause clearly discernible oscillations in GnRH levels in portal blood, leading to hourly surges in release of the gonadotropins LH and FSH. Early in the follicular phase of the cycle, when the gonadotrophs are not very GnRH sensitive, each burst of GnRH elicits only a small rise in LH ([Fig. 55-4A](#)). Later in the follicular phase, when the gonadotrophs in the anterior pituitary become much more sensitive to the GnRH in the portal blood, each burst of GnRH triggers a much larger release of LH (see [Fig. 55-4B](#)). 🧠 **N55-2**

FIGURE 55-4 Pulsatile release of GnRH and pulsatile secretion of LH. (Data from Wang CF, Lasley BL, Lein A, Yen SS: The functional changes of the pituitary gonadotrophs during the menstrual cycle. *J Clin Endocrinol Metab* 42:718–728, 1976.)

N55-1

Fetal Gonadotropin-Releasing Hormone

Contributed by Ervin Jones

GnRH is present in the hypothalamus at 14 to 16 weeks' gestation, and its target, the gonadotropin-containing cells (gonadotrophs), are present in the anterior pituitary gland as early as 10 weeks' gestation. The hypothalamic-pituitary system is functionally competent by ~23 weeks' gestation, at which time fetal tissues release GnRH.

N55-2

Control of Pulsing of Gonadotropin-Releasing Hormone Neurons

Contributed by Sam Mesiano

Although the mechanisms controlling the hourly pulses of GnRH remain unclear, the pulse generator for GnRH is thought to be located in the arcuate nucleus of the medial basal hypothalamus, where one group of GnRH neurons resides. GnRH neurons isolated from the rodent hypothalamus secrete GnRH in vitro in a rhythmic manner, with a frequency of approximately one pulse per hour. Those studies show that GnRH neurons have intrinsic pulsatile GnRH secretory activity and that the GnRH pulse generator resides within the GnRH neurons. In vivo studies show that bursts of nerve impulses from neurons in the arcuate nucleus correspond in time with the pulsatile release of GnRH from the hypothalamus and with the episodic release of LH from the anterior pituitary. These data suggest that a built-in system within the hypothalamus, and specifically the arcuate nucleus, controls the pulsatile discharge of GnRH from nerve terminals. Although the pulse generator is thought to be intrinsic to cells in the arcuate nucleus, it is significantly influenced by neurons from higher brain centers, predominantly in the cortex, that impact on the GnRH-secreting cells. Inhibitory and excitatory signals affect the pulse frequency of GnRH neurons. In general, **kisspeptin neurons** and **glutamate neurons** increase GnRH secretion frequency, whereas **GABA neurons** inhibit GnRH secretion and repress kisspeptin neurons. This GABA pathway is the main mechanism that keeps GnRH secretion relatively low during the juvenile prepubertal period.

At puberty, GnRH secretion and pulse frequency increase, mainly due to increased activity of kisspeptin neurons and reduction in tonic GABA inhibition. Decreased GABA activity also is thought to enhance the stimulation of kisspeptin neurons by glutamatergic signaling through *N*-methyl-D-aspartate (NMDA) receptors. Thus, the GnRH pulse-generating mechanism is intrinsic to the hypothalamic GnRH neurons, whose rhythmic activity is modulated by GABAergic, kisspeptinergic, and glutamatergic neurons from higher centers in the cortex. The modulation of GnRH pulse frequency via specific neurotransmitters in response to integration by higher brain centers is key to the control of puberty onset and cyclic reproductive function.

Reference

Terasawa E, Kurian JR, Guerriero KA, et al. Recent discoveries on the control of GnRH neurons in nonhuman primates. *J Neuroendocrinol*. 2010;22:630–638.

The *frequency* of GnRH release,  **N55-3** and thus LH release, determines the specific response of the gonad. Pulses spaced 60 to 90 minutes apart upregulate the GnRH receptors on the gonadotrophs, thus

stimulating release of gonadotropins and activating the ovaries. However, continuous administration of GnRH (or an analog) causes downregulation of the GnRH receptors, which suppresses gonadotropin release and gonadal function (Box 55-2).

Box 55-2

Therapeutic Uses of GnRH

Continuous administration of GnRH leads to downregulation (suppression) of gonadotropin secretion, whereas pulsatile release of GnRH causes upregulation (stimulation) of FSH and LH secretion. Clinical problems requiring upregulation of gonadotropin secretion, which leads to stimulation of the gonads, are therefore best treated by a pulsatile mode of GnRH administration. In contrast, when the patient requires gonadal inhibition, a continuous mode of administration is necessary.

An example of a disease requiring *pulsatile* GnRH administration is **Kallmann syndrome**. Disordered migration of GnRH cells during embryologic development causes Kallmann syndrome, which in adults results in **hypogonadotropic hypogonadism** and **anosmia** (loss of sense of smell). Normally, primordial GnRH cells originate in the nasal placode during embryologic development. These primitive cells then migrate through the forebrain to the diencephalon, where they become specific neuronal groups within the medial basal hypothalamus and preoptic area. In certain individuals, both male and female, proper migration of GnRH cells fails to occur. Females with Kallmann syndrome generally have amenorrhea (no menstrual cycles). However, the pituitary and gonads of these individuals can function properly when appropriately stimulated. Thus, females treated with exogenous gonadotropins or GnRH analogs—*pulsatile* administration with a programmed infusion pump—can have normal folliculogenesis, ovulation, and pregnancy.

An example of a disease requiring *continuous* GnRH administration to downregulate gonadal function is endometriosis. **Endometriosis** is a common condition caused by the aberrant presence of endometrial tissue outside the uterine cavity. This tissue responds to estrogens during the menstrual cycle and is a source of pain and other problems, including infertility. In patients with endometriosis, *continuous* administration of GnRH analogs inhibits replenishment of the receptor for GnRH in the gonadotrophs in the anterior pituitary. As a result, insufficient numbers of GnRH receptors are available for optimum GnRH action; this deficiency diminishes gonadotropin secretion and produces relative hypoestrogenism. Because estrogen stimulates the endometrium, continuous administration of GnRH or GnRH analogs causes involution and diminution of endometriotic tissue.

Leiomyomas (smooth-muscle tumors) of the uterus (also called uterine fibroids) are also estrogen dependent. When estrogen levels are decreased, the proliferation of these lesions is decreased. Therefore, leiomyomas of the uterus can also be effectively treated by *continuous* administration of GnRH analogs.

N55-3

Frequency versus Amplitude of Hypothalamic Releasing Hormones

Contributed by Eugene Barrett

For GnRH release, it appears that the important factor for signaling is the **frequency** of the GnRH pulses.

On the other hand, in the case of corticotropin-releasing hormone (CRH; see pp. 1023–1025), it appears that **amplitude** is the primary factor in controlling adrenocorticotrophic hormone (ACTH) release. Thus, depending on the target of the releasing hormone, either frequency or amplitude can be dominant.

In addition to the hourly rhythm of GnRH secretion, a monthly rhythm of GnRH secretion also occurs in females of reproductive age. A massive increase in GnRH secretion by neurons in the preoptic area at midcycle is, in part, responsible for the LH surge, which, as we will see below (see [p. 1116](#)), leads to ovulation.

GnRH stimulates gonadotrophs in the anterior pituitary to secrete FSH and LH

GnRH enters the anterior pituitary through the portal system and binds to GnRH receptors on the surface of the gonadotroph, thus initiating a series of cellular events that result in the synthesis and secretion of gonadotropins. As discussed for the male on [pages 1094–1095](#), occupation of the G protein–coupled **GnRH receptor (GnRHR)**  [N55-4](#) leads to the formation of inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol (DAG; see [p. 58](#)). The IP₃ causes an increase in [Ca²⁺]_i, triggering exocytosis and gonadotropin release ([Fig. 55-5](#)). In addition, the DAG stimulates protein kinase C, which indirectly leads to increases in gene transcription. The net effect is an increase in synthesis of the gonadotropins FSH and LH, which are in the same family as thyroid-stimulating hormone (TSH or thyrotropin; see [pp. 1014–1016](#)) and hCG (see [p. 1139](#)).  [N55-5](#)

N55-4

Gonadotropin-Releasing Hormone Receptor

Contributed by Ervin Jones

The GnRH receptor (GnRHR) is internalized and partially degraded in the lysosomes. However, a portion of the GnRHR is shuttled back to the cell surface. Return of the GnRHR to the cell membrane is referred to as **receptor replenishment** and is related to the upregulation of receptor activity discussed above in the text. The mechanism through which GnRH receptor replenishment occurs remains unclear.

N55-5

The TSH-FSH-LH-hCG Family of Glycoprotein Hormones

Contributed by Ervin Jones

FSH and LH are in the same family as TSH (see p. 1014) and hCG (see p. 1139). All four are glycoprotein hormones with α and β chains. The α chains of all four of these hormones are identical; in

humans, they have 92 amino acids and a molecular weight of ~20 kDa. The β chains are unique and confer the specificity of the hormones.

In the female, the rhythm of GnRH secretion influences the relative rates of expression of genes encoding the synthesis of the α , β_{FSH} , and β_{LH} subunits of FSH and LH. GnRH pulsatility also determines the dimerization of the α and β_{FSH} subunits, or α and β_{LH} , as well as their glycosylation. Differential secretion of FSH and LH is also affected by several other hormonal mediators, including ovarian steroids, inhibins, and activins. The role of these agents is discussed in the section on feedback control of the hypothalamic-pituitary-ovarian axis. Thus, depending on the specific hormonal milieu produced by different physiological circumstances, the gonadotroph produces and secretes the α and β subunits of FSH and LH at different rates. The secretion of LH and FSH is further modulated by neuropeptides, amino acids such as aspartate, neuropeptide Y, corticotropin-releasing hormone (CRH), and endogenous opioids.

Before ovulation, the LH and FSH act on cells of the developing follicles. The **theca cells** (see [p. 1117](#)) of the follicle have LH receptors, whereas the **granulosa cells** (see [p. 1117](#)) have both LH and FSH receptors. After ovulation, LH acts on the cells of the corpus luteum. Both the LH and the FSH receptors are coupled through $G\alpha_s$ to adenylyl cyclase (see [p. 53](#)), which catalyzes the conversion of ATP to cAMP. cAMP stimulates protein kinase A, which increases the expression of genes whose products enhance cell division or the production of peptide and steroid hormones.

The ovarian steroids (estrogens and progestins) feed back on the hypothalamic-pituitary axis

As summarized in [Figure 55-3](#), the ovarian steroids—primarily estradiol and progesterone—exert both negative and positive feedback on the hypothalamic-pituitary axis. Whether the feedback is negative or positive depends on both the concentration of the gonadal steroids and the duration of the exposure to these steroids (i.e., the time in the menstrual cycle). In addition, the ovarian peptides—the inhibins and activins—also feed back on the anterior pituitary.

Negative Feedback by Ovarian Steroids

Throughout most of the menstrual cycle, the estradiol and progesterone that are produced by the ovary feed back negatively on both the hypothalamus and the gonadotrophs of the anterior pituitary. The net effect is reduced release of both LH and FSH. Estradiol exerts negative feedback at both low and high concentrations, whereas progesterone is effective only at high concentrations.

Although estradiol inhibits the GnRH neurons in the arcuate nucleus and preoptic area of the hypothalamus, this inhibition is not direct. Rather, estradiol stimulates interneurons that inhibit the GnRH neurons. In the arcuate nucleus, these inhibitory neurons exert their inhibition via opiates. However, in the preoptic area, the inhibitory neurons exert their inhibitory effect via gamma-aminobutyric acid (GABA), a classic inhibitory neurotransmitter (see [p. 309](#)).

Positive Feedback by Ovarian Steroids

Although ovarian steroids feed back *negatively* on the hypothalamic-pituitary axis during most of the menstrual cycle, they have the opposite effect at the end of the follicular phase. Levels of estradiol rise

gradually during the first half the follicular phase of the ovarian cycle and then increase steeply during the second half (Fig. 55-6). After the estradiol levels reach a certain threshold for a minimum of 2 days—and perhaps because of the accelerated rate of estradiol secretion—the hypothalamic-pituitary axis reverses its sensitivity to estrogens. That is, estradiol now exerts *positive* feedback on the axis. One manifestation of this positive feedback is that estradiol *increases* the sensitivity of the gonadotrophs in the anterior pituitary gland to GnRH. As discussed in the next section, this switch to positive feedback promotes the LH surge. Indeed, pituitary cells that are cultured in the absence of estradiol have suboptimal responses to GnRH. Once high levels of estradiol have properly conditioned the gonadotrophs, rising levels of **progesterone** during the late follicular phase also produce a positive-feedback response and thus facilitate the LH surge.

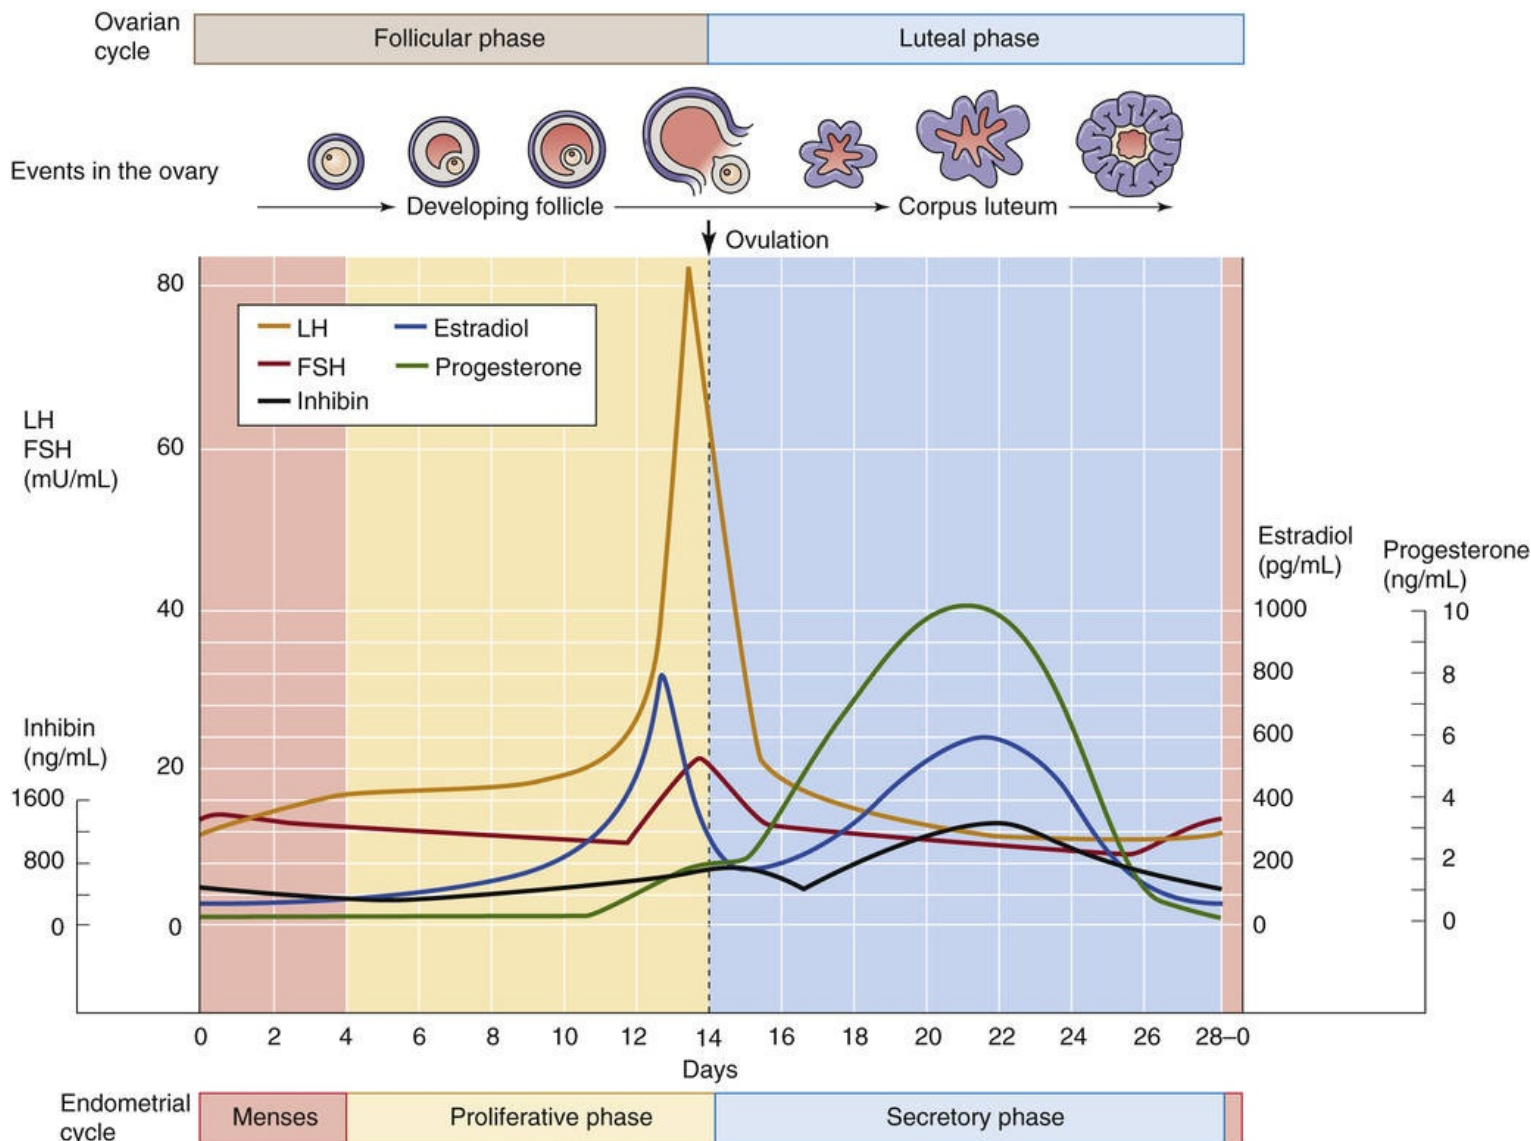

FIGURE 55-6 Hormonal changes during the menstrual cycle. The menstrual cycle is a cycle of the hypothalamic-pituitary-ovarian axis, as well as a cycle of the target of the ovarian hormones: the endometrium of the uterus. Therefore, the menstrual cycle includes both the ovarian cycle—which includes the follicular phase, ovulation, and the luteal phase—and the endometrial cycle—which includes the menstrual, the proliferative, and the secretory phases.

Ovaries produce peptide hormones—inhibins, activins, and

follistatins—that modulate FSH secretion

Inhibins, activins, and follistatins are gonadal peptide hormones, originally identified in follicular fluid, that selectively affect the production and secretion of FSH but do not affect LH. Inhibins *inhibit* FSH production by gonadotrophs, activins *activate* FSH production, and follistatins inhibit FSH production by binding to and thereby inhibiting activins.

The inhibins and the activins are glycoproteins that are members of the transforming growth factor- β (TGF- β) superfamily, which also includes antimüllerian hormone (AMH; see [p. 1080](#)). The inhibins and activins are dimers constructed from a related set of building blocks: a glycosylated 20-kDa α subunit and two nonglycosylated 12-kDa β subunits, one called β_A and the other called β_B ([Fig. 55-7](#)). The *inhibins* are always composed of one α subunit and either a β_A or a β_B subunit; the α and β subunits are linked by disulfide bridges. The α - β_A dimer is called inhibin A, whereas the α - β_B dimer is called inhibin B. The *activins*, however, are composed of two β -type subunits. Thus, three kinds of activins are recognized: β_A - β_A , β_B - β_B , and the heterodimer β_A - β_B . **Follistatin** is an unrelated monomeric polypeptide that binds to activin with high affinity.

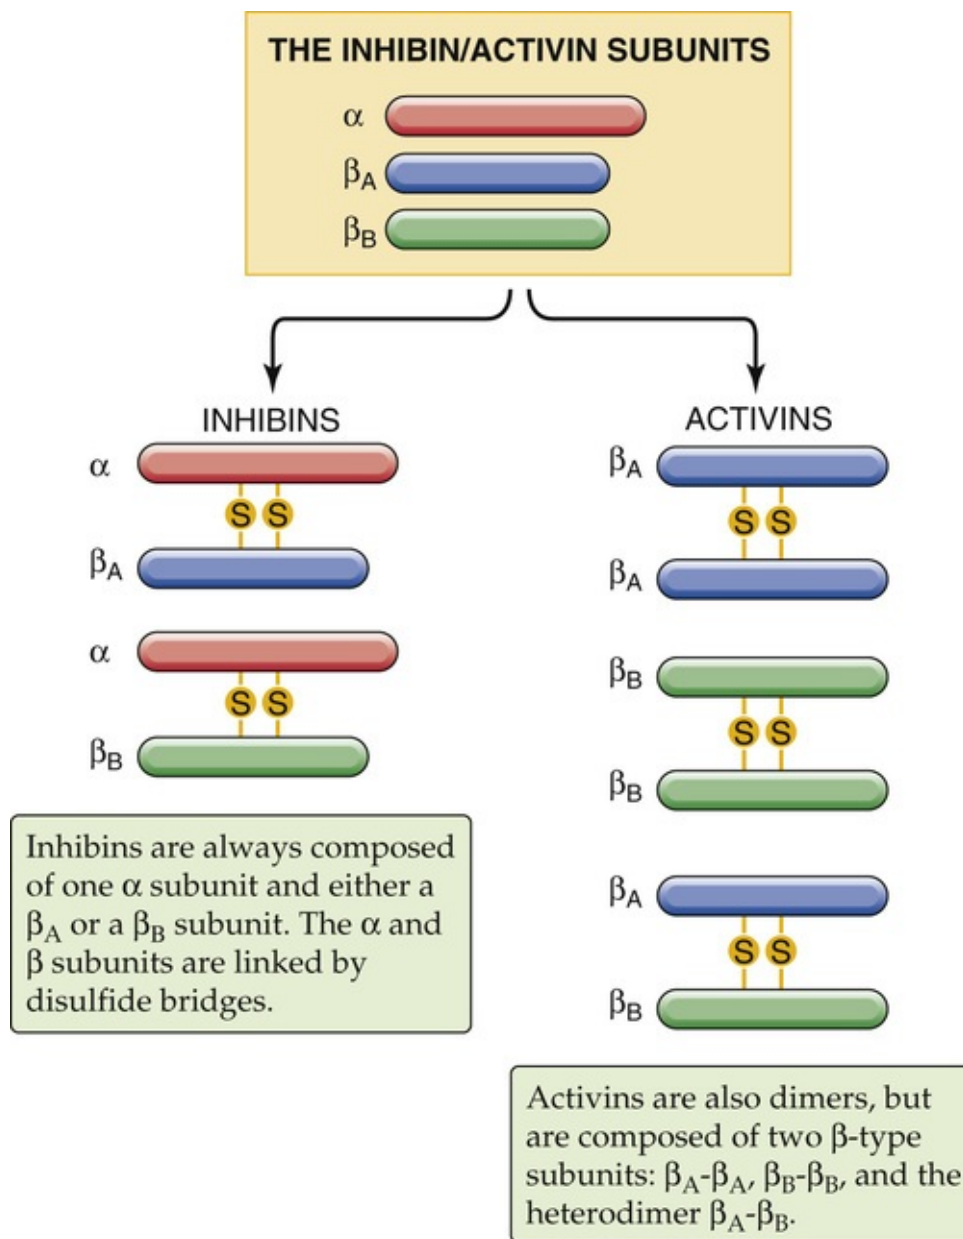

FIGURE 55-7 Inhibins and activins. The inhibins and activins are peptide hormones that are made up of a common set of building blocks. For both the inhibins and the activins, disulfide bonds link the two subunits.

Negative Feedback by the Inhibins

FSH specifically stimulates the granulosa cells to produce **inhibins**. Estradiol also stimulates inhibin production through an intraovarian mechanism. Just before ovulation, after the granulosa cells acquire LH receptors, LH also stimulates the production of inhibin by granulosa cells. Inhibins are also produced by other tissues—including the pituitary, the brain, the adrenal gland, the kidney, the bone marrow, the corpus luteum, and the placenta. Nevertheless, the biological action of the inhibins is primarily confined to the reproductive system.

The inhibins inhibit FSH secretion by the gonadotrophs of the anterior pituitary (hence the name inhibin) in a classic negative-feedback arrangement. The initial action of inhibin appears to be beyond the Ca^{2+} -mobilization step in FSH secretion. In cultured pituitary cells, even very small amounts of inhibin markedly reduce mRNA levels for both the $\alpha_{\text{LH/FSH}}$ and the β_{FSH} subunits. As a result, inhibins suppress FSH secretion. In contrast, inhibins have no effect on the mRNA levels of β_{LH} . In addition to their actions on the anterior pituitary, the inhibins also have the intraovarian effect of decreasing androgen production,

which can have secondary effects on intrafollicular estrogen production.

Positive Feedback by the Activins

The same tissues that produce the inhibins also produce the **activins**, which promote marked increases in β_{FSH} mRNA and FSH release with no change in β_{LH} formation. Activins augment GnRH production and release by hypothalamic neurons. However, the physiological role of activins in the female reproductive system is more complex than that of inhibins because multiple extragonadal tissues produce activin (and follistatin), which may affect the hypothalamic-pituitary-gonadal axis at many levels. Within the ovary, activins modulate folliculogenesis and steroid hormone production by the corpus luteum. Each of these effects is inhibited by inhibin and follistatin.

Activins bind to two types of cell-surface receptors (types I and II) that are serine/threonine kinases (see pp. 67–68). Upon ligand activation, the receptors couple to the SMAD second-messenger kinase cascade, which results in the modulation of transcription factors that affect the expression of a large variety of genes. Two cell-surface molecules that bind inhibin with high affinity antagonize the action of activin.

Modulation of gonadotropin secretion by positive and negative ovarian feedback produces the normal menstrual rhythm

In premenopausal women, the pulsatile release of GnRH from the hypothalamus, generally occurring every 60 to 90 minutes (see p. 1111), triggers a corresponding pulsatile release of LH and FSH from the gonadotrophs of the anterior pituitary. The gonadotropins induce the production and release of ovarian steroids, which in turn feed back on the hypothalamic-pituitary axis. This feedback loop is unusual because it elicits *negative* feedback on the hypothalamic-pituitary axis throughout most of the menstrual cycle but *positive* feedback immediately before ovulation.

Figure 55-6 illustrates the cyclic hormonal changes during the menstrual cycle. The time-averaged records of LH and FSH levels mask their hour-by-hour pulsatility. The **follicular phase** is characterized by a relatively high frequency of GnRH—and thus LH—pulses. Early in the follicular phase, when levels of estradiol are low but rising, the frequency of LH pulses remains unchanged, but their amplitude gradually *increases* with time. Figure 55-4 shows this increase in amplitude between the early and late follicular phases. Later in the follicular phase, the higher estradiol levels cause both the frequency and the amplitude of the LH pulses to increase gradually. During this time of high estradiol levels, the ovarian steroids are beginning to feed back positively on the hypothalamic-pituitary axis. Late in the follicular phase, the net effect of this increased frequency and amplitude of LH and FSH pulses is an increase in their time-averaged circulating levels (see Fig. 55-6).

The **LH surge** is an abrupt and dramatic rise in the LH level that occurs around the 13th to 14th day of the follicular phase in the average woman. The LH surge peaks ~12 hours after its initiation and lasts for ~48 hours. The peak concentration of LH during the surge is ~3-fold greater than the concentration before the surge (see Fig. 55-6). The LH surge is superimposed on the smaller FSH surge. Positive feedback of estrogens, progestins, and activins on the hypothalamic-pituitary axis is involved in the induction of this LH surge. The primary trigger of the gonadotropin surge is a rise in **estradiol** to very high threshold levels just before the LH surge. The rise in estrogen levels has two effects. First, the accelerated rate of increase in estradiol levels in the preovulatory phase sensitizes the gonadotrophs in the anterior pituitary to GnRH

pulses (see [Fig. 55-4](#)). Second, the increasing estrogen levels also modulate hypothalamic neuronal activity and induce a GnRH surge, presumably through GnRH neurons in the preoptic area of the hypothalamus. Thus, the powerful *positive-feedback* action of estradiol induces the midcycle surge of LH and, to a lesser extent, FSH. Gradually rising levels of the activins—secreted by granulosa cells—also act in a positive-feedback manner to contribute to the FSH surge. In addition, gradually increasing levels of LH trigger the preovulatory follicle to increase its secretion of progesterone. These increasing—but still “low”—levels of **progesterone** also have a positive-feedback effect on the hypothalamic-pituitary axis that is synergistic with the positive-feedback effect of the estrogens. Thus, although progesterone is not the primary trigger for the LH surge, it augments the effects of estradiol.

The gonadotropin surge causes ovulation and luteinization. The ovarian follicle ruptures, probably because of weakening of the follicular wall, and expels the oocyte and with it the surrounding cumulus and corona cells. This process is known as **ovulation**, and it is discussed in more detail in [Chapter 56](#). As discussed below, a physiological change—**luteinization**—in the granulosa cells of the follicle causes these cells to secrete progesterone rather than estradiol. The granulosa and theca cells undergo structural changes that transform them into luteal cells, a process known as *luteinization*. The pulsatile rhythm of GnRH release and gonadotropin secretion is maintained throughout the gonadotropin surge.

As the **luteal phase** of the menstrual cycle begins, circulating levels of LH and FSH rapidly decrease (see [Fig. 55-6](#)). This fall-off in gonadotropin levels reflects *negative* feedback by three ovarian hormones—estradiol, progesterone, and inhibin. Moreover, as gonadotropin levels fall, the levels of ovarian steroids also fall. Thus, immediately after ovulation we see more or less concurrent decreases in the levels of both gonadotropins and ovarian hormones.

Later, during the luteal phase, the luteal cells of the corpus luteum gradually increase their synthesis of estradiol, progesterone, and inhibin (see [Fig. 55-6](#)). The rise in the concentration of these hormones causes—in typical negative-feedback fashion—the continued decrease of gonadotropin levels midway through the luteal phase. One of the mechanisms of this negative feedback is the effect of progesterone on the hypothalamic-pituitary axis. Recall that at the peak of the LH surge, both the frequency and the amplitude of LH pulses are high. Progesterone levels rise, and high levels stimulate inhibitory opiodergic interneurons in the hypothalamus, which inhibits the GnRH neurons. This inhibition decreases the frequency of LH pulses, although the amplitude remains rather high.

By ~48 hours before onset of the menses, the pulsatile rhythm of LH secretion has decreased to one pulse every 3 to 4 hours. As a result, circulating levels of LH slowly fall during the luteal phase. During the late luteal phase, the gradual demise of the corpus luteum leads to decreases in the levels of progesterone, estradiol, and inhibin (see [Fig. 55-6](#)). After the onset of menstruation, the hypothalamic-pituitary axis returns to a follicular-phase pattern of LH secretion (i.e., a gradual increase in the frequency of GnRH pulses).

Ovarian Steroids

Starting from cholesterol, the ovary synthesizes estradiol, the major estrogen, and progesterone, the major progestin

Estrogens in female humans are derived from the ovary and the adrenal gland and from peripheral conversion of androgens in adipose tissue. In a *nonpregnant* woman, estradiol, the primary circulating estrogen, is secreted principally by the ovary. The precursor for the biosynthesis of the ovarian steroids, as it is for all other steroid hormones produced elsewhere in the body, is cholesterol. Cholesterol is a 27-carbon sterol that is both ingested in the diet and synthesized in the liver from acetate (see [p. 968](#)). Ovarian cells can synthesize their own cholesterol *de novo*. Alternatively, cholesterol can enter cells in the form of low-density lipoprotein (LDL) cholesterol and bind to LDL receptors.

As shown in [Figure 55-8](#), a **P-450 enzyme**  **N54-4** (see [Table 50-2](#)) known as the side-chain-cleavage enzyme (or 20,22-desmolase) catalyzes the conversion of cholesterol to **pregnenolone**. This reaction is the rate-limiting step in estrogen production. Ovarian cells then convert pregnenolone to progestins and estrogens. The initial steps of estrogen biosynthesis from pregnenolone follow the same steps as synthesis of the two so-called adrenal androgens **dehydroepiandrosterone (DHEA)** and **androstenedione**, both of which have 19 carbon atoms. We discuss these steps in connection with both substances (see [Figs. 50-2](#) and [54-6](#)). The Leydig cells in the testis can use either of two pathways to convert these weak androgens to **testosterone**. Cells in the ovaries are different because, as shown in [Figure 55-9](#), they have a **P-450 aromatase (P-450_{arom})** that can convert androstenedione to estrone and testosterone to estradiol. This aromatization also results in loss of the 19-methyl group (thus, the estrogens have only 18 carbons), as well as conversion of the ketone at position 3 to a hydroxyl in the A ring of the androgen precursor. Once formed, **estrone** can be converted into the more powerful estrogen **estradiol**, and vice versa, by 17 β -hydroxysteroid dehydrogenase (17 β -HSD). Finally, the liver can convert both estradiol and estrone into the weak estrogen **estriol**.

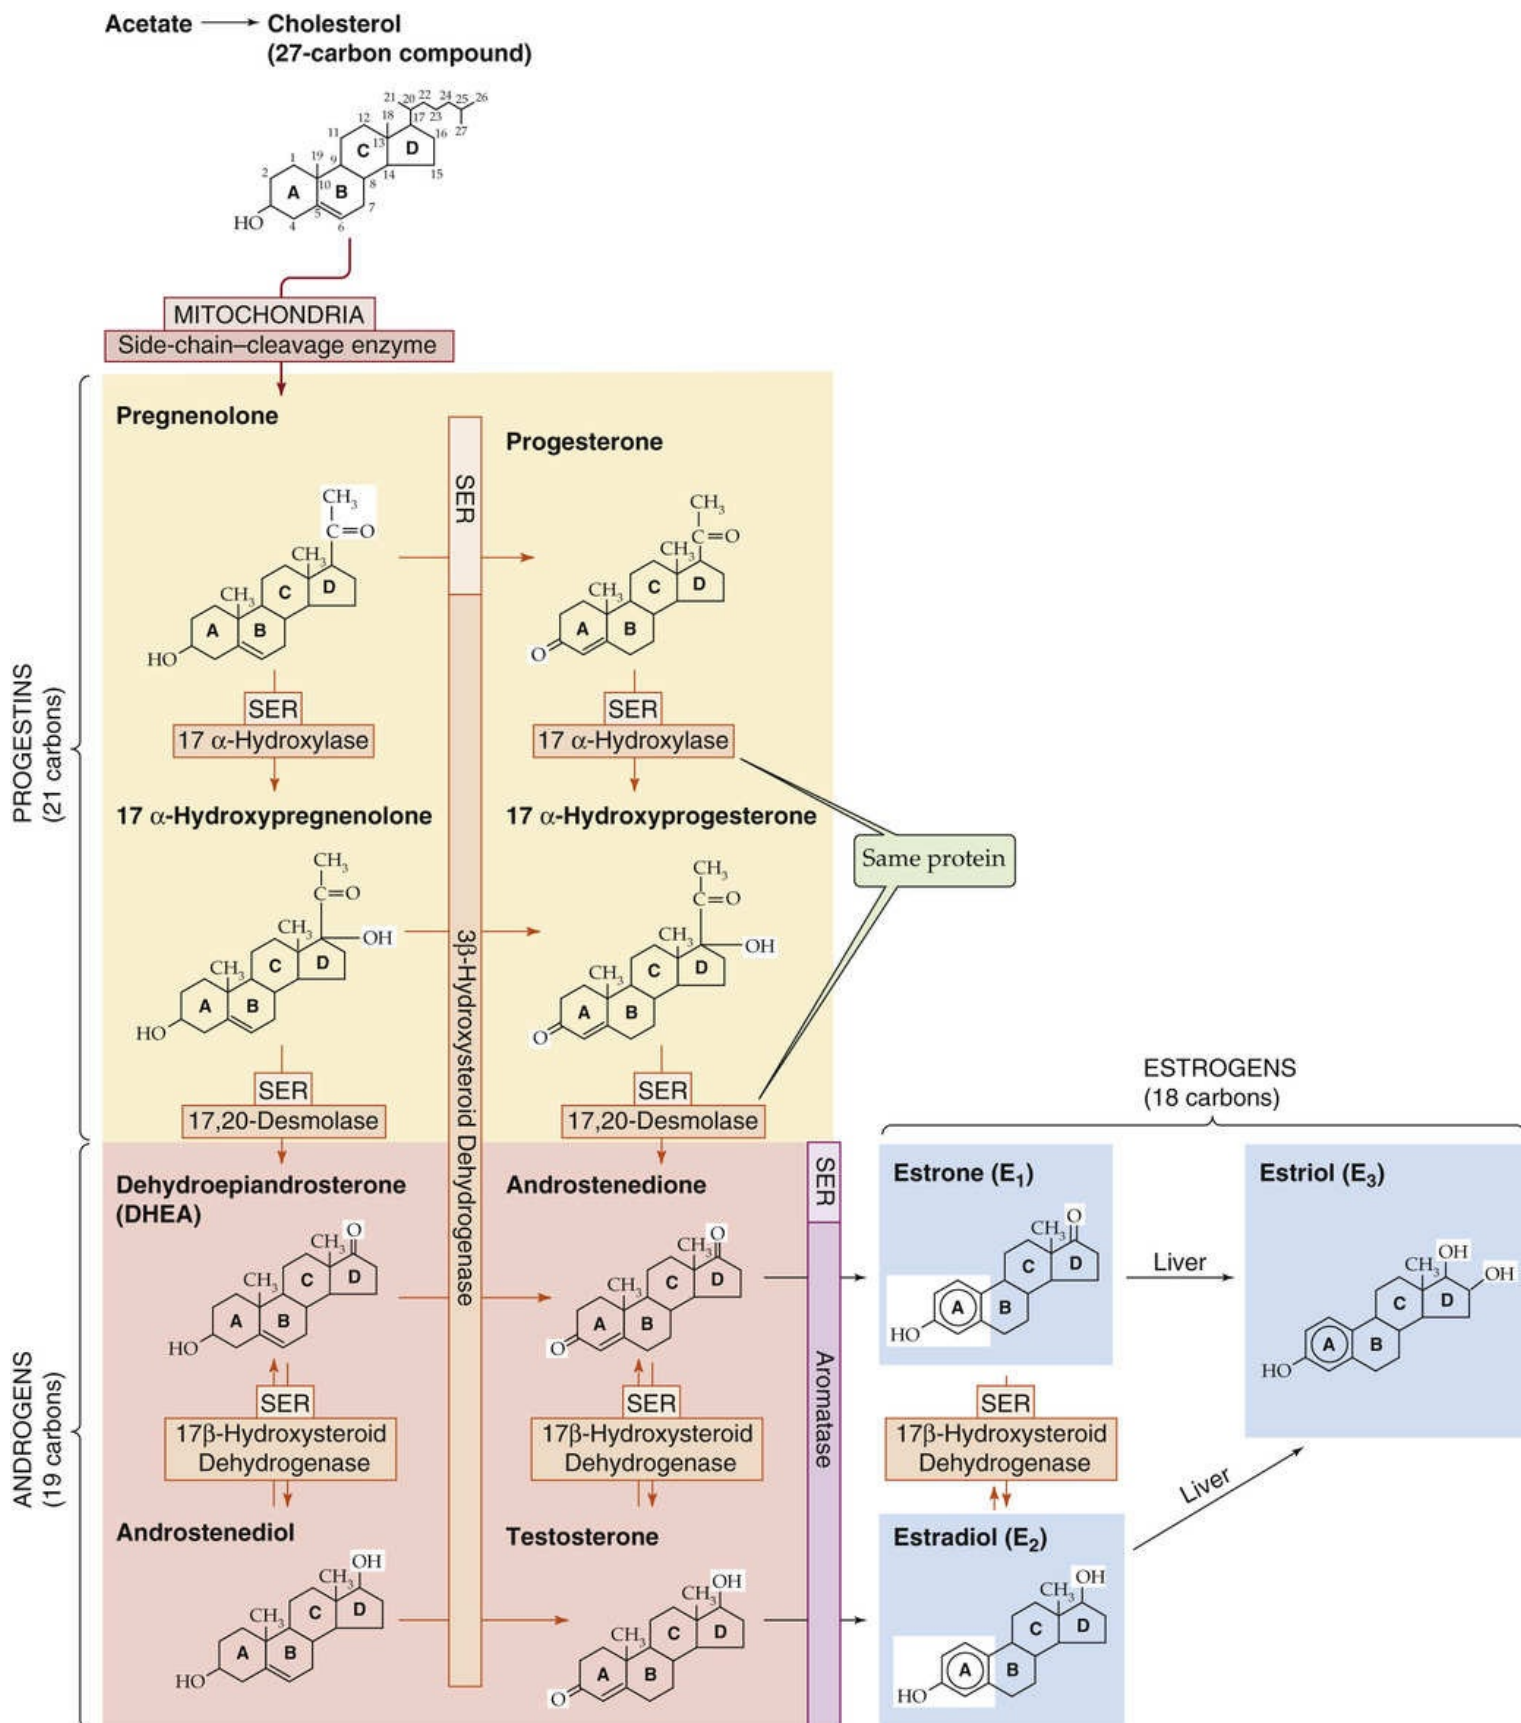

FIGURE 55-8 Biosynthesis of the ovarian steroids. This scheme summarizes the synthesis of the progestins and estrogens from cholesterol. The individual enzymes are shown in the horizontal and vertical boxes; they are located in either the smooth endoplasmic reticulum (SER) or the mitochondria. The side-chain-cleavage enzyme that produces pregnenolone is also known as 20,22-desmolase. The chemical groups modified by each enzyme are highlighted in the reaction product. The ovary differs from the testis in having aromatase, which converts androgens to estrogens. Certain of these pathways are shared in the biosynthesis of the glucocorticoids and mineralocorticoids (see Fig. 50-2) as well as androgens (see Fig. 54-6).

FIGURE 55-9 Two-cell, two-gonadotropin model. During the follicular phase, the major product of the follicle is estradiol, whereas during the luteal phase, the major products of the corpus luteum are the progestins, although estradiol synthesis is still substantial. In the follicular phase, LH primes the theca cell to convert cholesterol to androstenedione. Because the theca cell lacks aromatase, it cannot generate estradiol from this androstenedione. Instead, the androstenedione diffuses to the granulosa cell, whose aromatase activity has been stimulated by FSH. The aromatase converts the androstenedione to estradiol. In the luteal phase, the vascularization of the corpus luteum makes LDL available to the granulosa-lutein cells. Thus, both the theca-lutein and the granulosa-lutein cells can produce progesterone, the major product of the corpus luteum. For production of 17 α -hydroxyprogesterone (17 α -OH progesterone), some of the progesterone diffuses into the theca-lutein cell, which has the 17 α -hydroxylase activity needed for converting the progesterone to 17 α -hydroxyprogesterone. The theca-lutein cell can also generate androstenedione, which diffuses into the granulosa-lutein cell for estradiol synthesis. AC, adenylyl cyclase.

The two major **progestins**, **progesterone** and **17 α -hydroxyprogesterone**, are formed even earlier in the biosynthetic pathway than the adrenal androgens. Functionally, progesterone is the more important progestin, and it has higher circulating levels (Box 55-3).

Box 55-3

The Birth Control Pill

Hormonal contraception is the most commonly used method of contraception in the United States; ~30% of sexually active women take the oral contraceptive pill (OCP).

Types of Oral Contraceptives

Numerous combination (i.e., estrogen and progestin) oral contraceptives and progestin-only pills are available. The estrogens and progestins used in OCPs have varying potencies. In the United States, two estrogen compounds are approved for oral contraceptive use: ethinyl estradiol and mestranol. The progestins used in OCPs are modified steroids in which the methyl at position 19 (see Fig. 55-8) is removed; these progestins include norethindrone, norgestrel, norethynodrel, norethindrone acetate, and

ethynodiol diacetate. A new generation of progestins—including gestodene and norgestimate—have reduced androgenic effects.

The woman takes the OCPs daily for 21 days out of the 28-day cycle; she takes no pill, a placebo, or an iron pill during days 22 to 28. No medication is usually given during this fourth week to allow withdrawal bleeding to occur. Three regimens of contraceptive steroid administration are used:

1. **Monophasic or fixed-combination OCPs.** The pills taken for the first 21 days of the cycle are identical.
2. **Multiphasic or varying-dose OCPs.** The pills contain two or three different amounts of the same estrogen and progestin, the dosages of which vary at specific intervals during the 21-day medication period. Multiphasic OCPs generally maintain a low dose of estrogen throughout the cycle, combined with varying amounts of progestin. The rationale for this type of formulation is that the woman takes a lower total dose of steroid but is not at increased risk of breakthrough endometrial bleeding.
3. **Progestin-only OCPs (“minipill”).** These estrogen-free pills are taken daily for 3 weeks of a 4-week cycle. This regimen may be associated with irregular, low-grade breakthrough endometrial bleeding. The progestin-only OCP is a good option for nursing mothers as well as women for whom estrogens are contraindicated (e.g., those with thromboembolic disease, a history of cerebrovascular incidents, or hypertension).

Biological Action of Oral Contraceptives

The contraceptive effectiveness of OCPs accrues from several actions. Like natural ovarian steroids, contraceptive steroids feed back both directly at the level of the hypothalamus (decreasing secretion of GnRH) and at the level of the gonadotrophs in the anterior pituitary (see Fig. 55-3). The net effect is suppressed secretion of the gonadotropins FSH and LH. The low FSH levels are insufficient to stimulate normal folliculogenesis; the low LH levels obviate the LH surge and therefore inhibit ovulation. However, in the commonly used doses, contraceptive steroids do not completely abolish either gonadotropin secretion or ovarian function.

The progestin component of the OCP causes the cervical mucus to thicken and become viscid and scant. These actions inhibit sperm penetration into the uterus. The progestins also impair the motility of the uterus and oviducts and therefore decrease transport of both ova and sperm to the normal site of fertilization in the distal fallopian tube (see p. 1129). Progestins also produce changes in the endometrium that are not conducive for implantation of the embryo. These changes include decreased glandular production of glycogen and thus diminished energy for the blastocyst to survive in the uterus.

Progestin-only OCPs do not effectively inhibit ovulation, as do the combination pills. However, they do produce other actions, as noted above: mucus thickening, reduced motility, and impaired implantation. Because they are inconsistent inhibitors of ovulation, the progestin-only OCPs have a substantially higher failure rate than does the combined type of OCPs.

Side effects of the compounds in OCPs are those associated with estrogens and progestins and include nausea, edema, headaches, and weight gain. Specific side effects of progestins include depression, mastodynia, acne, and hirsutism. Many of the side effects associated with the progestin component of the pill, particularly acne and hirsutism, are the result of the androgenic actions of the progestins used. The potential benefits of the newer progestins include decreased androgenic effects, such as increased sex hormone-binding globulin, improved glucose tolerance (see p. 1038), and increased high-density and

decreased low-density lipoprotein cholesterol (see Table 46-4). The clinical impact of these changes remains to be determined. Table 55-1 lists the major benefits and risks of OCPs.

TABLE 55-1
Benefits and Risks of Oral Contraceptives

Oral Contraceptives Decrease the Risk of

- Ovarian cancer
- Endometrial cancer
- Ovarian retention cysts
- Ectopic pregnancy
- Pelvic inflammatory disease
- Benign breast disease

Oral Contraceptives Increase the Risk of

- Benign liver tumors
- Cholelithiasis (gallstones)
- Hypertension
- Heart attack
- Stroke
- Deep vein thrombosis
- Pulmonary embolus

Estrogen biosynthesis requires two ovarian cells and two gonadotropins, whereas progesterin synthesis requires only a single cell

A unique aspect of estradiol synthesis in the ovary is that it requires the contribution of two distinct cell types: the theca and granulosa cells within the follicle and the theca-lutein and granulosa-lutein cells within the corpus luteum (see Fig. 55-9).

The superficial **theca cells** and theca-lutein cells can take up cholesterol and produce DHEA and androstenedione (see Fig. 55-8), but they do not have the aromatase necessary for estrogen production. The deeper **granulosa cells** and granulosa-lutein cells have the aromatase, but they lack the 17 α -hydroxylase and 17,20-desmolase (which are the same protein) necessary for making DHEA and androstenedione. Another difference between the two cell types is that, in the follicle, the superficial theca cell is near blood vessels, which supply LDL cholesterol. The granulosa cell, conversely, is far from blood vessels and, instead, is surrounded by LDL-deficient follicular fluid. Thus, in the follicular stage, the granulosa cells obtain most of their cholesterol by de novo synthesis. However, after formation of the corpus luteum, the accompanying vascularization makes it possible for the granulosa-lutein cell to take up LDL cholesterol from the blood and to thus synthesize large amounts of progesterone. A final difference between the two cell types is that theca cells have LH receptors, whereas granulosa cells have both LH and FSH receptors.

Because of their unique physiological properties, neither the theca/theca-lutein cells nor the granulosa/granulosa-lutein cells can make estrogens by themselves. According to the **two-cell, two-gonadotropin hypothesis**, estrogen synthesis occurs in the following steps:

Step 1: LH stimulates the theca cell, through the adenylyl cyclase pathway, to increase its synthesis of LDL receptors and the side-chain-cleavage enzyme.

Step 2: Thus stimulated, the theca cell increases its synthesis of androstenedione.

Step 3: The androstenedione synthesized in the theca cells freely diffuses to the granulosa cells.

Step 4: FSH, also acting through the adenylyl cyclase pathway, stimulates the granulosa cell to produce aromatase.

Step 5: The aromatase converts androstenedione to estrone (see [Fig. 55-8](#)). 17β -HSD then converts the estrone to estradiol. Alternatively, 17β -HSD can first convert the same androstenedione to testosterone, and then the aromatase can convert this product to estradiol. By these pathways, theca-derived androgens are converted to estrogens in the granulosa cell.

Step 6: The estradiol diffuses into the blood vessels.

At low concentrations, the weak androgens produced by the theca cells are substrates for estrogen synthesis by the granulosa cells, in addition to enhancing the aromatase activity of granulosa cells. However, at high concentrations, conversion of androgens to estrogens is diminished. Instead, the weak androgens are preferentially converted by 5α -reductase (see [Fig. 54-6](#)) to more potent androgens, such as **dihydrotestosterone**, a substance that cannot be converted to estrogen. Furthermore, these 5α -reduced androgens inhibit aromatase activity. Thus, the net effect of a high-androgen environment in the follicle is to decrease estrogen production. These androgens also inhibit LH receptor formation on follicular cells.

In the luteal phase of the cycle, luteinization of the follicle substantially changes the biochemistry of the theca and granulosa cells. As part of the formation of the corpus luteum, blood vessels invade deep toward the granulosa-lutein cells. Recall that in the follicle, the granulosa cells had been surrounded by follicular fluid, which is poor in LDL cholesterol. The increased vascularity facilitates the delivery of LDL cholesterol to the granulosa-lutein cells. In addition, LH stimulates the granulosa-lutein cells to take up and process cholesterol—as it does the theca cells. The net effect is the increased progesterone biosynthesis that is characteristic of the midluteal phase. Indeed, the major products of the corpus luteum are **progesterone** and 17α -hydroxyprogesterone, although the corpus luteum also produces estradiol. As indicated in [Figure 55-9](#), the granulosa-lutein cells cannot make either 17α -hydroxyprogesterone or estradiol directly because these cells lack the protein that has dual activity for 17α -hydroxylase and $17,20$ -desmolase (see [Fig. 55-8](#)). Thus, 17α -hydroxyprogesterone synthesis necessitates that progesterone first moves to the theca-lutein cell (see [Fig. 55-9](#)), which can convert progesterone to **17α -hydroxyprogesterone**, as well as androstenedione. Furthermore, estradiol synthesis necessitates that androstenedione from the theca-lutein cell move to the granulosa-lutein cell for aromatization and formation of **estradiol**.

Estrogens stimulate cellular proliferation and growth of sex

organs and other tissues related to reproduction

Most estrogens in blood plasma are bound to carrier proteins, as are testosterone and other steroid hormones. In the case of estradiol, 60% is bound to **albumin** and 38% to **sex hormone–binding globulin (SHBG)**; see [p. 1099](#))—also known as testosterone-binding globulin (TeBG). TeBG is doubly a misnomer because this protein binds estradiol and, moreover, its levels are twice as high in women as in men. At least one reason for the higher levels in women is that estrogens (including birth control pills) stimulate the synthesis of SHBG. Only 2% of total plasma estradiol circulates as the free hormone, which readily crosses cell membranes. The nuclear **estrogen receptors ER α** and **ER β** function as dimers ($\alpha\alpha$, $\alpha\beta$, or $\beta\beta$; see [Table 3-6](#)). When bound to estrogen, the ER dimer interacts with steroid response elements on chromatin and induces the transcription of specific genes. Over the next several hours, DNA synthesis increases, and the mitogenic action of estrogens becomes apparent. Estrogens almost exclusively affect particular target sex organs—including uterus and breasts—that have ERs.

In addition to acting through nuclear receptors, estrogens can also exert nongenomic actions (see [p. 989](#)) by binding to the G protein–coupled receptor GPR30.

The **progestins**, particularly progesterone, stimulate glandular secretion in reproductive tissue and promote the maturation of certain estrogen-stimulated tissue. One of the most prominent actions of progesterone, which binds to the dimeric **progesterone receptor (PR)**; see [Table 3-6](#)), is the induction of secretory changes in the endometrium. In part because estrogens induce PR expression in endometrial cells, estrogens must condition the endometrium for progesterone to act effectively, as during the luteal phase. During the latter half of the menstrual cycle, progesterone induces final maturation of the uterine endometrium for reception and implantation of the fertilized ovum.

The Ovarian Cycle: Folliculogenesis, Ovulation, and Formation of the Corpus Luteum

Female reproductive life span is determined by the number of primordial follicles established during fetal life

Unlike the male—which produces large numbers of mature gametes (sperm) continuously beginning at puberty and for the remainder of the man's life—the female has a limited total number of gametes, determined by the number of oocytes formed during fetal life (see [p. 1078](#)). Oocyte maturation—the production of a haploid female gamete capable of fertilization by a sperm—begins in the fetal ovary. Beginning at around the fourth week of gestation, **primordial germ cells** migrate from the endoderm of the yolk sac to the gonadal ridge (see [Fig. 53-4B and C](#)), where they develop into **oogonia**—immature germ cells that proliferate by mitosis.

Primary Oocytes

By ~8 weeks' gestation, ~300,000 oogonia are present in each ovary. At around this time, some oogonia enter prophase of meiosis I and become primary oocytes ([Fig. 55-10A](#)). From this point onward, the number of germ cells is determined by three ongoing processes: mitosis, meiosis, and death by apoptosis (see [p. 1241](#)). By 20 weeks, all the mitotic divisions of the female germ cells have been completed, and the total number of germ cells peaks at 6 to 7 million. All oogonia that have not already entered prophase of meiosis I by the 28th to 30th week of gestation die by apoptosis. The oocytes then arrest in the diplotene stage of prophase I. This prolonged state of meiotic arrest is known as the **dictyotene** state, which lasts until just before ovulation many years later, when the meiosis resumes and the first polar body is extruded. The second meiotic division occurs at syngamy (see [p. 1072](#)), at which stage maturation of the haploid oocyte is complete.

Primordial Follicles

In the fetal ovary, dictyotene oocytes are surrounded by a single layer of flat, spindle-shaped pregranulosa cells to form a primordial follicle (see [Fig. 55-10B](#)). Each primordial follicle is 30 to 60 μm in diameter and enclosed by a basement membrane. By the 30th week of gestation, the ovaries contain around 5 to 6 million primordial follicles. Unlike *male* gametes, new oocytes cannot form after this time because all gametogenic stem cells, in this case oogonia, have either died or entered meiosis. Therefore, by midgestation, the female gamete endowment is established. For the remainder of the female's life, the number of primordial follicles gradually decreases. One reason for the decline is that primordial follicles undergo a relentless process of apoptosis that begins at midgestation and ends at menopause when the endowment of primordial follicles is virtually exhausted. This progressive exhaustion is independent of gonadotropic hormones and is unaffected by pregnancy or the use of oral contraceptives. In addition, after puberty, each month a cohort of 10 to 30 primordial follicles is recruited to enter the irreversible process of folliculogenesis, which culminates in either ovulation (rupture of the follicle and expulsion of the ova) or atresia (a coordinated process in which the oocyte and other follicle cells undergo apoptosis, degeneration, and resorption). The mechanism by which some primordial follicles initiate folliculogenesis whereas others remain dormant is not known. Thus, even though the ovaries are invested with ~ 7 million oogonia at midgestation, the pool of primordial follicles is continually depleted, so that ~ 1 million exist at birth, $\sim 300,000$ remain at puberty, and there are virtually none at menopause. Of the $\sim 300,000$ primordial follicles present at puberty, only 400 to 500 are destined for ovulation between puberty and menopause (e.g., 12 per year for 40 years). Another 5000 to 15,000 are part of the monthly cohorts that undergo atresia. However, the vast majority of primordial and primary ovarian follicles are lost as a result of the rapid, continuous process of atresia during the reproductive life of the individual.

The female gametes are stored in the ovarian follicles—the primary functional units of the ovary. Over the course of a female's life, 90% to 95% of all primordial follicles never progress into folliculogenesis. Primordial follicles are dormant for most of their life. At any given time, a small proportion of primordial follicles begins a series of changes in size, morphology, and function referred to as **folliculogenesis**—the central event in the human female reproductive system. Folliculogenesis—controlled by intrinsic factors within the ovary and by the gonadotropins (FSH and LH)—occurs by three processes: (1) enlargement and maturation of the oocyte, (2) differentiation and proliferation of granulosa and theca cells, and (3) formation and accumulation of a fluid.

Primary Follicles

The first step in folliculogenesis is the emergence of a primordial follicle from its quiescent state to become a primary follicle (see [Fig. 55-10C](#)). This process involves proliferation of granulosa cells and their differentiation from flattened pregranulosa cells to cuboidal cells. In addition, the oocyte increases in size and forms the **zona pellucida**—a glycoprotein shell surrounding the plasma membrane of the oocyte.

Secondary Follicles

The further proliferation of granulosa cells and the appearance of the theca-cell layer converts the primary follicle into a secondary follicle (see [Fig. 55-10D](#)). Secondary follicles contain a primary

oocyte surrounded by *several* layers of cuboidal granulosa cells. In addition, cells in the ovarian stroma surrounding the follicle are induced to differentiate into **theca cells** that populate the outside of the follicle's basement membrane. The oocyte increases in size to a mean diameter of $\sim 80\ \mu\text{m}$ and the follicular diameter grows to 110 to 120 μm . As the developing follicle increases in size—becoming a late-stage secondary follicle—the number of granulosa cells increases to ~ 600 and the theca cells show increasing differentiation to form the **theca interna** layer closest to the granulosa and the **theca externa** that compresses the surrounding ovarian stroma. Progression to secondary follicles also involves the formation of a blood supply from arterioles that terminate in a wreath-like network of capillaries adjacent to the basement membrane surrounding the granulosa-cell layer, which remains avascular. The theca cells proliferate and acquire LH receptors, as well as the ability to synthesize steroids. Gap junctions also form between the oocyte and the adjacent layer of granulosa cells and between granulosa cells. The oocyte-granulosa junctions may function as thoroughfares to transport nutrients and information from the granulosa cells to the oocyte and vice versa. The granulosa cells in this context are analogous to the Sertoli cells (see pp. 1101–1102) in that they nurse the gamete and act as the barrier between the oocyte and the blood supply.

Tertiary Follicles

The next stage of follicular growth is the maturation of secondary follicles into **tertiary follicles** (see Fig. 55-10E) as the increasingly abundant granulosa cells secrete fluid into the center of the follicle to form a fluid-filled space called the **antrum**. Tertiary follicles represent the first of two *antral* stages (the second being the graafian follicle, below). FSH induces the transition of *preantral* secondary follicles to *antral* tertiary follicles.

Graafian Follicles

As the antrum enlarges, it nearly encircles the oocyte, except for a small mound or cumulus that attaches the oocyte to the rest of the follicle. At this second antral stage, the diameter of the follicle increases to 20 to 33 mm and it is called a **preovulatory** or **graafian follicle** (see Fig. 55-10F).

The granulosa cells of the tertiary and graafian follicles are of three types: (1) **Mural granulosa cells**, which are the farthest from the center of the follicle, are the most metabolically active and contain large quantities of LH receptors and enzymes that are necessary for the synthesis of steroids. (2) **Cumulus granulosa cells** are shed with the oocyte at the time of ovulation. (3) **Antral granulosa cells**, which face the antrum, are left behind within the follicle to become the large luteal cells of the corpus luteum. The capacity of the three types of granulosa cells to generate steroids differs. Cumulus cells contain neither the side-chain-cleavage enzyme ($\text{P-450}_{\text{SCC}}$) nor aromatase ($\text{P-450}_{\text{arom}}$) and therefore cannot generate estrogens. Moreover, cumulus cells respond less to LH and have a low overall LH receptor content. The exact role of the cumulus layer has not been definitively established, although investigators have postulated that the cumulus layer may function as a feeder layer and may provide stem cells that differentiate into other granulosa-cell types.

The antral fluid provides a unique environment for oocyte growth and development. It facilitates the release of the oocyte-cumulus at the time of ovulation and serves as a medium for nutrient exchange and waste removal in the avascular compartment. The accumulation of antral fluid is a major factor in the formation of the dominant follicle. Between 5 and 6 days before ovulation the dominant follicle undergoes accelerated expansion, forming a cystic bulge on the surface of the ovary. After this final phase of growth, the follicle—now a graafian follicle—is prepared for ovulation (see Fig. 55-10G).

The oocyte grows and matures during folliculogenesis

The principal role of folliculogenesis is to produce a mature oocyte that is capable of fertilization and formation of an embryo. The oocyte contributes the majority of the cytoplasmic and nuclear factors needed for embryo development, and these factors are not completely established until after the secondary follicle stage (see [Fig. 55-10D](#)). In addition, oocyte growth and maturation benefits from the gap junctions that connect cumulus granulosa cells to the oocyte, permitting the bidirectional exchange of nutrients, growth factors, and other molecules. Oocyte growth and maturation includes formation of the zona pellucida, formation of increased numbers of mitochondria, acquisition of competence to complete meiosis I. During maturation, the oocyte also re-establishes genomic imprints. **Genomic imprinting** (see [p. 94](#)) is the process by which certain genes—about 1% of the genome—are silenced; particular genes are silenced only in female gametes and others, only in male gametes. 🍌 [N55-6](#)

N55-6

Genomic Imprinting

Contributed by Emile Boulpaep, Walter Boron, Sam Mesiano

Genomic imprinting is the process by which certain genes—about 1% of the genome—are silenced; particular genes are silenced only in female gametes and others, only in male gametes. Thus, these genes are expressed in a manner specific to the parent of origin.

Note that a female diploid oogonium has some paternal genes imprinted or silenced (i.e., only the maternal gene is active) and some maternal genes silenced (i.e., only the paternal gene is active). When the 2N genome splits into two 1N genomes, it is important that all genes in the oocyte have the *female* pattern of imprinting, which occurs during oocyte maturation.

Failure of proper genomic imprinting causes aberrant gene expression and is associated with several human diseases, including Beckwith-Wiedemann, Prader-Willi, and Angelman syndromes. For example, the *IGF2* gene is normally *maternally* imprinted (i.e., silenced). In **Beckwith-Wiedemann syndrome**, the maternal *IGF2* gene becomes reactivated (by removal of methyl tags) during oocyte formation in the mother or early embryonic development. The result is that the offspring has two (rather than one) active copies of *IGF2* and thus excess IGF2 protein. The most obvious sign is macrosomia (large body size) in the newborn.

FSH and LH stimulate the growth of a cohort of follicles

As described above, the development of primordial follicles to secondary follicles occurs continually from fetal life until menopause. However, almost all of these follicles undergo **atresia** (death of the ovum, followed by collapse of the follicle and scarring) at some stage in their development. This gonadotropin-independent folliculogenesis and atresia is thought to be controlled by factors within the ovary, and especially between somatic cells and the oocyte, acting in a paracrine manner. Some key factors in this

process are activin A, the forkhead transcription factor FOXO3, basic fibroblast growth factor, and kit ligand.

At the time of puberty, increased levels of FSH and LH stimulate cohorts of secondary follicles to progress to the tertiary and preovulatory stages. Along the course of this development, most follicles undergo atresia until one dominant graafian follicle remains at the time of ovulation. Controversy exists about the length of this developmental process. Some believe that the entire developmental process occurs over three to four monthly cycles, so that the graafian follicle of the present ovulatory cycle was part of a cohort of secondary follicles recruited three to four cycles earlier. An alternative view is that FSH and LH induce the recruitment of a cohort of follicles during the end of one cycle, and one of these follicles develops into the dominant graafian follicle in the next cycle. In any case, FSH is necessary for continued development of follicles beyond the secondary stage, and only a portion of the cohort of follicles continues to develop in response to FSH and LH. The other follicles undergo atresia.

Each month, one follicle achieves dominance

Although the mechanism of selection of the dominant follicle is not completely understood, it is thought to be caused by estrogen-induced events within the follicles. As estrogen levels rise during the follicular phase of the cycle, the pituitary gradually lowers its secretion of FSH (see [Fig. 55-6](#)). Rising inhibin levels also feed back on the anterior pituitary to decrease FSH secretion. Peak inhibin levels correlate with the number of follicles present and rise in parallel with circulating estradiol levels.

Decreased levels of FSH cause a decline in FSH-dependent aromatase activity in granulosa cells (see [p. 1117](#)), which results in a decrease in estradiol production in the less-mature follicles (see [Fig. 55-8](#)). Conversely, estrogen *increases* the effectiveness of FSH in the more mature follicles by increasing the number of FSH receptors. The dominant follicle therefore has more FSH receptors, a greater rate of granulosa-cell proliferation, more FSH-dependent aromatase activity, and more estrogen production than the less dominant follicles. Because the less dominant follicles have less aromatase activity, they convert less androstenedione to estradiol. Thus, the weak androgen androstenedione either builds up or is converted to other androgens. As a result, the less dominant follicles have a lower estrogen/androgen ratio than the dominant follicle, and they undergo atresia under the influence of androgens in their local environment. In contrast, the production of estradiol and inhibins allows the dominant follicle to become prominent and to gain an even greater edge over its competitors. The vascular supply to the theca of the dominant follicle also increases rapidly, which may allow greater FSH delivery to the dominant follicle and thus help to maintain dominance of the follicle selected for ovulation.

Estradiol secretion by the dominant follicle triggers the LH surge and thus ovulation

Ovulation occurs at the midpoint of every normal menstrual cycle, triggered by the LH surge, which in turn is stimulated by rapidly rising levels of estradiol. Estradiol secretion by the dominant follicle increases rapidly near the end of the late follicular phase (see [Fig. 55-6](#)). This dramatic rise in circulating estradiol switches the *negative*-feedback response of estradiol on the hypothalamus and anterior pituitary to a *positive*-feedback response and also sensitizes the anterior pituitary to GnRH. The result is the LH surge, which generally begins 24 to 36 hours after peak estradiol secretion. Ovulation usually occurs ~36 hours after onset of the LH surge, and ~12 hours after its peak. Thus, it appears that the developing follicle, through its increased estradiol secretion, signals the hypothalamic-pituitary system that follicular

maturation is complete and that the hypothalamic-pituitary axis can now release a bolus of gonadotropin to induce ovulation. The LH surge appears to terminate in part as a result of rising levels of progesterone, through negative feedback, and in part as a result of loss of the positive feedback that is derived from estradiol. Depletion of gonadotropin stores in the anterior pituitary gland may also contribute to termination of the LH surge.

At the time of the LH surge, the primary oocyte (4N DNA), which had been arrested in the prophase of its first meiotic division since fetal life (see [Fig. 53-2C](#)), now resumes meiosis and completes its first meiotic division several hours before ovulation. The result of this first meiotic division is a small **first polar body**, which degenerates or divides to form nonfunctional cells, and a much larger **secondary oocyte**. Both the first polar body and the secondary oocyte, like secondary spermatocytes (see [p. 1100](#)), have a haploid number of duplicated chromosomes (2N DNA): 22 duplicated somatic chromosomes and 1 duplicated X chromosome. This secondary oocyte begins its second meiotic division, but it becomes arrested in metaphase until the time of fertilization (see [pp. 1131–1132](#)). The secondary oocyte is surrounded by the zona pellucida and one or more layers of follicular cells, the **corona radiata**. Before ovulation, the **cumulus oophorus** expands under the influence of LH, and eventually the oocyte and its surrounding cells break free from the inner follicular-cell layer and, with their “stalk,” float inside the antrum, surrounded by follicular fluid. Breaking away of the oocyte-cumulus complex is probably facilitated by increased hyaluronidase synthesis that is stimulated by FSH.

Release of the oocyte from the follicle—**ovulation**—follows thinning and weakening of the follicular wall, probably under the influence of LH, progesterone, and prostaglandins (particularly those in the E and F series). These agents enhance the activity of proteolytic enzymes (e.g., collagenase) within the follicle, which leads to the digestion of connective tissue in the follicular wall. Ultimately, a **stigma**—or spot—forms on the surface of the dominant follicle, in an area devoid of blood vessels. As this stigma balloons out under the influence of increased follicular pressure and forms a vesicle, it ruptures and the oocyte is expelled.

The expelled oocyte, with its investment of follicular cells, is guided toward the fallopian tube by the fimbriae that cover the surface of the nearby ovary (see [Fig. 55-1](#)). The oocyte is then transported through the infundibulum into the ampulla by ciliary movement of the tubal epithelium, as well as by muscular contractions of the tube. Fertilization, if it occurs, takes place in the ampullary portion of the fallopian tube. The resulting zygote resides in the ampulla for ~72 hours, followed by rapid transport through the isthmus to the uterine cavity, where it floats free for an additional 2 to 3 days before attaching to the endometrium.

After ovulation, theca and granulosa cells of the follicle differentiate into theca-lutein and granulosa-lutein cells of the corpus luteum

After expulsion of the oocyte, the remaining follicular granulosa and theca cells coalesce into folds that occupy the follicular cavity and, under the influence of LH, undergo a phenotypic transformation to form the **corpus luteum**—a temporary endocrine organ whose major product is progesterone. The mature corpus luteum is composed of two cell types, **granulosa-lutein cells** (also known as large luteal cells) derived from the granulosa cells, and **theca-lutein cells** (also known as small luteal cells) derived from the theca cell. The corpus luteum is highly vascularized, consistent with its primary function as an endocrine organ. During the early luteal phase, progesterone and estradiol produced by the corpus luteum

exert negative feedback on the hypothalamic-pituitary axis to suppress gonadotropin secretion and thus inhibit folliculogenesis. If pregnancy is not established, the corpus luteum regresses ~11 days after ovulation. One possible mechanism for this regression—or **luteolysis**—is that withdrawal of trophic support results in demise of the corpus luteum. A second possibility is that local factors, such as prostaglandin $F_{2\alpha}$ produced by the endometrium, inhibit luteal function and terminate the life of the corpus luteum.

Growth and involution of the corpus luteum produce the rise and fall in estradiol and progesterone during the luteal phase

Although the corpus luteum produces both estradiol and progesterone, the luteal phase is primarily dominated by progesterone secretion. Estradiol production by the corpus luteum is largely a function of the theca-lutein cells, which also produce androgens. Progesterone production in the corpus luteum is primarily a function of the granulosa-lutein cells (see [Fig. 55-9](#)), which also produce estradiol.

Progesterone production rises modestly before follicular rupture but increases sharply after ovulation, peaking in ~7 days. Progesterone acts locally to inhibit follicular growth during the luteal phase. In addition, progesterone may act centrally by inhibiting gonadotropin secretion. Progesterone is also an antiestrogen in that it inhibits expression of ERs, thereby reducing estrogen responsiveness. The net effect is that increasing progesterone production suppresses folliculogenesis.

Estradiol levels also rise during the luteal phase (see [Fig. 55-6](#)), which reflects production by the corpus luteum. Because estrogens induce expression of PRs in target cells, the estradiol produced during the luteal phase is necessary for progesterone-induced changes in the endometrium.

Unless rescued by hCG—produced by the syncytial trophoblasts of the blastocyst (see [p. 1136](#))—luteal production of progesterone ceases toward the end of the menstrual cycle. hCG produced by the developing conceptus maintains steroidogenic function of the corpus luteum until approximately the ninth week of gestation, at which time placental function is well established. If not rescued by pregnancy, the hormone-producing cells of the corpus luteum degenerate and leave behind a fibrotic **corpus albicans**.

The Endometrial Cycle

In the human female fetus, the uterine mucosa is capable of responding to steroid hormones by the 20th week of gestation. Indeed, some of the uterine glands begin secreting material by the 22nd week of gestation. Endometrial development in utero apparently occurs in response to estrogens derived from the maternal placenta. By the 32nd week of gestation, glycogen deposition and stromal edema are present in the endometrium. As estrogenic stimulation is withdrawn after delivery, the endometrium regresses, and at ~4 weeks after birth, the glands are atrophic and lack vascularization. The endometrium remains in this state until puberty.

The ovarian hormones drive the morphological and functional changes of the endometrium during the monthly cycle

The ovarian steroids—primarily estradiol and progesterone—control the cyclic monthly growth and breakdown of the endometrium. The endometrial cycle has three major phases: the menstrual, proliferative, and secretory phases.

The Menstrual Phase

If the oocyte was not fertilized and pregnancy did not occur in the previous cycle, a sudden diminution in estradiol and progesterone secretion will signal the demise of the corpus luteum. As hormonal support of the endometrium is withdrawn, the vascular and glandular integrity of the endometrium degenerates, the tissue breaks down, and menstrual bleeding ensues; this moment is defined as the start of day 1 of the menstrual cycle ([Fig. 55-11](#)). After menstruation, all that remains on the inner surface of most of the uterus is a thin layer of *nonepithelial* stromal cells and some remnant glands. However, epithelial cells remain in the lower uterine segments as well as regions close to the fallopian tubes.

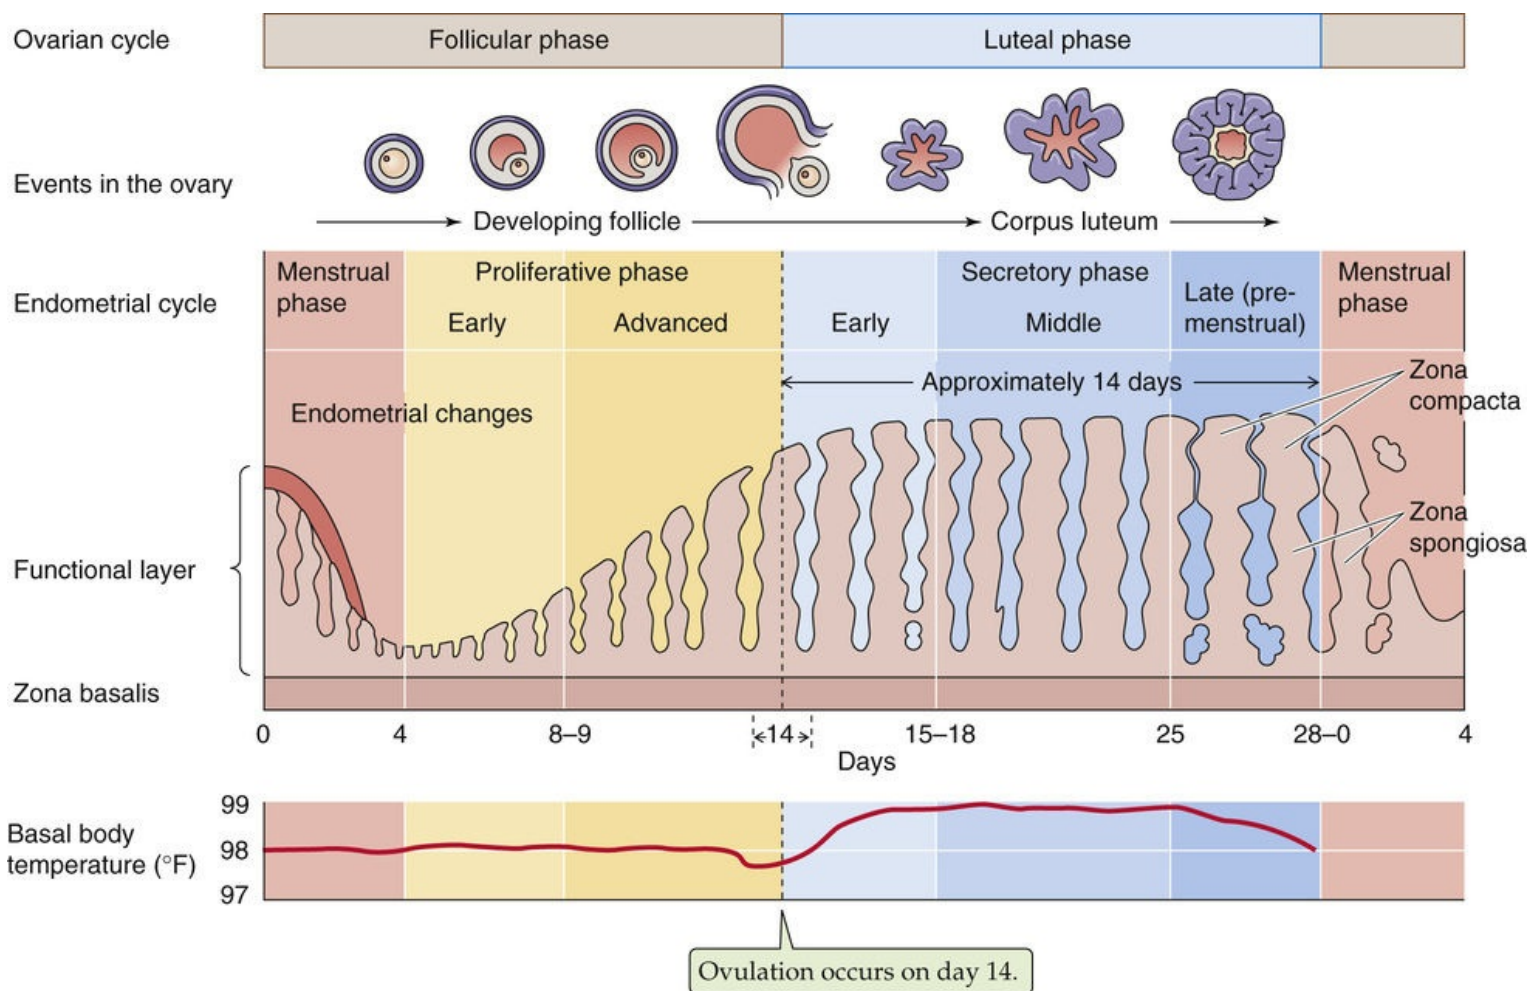

FIGURE 55-11 Endometrial cycle. The ovarian cycle includes the follicular phase (in which the follicle develops) and the luteal phase (in which the remaining follicular cells develop into the corpus luteum). The endometrial cycle has three parts: the menstrual, the proliferative, and the secretory phases.

The Proliferative Phase

After menstruation, the endometrium is restored by about the fifth day of the cycle (see Fig. 55-11) as a result of proliferation of the basal stromal cells on the denuded surface of the uterus (the *zona basalis*) as well as the proliferation of epithelial cells from other parts of the uterus. The stroma gives rise to the connective tissue components of the endometrium. Increased mitotic activity of the stromal and glandular epithelium continues throughout the follicular phase of the cycle and beyond, until ~3 days after ovulation. Cellular hyperplasia and increased extracellular matrix result in thickening of the endometrium during the late proliferative phase. The thickness of the endometrium increases from ~0.5 mm to as much as 5 mm during the proliferative phase.

Proliferation and differentiation of the endometrium are stimulated by estrogen that is secreted by the developing follicles. Levels of estrogen rise early in the follicular phase and peak just before ovulation (see Fig. 55-6). ER levels in the endometrium also increase during the follicular phase of the menstrual cycle. Levels of endometrial ER are highest during the proliferative phase and decline after ovulation in response to changing levels of progesterone.

Estradiol is believed to act on the endometrium in part through its effect on the expression of proto-oncogenes (see p. 70). Estradiol also stimulates the synthesis of growth factors such as insulin-like growth factors (IGFs; see p. 996), transforming growth factors (TGFs), and epidermal growth factor (EGF) by endometrial cells that then act in an autocrine and paracrine manner to induce maturation and growth of the endometrium. Estradiol also induces the synthesis of PRs in endometrial tissue. Levels of

PRs peak at ovulation, when estradiol levels are highest, to prepare the cells for the high progesterone levels of the luteal phase of the cycle.

Progesterone, in contrast, opposes the action of estradiol on the epithelial cells of the endometrium by inhibiting ER expression and stimulating expression of 17 β -HSD and sulfotransferase. 17 β -HSD converts estradiol to estrone (see Fig. 55-8), which is a weaker estrogen. Sulfotransferase conjugates estrogens to sulfate, making them biologically inactive.

The Secretory Phase

During the early luteal phase of the ovarian cycle, progesterone further stimulates the 17 β -HSD and sulfation reactions (see above) and decreases ER levels in endometrial cells. These three antiestrogenic effects halt the proliferative phase of the endometrial cycle. Progesterone also stimulates the glandular components of the endometrium and thus induces secretory changes in the endometrium. The epithelial cells exhibit a marked increase in secretory activity, as indicated by increased amounts of endoplasmic reticulum and mitochondria. These increases in synthetic activity occur in anticipation of the arrival and implantation of the blastocyst. The **early secretory phase** of the menstrual cycle (see Fig. 55-11) is characterized by the development of a network of interdigitating tubes within the nucleolus—the **nucleolar channel system**—of the endometrial epithelial cells.

During the **middle to late secretory phase**, the secretory capacity of the endometrial glands increases. Vascularization of the endometrium increases, the glycogen content increases, and the thickness of the endometrium increases to 5 to 6 mm. The endometrial glands become engorged with secretions. They are no longer straight; instead, they become tortuous and achieve maximal secretory activity at approximately day 20 or 21 of the menstrual cycle.

The changes in the endometrium are not limited to the glands; they also occur in the stromal cells between the glands. Beginning 9 to 10 days after ovulation, stromal cells that surround the spiral arteries of the uterus enlarge and develop eosinophilic cytoplasm, with a prominent Golgi complex and endoplasmic reticulum. This process is referred to as **predecidualization**. Under the influence of progesterone, spindle-shaped stromal cells become rounded **decidual cells** and form an extracellular matrix consisting of laminin, fibronectin, heparin sulfate, and type IV collagen. Multiple foci of decidual cells spread throughout the upper layer of the endometrium and form a dense layer called the **zona compacta** (see Fig. 55-11). This spreading is so extensive that the glandular structures of the zona compacta become inconspicuous. Inflammatory cells accumulate around glands and blood vessels. Edema of the midzone of the endometrium distinguishes the compact area from the underlying **zona spongiosa**, where the endometrial glands become more prominent.

Together, the superficial *zona compacta* and the midlevel *zona spongiosa* make up the so-called **functional layer** of the endometrium. This functional layer is the region that proliferates early in the monthly endometrial cycle, that later interacts with the embryo during pregnancy, that is shed after pregnancy, and that is also shed each month during menstruation. The deepest layer of the endometrium—the **zona basalis**—is the layer left behind after parturition or menstruation. The cells of the zona basalis give rise to the proliferation at the beginning of the next endometrial cycle.

During the late luteal phase of the menstrual cycle, just before the next menstruation, levels of both estrogens and progestins diminish, and these decreased ovarian steroid levels lead to eventual demise of the upper two thirds of the endometrium. During this period, the spiral arteries rhythmically go into spasm and then relax. This period of the cycle is sometimes referred to as the **ischemic phase**. As cells begin to die, hydrolases are released from lysosomes and cause further breakdown of the endometrium. Prostaglandin production increases as a result of the action of phospholipases liberated from lysosomes.

Necrosis of vascular cells leads to microhemorrhage. The average loss of blood, tissues, and serous fluid amounts to ~30 mL. Menstrual blood does not clot because of the presence of fibrolyns released from necrotic endometrial tissue.

The effective implantation window is 3 to 4 days

Based on studies of embryo transfer to recipient mothers in oocyte donation programs (see [Box 56-1](#)) when both the age of the donated embryo and the time of the endometrial cycle of the recipient are known, the period of endometrial receptivity for implantation of the embryo is estimated to extend from as early as day 16 to as late as day 19 of the menstrual cycle. Of course, because implantation must normally follow the ovulation that occurs on day 14 and because fertilization normally occurs within 1 day of ovulation, the effective window is <4 days, from day 16 to day 19. In contrast, when embryos are transferred on cycle days 20 through 24, no pregnancies are achieved. 🟡 [N55-7](#)

N55-7

Implantation Window

Contributed by Ervin Jones

The numerical values presented on page 1126 for the implantation window (days 16 to 19 of the cycle) come from embryo-transfer studies in which the woman has received gonadotropins to overstimulate the ovary to enhance the development of many ova, and then received hCG to mimic the LH surge (see [Box 56-1](#)). As discussed on pages 1132–1133, in a *natural* menstrual cycle that involves fertilization, the implantation takes place 6 to 7 days after ovulation, that is, between days 20 and 21.

Although the mechanisms underlying endometrial receptivity remain unclear, the formation of microvilli and pinopods (i.e., protrusions of endometrial cells near gland openings) during the midluteal phase and the secretion of extracellular matrix composed of materials such as glycoproteins, laminin, and fibronectin may provide a surface that facilitates attachment of the embryo (see [pp. 1135–1136](#)).

Female Sex Act

Female sexual desire—**libido**—is a complex phenomenon that includes physical and psychological effects, all modulated by circulating sex steroids. Libido varies during the ovarian cycle, and the frequency of female sexual activity increases around the time of ovulation. There may also be an increase in the rate of initiation of sexual activity by women around the time of ovulation. These changes may, in part, reflect the increased secretion of androgenic steroids that occurs just before and during ovulation secondary to the LH surge.

The female sex response occurs in four distinct phases

Although sexual function has a strong physiological basis, it is not possible to separate sexual response from the other emotional and contributing factors involved in sexual relationships. 🍷 **N55-8** The four stages of the sex response in women are excitement or seduction, plateau, orgasm, and resolution.

N55-8

Kinsey, and Masters and Johnson

Contributed by Ed Moczydlowski

Masters and Johnson, in their now classic work *Human Sexual Response*, published a discussion of data obtained on the sexual cycles of 700 subjects. Our current understanding of the female sex response is based on their findings. Masters and Johnson described four stages of the sex response in women: excitement or seduction, plateau, orgasm, and resolution. A brief description of each stage is provided in the text. Masters and Johnson suggested that prolonged stimulation during the excitement phase leads to more pronounced orgasmic activity.

This work by Masters and Johnson followed the so-called Kinsey Reports by Alfred C. Kinsey and coworkers, who wrote *Sexual Behavior of the Human Male* (1948) and *Sexual Behavior of the Human Female* (1953).

Excitement

The excitement or arousal phase of the female sex response may be initiated by a multitude of internal or external stimuli, including psychological factors, such as thoughts and emotions, and physical factors, such as sight and tactile stimuli. [Table 55-2](#) summarizes the responses of the excitement phase, many of

which reflect activity of the parasympathetic division of the autonomic nervous system (ANS). Sexual intensity rises in crescendo fashion.

TABLE 55-2
Female Sex Response Cycle

Excitement
Warmth and erotic feelings
Increased sexual tension
Deep breathing
Increased heart rate
Increased blood pressure
Generalized vasocongestion
Skin flush
Breast engorgement
Nipple erection (myotonic effect)
Engorgement of labia and clitoris
Vaginal “sweating” (transudative lubrication)
Secretions from Bartholin's glands
Uterine tenting into pelvis
Plateau
Marked vasocongestion
“Sex flush” (maculopapular rash on breasts, chest, and epigastrium)
Nipple erection
Engorgement of the labia
Engorgement of lower third of the vagina, with narrowing of diameter
Dilation of upper two thirds of vagina
Clitoral swelling and erection
Vaginal “sweating”
Uterine tenting
Orgasm
Release of tension
Generalized, rhythmic myotonic contractions
Contractions of perivaginal muscles and anal sphincter
Uterine contractions
Resolution
Return to pre-excitement state
Personal satisfaction and well-being
New excitement cycles may be initiated

Plateau

The plateau stage is the culmination of the excitement phase as it reaches its peak. It is associated with a marked degree of vasocongestion throughout the body.

Orgasm

During orgasm, the sexual tension that has built up in the entire body is released. The climax, or orgasm, is intense and includes a myotonic response throughout the body. Muscle contractions start 2 to 4 seconds after the woman begins to experience orgasm, and they repeat at 0.8-second intervals. The actual number of contractions, as well as their intensity, varies from woman to woman. Some women observed to have orgasmic contractions are not aware that they are having an orgasm. Whereas the excitement phase is under the influence of the parasympathetic division of the ANS, as is the erection phase in men, orgasm seems to be related to the sympathetic division, as is the emission phase in men (see pp. 1106–1107).

Resolution

The last phase of the female sex response is a return of the woman's physiological state to the pre-excitement level. During the resolution phase, the woman generally experiences a feeling of personal satisfaction, well-being, and relaxation of sexual desire. A new sexual excitement cycle may be initiated at any time after orgasm without the refractory phase that occurs in men.

Both the sympathetic and the parasympathetic divisions control the female sex response

Much of the response in the excitement phase results from stimulation of the **parasympathetic fibers** of the ANS. In some cases, anticholinergic drugs may interfere with a full response in this stage. Dilatation of blood vessels in the erectile tissues causes engorgement with blood and erection of the clitoris, as well as distention of the peri-introital tissues and subsequent narrowing of the lower third of the vagina. Parasympathetic fibers emanating from the sacral plexus (see [p. 339](#)) innervate these erectile tissues, just as in men (see [pp. 1105–1106](#)). In addition, the parasympathetic system innervates Bartholin's glands, which empty into the introitus, as well as the vaginal glands. Adequate lubrication is necessary to minimize the friction of intercourse and thus maximize the stimulation to achieve orgasm.

Both physical and psychological stimuli are important for female orgasm. Psychological stimuli are coordinated via the cerebrum, which causes the generalized tension throughout the body, as discussed above, and also modulates the autonomic response. The female orgasm is also coordinated via a spinal cord reflex that results in rhythmic contractions of the perineal muscles. The afferent pathways for this spinal cord reflex follow the pudendal nerves, which emanate via sacral segments 2 to 4 and are the primary innervation to the perineum and the female external genitalia. This spinal cord reflex is similar to that observed in men.

The female sex response facilitates sperm transport through the female reproductive tract

The spinal reflexes previously discussed may also increase uterine and cervical activity and may thus promote transport of gametes. The cervix dilates during orgasm, which facilitates sperm transport into the upper part of the reproductive tract. The release of oxytocin at the time of orgasm stimulates uterine contractility, which also facilitates gamete transport. Although 150 to 600 million sperm cells (see [p. 1103](#)) are normally deposited in the vagina during sexual intercourse, ~100,000 reach the cavity of the uterus and only 50 to 100 viable sperm reach the distal fallopian tube where fertilization occurs. Aside from the one or more sperm that will fertilize the ovum (or ova), most sperm degenerate, to be disposed of by the female genital tract. Sperm transport is accomplished by swimming movements of the sperm tail through the mucus of the cervical canal. The sperm reach the ampulla of the fallopian tubes within 5 minutes of ejaculation. Clearly, this rapid rate of transport could not be achieved by the swimming activity of the sperm alone. Therefore, uterine or tubal activity must play a major role in sperm transport.

Menopause

Menopause, or the climacteric, signals the termination of reproductive function in women. Cyclic reproductive function ceases, menstruation comes to an end, and childbearing is generally no longer possible. Also occurring are significant physiological changes (Table 55-3) that have a major impact on health.

TABLE 55-3
Menopausal Syndrome and Physical Changes in Menopause

MENO PAUSAL SYNDROME	PHYSICAL CHANGES IN MENOPAUSE
Vasomotor instability	Atrophy of the vaginal epithelium
Hot flashes	Changes in vaginal pH
Night sweats	Decrease in vaginal secretions
Mood changes	Decrease in circulation to vagina and uterus
Short-term memory loss	Pelvic relaxation
Sleep disturbances	Loss of vaginal tone
Headaches	Cardiovascular disease
Loss of libido	Osteoporosis
	Alzheimer disease

Only a few functioning follicles remain in the ovaries of a menopausal woman

Progressive loss of ovarian follicular units occurs throughout life (see pp. 1120–1121). In the United States, puberty generally occurs at an age of ~12.5 years (see p. 1088) and menopause at 51.5 years. At menopause and during the ensuing 5 years, the ovary contains only an occasional secondary follicle and a few primary follicles in a prominent stroma. The massive loss of oocytes over the reproductive life of a woman—from 300,000 at puberty (see p. 1121) to virtually none at menopause—is the result of the process of atresia during reproductive life.

During menopause, levels of the ovarian steroids fall, whereas gonadotropin levels rise

The loss of functional ovarian follicles is primarily responsible for menopause in primates. Even before the onset of menopause, significant hormonal changes occur very early during reproductive life. Because of a gradual decline in the number of follicles, the decreased ovarian production of estradiol reduces the negative feedback to the anterior pituitary and leads to increased levels of FSH. Increased levels of FSH are seen as early as 35 years of age, even though cyclic reproductive function continues. When compared with younger women, older—but premenopausal—women have diminished estradiol production and decreased luteal function during natural cycles. Diminished inhibin production by the aging ovary may also contribute to the sharp rise in FSH levels that occurs in the perimenopausal period of life (see Fig. 53-11A).

During menopause, estradiol levels are generally <30 pg/mL, and progesterone levels are often <1 ng/mL of plasma. Both these values are somewhat less than the lowest levels seen during the menstrual cycle of a younger woman (see Fig. 55-6). Ovarian production of androstenedione is minimal during menopause, although androstenedione production by the adrenal cortex remains normal.

Because the output of estrogens, progestins, and inhibins from the ovaries falls to very low levels during menopause, negative feedback on the hypothalamic-pituitary-ovarian axis (see [Fig. 55-3](#)) becomes minimal. As a result, levels of FSH and LH may be higher than those seen during the midcycle surge in premenopausal women—the futile attempt of the axis to stimulate follicular development and production of the female sex steroids. During menopause, the anterior pituitary still secretes FSH and LH in pulses, presumably after cyclic release of GnRH from the hypothalamus (see [Fig. 53-11A](#)). Although gonadotropins cannot generally stimulate the postmenopausal ovary, it appears that the gonadotrophs in the anterior pituitary can respond to exogenous GnRH ([Box 55-4](#)).

Box 55-4

Hormone Replacement Therapy During Menopause

Although the mean age at menopause is ~51.5 years, changes in hormone secretion patterns begin much earlier. Increases in levels of FSH occur as early as 35 years of age. The mechanisms responsible for this change remain to be elucidated. However, it is clear that ovarian function begins to diminish far in advance of a woman's last menstrual period. The increase in gonadotropin secretion is probably a result of decreased folliculogenesis leading to decreased secretion of sex steroids and inhibin and thus lowered negative feedback on the gonadotrophs during the perimenopausal period.

The characteristic changes associated with menopause are primarily the result of low circulating estrogen levels. Estrogens are very important regulatory hormones in females. In addition to their roles in reproductive processes, these hormones have profound effects on several other physiological systems (see [Table 55-3](#)).

Hormone replacement therapy (HRT) is indicated during menopause to alleviate menopausal syndrome and to prevent or diminish the physical changes that occur as a result of estrogen deficiency. Menopausal HRT consists of estrogen and progestin administration. The reason for administering progestins is that the endometrium is at significant risk of neoplasia from unopposed actions of estrogens. Thus, progestins are not generally administered to women who have had hysterectomies. Estrogen replacement is very effective against menopausal syndrome as well as against osteoporosis. However, because of side effects (e.g., menstruation) and concern about endometrial and breast cancer, compliance with HRT is often compromised.

The **selective estrogen receptor modulators (SERMs)** comprise a group of structurally dissimilar compounds that interact with ERs. SERMs act as either estrogen agonists or estrogen antagonists, depending on the target tissue and hormonal status of the individual. The mechanisms by which SERMs elicit their sometimes opposite effects in specific tissues are complex. SERMs such as tamoxifen and raloxifene have estrogen-agonist effects on bone and the cardiovascular system, but estrogen-antagonist effects in reproductive tissue. The estrogen-antagonist effects of SERMs may reflect classic competition for ERs. The ideal SERM for HRT would have all the beneficial effects of estrogens—including alleviating menopausal syndrome, protecting against cardiovascular and Alzheimer disease, and acting as estrogen agonists in certain reproductive tissues—without their carcinogenic side effects.

Fertilization, Pregnancy, and Lactation

Sam Mesiano, Ervin E. Jones

Transport of Gametes and Fertilization

Cilia and smooth muscle transport the egg and sperm within the female genital tract

Following ovulation, the fimbriae of the fallopian tube sweep over the ovarian surface and pick up the oocyte—surrounded by its complement of granulosa cells, the cumulus oophorus, and corona radiata (see p. 1122)—and deposit it in the fallopian tube. Shortly after ovulation, movements of the cilia and the smooth muscle of fallopian tube propel the oocyte-cumulus complex toward the uterus.

A man normally deposits 150 to 600 million sperm cells into the vagina at the time of ejaculation. Only 50 to 100 of these cells actually reach the ampullary portion of the fallopian tube, where fertilization normally occurs. However, the sperm get there very quickly, within ~5 minutes of ejaculation. The swimming motion of the sperm alone cannot account for such rapid transport. Forceful contractions of the uterus, cervix, and fallopian tubes propel the sperm into the upper reproductive tract during female orgasm. Prostaglandins in the seminal plasma may induce further contractile activity.

The “capacitation” of the spermatozoa that occurs in the female genital tract enhances the ability of the sperm cell to fertilize the ovum

Maturation of sperm continues while they are stored in the epididymis (see pp. 1102–1103). In most species, neither freshly ejaculated sperm cells nor sperm cells that are removed from the epididymis are capable of fertilizing the egg until these cells have undergone further maturation—capacitation—in the female reproductive tract or in the laboratory. **Capacitation** is a poorly understood physiological process by which spermatozoa acquire the ability to penetrate the zona pellucida of the ovum. The removal or modification of a protective protein coat from the sperm cell membrane appears to be an important molecular event in the process of capacitation. N56-0

N56-0

Role of a Bicarbonate-Activated Adenylyl Cyclase in Sperm Capacitation

Contributed by Emile Boulpaep, Walter Boron

It has long been recognized that the capacitation of mammalian sperm requires both HCO_3^- and adenylyl-cyclase activity, which led to the discovery of a HCO_3^- -stimulated soluble adenylyl cyclase (sAC). Recall that the adenylyl cyclase activated by heterotrimeric G proteins is a membrane-bound enzyme (p. 53). In contrast, sAC is present in the cytosol.

Reference

Wuttke MS, Buck J, Levin LR. Bicarbonate-regulated soluble adenylyl cyclase. *J Pancreas*.

Sperm cells do not need to pass through the cervix and uterus to achieve capacitation. Successful pregnancy can occur with gamete intrafallopian transfer (GIFT), in which spermatozoa and oocytes are placed directly into the ampulla of the fallopian tube, and also with direct ultrasound-guided intraperitoneal insemination, in which the sperm are deposited in the peritoneal cavity, near the fimbria. Thus, capacitation of sperm in the reproductive tract is not strictly organ specific. As evidenced by the success of **in vitro fertilization (IVF)** and **embryo transfer (ET)**—discussed in [Box 56-1](#)—capacitation is possible even if the sperm does not make contact with the female reproductive tract.

Box 56-1

In Vitro Fertilization and Embryo Transfer

IVF is a procedure in which an oocyte or oocytes are removed from a woman and then fertilized with sperm under laboratory conditions. Early development of the embryo also proceeds under laboratory conditions. Finally, the physician transfers one or more embryos to the uterine cavity, where the embryo will hopefully implant and develop.

Indications for IVF-ET

Indications for IVF-ET include disorders that impair the normal meeting of the sperm and the egg in the distal portion of the fallopian tube. In addition to ovulatory dysfunction, these disorders include tubal occlusion, tubal-peritoneal adhesions, endometriosis, and other disease processes of the female peritoneal cavity. In addition, IVF-ET is indicated in some cases of male-factor infertility (abnormalities in male reproductive function) or unexplained infertility.

Ovarian Stimulation

Because the success rates are <100% for each of the stages of IVF-ET, the physician needs several oocytes, all obtained in a single ovarian cycle. However, woman normally develops a single dominant follicle each cycle (see p. 1123). Thus, to obtain the *multiple* oocytes for IVF-ET, the physician must stimulate the development of multiple follicles in the woman by controlled ovarian hyperstimulation. Although this procedure qualitatively mimics the hormonal control of the normal cycle, the high dose of gonadotropins triggers the development of *many* follicles. The physician administers some combination of FSH and LH, or pure FSH, either intramuscularly or subcutaneously. Because exogenous gonadotropins stimulate the ovaries directly, GnRH analogs (see Box 55-2) are often used to downregulate the hypothalamic-pituitary axis during controlled ovarian stimulation. One usually administers these GnRH analogs before initiating gonadotropin therapy, primarily to prevent a premature LH surge and ovulation.

Cycle Monitoring

After administering the gonadotropins, the physician monitors the stimulated follicular growth in the ovaries with sonographic imaging. Size, number, and serial growth of ovarian follicles may be assessed daily or at other appropriate intervals. Serum estradiol levels provide an additional measure of follicular growth and function. When estradiol levels and follicular growth indicate—by established criteria—appropriate folliculogenesis, the physician simulates a natural LH surge by injecting hCG, which mimics the actions of LH (see p. 1111). However, in this case, the simulated LH surge completes the final

maturation of *multiple* follicles and oocytes. Because ovulation usually occurs 36 to 39 hours following the beginning of the LH surge (see p. 1123), the physician plans oocyte retrieval in such a way that maximal follicular maturation can occur but the oocytes are still harvested *prior to* ovulation. Thus, retrievals are scheduled for 34 to 36 hours following the administration of hCG.

Oocyte Retrieval

The physician retrieves oocytes by aspirating them from individual follicles under sonographic guidance. With the patient under conscious or unconscious sedation, and after a local anesthetic is applied to the posterior vaginal wall, the physician inserts a probe equipped with a needle guide into the vagina. After inserting a 16- to 18-gauge needle through the vaginal wall, the physician aspirates the follicular fluid from each mature follicle and collects it in a test tube containing a small amount of culture medium. The eggs are identified in the follicular fluid, are separated from the fluid and other follicular cells, and are then washed and prepared for insemination. This procedure normally yields 8 to 15 oocytes.

Insemination

The sperm sample is subjected to numerous washes, followed by gradient centrifugation to separate the sperm cells from the other cells and from debris found in the ejaculate. Each egg is inseminated with 50,000 to 300,000 motile sperm cells in a drop of culture medium and is incubated overnight. Fertilization can usually be detected by the presence of two pronuclei in the egg cytoplasm after 16 to 20 hours. Fertilization rates generally range from 60% to 85%. Embryo development is allowed to continue in vitro for another 48 to 120 hours until embryos are transferred to the uterus.

Among couples whose male partner has very low numbers of motile sperm, high fertilization rates can be achieved using **intracytoplasmic sperm injection (ICSI)**. Micromanipulation techniques are used to inject a sperm cell into the cytoplasm of each egg in vitro. Fertilization rates after ICSI are generally 60% to 70%, or approximately equivalent to conventional insemination in vitro.

Embryo Transfer

After culturing the cells for 48 to 120 hours, the physician transfers three or four embryos to the uterus at the four- to eight-cell stage (after 2 days) or fewer embryos at the blastocyst stage (after 5 days). Embryos are selected and are loaded into a thin, flexible catheter, which is inserted into the uterine cavity to the desired depth under ultrasonic guidance. The woman usually receives supplemental progesterone to support implantation and pregnancy. In certain cases, the embryos are transferred to the fallopian tube during laparoscopy. This procedure is referred to as **tubal embryo transfer (TET)**. The rationale for this procedure is that the fallopian tube contributes to the early development of the embryo as it travels down the tube to the uterus.

Success Rates

Implantation rates usually range from 8% to 15% per embryo transferred. In the United States, the mean live birth rate per ET procedure is ~33%. Success rates in IVF-ET depend on numerous factors, including age as well as the type and severity of the disease causing infertility.

Fertilization begins as the sperm cell attaches to the zona pellucida and undergoes the acrosomal reaction, and it ends with the fusion of the male and female pronuclei

After ovulation, the egg in the fallopian tube is in a semidormant state. If it remains unfertilized, the ripe egg will remain quiescent for some time and eventually degenerate. When fertilization occurs, the sperm normally comes into contact with the oocyte in the ampullary portion of the tube, usually several hours after ovulation. Fertilization causes the egg to awaken (**activation**) and initiates a series of morphological and biochemical events that lead to cell division and differentiation. **Fertilization** occurs in eight steps:

Step 1: The sperm head weaves its way past the follicular cells and attaches to the zona pellucida that surrounds the oocyte (Fig. 56-1). The zona pellucida is composed of three glycoproteins; ZP1 cross-links the filamentous ZP2 and ZP3 into a latticework. Receptors on the plasma membrane of the sperm cell bind to ZP3, thereby initiating a signal-transduction cascade.

FIGURE 56-1 Fertilization. The illustration summarizes the eight steps of fertilization.

Step 2: As a result of the sperm-ZP3 interaction, the sperm cell undergoes the acrosomal reaction, a prelude to the migration of the sperm cell through the mucus-like zona pellucida. The acrosome (see p. 1103) is a unique sperm organelle containing hydrolyzing enzymes that are necessary for the sperm to penetrate the zona pellucida. During the acrosomal reaction, an increase in intracellular free Ca^{2+} concentration ($[\text{Ca}^{2+}]_i$) triggers fusion of the outer acrosomal membrane with the sperm cell's plasma membrane, resulting in the exocytosis of most of the acrosomal contents.

Step 3: The spermatozoon penetrates through the zona pellucida. One mechanism of this penetration is the action of the acrosomal enzymes.  **N56-2** Protease inhibitors can block the penetration of spermatozoa through the zona pellucida. The sperm cell also penetrates the zona pellucida by mechanical action. The sperm head rapidly oscillates about a fulcrum that is situated in the neck region. This rapid, vigorous, rocking action occurs at a frequency of ~6 to 8 per second. The sperm penetrates the zona pellucida at an angle, which creates a tangential cleavage slit and leaves the sperm head lying sideways against the oocyte membrane.

N56-2

Acrosomal Enzymes

Contributed by Ervin Jones

Among the many enzymes in the acrosome are acid hydrolases, the best characterized of which is proacrosin, the precursor to acrosin. **Acrosin** is a member of the serine protease superfamily; it is expressed only in spermatogenic cells. Two other enzymes released from the acrosome are **neuraminidase** and a special form of hyaluronidase. This particular **hyaluronidase** can be distinguished from the common lysosomal form of the enzyme, and it appears to be a spermatogenic cell-specific isozyme. Acrosin, hyaluronidase, and neuraminidase help the sperm penetrate the zona pellucida by hydrolyzing the sugar chains and the peptide chains of the glycoproteins of the zona pellucida.

Step 4: The cell membranes of the sperm and the oocyte fuse. Microvilli on the oocyte surface envelop the sperm cell, which probably binds to the oocyte membrane via specific proteins on the surfaces of the two cells. The posterior membrane of the acrosome—which remains part of the sperm cell after the acrosomal reaction—is the first portion of the sperm to fuse with the plasma membrane of the egg. The sperm cell per se does not enter the oocyte. Rather, the cytoplasmic portions of the head and tail enter the oocyte, leaving the sperm-cell plasma membrane behind, an action similar to a snake's crawling out of its skin.

Step 5: The oocyte undergoes the cortical reaction. As the spermatozoon penetrates the oocyte's plasma membrane, it initiates formation of inositol 1,4,5-trisphosphate (IP_3); IP_3 causes Ca^{2+} release from internal stores (see p. 60), which leads to an increase in $[\text{Ca}^{2+}]_i$ and $[\text{Ca}^{2+}]_i$ waves. This rise in $[\text{Ca}^{2+}]_i$, in turn, triggers the oocyte's second meiotic division—discussed below (see step 6)—and the cortical reaction. In the **cortical reaction**, small electron-dense granules that lie just beneath the plasma membrane fuse with the oocyte's plasma membrane. Exocytosis of these granules releases enzymes that act on glycoproteins in the zona pellucida, causing the zona pellucida to harden. This hardening involves the release of polysaccharides that impede the progression of the runners-up (i.e., sperm cells still in the zona pellucida). The cortical reaction also leads to the destruction of ZP receptors, which

prevents further binding of sperm cells to the zona pellucida. From a teleological perspective, the cortical granule reaction prevents **polyspermy**. 🟡N56-3 Polyspermic embryos are abnormal because they are polyploid. They do not develop beyond the early cleavage stages.

N56-3

Block to Polyspermy

Contributed by Ervin Jones

Unlike the situation in some laboratory animals, in humans the block to polyspermy during fertilization does not involve receptors on the zona pellucida or on the cell membrane. It appears that the block to polyspermy in humans is due only to alterations of the inner aspect of the zona pellucida. In experiments on monospermic oocytes fertilized in vitro, other sperm cells added later can partially penetrate the zona pellucida but do not reach the inner half of the zona. When unfertilized oocytes, monospermic oocytes, and polyspermic oocytes are examined in vitro, similar numbers of sperm are found on and within the zona pellucida of each type of oocyte. Further evidence that the zona pellucida is the primary barrier to polyspermy in humans comes from experiments in which the zona pellucida is removed. In this case, the egg is usually penetrated by many sperm. In the in vitro fertilization of normal human oocytes, the rate of polyspermy is quite low, ~5% to 8%, even though 50,000 to 300,000 sperm are available to the oocyte. Thus, the zona pellucida block to polyspermy in humans is highly efficient.

Step 6: The oocyte completes its second meiotic division. The oocyte, which had been arrested in the prophase of its first meiotic division since fetal life (see p. 1073), completed its first meiotic division at the time of the surge of luteinizing hormone (LH), which occurred several hours before ovulation (see p. 1116). The result was the first polar body and a secondary oocyte with a haploid number of duplicated chromosomes (see Fig. 53-2C). Before fertilization, this secondary oocyte had begun a second meiotic division, which was arrested in metaphase. The rise in $[Ca^{2+}]_i$ inside the oocyte—which the sperm cell triggers, as noted in step 5—causes not only the cortical reaction, but also the completion of the oocyte's second meiotic division. One result is the formation of the **second polar body**, which contains a haploid number of unduplicated maternal chromosomes. 🟡N56-4 The oocyte extrudes the chromosomes of the second polar body, together with a small amount of ooplasm, into a space immediately below the zona pellucida; the second polar body usually lies close to the first polar body. The nucleus of the oocyte also contains a haploid number of unduplicated chromosomes. As its chromosomes decondense, the nucleus of this mature ovum becomes the **female pronucleus**.

N56-4

Three Polar Bodies

Contributed by Sam Mesiano

Interestingly, although the small polar bodies are nonfunctional, they contain a full set of chromosomes and are responsive to cell cycle–regulatory mechanisms. Consequently, the first polar body also divides during the second meiotic division to produce a total of three polar bodies and a mature oocyte, each of which contain a haploid number of chromosomes. Thus, as with spermatogenesis, one diploid oogonia produces four haploid daughters; however, in oogenesis only one daughter becomes an functional gamete.

Step 7: The sperm nucleus decondenses and transforms into the **male pronucleus**, which, like the female pronucleus, contains a haploid number of unduplicated chromosomes (see [Fig. 54-7](#)). The cytoplasmic portion of the sperm's tail degenerates.

Step 8: The male and female pronuclei fuse, forming a new cell, the **zygote**. The mingling of chromosomes (syngamy) can be considered as the end of fertilization and the beginning of embryonic development. Thus, fertilization results in a conceptus that bears 46 chromosomes, 23 from the maternal gamete and 23 from the paternal gamete. Fertilization of the ovum by a sperm bearing an X chromosome produces a zygote with XX sex chromosomes; this develops into a female (see pp. [1073–1075](#)). Fertilization with a Y-bearing sperm produces an XY zygote, which develops into a male. Therefore, chromosomal sex is established at fertilization.

Implantation of the Developing Embryo

As discussed on page 1129, the ovum is fertilized in the ampullary portion of the fallopian tube several hours after ovulation (Fig. 56-2), and the conceptus remains in the fallopian tube for ~72 hours, during which time it develops to the **morula** stage (i.e., a mulberry-shaped solid mass of 12 or more cells), receiving nourishment from fallopian-tube secretions. During these 3 days, smooth-muscle contractions of the isthmus prevent advancement of the conceptus into the uterus while the endometrium is preparing for implantation. The mechanisms by which the ovum is later propelled through the isthmus of the fallopian tube to the uterus probably include beating of the cilia of the tubal epithelium and contraction of the fallopian tube.

FIGURE 56-2 Transport of the conceptus to the uterus.

After the morula rapidly moves through the isthmus to the uterine cavity, it floats freely in the lumen of the uterus and transforms into a blastocyst (see Fig. 56-2). A **blastocyst** is a ball-like structure with a fluid-filled inner cavity. Surrounding this cavity is a thin layer of **trophoectoderm** cells that forms the trophoblast, which develops into a variety of supporting structures, including the amnion, the yolk sac, and the fetal portion of the placenta. On one side of the cavity, attached to the trophoblast, is an **inner cell mass**, which develops into the embryo proper. The conceptus floats freely in the uterine cavity for ~72 hours before it attaches to the endometrium. Thus, implantation of the human blastocyst normally occurs 6

to 7 days following ovulation. Numerous maturational events occur in the conceptus as it travels to the uterus. The embryo must be prepared to draw nutrients from the endometrium on arrival in the uterine cavity, and the endometrium must be prepared to sustain the implantation of the blastocyst. Because of the specific window in time during which implantation can occur, temporal relationships between embryonic and endometrial maturation assume extreme importance.

The presence of an embryo leads to decidualization of the endometrium

During the middle to late secretory phase of the normal endometrial cycle, the endometrium becomes more vascularized and thicker, and the endometrial glands become tortuous and engorged with secretions (see pp. 1125–1126). These changes, driven by progesterone from the corpus luteum, peak at ~7 days after ovulation. Additionally, beginning 9 to 10 days after ovulation, a process known as **predecidualization** (see pp. 1125–1126) begins near the spiral arteries. During predecidualization, stromal cells transform into rounded decidual cells, and these cells spread across the superficial layer of the endometrium to make it more compact (zona compacta) and separating it from the deeper, more spongy layer (zona spongiosa; see Fig. 55-11). If conception fails to occur, the secretory activity of the endometrial glands decreases, followed by regression of the glands 8 to 9 days after ovulation, which is ultimately followed by menstruation.

When pregnancy occurs, the predecidual changes in the endometrium are sustained and extended, which completes the process of **decidualization**. The **decidua** is the specialized endometrium of pregnancy. Its original name was *membrana decidua*, a term referring to the membranes of the endometrium that are shed following pregnancy, like the leaves of a deciduous tree. Because the degree of decidualization is considerably greater in conception cycles than in nonconception cycles, it is likely that the blastocyst itself promotes decidualization. Indeed, either the presence of the embryo or a traumatic stimulus that mimics the embryo's invasion of the endometrium induces changes in the endometrium. 🍌N56-5

N56-5

Onset of Decidualization

Contributed by Ervin Jones

One of the earliest signs that the blastocyst has transmitted an embryonic signal to the endometrium is a marked increase in the permeability of endometrial capillaries. One can detect this permeability increase by injecting laboratory rats intravenously with a dye, such as Evans blue, which binds to albumin. Accumulation of blue dye in the area of the blastocyst is an index of increased capillary permeability to albumin. Increased endometrial capillary permeability precedes the decidual response and may be triggered by vasoactive substances released by the blastocyst just prior to implantation. Because inhibitors of histidine decarboxylase (which converts histidine to histamine) interrupt implantation, histamine is one candidate for the vasoactive substance.

The area underneath the implanting embryo becomes the **decidua basalis** (Fig. 56-3). Other portions of the decidua that become prominent later in pregnancy are the **decidua capsularis**, which overlies the embryo, and the **decidua parietalis**, which covers the remainder of the uterine surface. The upper zona compacta layer and the middle zona spongiosa layer of the nonpregnant endometrium are still

recognizable in the decidualized endometrium of pregnancy. The glandular epithelium within the zona spongiosa continues its secretory activity during the first trimester. Some of the glands take on a hypersecretory appearance in what has been referred to as the *Arias-Stella* phenomenon of early pregnancy—named after the pathologist Javier Arias-Stella. Although the decidualized endometrium is most prominent during the first trimester, prior to the establishment of the definitive placenta, elements of decidualization persist throughout gestation.

FIGURE 56-3 Three decidual zones during early embryonic development (about 13 to 14 days postfertilization). The figure shows a sagittal section through a pregnant uterus, with the anterior side to the right.

Uterine secretions nourish the preimplantation embryo, promote growth, and prepare it for implantation

Before the embryo implants in the endometrium and establishes an indirect lifeline between the mother's blood and its own, it must receive its nourishment from uterine secretions. Following conception, the endometrium is primarily controlled by progesterone, which initially comes from the corpus luteum (see p. 1124). The uterine glandular epithelium synthesizes and secretes several steroid-dependent proteins

([Table 56-1](#)) that are thought to be important for the nourishment, growth, and implantation of the embryo. The endometrium secretes cholesterol, steroids, and various nutrients, including iron and fat-soluble vitamins. It also synthesizes matrix substances, adhesion molecules, and surface receptors for matrix proteins, all of which may be important for implantation.

TABLE 56-1
Endometrial Proteins, Glycoproteins, and Peptides Secreted by the Endometrial Glands during Pregnancy

- Mucins
- Prolactin
- Insulin-like growth factor-binding protein 1 (IGFBP-1)

Pinopodes appear as small, finger-like protrusions on endometrial cells between day 19 (about the time the embryo would arrive in the uterus) and day 21 (about the time of implantation) of the menstrual cycle; they persist for only 2 to 3 days. Pinopode formation appears to be progesterone dependent and is inhibited by estrogens. Pinopodes endocytose macromolecules and uterine fluid and absorb most of the fluid in the lumen of the uterus during the early stages of embryo implantation. By removing uterine luminal fluid, the pinopodes may allow the embryo and the uterine epithelium to approximate one another more closely. Because apposition and adhesion of the embryo to the uterus are the first events of implantation, the presence and action of pinopodes may determine the extent of the implantation window.

The blastocyst secretes substances that facilitate implantation

If the blastocyst is to survive, it must avoid rejection by the maternal cellular immune system. It does so by releasing immunosuppressive agents ([Table 56-2](#)). The embryo also synthesizes and secretes macromolecules that promote implantation, the development of the placenta, and the maintenance of pregnancy.

TABLE 56-2
Substances Secreted by the Blastocyst

Immunoregulatory Agents
Platelet-activating factor (PAF)
Immunosuppressive factor
PGE ₂
Interleukins 1α, 6, and 8
Interferon-α
Leukemia inhibitory factor
Colony-stimulating factor
HLA-6
Fas ligand
Metalloproteases (facilitate invasion of the trophoblast into the endometrium)
Collagenases: digest collagen types I, II, III, VII, and X
Gelatinases: two forms, digest collagen type IV and gelatin
Stromelysins: digest fibronectin, laminin, and collagen types IV, V, and VII
Serine Proteases (facilitate invasion of trophoblast into the endometrium)
Other Factors or Actions
hCG: autocrine growth factor
Ovum factor
Early pregnancy factor (EPF)
Embryo-derived histamine-releasing factor
Plasminogen activator and its inhibitors
Insulin-like growth factor 2 (IGF-2): promotes trophoblast invasiveness
Estradiol
β ₁ integrin
Fibroblast growth factor (FGF)
Transforming growth factor-α (TGF-α)
Inhibins

Both short-range and long-range embryonic signals may be necessary for implantation, although the nature of some of these signals remains enigmatic. One short-range signal from the blastocyst may stimulate local changes in the endometrium at the time of its apposition to the endometrium. A long-range signal that is secreted by the early blastocyst is **human chorionic gonadotropin (hCG)**, which is closely related to LH (see p. 1111) and sustains the corpus luteum in the face of rapidly falling levels of maternal LH.

hCG is one of the most important of the factors secreted by the trophoblast of the blastocyst, both before and after implantation. Besides rescuing the corpus luteum, hCG acts as an autocrine growth factor and promotes trophoblast growth and placental development. hCG levels are high in the area where the trophoblast faces the endometrium. hCG may have a role in the adhesion of the trophoblast to the endometrium and also has protease activity.

During implantation, the blastocyst apposes itself to the endometrium, adheres to epithelial cells, and finally invades the stroma

As noted on pages 1132–1133, the conceptus lies unattached in the uterine cavity for ~72 hours. About halfway through this period (i.e., 5 to 6 days after ovulation), the morula transforms into the blastocyst (Fig. 56-4A). Before the initiation of implantation, the zona pellucida that surrounds the blastocyst degenerates. This process, known as **hatching** of the embryo, occurs 6 to 7 days after ovulation. Lytic factors in the endometrial cavity appear to be essential for the dissolution of the zona pellucida. The blastocyst probably also participates in the process of zona lysis and hatching; when an *unfertilized* egg is placed in the uterus under the same conditions, its zona pellucida remains intact. A factor produced by the blastocyst may activate a lytic factor that is derived from a uterine precursor. Plasmin, produced from plasminogen, is a plausible candidate for this uterine factor, because plasmin exhibits a lytic effect on the

zona pellucida in vitro, and inhibitors of plasmin block in vitro hatching of rat blastocysts. Implantation occurs in three stages: (1) apposition, (2) adhesion, and (3) invasion.

A HATCHING

B APPPOSITION

C ADHESION

D INVASION

FIGURE 56-4 Embryo hatching, apposition, adhesion, and invasion.

Apposition

The earliest contact between the blastocyst wall, the trophoectoderm, and the endometrial epithelium is a loose connection called *apposition* (see Fig. 56-4B). Apposition usually occurs in a crypt in the endometrium. From the standpoint of the blastocyst, it appears that apposition occurs at a site where the zona pellucida is ruptured or lysed and where it is possible for the cell membranes of the trophoblast to make direct contact with the cell membranes of the endometrium. **N56-6** Although the preimplantation blastocyst is asymmetric, it seems that the entire trophoectoderm has the potential to interact with the endometrium, and the final correct orientation—with the inner cell mass pointing toward the endometrium

—occurs by free rotation of the inner cell mass within the sphere of overlying trophoectoderm cells.

N56-6

Mechanisms of Apposition

Contributed by Ervin Jones

A mutual reduction in the electrostatic repulsion between the blastocyst and the endometrial membranes occurs at the time of implantation. The loss of zona pellucida proteins during zona lysis and hatching, as well as changes in glycoproteins and their terminal sugars, may decrease the electrostatic repulsive forces between the conceptus and the endometrium. Inhibitors of protein glycosylation may diminish blastocyst attachment. Further evidence that changes in the zona pellucida are necessary to complete apposition is the fact that neither an unfertilized egg nor the preblastocyst-stage conceptus, each of which is still surrounded by a zona pellucida, shows evidence of adhesion. Changes in the integrity of the cytotalkyx lining the surface of the uterine epithelium are also important for apposition.

Adhesion

The trophoblast appears to attach to the uterine epithelium via the microvilli of the trophoblast; ligand-receptor interactions are probably involved in adhesion (see [Fig. 56-4C](#)). The receptors for these ligand-receptor interactions are often members of the **integrin family** (see p. 17) and can be either on the blastocyst or on the endometrium. Integrins are bifunctional integral membrane proteins; on their intracellular side, they interact with the cytoskeleton, whereas on their extracellular side, they have receptors for **matrix proteins** such as collagen, laminin, fibronectin, and vitronectin. Therefore, ligand-receptor interactions have two possible orientations. For the first, the extracellular surface of the *trophoblast* has integrins for binding fibronectins, laminin, and collagen type IV. Thus, during implantation, the trophoblast binds to the laminin that is distributed around the stromal (decidual) cells of the endometrium. Fibronectin, a component of the basement membrane, probably guides the implanting embryo (see below) and is subsequently broken down by the trophoblast.

For the second orientation of matrix-integrin interactions, the extracellular surface of the *glandular epithelium* also expresses integrins on days 20 to 24 of the menstrual cycle, the implantation window (see p. 1126). The expression of receptors for fibronectin and vitronectin (i.e., integrins) may serve as markers of the endometrial capacity for implantation. Small peptides containing sequences that are homologous to specific sequences of fibronectin block blastocyst attachment and outgrowth on fibronectin.

In addition to the integrin-matrix interactions, another important class of ligand-receptor interactions appears to be between heparin proteoglycans or heparan sulfate proteoglycans (see p. 39), which are attached to the surface of the blastocyst, and surface receptors on the uterine epithelial cell. These endometrial proteoglycan receptors increase in number as the time of implantation approaches.

Any of the foregoing ligand-receptor interactions can lead to cytoskeletal changes. Thus, adhesion of the trophoblast via ligand-receptor interactions may dislodge the uterine epithelial cells from their basal lamina and thereby facilitate access of the trophoblast to the basal lamina for penetration.

Invasion

As the blastocyst attaches to the endometrial epithelium, the trophoblastic cells rapidly proliferate, and the trophoblast differentiates into two layers: an inner **cytotrophoblast** and an outer syncytiotrophoblast

(see Fig. 56-4D). The **syncytiotrophoblast** arises from the fusion of cytotrophoblast cells to form a giant multinucleated cell that constitutes the principal component of the maternal-fetal interface. During implantation, long protrusions from the syncytiotrophoblast extend among the uterine epithelial cells. The protrusions dissociate these endometrial cells by secreting tumor necrosis factor- α (TNF- α), which interferes with the expression of cadherins (cell-adhesion molecules; see p. 17) and β catenin (an intracellular protein that helps anchor cadherins to the cytoskeleton).  **N56-7** The syncytiotrophoblast protrusions then penetrate the basement membrane of the uterine epithelial cells and ultimately reach the uterine stroma.

N56-7

Uterine E-Cadherin and β -Catenin at the Implantation Site

Contributed by Emile Boulpaep, and Walter Boron

The blastocyst can only implant into a receptive endometrium. Conversely, the endometrium can become receptive only when it receives the appropriate signals from the nearby blastocyst, which result in the upregulation of certain genes such as those encoding E-cadherin and β -catenin.

In the endometrial epithelial cells of the peri-implantation uterus, **E-cadherin** (see pp. 17 and 44–45)—a transmembrane protein that mediates cell-cell contacts—is expressed at high levels at the apical membrane at the prospective sites of implantation, and much less elsewhere. In addition, **β -catenin** (see pp. 44–45 and 50)—a cytoskeletal anchor protein that attaches to the cytosolic domain of the cadherin—is also expressed at the apical membrane of these same cells. These changes are part of the adhesive phenotype of the endometrium during the implantation window.

The trophoblast secretes several autocrine factors, which appear to stimulate invasion of the endometrial epithelium, as well as proteases (see Table 56-2). By degrading the extracellular matrix, metalloproteases and serine proteases may control both the proliferation and the invasion of the trophoblast into the endometrium.

Around the site of penetration of the syncytiotrophoblast, uterine stromal cells take on a polyhedral shape and become laden with lipids and glycogen. These are the **decidual cells** discussed above. The degeneration of decidual cells near the invading syncytiotrophoblast thus provides nutrients to the developing embryo. The blastocyst superficially implants in the zona compacta of the endometrium and eventually becomes completely embedded in the decidua. As the finger-like projections of the syncytiotrophoblast invade the endometrium, they reach the maternal blood supply and represent a primordial form of the chorionic villus of the mature placenta, as discussed in the next subchapter.

The blastocyst is genetically distinct from maternal tissue. Thus, implantation represents a breach of maternal immune defenses that could lead to immune attack and destruction of the embryo. The problem is

confounded by the presence—within the decidual compartment—of uterus-specific large granular lymphocytes also known as decidual natural killer (NK) cells. To avoid attack, cytotrophoblasts that lie at the maternal-fetal interface produce a unique immunogenic molecule, HLA-G, on their cell surface. HLA-G may prevent immunological recognition by activated NK cells. In addition, trophoblast cells express the Fas ligand (see pp. [1241–1242](#)), which induces apoptosis in immune cells that carry the Fas receptor. Thus, the embryo may escape attack by the maternal immune system by camouflaging itself with HLA-G and by inducing apoptosis in maternal lymphocytes that may mount an attack.

Physiology of the Placenta

Eventually, almost all the materials that are necessary for fetal growth and development move from the maternal circulation to the fetal circulation across the placenta, either by passive diffusion or by active transport. Except for CO₂, waste products are largely excreted via the amniotic fluid.

At the placenta, the space between the fetus's chorionic villi and the mother's endometrial wall contains a continuously renewed pool of extravasated maternal blood

Within the syncytium of the invading syncytiotrophoblast, fluid-filled holes called **lacunae** develop 8 to 9 days after fertilization ([Fig. 56-5A](#)). Twelve to 15 days after fertilization, the finger-like projections of the syncytiotrophoblast finally penetrate the endothelial layer of small veins of the endometrium. Later, these projections also penetrate the small spiral arteries. The result is a free communication between the lacunae of the syncytiotrophoblast and the lumina of maternal blood vessels (see [Fig. 56-5B](#)). Within 12 to 15 days after fertilization, some cytotrophoblasts proliferate and invade the syncytiotrophoblast to form finger-like projections that are the **primary chorionic villi**.

A 8 DAYS AFTER FERTILIZATION

B 12-15 DAYS

C 20 DAYS

FIGURE 56-5 Development of the placenta. **A**, Shortly after the blastocyst has implanted (6 to 7 days after fertilization), the syncytiotrophoblast invades the stroma of the uterus (i.e., the decidua). Within the syncytiotrophoblast are lacunae. **B**, The invading syncytiotrophoblast breaks through into endometrial veins first, and then later into the arteries, creating direct communication between lacunae and maternal vessels. In addition, the proliferation of cytotrophoblasts creates small mounds known as *primary chorionic villi*. **C**, The primary chorionic villus continues to grow with the proliferation of cytotrophoblastic cells. In addition, mesenchyme from the extraembryonic coelom invades the villus, forming the secondary chorionic villus. Eventually, these mesenchymal cells form fetal capillaries; at this time, the villus is known as a tertiary chorionic villus. The lacunae also enlarge by merging with one another.

With further development, mesenchymal cells from the extraembryonic mesoderm invade the primary chorionic villi, which now are known as **secondary chorionic villi**. Eventually, these mesenchymal cells form fetal blood vessels de novo, at which point the villi are known as **tertiary chorionic villi** (see Fig. 56-5C). Continued differentiation and amplification of the surface area of the fetal tissue that is protruding into the maternal blood creates mature chorionic villi. The outer surface of each villus is lined with a very thin layer of syncytiotrophoblast, which has prominent microvilli (brush border) that face the maternal blood. Beneath the syncytiotrophoblast lie cytotrophoblasts, mesenchyme, and fetal blood vessels. The lacunae, filled with maternal blood, eventually merge with one another to create one massive, intercommunicating **intervillous space** (Fig. 56-6). The fetal villi protruding into this space resemble a thick forest of trees arising from the chorionic plate, which is the analog of the soil from which the trees sprout. Thus, in the mature placenta, fetal blood is separated from maternal blood only by the fetal capillary endothelium, some mesenchyme and cytotrophoblasts, and syncytiotrophoblast.

FIGURE 56-6 Mature placenta. With further development beyond that shown in Figure 56-5C, the outer surface of the mature chorionic villus is covered with a thin layer of syncytiotrophoblast. Under this are cytotrophoblasts, mesenchyme, and fetal blood vessels. The lacunae into which the villi project gradually merge into one massive intervillous space. Maternal blood is trapped in this intervillous space, between the endometrium on the maternal side and the villi on the fetal side. In the mature placenta (shown here), spiral arteries from the mother empty directly into the intervillous space, which is drained by maternal veins. The villi look like a thick forest of trees arising from the chorionic plate, which is the analog of the soil from which the trees sprout.

Maternal Blood Flow

The maternal arterial blood is discharged from ~120 spiral arteries; these arteries may have multiple openings, not all of which need be open at the same time. Blood enters in pulsatile spurts through the wall of the uterus and moves in discrete streams into the intervillous space toward the chorionic plate (see Fig. 56-6). Small lakes of blood near the chorionic plate dissipate the force of the arterial spurts and reduce blood velocity. The maternal blood spreads laterally and then reverses direction and cascades over the closely packed villi. Blood flow slows even more, which allows adequate time for exchange. After bathing the chorionic villi, the maternal blood drains through venous orifices in the basal plate, enters the larger maternal placental veins, and ultimately flows into the uterine and other pelvic veins. No capillaries are present between the maternal arterioles and venules; the intervillous space is the functional capillary. Because the intervillous spaces are very narrow, and the arterial and venous orifices are randomly scattered over the entire base of the placenta, the maternal blood moves efficiently among the chorionic villi and avoids arteriovenous shunts.

The spiral arteries are generally perpendicular, and the veins are generally parallel to the uterine wall. Thus, because of both the geometry of the maternal blood vessels and the difference between maternal arterial and venous pressure, the uterine contractions that occur periodically during pregnancy, as well as during delivery, attenuate arterial inflow and completely interrupt venous drainage. Therefore, the volume of blood in the intervillous space actually increases, providing continual, albeit reduced, exchange. The principal factors that regulate the flow of maternal blood in the intervillous space are maternal arterial blood pressure, intrauterine pressure, and the pattern of uterine contraction.

Fetal Blood Flow

The fetal blood originates from two **umbilical arteries**. Unlike *systemic* arteries after birth, umbilical arteries carry *deoxygenated* blood. As these umbilical arteries approach the placenta, they branch repeatedly beneath the amnion, penetrate the chorionic plate, and then branch again within the chorionic villi, forming a capillary network. Blood that has obtained a significantly higher O_2 and nutrient content returns to the fetus from the placenta through the single **umbilical vein**.

The **amniotic fluid** that fills the amniotic cavity serves two important functions. First, it serves as a mechanical buffer and thus protects the fetus from external physical insults. Second, it serves as a mechanism by which the fetus excretes many waste products. The water in the amniotic fluid turns over at least once a day. After the fetal kidneys mature (10 to 12 weeks), the fetus's renal excretions provide ~75% of amniotic-fluid production, with pulmonary secretions providing the rest. Fluid removal occurs through the actions of the fetal gastrointestinal tract (~55%), amnion (~30%), and lungs (~15%).

Gases and other solutes move across the placenta

The placenta is the major lifeline between the mother and the fetus. It provides nutrients and O_2 to the fetus, and it removes CO_2 and certain waste products from the fetus.

O_2 and CO_2 Transport

The maternal blood coming into the intervillous space has a gas composition similar to that of systemic arterial blood: a partial pressure of oxygen (P_{O_2}) of ~100 mm Hg (Table 56-3), a P_{CO_2} of ~40 mm Hg, and a pH of 7.40. However, the diffusion of O_2 from the maternal blood into the chorionic villi of the fetus causes the P_{O_2} of blood in the intervillous space to fall, so the average P_{O_2} is 30 to 35 mm Hg. Given the

O₂ dissociation curve of maternal (i.e., adult) hemoglobin (Hb), this P_{O₂} translates to an O₂ saturation of ~65% (see Fig. 29-3). The P_{O₂} of blood in the umbilical vein is even lower. Despite the relatively low P_{O₂} of the maternal blood in the intervillous space, the fetus does not suffer from a lack of O₂. Because fetal Hb has a much higher affinity for O₂ than does maternal Hb (see Box 29-1), the fetal Hb can extract O₂ from the maternal Hb. Thus, a P_{O₂} of 30 to 35 mm Hg, which yields an Hb saturation of ~65% in the intervillous space in the mother's blood, produces an Hb saturation of ~85% in the umbilical vein of the fetus (see Table 56-3), assuming that the O₂ fully equilibrates between intervillous and fetal blood. Other mechanisms of ensuring adequate fetal oxygenation include the relatively high cardiac output per unit body weight of the fetus and the increasing O₂-carrying capacity of fetal blood late in pregnancy as the Hb concentration rises to a level 50% higher than that of the adult.

TABLE 56-3
Maternal and Fetal Oxygen Levels

SITE	P _{O₂}	Hb SATURATION (%)
Maternal Values		
Uterine artery	100	97.5
Intervillous space	30–35	57–67
Uterine vein	30	57
Fetal Values		
Umbilical arteries	23	60.5
Umbilical vein	30	85.5

The transfer of CO₂ from the fetus to the mother is driven by a concentration gradient between the blood in the umbilical arteries and that in the intervillous space. Near the end of pregnancy, the P_{CO₂} in the umbilical arteries is ~48 mm Hg, and the P_{CO₂} in the intervillous space is ~43 mm Hg, a gradient of ~5 mm Hg. The fetal blood also has a somewhat lower affinity for CO₂ than does maternal blood, which favors the transfer of CO₂ from the fetus to mother.

Other Solutes

Solutes besides O₂ and CO₂ move across the placenta between the mother and the fetus, availing themselves of numerous transport mechanisms. Some of these solutes, such as the waste products urea and creatinine, probably move passively from fetus to mother. The lipid-soluble steroid hormones shuttle among the mother, the placenta, and the fetus, perhaps by simple diffusion. Glucose moves from the mother to the fetus by facilitated diffusion (see p. 114), and amino acids move by secondary active transport (see p. 115). The placenta also transports several other essential substances, such as vitamins and minerals, that are needed for fetal growth and development. Many substances are present in the fetal circulation at concentrations higher than in the maternal blood, and they must be actively transported against concentration or electrochemical gradients. The necessary energy (i.e., ATP) is derived from glycolysis and the citric acid cycle, for which the enzymes are present in the human placenta at term. Also present are the enzymes for the pentose phosphate pathway, an alternative pathway for the oxidation of glucose, which provides the reduced nicotinamide adenine dinucleotide phosphate (NADPH) necessary for several synthetic pathways that require reducing equivalents in the human placenta at term. N58-5

The placenta takes up large molecules from the mother through receptor-mediated endocytosis (see p. 42). The uptake of substances such as low-density lipoproteins (LDLs), transferrin, hormones (e.g.,

insulin), and antibodies (e.g., immunoglobulin G) increases throughout gestation until just before birth.

The placenta makes a variety of peptide hormones, including hCG and human chorionic somatomammotropin

The placenta plays a key role in steroid synthesis, as discussed in the next subchapter. In addition, the placenta manufactures numerous amines, polypeptides (including peptide hormones and neuropeptides), proteins, glycoproteins, and steroids (Table 56-4). Among these peptides are the placental variants of all known hypothalamic releasing hormones (see Table 47-2). These placental releasing hormones may act in a paracrine fashion, controlling the release of local placental hormones, or they may enter the maternal or fetal circulations. In addition, several proteases are also present in the placenta. Although the placenta synthesizes a wide variety of substances, the significance of many of these substances is not clear.

TABLE 56-4
Hormones Made by the Placenta

Peptide Hormones and Neuropeptides
Human chorionic gonadotropin (hCG) Thyrotropin (thyroid-stimulating hormone [TSH]) Placental-variant growth hormone (pvGH) Human chorionic somatomammotropins 1 and 2 (hCS1 and hCS2), also known as human placental lactogens 1 and 2 (hPL1 and hPL2) Placental proteins PP12 and PP14 Thyrotropin-releasing hormone (TRH) Corticotropin-releasing hormone (CRH) Growth hormone–releasing hormone (GHRH) Gonadotropin-releasing hormone (GnRH) Substance P Neurotensin Somatostatin Neuropeptide Y Adrenocorticotrophic hormone (ACTH)–related peptide Inhibins
Steroid Hormones
Progesterone Estrone Estradiol Estriol

The most important placental peptide hormone is **hCG**. In the developing blastocyst, and later in the mature placenta, the syncytiotrophoblast cells synthesize hCG, perhaps under the direction of progesterone and estrogens. The placenta also produces two **human chorionic somatomammotropins**, hCS1 and hCS2, also called *human placental lactogens* (hPL1, hPL2). hCS1 and hCS2 are polypeptide hormones structurally related to growth hormone (GH) and placental-variant growth hormone (pvGH), as well as to prolactin (PRL; see Table 48-1). They play a role in the conversion of glucose to fatty acids and ketones, and thus coordinate the fuel economy of the fetoplacental unit. The fetus and placenta use fatty acids and ketones as energy sources and store them as fuels in preparation for the early neonatal period, when a considerable reservoir of energy is necessary for the transition from intrauterine life to life outside the uterus. hCS1 and hCS2 also promote the development of maternal mammary glands during pregnancy.

In addition to secreting various substances, the placenta also stores vast amounts of proteins, polypeptides, glycogen, and iron. Many of these stored substances can be used at times of poor maternal nutrition and also during the transition from intrauterine to extrauterine life.

The Maternal-Placental-Fetal Unit

During pregnancy, progesterone and estrogens rise to levels that are substantially higher than their peaks in a normal cycle

Following ovulation during a normal or nonconception cycle, the cells of the ovarian follicle functionally transform into luteal cells, which produce mainly progesterone but also estrogens (see pp. [1116–1117](#)). However, the corpus luteum has a life span of only ~12 days before it begins its demise in the face of declining LH levels. As a consequence of luteal demise, levels of both progesterone and estrogens decline.

In contrast, during pregnancy, maternal levels of progesterone and estrogens (estradiol, estrone, estriol) all increase, reaching levels substantially higher than those achieved during a normal menstrual cycle ([Fig. 56-7](#)). These elevated levels are necessary for maintaining pregnancy. For example, progesterone—the progestational hormone—reduces uterine motility and inhibits propagation of contractions. How are these elevated levels of female steroids achieved? Early in the first trimester, hCG that is manufactured by the syncytiotrophoblast rescues the corpus luteum, which is the major source of progesterone and estrogens. This function of the corpus luteum in the ovary continues well into early pregnancy. However, by itself, the corpus luteum is not adequate to generate the very high steroid levels that are characteristic of late pregnancy. The developing placenta itself augments its production of progesterone and estrogens, so by 8 weeks of gestation the placenta has become the major source of these steroids—the luteal-placental shift. Removal of the ovaries (with the corpus luteum) before the luteal-placental shift leads to miscarriage, whereas pregnancy continues normally if the ovaries are removed after the luteal-placental shift. The placenta continues to produce large quantities of estrogens, progestins, and other hormones throughout gestation.

FIGURE 56-7 Maternal levels of progesterone and estrogens just before and during pregnancy. The y-axis scale is logarithmic. The zero point on the x-axis is the time of fertilization. The progesterone spikes near -8 and -4 weeks refer to the two menstrual cycles before the one that resulted in the pregnancy. Estriol, produced from fetal adrenal androgens, increases only after 8 to 10 weeks, when fetal adrenal androgen production increases exponentially. (Data from Wilson JD, Foster DW, Kronenberg M, Larsen PR: Williams Textbook of Endocrinology, 9th ed. Philadelphia, WB Saunders, 1998.)

Estriol, which is not important in nonpregnant women, is a major estrogen—based on circulating levels—during pregnancy (see Fig. 56-7). 📌 **N56-1**

N56-1

Role of the Fetal Hypothalamic-Pituitary-Adrenal Axis in Estriol Synthesis

Contributed by Sam Mesiano

Because 16 α -hydroxylase is expressed only by the fetal liver, the level of estriol in the maternal circulation during pregnancy reflects the activity of the fetal hypothalamic-pituitary-adrenal axis. See Figure 56-9 for the enzymatic pathways in fetus and placenta. See Table 50-2 for a listing of the required P-450 enzymes.

After 8 weeks of gestation, the maternal-placental-fetal unit maintains high levels of progesterone and estrogens

Although it emerges as the major source of progesterone and estrogens (Table 56-5), the human placenta

cannot synthesize these hormones by itself; it requires the assistance of both mother and fetus. This joint effort in steroid biosynthesis has led to the concept of the **maternal-placental-fetal unit**. [Figure 56-8](#)—which resembles the maps describing the synthesis of glucocorticoids, mineralocorticoids (see [Fig. 50-2](#)), male steroids (see [Fig. 54-6](#)), and female steroids (see [Fig. 55-8](#))—illustrates the pathways that the maternal-placental-fetal unit uses to synthesize progesterone and the estrogens. [Figure 56-9](#) summarizes the exchange of synthetic intermediates among the three members of the maternal-placental-fetal unit.

TABLE 56-5
Roles of the Mother, Placenta, and Fetus in Steroid Biosynthesis

	NEEDS	CONTRIBUTES	LACKS
Mother	Progesterone Estrone Estradiol Estriol	LDL cholesterol	Adequate synthetic capacity for progesterone and estrogens
Placenta		3β-Hydroxysteroid dehydrogenase Aromatase (P-450 _{arom}) Sulfatase	Adequate cholesterol-synthesizing capacity 17α-Hydroxylase (P-450 _{c17} ; needed to synthesize estrone and estradiol) 17,20-Desmolase (P-450 _{c17} ; needed to synthesize estrone and estradiol) 16α-Hydroxylase (needed to synthesize estriol)
Fetus		17α-Hydroxylase (P-450 _{c17} ; needed to synthesize estrone and estradiol) in adrenal cortex 17,20-Desmolase (P-450 _{c17} ; needed to synthesize estrone and estradiol) in adrenal cortex 16α-Hydroxylase (needed to synthesize estriol) in liver	3β-Hydroxysteroid dehydrogenase Aromatase (P-450 _{arom})

FIGURE 56-8 Synthesis of progesterone and the estrogens by the maternal-placental-fetal unit. Individual enzymes are shown in horizontal and vertical boxes. See [Figures 50-2](#), [54-6](#), and [55-8](#) for cellular localizations of enzymes. Chemical groups modified by each enzyme are highlighted in the reaction product. The fetus lacks 3 β -hydroxysteroid dehydrogenase and aromatase (P-450_{arom}), shown

with blue background. The placenta lacks 17 α -hydroxylase and 17,20-desmolase activity (contributed by the same protein, P-450_{c17}) and 16 α -hydroxylase (expressed only by the fetal liver); all three are shown with a brown background. Blue and brown color coding of enzymes distinguishes fetus from placenta, whereas color coding in previous steroidogenesis figures indicated subcellular localization.

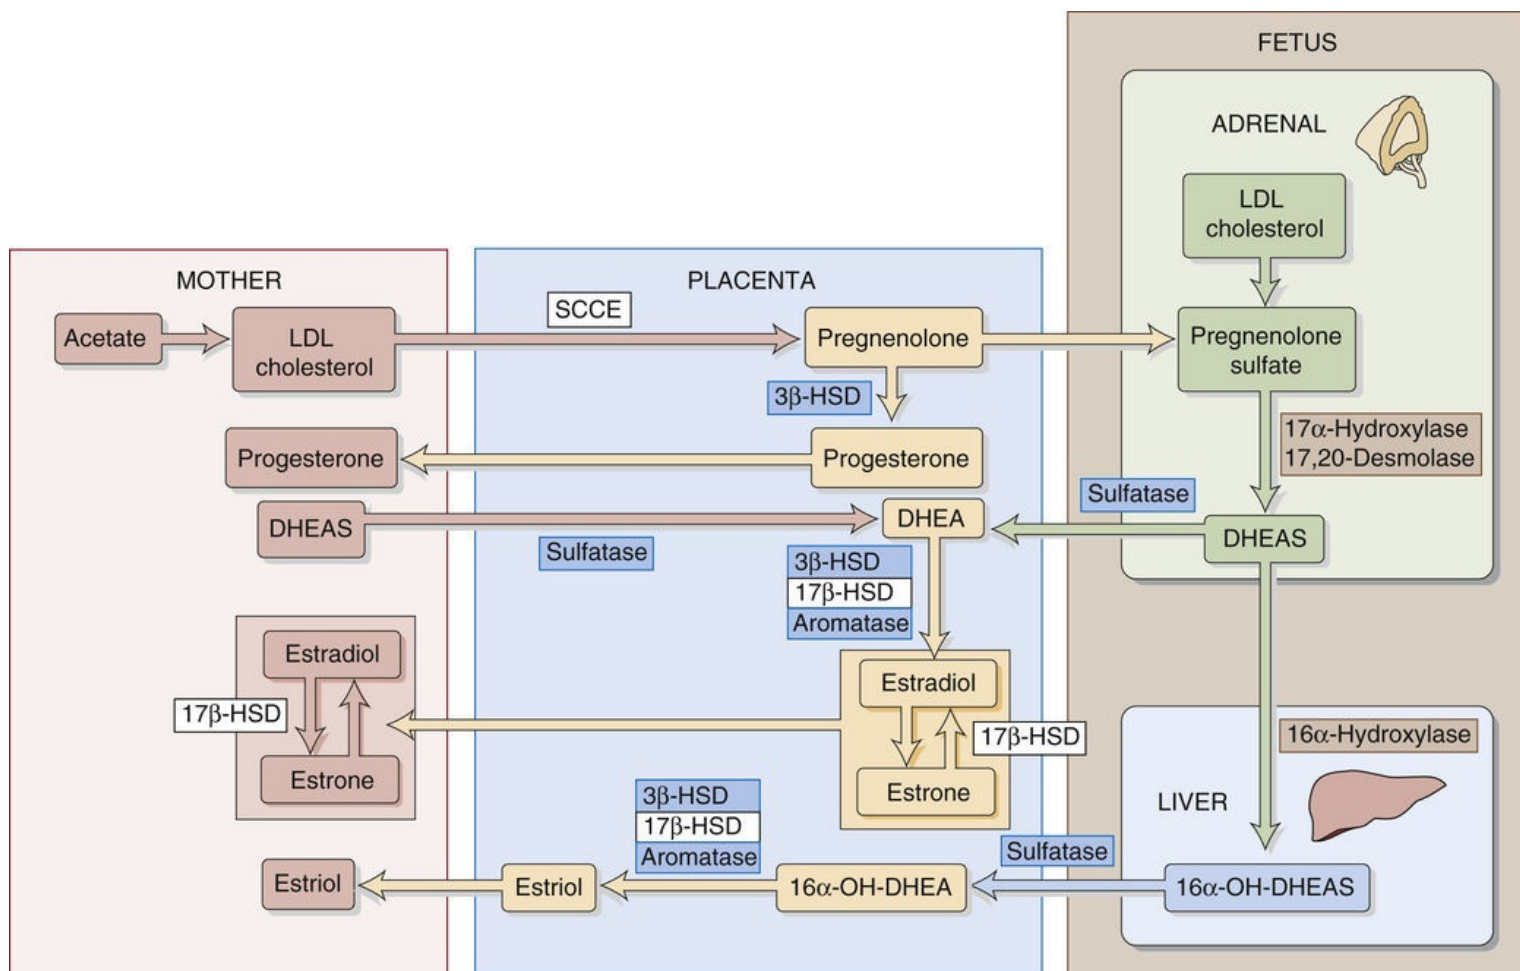

FIGURE 56-9 Interactions of the maternal-placental-fetal unit. The details of the enzymatic reactions are provided in Figure 56-8. **N56-1**; HSD, hydroxysteroid dehydrogenase; SCCE, the side-chain-cleavage enzyme.

Unlike the corpus luteum, which manufactures progesterone, estrone, and estradiol early in pregnancy (see p. 1116), the placenta is an imperfect endocrine organ. First, the placenta cannot manufacture adequate cholesterol, the precursor for steroid synthesis. Second, the placenta lacks two crucial enzymes that are needed for synthesizing estrone and estradiol. Third, the placenta lacks a third enzyme that is needed to synthesize estriol. The enzymes missing from the placenta are listed in Table 56-5, and they also are indicated with a brown background in Figures 56-8 and 56-9.

The maternal-placental-fetal unit overcomes these placental shortcomings in two ways. First, the mother supplies most of the cholesterol as LDL particles (see p. 968). With this supply of maternal cholesterol, the placenta can generate large amounts of progesterone and export it to the mother, which solves the problem of maintaining maternal progesterone levels after the corpus luteum becomes inadequate. Second, the fetal adrenal gland and liver supply the three enzymes that the placenta lacks. The fetal adrenal glands are up to this metabolic task; at term, these glands are as large as those of an adult.

The fetus does not synthesize estrogens without assistance, for two reasons. First, it *cannot*, because the fetus lacks the enzymes that catalyze the last two steps in the production of estrone, the precursor of

estradiol. These two enzymes are also necessary to synthesize estriol. The enzymes missing from the fetus are listed in [Table 56-5](#), and they also are indicated with a blue background in [Figures 56-8](#) and [56-9](#). Second, the fetus *should not* synthesize estrogens without assistance. If the fetus were to carry out the complete classic biosynthesis of progesterone and the estrogens, it would expose itself to dangerously high levels of hormones that are needed not by the fetus but by the mother.

The fetus and its placenta use three strategies to extricate themselves from this conundrum. First, because the fetus lacks the two enzymes noted above, it never makes anything beyond dehydroepiandrosterone (DHEA) and 16 α -hydroxy-DHEA (see [Fig. 56-8](#)). In particular, the fetus cannot make progesterone or any of the three key estrogens. Second, the placenta is a massive sink for the weak androgens that the fetus does synthesize, which prevents the masculinization of female fetuses. Third, the fetus conjugates the necessary steroid intermediates to sulfate, which greatly reduces their biological activity (see [Fig. 56-9](#)). Thus, as pregnenolone moves from the placenta to the fetus, it is sulfated. The products of fetal pregnenolone metabolism are also sulfated (DHEAS and 16 α -hydroxy-DHEAS) as long as they reside inside the fetus. It is only when DHEAS and 16 α -hydroxy-DHEAS finally move to the placenta that a sulfatase removes the sulfate groups, and thus the placenta can complete the process of steroidogenesis and can export the hormones to the mother.

Response of the Mother to Pregnancy

The **mean duration of human pregnancy** is ~266 days (38 weeks) from the time of ovulation or 280 days (40 weeks) from the first day of the last menstrual period. During this time, the mother experiences numerous and profound adaptive changes in her cardiovascular system, fluid volume, respiration, fuel metabolism, and nutrition. These orderly changes reflect the effects of various hormones as well as the increase in the size of the pregnant uterus.

Both maternal cardiac output and blood volume increase during pregnancy

The maternal **blood volume** starts to increase during the first trimester, expands rapidly during the second trimester, rises at a much lower rate during the third trimester, and finally achieves a plateau during the last several weeks of pregnancy. Maternal blood volume may have increased by as much as 45% near term in singleton pregnancies and up to 75% to 100% in twin or triplet pregnancies. The increase in blood volume is due to an increase in the volume of both the plasma and erythrocytes. However, the rise in plasma volume begins earlier and is ultimately greater (~50%) than the rise in total erythrocyte volume (~33%). A proposed mechanism for the increase in plasma volume is that elevated progesterone and estrogens cause a vasodilation that decreases peripheral vascular resistance and thus renal perfusion. One mechanism of the vasodilation is refractoriness to the pressor effects of angiotensin II. The renin-angiotensin-aldosterone axis responds by increasing aldosterone (see pp. 841–842), which augments renal reabsorption of salt and water. In addition, pregnancy causes a leftward shift of the relationship between arginine vasopressin (AVP) release and plasma osmolality (see Fig. 40-7). Immediately after the delivery of the placenta, with the attendant decreases in progesterone and estrogen levels, the mother commences a vigorous diuresis.

The increase in blood volume is needed to meet the demands of the enlarged pregnant uterus with its greatly hypertrophied vascular system. It also protects mother and fetus against the deleterious effects of impaired venous return in the supine and erect positions, and it safeguards the mother against the adverse effects of the blood loss associated with parturition.

Cardiac output increases appreciably during the first trimester of pregnancy (by 35% to 40%), but increases only slightly during the second and third trimesters (~45% at term). The increase in cardiac output, which reflects mainly an increase in stroke volume but also in heart rate, is highly targeted. Renal blood flow increases 40%. Uterine blood flow rises from just 1% to 15% of cardiac output. Blood flow to the heart (to support increased cardiac output), skin (to increase heat radiation), and breasts (to support mammary development) also increases. However, no change occurs in blood flow to the brain, gut, or skeleton. The increase in cardiac output with physical activity is greater in pregnant women (for most of the pregnancy) than it is in nonpregnant women.

Despite the large increase in plasma volume, **mean arterial pressure (MAP)** usually decreases during midpregnancy and then rises during the third trimester, although it normally remains at or lower than normal. The reason for this initial fall in MAP is a decrease in peripheral vascular resistance, possibly reflecting—in part—the aforementioned vasodilating effects of progesterone and estradiol.

Posture has a major effect on cardiac output (see pp. 575–576). In late pregnancy, cardiac output is typically higher when the mother is in the lateral recumbent position than when she is in the supine

position. In the supine position, the fundus of the enlarged uterus rests on the inferior vena cava near L5, thereby impeding venous return to the heart.

Increased levels of progesterone during pregnancy increase alveolar ventilation

During pregnancy, hormonal and mechanical factors lead to several anatomical changes that have the net effect of increasing alveolar ventilation. The level of the diaphragm rises ~4 cm, which probably reflects the relaxing effects of progesterone on the diaphragm muscle and fascia. At the same time, the costovertebral angle widens appreciably as the transverse diameter of the thoracic cage increases ~2 cm. Although these two changes have opposite effects on the residual volume (RV) of air in the lungs (see p. 602), the elevation of the diaphragm dominates, which causes a net decrease in RV and functional residual capacity (FRC). Vital capacity (VC), maximal pulmonary ventilation, and pulmonary compliance do not change appreciably. Total pulmonary resistance falls, which facilitates airflow. Because of the increased size of the abdominal contents during pregnancy, the abdominal muscles are less effective in aiding forced expirations.

Although pregnancy has little effect on respiratory rate, it increases tidal volume (V_T) markedly—by ~40%—and thereby increases **alveolar ventilation** (\dot{V}_A ; see pp. 675–676). These increases in V_T and \dot{V}_A are some of the earliest physiological changes during pregnancy, beginning 6 weeks after fertilization. They may reflect, at least in part, a direct stimulatory effect of progesterone and, to a lesser extent, estrogen on the medullary respiratory centers. The physiological effect of the increased \dot{V}_A during pregnancy is a fall in maternal arterial P_{CO_2} , which typically decreases from ~40 mm Hg before pregnancy to ~32 mm Hg, despite the net increase in CO_2 production that reflects fetal metabolism. A side effect is mild respiratory alkalosis for which the kidneys compensate by lowering plasma $[HCO_3^-]$ modestly (see p. 641).

Pregnancy increases the demand for dietary protein, iron, and folic acid

During pregnancy, an additional 30 g of protein will be needed each day to meet the demand of the growing fetus, placenta, uterus, and breasts, as well as the increased maternal blood volume. Most protein should come from animal sources, such as meat, milk, eggs, cheese, poultry, and fish, because these foods furnish amino acids in optimal combinations.

Almost any diet that includes iodized salt and adequate caloric intake to support the pregnancy also contains enough minerals, except **iron** (see Table 45-4). Pregnancy necessitates a net gain of ~800 mg of circulating iron to support the expanding maternal Hb mass, the placenta, and the fetus. Most of this iron is used during the latter half of pregnancy. A *nonpregnant* woman of reproductive age needs to *absorb* ~1.5 mg/day of iron in a diet that contains 15 to 20 mg/day (see p. 939). In contrast, during pregnancy, the average required iron uptake rises to ~7 mg/day. Very few women have adequate iron stores to supply this amount of iron, and a typical diet seldom contains sufficient iron. Thus, the recommended supplementation of elemental iron is 60 mg/day, taken in the form of a simple ferrous iron salt.

Maternal **folate** requirements increase significantly during pregnancy, in part reflecting an increased demand for producing blood cells. This increased demand can lead to lowered plasma folate levels or, in

extreme cases, to maternal megaloblastic anemia (see pp. 933–935). Folate deficiency may cause neural tube defects in the developing fetus. Because oral supplementation of 400 to 800 µg/day of folic acid produces a vigorous hematological response in pregnant women with severe megaloblastic anemia, this dosage would almost certainly provide very effective prophylaxis.

Less than one third of the total maternal weight gain during pregnancy represents the fetus

The recommended weight gain during a singleton pregnancy for a woman with a normal ratio of weight to height (i.e., body mass index) is 11.5 to 16 kg. This number is higher for women with a low body mass index. A weight gain of 14 kg would include 5 kg for intrauterine contents—the fetus (3.3 kg), placenta and membranes (0.7 kg), and amniotic fluid (1 kg). The maternal contribution of 9 kg would include increases in the weight of the uterus (0.7 kg), N56-8 the blood (1.3 kg), and the breasts (2.0 kg), as well as adipose tissue and interstitial fluid (5.0 kg). The interstitial fluid expansion may be partly the result of increased venous pressure created by the large pregnant uterus and, as noted above, partly caused by aldosterone-dependent Na⁺ retention (see p. 1142).

N56-8

Uterine Growth during Pregnancy

Contributed by Sam Mesiano

During the first weeks of pregnancy, most of uterine growth is due to hyperplasia, whereas during the latter part of pregnancy, the growth is due mainly to stretch-induced hypertrophy.

For a woman whose weight is normal before pregnancy, a weight gain in the recommended range correlates well with a favorable outcome of the pregnancy. Most pregnant women can achieve an adequate weight gain by eating—according to appetite—a diet adequate in calories, protein, minerals, and vitamins. Seldom, if ever, should maternal weight gain be deliberately restricted to less than this level. Failure to gain weight is an ominous sign; birth weight parallels maternal weight, and neonatal mortality rises with low birth weight, particularly for babies weighing <2500 g.

Parturition

Human birth usually occurs at around the 40th week of gestation

As we will see in [Chapter 57](#), after birth, the fetus—now a neonate—must maintain physiological homeostasis even though it has lost its placenta and been thrust into a markedly altered environment. Therefore, birth should occur only after organ systems have matured sufficiently to allow the neonate to survive outside the uterus. At the ~40th week of gestation, critical organ systems, especially those that interface with the environment (e.g., lungs, gut, and immune system) and those that maintain homeostasis (e.g., the hypothalamic-pituitary-adrenal axis, kidneys, liver, and pancreas), are functionally competent, and with maternal nurturing, the neonate has a high probability of survival. However, birth prior to 40 weeks is associated with neonatal morbidity and mortality, the severity of which increases the earlier birth occurs.

Parturition—the process of birth—is an integral and pivotal event in the reproductive cycle of all viviparous species. The process involves (1) transformation of the myometrium (smooth-muscle component of the uterine wall) from a quiescent to a highly contractile state to become the engine for birth, (2) remodeling of the uterine cervix such that it softens (effacement) and dilates to open the gateway for birth, (3) rupture of the fetal membranes, (4) expulsion of the uterine contents, and (5) return of the uterus to its prepregnant state.

Parturition occurs in distinct stages, numbered 0 to 3

Stage 0—Quiescence

Throughout most of pregnancy the uterus is relaxed, quiescent, and relatively insensitive to uterotonins—hormones that stimulate contractions, such as prostaglandins (PGs) and oxytocin (OT)—and the uterine cervix remains closed and rigid. The quiescent uterus grows and distends to accommodate the developing conceptus (fetus, placenta, and amniotic fluid), and myometrial cells undergo significant hypertrophy. Weak and irregular contractions, known as **Braxton Hicks contractions**, occur toward the end of pregnancy and may increase in frequency and intensity near term. These contractions are not powerful enough to induce labor, however, and are thought to prepare the uterus for parturition.

Stage 1—Transformation/Activation

Before labor, the myometrium transforms to a more contractile state. This awakening of myometrial cells involves increased expression of genes that encode factors collectively referred to as **contraction-associated proteins (CAPs)**. Some important CAPs are receptors for uterotonic hormones (e.g., prostaglandin F_2 [$PGF_{2\alpha}$] receptor and OT receptor), enzymes involved in PG synthesis (e.g., cyclooxygenase 2), and components of gap junction complexes (e.g., connexin-43). Gap junctions are especially important because they form electrochemical connections between myometrial cells to synchronize contractions over the entire uterus (see pp. [243–244](#)). The cervix also begins to express genes encoding enzymes that break down the collagen matrix to facilitate effacement and dilation.

Stage 2—Active Labor

Three major factors induce the forceful and rhythmic contractions that, in association with effacement and dilation of the cervix, constitute the obstetrical definition of labor: (1) increased levels of PGs (especially $\text{PGF}_{2\alpha}$) produced by the myometrium and fetal membranes, (2) increased myometrial cell interconnectivity, and (3) increased myometrial responsiveness to PGs and OT. Each contraction forces the fetal head against the cervix, which becomes progressively more compliant as its extracellular matrix remodels. Eventually, the cervix dilates enough to allow the contractions of labor to force the fetus and then the placenta through the birth canal. Labor may last for several hours, a day, or even longer and eventually results in the expulsion of the fetus, placenta, and membranes through the vaginal canal.

Stage 3—Involution

Immediately after expulsion of the uterine contents, it is mainly OT that causes the sustained and forceful myometrial contraction that helps constrict the spiral arterioles and thereby facilitates postpartum uterine hemostasis. This contraction is critical to avoid a potentially lethal postpartum hemorrhage through the vascular lakes once occupied by the placental villi. The maternal endocrine milieu changes dramatically after birth. Estrogens produced by the placenta during pregnancy are uterotrophic; that is, they stimulate growth of the uterus,  **N56-8** primarily hypertrophy of the myometrium. Estrogens also increase the vascularity of the uterus. The decline in estrogen levels after birth causes myometrial atrophy. As the organ reverts to its nonpregnant size during the first 3 to 6 weeks after birth, uterine vasculature regresses, which curtails blood flow and leads to further involution. At the same time, the cervix remodels and reverts to the closed and rigid state. Within 3 to 5 months, the endometrium re-establishes cyclic activity as the menstrual cycle resumes.

Reciprocal decreases in progesterone receptors and increases in estrogen receptors are critical for the onset of labor

Although not all of the factors leading to the initiation of labor are known, endocrine and paracrine interactions, signals elicited in response to inflammation (e.g., in response to intrauterine infection), and mechanical stretching of the uterus appear to play key roles. Once labor is initiated, it is sustained by a series of positive-feedback mechanisms involving inflammation within the gestational tissues—myometrium, cervix, decidua, placenta, nonplacental chorion, and amnion—until the uterine contents are expelled.

The principal hormones that affect parturition are progesterone and estrogens (a mix of estradiol, estrone, and estriol).

Progesterone promotes pregnancy mainly by inducing myometrial relaxation and blocking the contractions of labor. Treatment of women with nuclear progesterone receptor antagonists, such as mifepristone (RU486), increases myometrial contractility and excitability and in most cases induces labor at any stage of pregnancy.

Estrogens augment myometrial contractility and thus cervical dilation. They are thought to oppose the actions of progesterone by increasing the responsiveness of myometrial cells to OT and PGs and by stimulating the formation of gap junctions between myometrial cells. Estrogens also increase the production and release of PGs by the fetal membranes, and in the cervix, estrogens stimulate expression of proteolytic enzymes (e.g., collagenase), which degrade the extracellular matrix to facilitate effacement and dilation.

In most viviparous species, the onset of labor is triggered by a coordinated decrease in circulating progesterone levels (progesterone withdrawal) and an increase in circulating estrogen levels (estrogen activation). In women, however, uterine cells are exposed to high levels of progesterone and estrogens for most of pregnancy, and progesterone level remains elevated during labor and delivery, declining only when the placenta is expelled. Thus, human parturition is not associated with *systemic* progesterone withdrawal. Instead, labor in women is thought to be initiated by *desensitization* of uterine cells to the progestational actions of progesterone (i.e., functional progesterone withdrawal). Because progesterone inhibits estrogen receptor expression, the functional desensitization to progesterone leads to increased expression of estrogen receptors. The result is an increased responsiveness to circulating estrogens, which induces genes encoding CAPs that augment contractility and transform the myometrium from a quiescent to a laboring phenotype. The shift from progesterone to estrogen dominance is thought to be the pivotal trigger event for human parturition and is mediated by reciprocal changes in progesterone and estrogen receptor levels in myometrial and cervical cells.

Signals from the fetus may initiate labor

Studies in sheep demonstrate the importance of the fetal hypothalamic-pituitary-adrenal axis in the preparation for, or initiation of, parturition. In the fetal lamb, transection of the hypothalamic portal vessels—or removal of the fetal pituitary—prolongs gestation. Infusing adrenocorticotrophic hormone (ACTH; see pp. [1023–1025](#)) into fetal lambs with intact adrenal glands, or directly infusing cortisol into the fetus, causes premature maturation of fetal organ systems (especially the lungs) and premature parturition. Indeed, a surge in fetal adrenal cortisol production triggers normal parturition in sheep. Cortisol, in turn, induces the expression of placental enzymes that convert progesterone to estrogens (see [Fig. 56-9](#)), triggering a shift from progesterone to estrogen dominance and thereby inducing labor and delivery. **N56-9** In humans, the fetal hypothalamic-pituitary-adrenal axis does not play as critical a role in controlling the timing of birth. In fact, the maternal and fetal/placental signals that initiate labor in women are not clearly understood.

N56-9

Fetal Hypothalamic-Pituitary-Adrenal Axis near the End of Pregnancy in Sheep

Contributed by Sam Mesiano

In sheep, the timing of birth is determined by the activity of the fetal hypothalamic-pituitary-adrenal axis, which not only triggers labor but also stimulates the functional maturation of key fetal organ systems, so that the fetus is prepared for life as a neonate. These studies in sheep led directly to the development of synthetic glucocorticoid therapy to promote fetal lung maturation in women experiencing preterm labor and threatened preterm birth.

PGs initiate uterine contractions, and both PGs and OT sustain labor

Whereas OT, produced by the maternal posterior pituitary, and PGs, produced locally within the

gestational tissues, play an important role in stimulating the contractions that *sustain* labor, only PGs are believed to have a key role in *initiating* labor.

Prostaglandins

The uterus, the placenta, and the fetal membranes synthesize and release PGs (see p. 64). Arachidonic acid, the precursor of PG production, is present in very high concentrations in the fetal membranes near term. $\text{PGF}_{2\alpha}$ and PGE_2 from the uterine decidual cells act by a paracrine mechanism on adjacent myometrial cells. OT stimulates uterine decidual cells to increase $\text{PGF}_{2\alpha}$ synthesis. Thus, PGs and OT act synergistically to augment uterine contractility.

PGs have three major effects. First, PGs strongly stimulate myometrial contraction. Second, $\text{PGF}_{2\alpha}$ potentiates OT-induced contractions by promoting formation of **gap junctions** (see pp. 158–159) between uterine smooth-muscle cells. Third, PGs also cause effacement of the cervix, which occurs early during labor. This softening is akin to an inflammatory reaction in that it is associated with an invasion by polymorphonuclear leukocytes (see p. 435). Because of these effects, PGs are used to induce labor and delivery in certain clinical settings.

PGs may physiologically initiate labor. Both $\text{PGF}_{2\alpha}$ and PGE_2 evoke myometrial contractions at *any* stage of gestation, regardless of the route of administration. The levels of PGs or their metabolic products naturally increase in the blood and amniotic fluid just before and during labor. Arachidonic acid instilled into the amniotic cavity causes the uterus to contract and to expel its contents. Aspirin, which inhibits the enzyme cyclooxygenases (see pp. 62–64), reduces the formation of $\text{PGF}_{2\alpha}$ and PGE_2 , thus inhibiting labor and prolonging gestation.

Oxytocin

The nonapeptide OT is closely related to AVP (Fig. 56-10),  N56-10 and both are synthesized in the cell bodies of the neurons in the supraoptic and paraventricular nuclei of the hypothalamus of the fetus and mother. Both OT and AVP then move by fast axonal transport to the posterior pituitary gland, where they are stored in the nerve terminals until released—along with neurophysins (see pp. 845 and 981)—in response to the appropriate stimuli.

FIGURE 56-10 Comparison of the structures of OT and AVP. DDAVP (desmopressin acetate) is a synthetic AVP in which the N-terminal cysteine is deaminated and L-arginine at position 8 is replaced with D-arginine (see [Box 38-1](#)).

N56-10

Vasotocin, Oxytocin, and Arginine Vasopressin

Contributed by Ervin Jones

OT and AVP apparently evolved from vasotocin, the single neurohypophyseal hormone in nonmammalian vertebrates. OT and AVP, which both differ from vasotocin by a single amino acid, are synthesized in the cell bodies of the neurons in the supraoptic and paraventricular nuclei of the hypothalamus.

Circulating OT binds to $G\alpha_q$ -coupled **OT receptors (OTRs)** on the plasma membrane of myometrial cells, triggering the phospholipase C cascade (see p. 58). Presumably, formation of IP_3 leads to Ca^{2+} release from internal stores and to an increase in $[Ca^{2+}]_i$. The rise in $[Ca^{2+}]_i$ activates calmodulin, which stimulates myosin light-chain kinase to phosphorylate the regulatory light chain; the result is contraction of uterine smooth muscle (see pp. 247–248) and increased intrauterine pressure. OT also binds to a receptor on decidual cells, thereby stimulating $PGF_{2\alpha}$ production, as discussed above.

Estrogen increases the *number* of OTRs in the myometrium and decidua during pregnancy. The uterus actually remains *insensitive* to OT until ~20 weeks' gestation, at which time the number of OTRs increases progressively to 80-fold higher than baseline values by ~36 weeks, plateaus just before labor, and then rises again to 200-fold higher than baseline values during early labor. The time course of the expression of OTRs may account for the increase in spontaneous myometrial contractions even in the absence of increased plasma OT levels. Whereas the uterus is sensitive to OT only at the end of pregnancy, it is susceptible to PGs throughout pregnancy.

Maternal plasma OT levels rise gradually during the 40 weeks of pregnancy and then rise further with active labor (stage 2), with **maternal OT** being released in bursts and the frequency of these bursts increasing as labor progresses. The primary stimulus for the release of maternal OT appears to be distention of the cervix; this effect is known as the **Ferguson reflex**. OT is an important stimulator of myometrial contraction late in labor. During the second stage of labor, OT release may play a synergistic role in the expulsion of the fetus by virtue of its ability to stimulate PG release.

During the third stage of labor, uterine contractions induced by OT are also important for constricting

uterine blood vessels at the site where the placenta used to be, which promotes hemostasis (i.e., blood coagulation). At about 60 minutes after delivery, maternal plasma OT levels return to prepartum levels.

Relaxin

Relaxin is a polypeptide hormone of 48 amino acids, structurally related to insulin, that is produced by the corpus luteum, the placenta, and the decidua. Relaxin may play a role in keeping the uterus in a quiet state during pregnancy. Production and release of relaxin increase during labor, when relaxin may soften and thus help dilate the cervix.

Mechanical Factors

Mechanical stretch placed on the uterine muscle may lead to the rhythmic contractions of labor. Thus, the increase in the size of the uterine contents to a critical level may stimulate uterine contractions and thereby lead to initiation of labor.

Positive Feedback

Once labor is initiated, several positive-feedback loops involving PGs and OT help to sustain it. First, uterine contractions stimulate PG release, which itself increases the intensity of uterine contractions. Second, uterine activity stretches the cervix, which stimulates OT release via the Ferguson reflex. Because OT stimulates further uterine contractions, these contractions become self-perpetuating.

Lactation

The fundamental secretory unit of the breast ([Fig. 56-11A](#)) is the alveolus (see [Fig. 56-11B, C](#)), which is surrounded by contractile myoepithelial cells and adipose cells. These alveoli are organized into secretory lobules, each of which drains into a ductule. A group of 15 to 20 ductules drain into a lactiferous duct, which widens at the ampulla—a small reservoir. The lactiferous ducts carry the secretions to the outside.

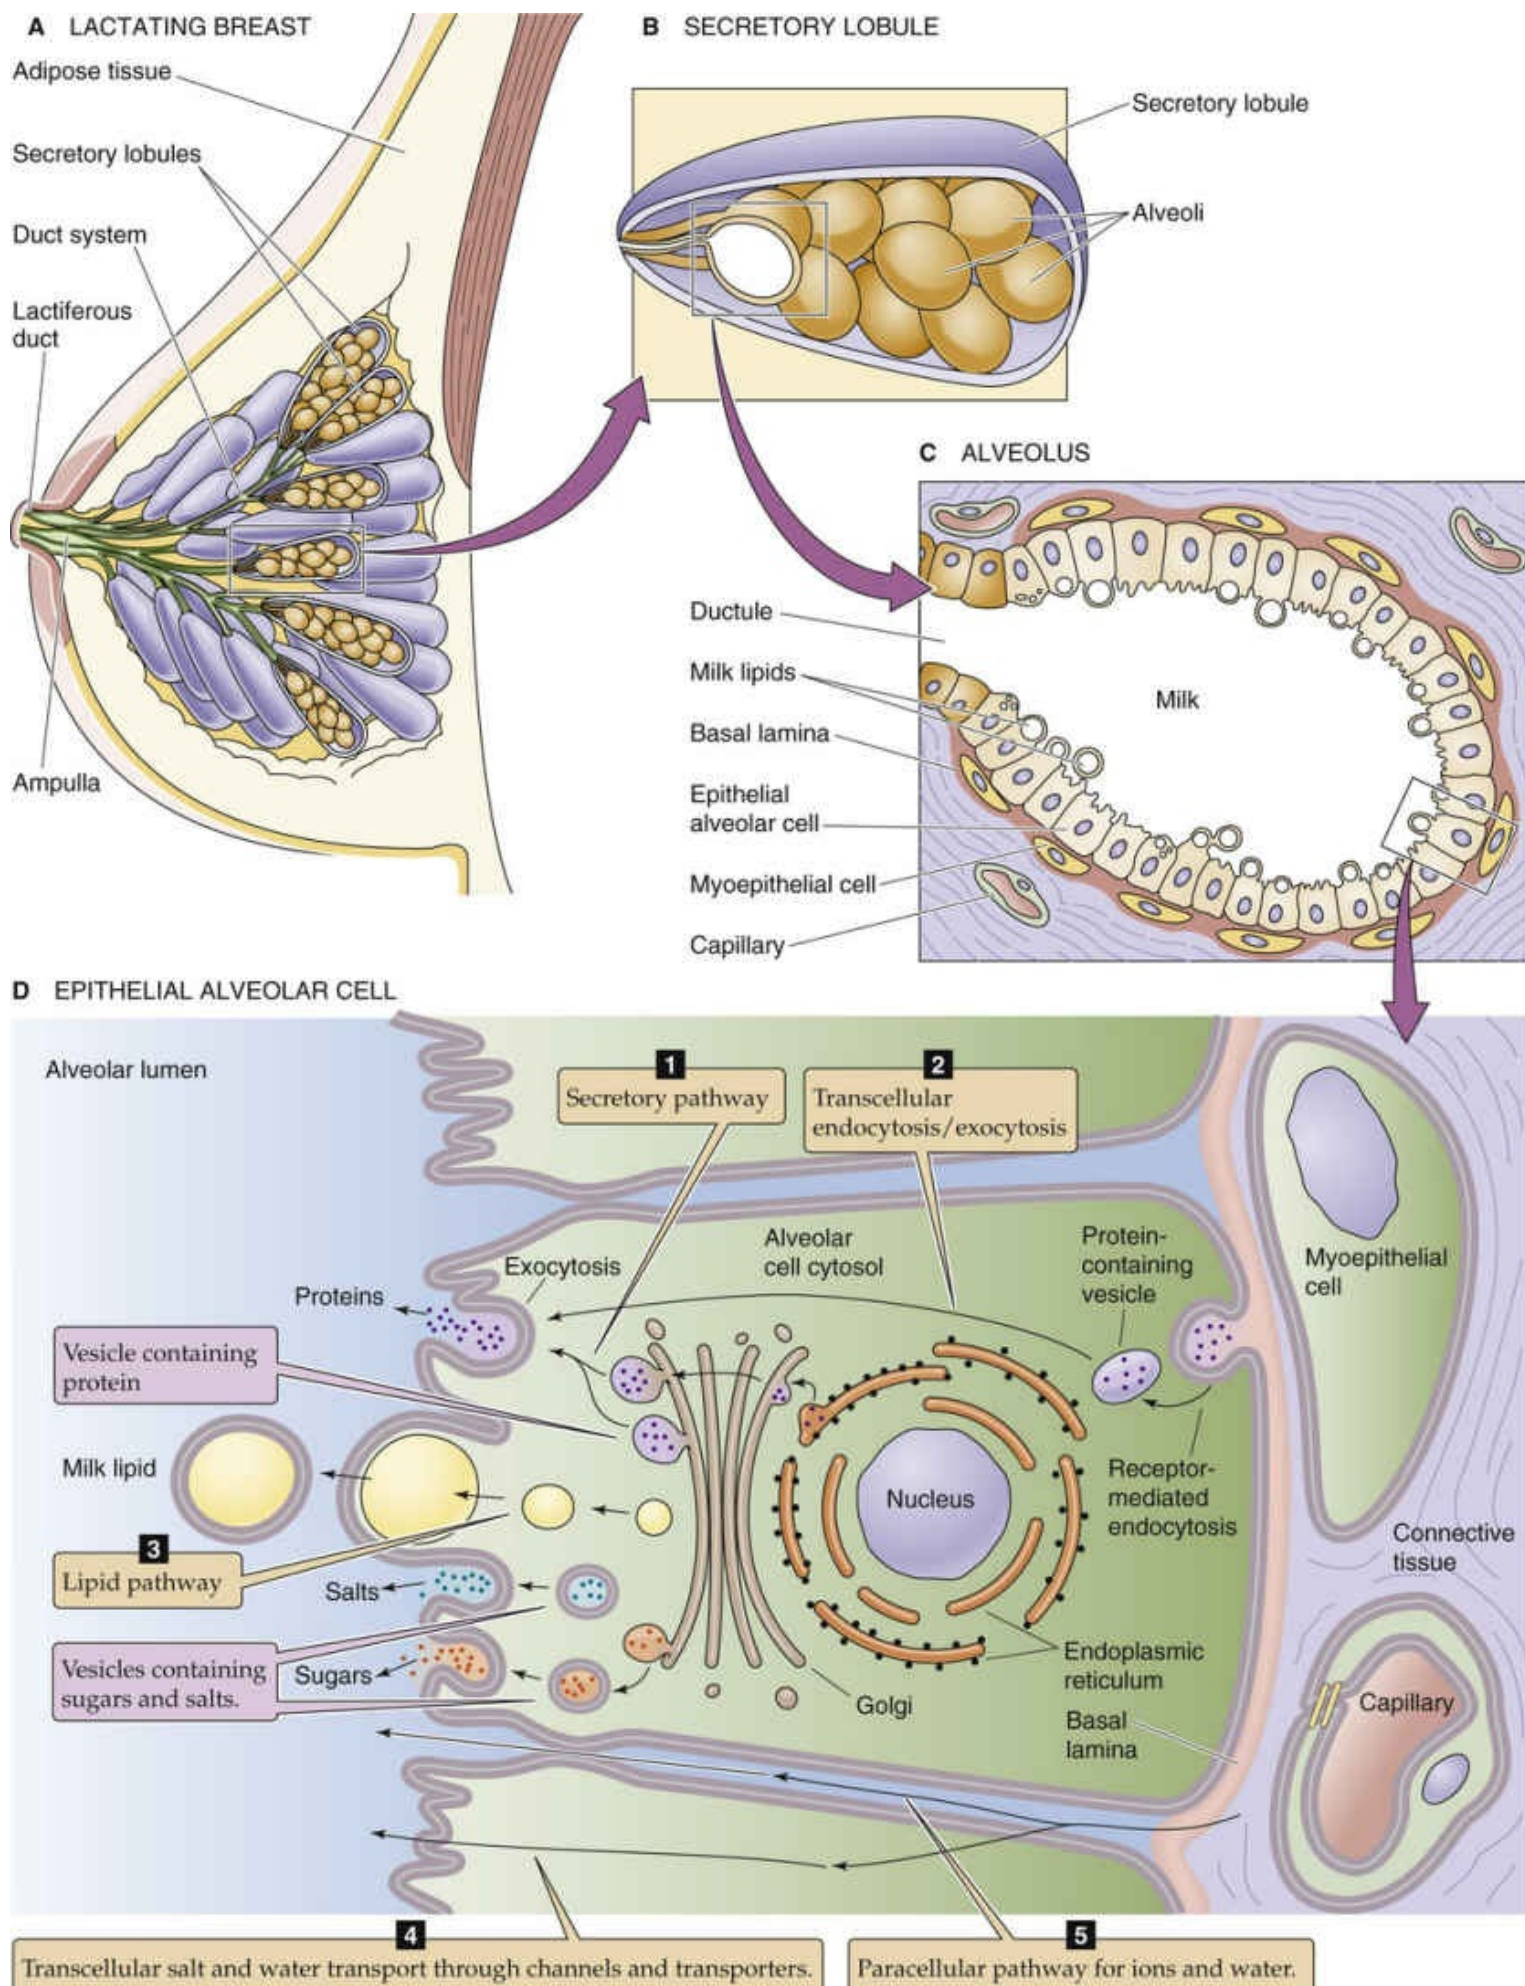

FIGURE 56-11 Cross section of the breast and milk production. **A**, The breast consists of a series of secretory lobules, which empty into ductules. The ductules from 15 to 20 lobules combine into a duct,

which widens at the ampulla—a small reservoir. The lactiferous duct carries the secretions to the outside. **B**, The lobule is made up of many alveoli, the fundamental secretory units. **C**, Each alveolus consists of secretory epithelial cells (alveolar cells) that actually secrete the milk, as well as contractile myoepithelial cells, which are in turn surrounded by adipose cells. **D**, The epithelial alveolar cell secretes the components of milk via five pathways.

Breast development at puberty depends on several hormones, but primarily on the estrogens and progesterone. During pregnancy, gradual increases in levels of PRL and hCS, as well as very high levels of estrogens and progesterone, lead to full development of the breasts.

As indicated in Table 56-6, hormones affecting the breast are **mammogenic** (promoting the proliferation of alveolar and duct cells), **lactogenic** (promoting initiation of milk production by alveolar cells), **galactokinetic** (promoting contraction of myoepithelial cells and thus milk ejection), or **galactopoietic** (maintaining milk production after it has been established).

Galactokinetic Hormones (promote contraction of myoepithelial cells and thus milk ejection)
OT
AVP (1%–20% as powerful as OT)
Galactopoietic Hormones (maintain milk production after it has been established)
PRL (primary)
Cortisol and other metabolic hormones (permissive)

IGF-1, insulin-like growth factor 1.

The epithelial alveolar cells of the mammary gland secrete the complex mixture of sugars, proteins, lipids, and other substances that constitute milk

Milk is an emulsion of fats in an aqueous solution containing sugar (lactose), proteins (lactalbumin and casein), and several cations (K^+ , Ca^{2+} , and Na^+) and anions (Cl^- and phosphate). The composition of human milk differs from that of human **colostrum** (the thin, yellowish, milk-like substance secreted during the first several days after parturition) and cow's milk (Table 56-7). Cow's milk has more than three times more protein than human milk, almost exclusively a result of its much higher casein concentration. It also has a higher electrolyte content. The difference in composition between human milk and cow's milk is important because a newborn, with his or her delicate gastrointestinal tract, may not tolerate the more

concentrated cow's milk.

TABLE 56-7
Composition of Human Colostrum, Human Milk, and Cow's Milk (per Deciliter of Fluid)

COMPONENT	HUMAN COLOSTRUM	HUMAN MILK	COW'S MILK
Total protein (g)	2.7	0.9	3.3
Casein (% of total protein)	44	44	82
Total fat (g)	2.9	4.5	3.7
Lactose (g)	5.7	7.1	4.8
Caloric content (kcal)	54	70	69
Calcium (mg)	31	33	125
Iron (µg)	10	50	50
Phosphorus (mg)	14	15	96
Cells (macrophages, neutrophils, and lymphocytes)	7–8 × 10 ⁶	1–2 × 10 ⁶	—

The epithelial cells in the alveoli of the mammary gland secrete the complex mixture of constituents that make up milk by five major routes (see Fig. 56-11D).

- 1. Secretory pathway.** The milk proteins **lactalbumin** and **casein** are synthesized in the endoplasmic reticulum and sorted to the Golgi apparatus (see p. 21). Here alveolar cells add **Ca²⁺** and **phosphate** to the lumen. Lactose synthetase in the lumen of the Golgi catalyzes synthesis of **lactose**, the major carbohydrate. Lactose synthetase has two components, a galactosyltransferase and lactalbumin, both made in the endoplasmic reticulum. Water enters the secretory vesicle by osmosis. Finally, exocytosis discharges the contents of the vesicle into the lumen of the alveolus.
- 2. Transcellular endocytosis and exocytosis.** The basolateral membrane takes up maternal immunoglobulins by receptor-mediated endocytosis (see p. 42). Following transcellular transport of these vesicles to the apical membrane, the cell secretes these immunoglobulins (primarily immunoglobulin A) by exocytosis. The gastrointestinal tract of the infant takes up these immunoglobulins (see p. 922), which are important for conferring immunity before the infant's own immune system matures.
- 3. Lipid pathway.** Epithelial cells synthesize short-chain fatty acids. However, the longer-chain fatty acids (>16 carbons) that predominate in milk originate primarily from the diet or from fat stores. The fatty acids form into lipid droplets and move to the apical membrane. As the apical membrane surrounds the droplets and pinches off, it secretes the **milk lipids** into the lumen in a membrane-bound sac.
- 4. Transcellular salt and water transport.** Various transport processes at the apical and basolateral membranes move small electrolytes from the interstitial fluid into the lumen of the alveolus. Water follows an osmotic gradient generated primarily by lactose (present at a final concentration of ~200 mM) and, to a lesser extent, by the electrolytes.
- 5. Paracellular pathway.** Salt and water can also move into the lumen of the alveolus via the tight junctions (see p. 137). In addition, cells, primarily leukocytes, also squeeze between cells and enter the milk.

PRL is essential for milk production, and suckling is a powerful stimulus for PRL secretion

PRL is a polypeptide hormone that is structurally related to GH, pvGH, and hCS1 and hCS2 (see Table

48-1). Like GH, PRL is made and released in the anterior pituitary; however, lactotrophs rather than somatotrophs are responsible for PRL synthesis. Another difference is that, whereas GH-releasing hormone *stimulates* somatotrophs to release GH, **dopamine (DA)** *inhibits* the release of PRL from lactotrophs. Thus, the removal of inhibition promotes PRL release.

The actions of PRL on the mammary glands (see [Table 56-6](#)) include promotion of mammary growth (mammogenic effect), initiation of milk secretion (lactogenic effect), and maintenance of milk production once it has been established (galactopoietic effect). Although the initiation of lactation requires the coordinated action of several hormones, PRL is the classic lactogenic hormone. Initiation of milk production also necessitates the abrupt fall in estrogens and progesterone that accompanies parturition. PRL is also the primary hormone responsible for maintaining milk production once it has been initiated.

PRL binds to a tyrosine kinase–associated receptor (see p. [70](#)) in the same family of receptors as the GH receptor. PRL receptors, which have equal affinities for GH, are present in tissues such as breast, ovary, and liver. Presumably via pathways initiated by protein phosphorylation at tyrosine residues, PRL stimulates transcription of the genes that encode several milk proteins, including lactalbumin and casein.

Suckling is the most powerful physiological stimulus for PRL release. Nipple stimulation triggers PRL secretion via an afferent neural pathway through the spinal cord, thereby inhibiting dopaminergic neurons in the median eminence of the hypothalamus ([Fig. 56-12](#)). Because **DA** normally inhibits PRL release from the lactotrophs, it is called a **PRL-inhibitory factor (PIF)**. Thus, because suckling decreases DA delivery via the portal vessels, it relieves the inhibition on the lactotrophs in the anterior pituitary and stimulates bursts of PRL release. Treating women with DA receptor agonists rapidly inhibits PRL secretion and milk production.

FIGURE 56-12 Effect of suckling on the release of PRL, OT, and GnRH. Suckling has four effects. First, it stimulates sensory nerves, which carry the signal from the breast to the spinal cord, where these nerves synapse with neurons that carry the signal to the brain. Second, in the arcuate nucleus of the hypothalamus, the afferent input from the nipple inhibits neurons that release DA. DA normally travels via the hypothalamic-portal system to the anterior pituitary, where it inhibits PRL release by lactotrophs. Thus, inhibition of DA release leads to an increase in PRL release. Third, in the supraoptic and paraventricular nuclei of the hypothalamus, the afferent input from the nipple triggers the production and release of OT in the posterior pituitary. Fourth, in the preoptic area and arcuate nucleus, the afferent input from the nipple inhibits GnRH release. GnRH normally travels via the hypothalamic-portal system to the anterior pituitary, where it stimulates the synthesis and release of FSH and LH. Thus, inhibiting GnRH release inhibits FSH and LH release and thereby inhibits the ovarian cycle.

Several factors act as **PRL-releasing factors (PRFs)**: thyrotropin-releasing hormone (TRH), angiotensin II, substance P, β endorphin, and AVP. In rats, suckling stimulates the release of **TRH** from the hypothalamus. In lactating women, TRH leads to increased milk production. **Estradiol** modulates PRL release in two ways. First, estradiol increases the sensitivity of the lactotroph to stimulation by TRH. Second, estradiol decreases the sensitivity of the lactotroph to inhibition by DA.

During the first 3 weeks of the neonatal period, maternal PRL levels remain tonically elevated.

Thereafter, PRL levels decrease to a constant baseline level that is higher than that observed in women who are not pregnant. If the mother does *not* nurse her young, PRL levels generally fall to nonpregnancy levels after 1 to 2 weeks. If the mother *does* breast-feed, increased PRL secretion is maintained for as long as suckling continues. Suckling causes episodic increases in PRL secretion with each feeding, thus producing peaks in PRL levels superimposed on the elevated baseline PRL levels. After the infant completes a session of nursing, PRL levels return to their elevated baseline and remain there until the infant nurses again.

OT and psychic stimuli initiate milk ejection (“let-down”)

OT, which can promote uterine contraction, also enhances milk ejection by stimulating the contraction of the network of myoepithelial cells surrounding the alveoli and ducts of the breast (galactokinetic effect). Nursing can sometimes cause uterine cramps. During nursing, suckling stimulates nerve endings in the nipple and triggers rapid bursts of OT release (see [Fig. 56-12](#)). This neurogenic reflex is transmitted through the spinal cord, the midbrain, and the hypothalamus, where it stimulates neurons in the paraventricular and supraoptic nuclei that release OT from their nerve endings in the *posterior pituitary*. From the posterior pituitary, OT enters the systemic circulation and eventually reaches the myoepithelial cells that are arranged longitudinally on the lactiferous ducts and around the alveoli in the breast (see [Fig. 56-11C, D](#)). Activation of OTRs causes these cells to contract by mechanisms similar to those for the contraction of uterine smooth muscle (see p. [1146](#)). The result is to promote the release of pre-existing milk after 40 to 60 seconds, a process known as the **let-down reflex**.

In addition to the suckling stimulus, many different psychic stimuli emanating from the infant, as well as neuroendocrine factors, promote OT release. The site or sound of an infant may trigger milk let-down, a phenomenon observed in many mammals. Thus, the posterior pituitary releases OT episodically even in anticipation of suckling. Fear, anger, or other stresses suppress this psychogenic reflex, thus inhibiting OT release and suppressing milk outflow.

Suckling inhibits the ovarian cycle

Lactation generally inhibits cyclic ovulatory function. Suckling likely reduces the release of gonadotropin-releasing hormone (GnRH) by neurons in the arcuate nucleus and the preoptic area of the hypothalamus (see [Fig. 56-12](#)). Normally, GnRH travels through the portal vessels to the gonadotrophs in the anterior pituitary. Thus, the decreased GnRH release induced by suckling reduces the secretion of follicle-stimulating hormone (FSH) and LH and has a negative effect on ovarian function. As a result, breast-feeding delays ovulation and normal menstrual cycles. However, if the mother continues to nurse her infant for a prolonged period, ovulatory cycles will eventually resume. Suckling intensity and frequency, which decrease with the introduction of supplementary foods to the infant, determine the duration of anovulation and amenorrhea in well-nourished women. In breast-feeding women in Bangladesh, the period of anovulation averages 18 to 24 months. If the mother does *not* nurse her child after delivery, ovulatory cycles resume, on average, 8 to 10 weeks after delivery, with a range of up to 18 weeks.

Fetal and Neonatal Physiology

George Lister, Ervin E. Jones

Fetal development is a highly organized process. The most rapid phase of growth transpires in at a degree of hypoxemia that mimics ascent to Mount Everest, while nutrients reach the fetus indirectly, from the maternal circulation. The transition to the extrauterine environment occurs abruptly and is likewise extraordinarily well orchestrated. Indeed, within a matter of seconds, the breathing infant can supply sufficient oxygen to the tissues because of gas exchange in the previously fluid-filled newborn lung and rapid redirection of blood flow from fetal to adult pathways. Finally, the newborn must acclimate to its new milieu, where numerous homeostatic challenges confront the newly autonomous organs. Accordingly, the subchapters here address the growth of the fetus, the development of the cardiopulmonary system, the transition to the extrauterine environment, and early neonatal functions.

Biology of Fetal Growth

Growth of the fetus begins soon after fertilization, when the first cell division occurs. Cell division, hypertrophy, and differentiation are well-coordinated events that result in the growth and development of specialized organ systems. The fetus, fetal membranes, and placenta develop and function as a unit throughout pregnancy, and their development is interdependent. The growth trajectory of fetal mass is relatively flat during the first trimester, increases linearly at the beginning of the second trimester, and rises rapidly during the third trimester. Before addressing the details of growth, we describe the physiological factors that govern transport of nutrients and waste between the fetus and the placenta.

Two distinct circulations—fetoplacental and uteroplacental—underlie the transfer of gases and nutrients

The fundamental difference between the circulatory system of the fetus and that of the infant/adult is the presence of the placenta, which produces essential hormones (e.g., progestins, estrogens, chorionic gonadotropins) and performs a number of vital functions (e.g., gas exchange, nutrient transport, fluid balance, and waste removal) that other systems provide in extrauterine life. The fetus accomplishes these tasks by directing a large fraction of fetal blood flow from the aorta via the two umbilical arteries to the *fetoplacental circulation* within chorionic villi (see [p. 1137](#)). There the umbilical arteries branch into small tufts of vessels (villus capillaries) that come into apposition with the maternal *uteroplacental circulation*, which has a high blood flow (see [pp. 1136–1137](#)). The placental membranes (the syncytiotrophoblast) that separate these two distinct circulations permit the efficient exchange of respiratory gases, fluid, and larger molecules that are critical to sustain growth and maintain homeostasis. Accordingly, disturbances in the placental circulation or delivery of nutritive substrates can have serious consequences for the growth and development of the fetus.

The transfer of respiratory gases occurs by diffusion, driven by the partial pressure differences of these gases in various compartments, as is the case in the lungs after birth (see [pp. 660–661](#)). The uterine arterial blood enters the placenta with a P_{O_2} of 80 to 100 mm Hg, whereas umbilical arterial blood enters with a P_{O_2} of ~20 mm Hg, so that O_2 diffuses from the uterine to the umbilical circulation. The result is that the effluent umbilical venous blood has a P_{O_2} of about 35 to 50 mm Hg, whereas the uterine venous P_{O_2} is consistently higher by 4 to 15 mm Hg. This difference is analogous to the alveolar-arterial P_{O_2} gradient (see [p. 698](#)). However, with some substances, such as creatinine, the concentration is the same in fetal and maternal blood. Amino acids are transported across the syncytiotrophoblast and then diffuse into the fetal circulation. Transfer of immunoglobulin G, a protein that provides passive immunity from the mother, is by receptor-mediated endocytosis (see [p. 42](#)). Fluid movement obeys the principles of Starling forces (see [pp. 467–468](#)).

Growth occurs by hyperplasia and hypertrophy

The growth of an organ occurs as a result of an increase in cell number (**hyperplasia**), an increase in cell size (**hypertrophy**), or both. Growth follows three sequential phases that are organ specific: (1) pure hyperplasia, (2) hyperplasia and concomitant hypertrophy, and (3) hypertrophy alone. For example, the

placenta goes through all three phases of growth, but these phases are compressed because the placental life span is relatively short. Moreover, simple hypertrophy is the primary form of placental growth. Thus, the weight, RNA content, and protein content of the human placenta increase linearly until term, but cell number does not increase during the third trimester. Disturbances of placental growth have secondary consequences for the fetus. Perhaps the most important factor that currently can be modified is maternal smoking, which contributes to a reduction of birth weight and raises the risk of chronic disease in the offspring, as both a child and an adult.

In contrast to placental growth and development, growth of the **fetus** occurs almost entirely by hyperplasia. Thus, DNA content increases linearly in all fetal organs beginning early in the second trimester. Stimuli that either increase or decrease cell number, cell size, or both may accelerate or retard the growth of the whole fetus or of individual organs. The phase of growth during which the stimulus acts determines the response of the organ. For example, chromosomal aneuploidy is likely to have an effect on growth throughout gestation, whereas malnutrition or substance abuse will impair growth only when the exposure is present. Although some effects—such as those of malnutrition on growth—are reversible, there may also be long-term consequences for health.

Growth depends primarily on genetic factors during the first half of gestation and on epigenetic factors thereafter

The fertilized egg contains the genetic material that directs cell multiplication and differentiation and guides development of the human phenotype. For specific developmental events to occur at precise times, a programmed sequence of gene activation and suppression is necessary.  **N57-1** Ignoring apoptosis, the fertilized egg must undergo an average of ~42 divisions before newborn size is reached. A fertilized ovum weighing less than 1 ng gives rise to a newborn weighing slightly more than 3 kg (an increase of >10¹² fold). Not only must the total cell number in a term fetus lie within relatively narrow limits, but also the developmental program must trigger cell differentiation after a specified number of cell divisions. After birth, only approximately five additional divisions are necessary for the net increase in mass that is necessary to achieve adult size. However, many tissues (e.g., gastrointestinal tract, skin, blood cells) must continually undergo cell division to replenish cells lost by apoptosis.

N57-1

Chronological Development of Organs, Systems, and Body Form

Contributed by Ervin Jones

eTable 57-1 summarizes major developmental events during the first 7 weeks of intrauterine life.

eTABLE 57-1

Chronological Development of Organs, Systems, and Body Form

ORGAN	CHRONOLOGY OF DEVELOPMENT
Bronchial apparatus and pharyngeal pouches	4th week, ridges and grooves appear over the future neck region
Thyroid gland	4th week, endoderm appears over the floor of the pharynx
Tongue	4th week, primordia appear in the floor of the pharynx
Face	End of 4th week, primordia appear
Palate	Begins in the 5th week
Upper respiratory system	4th week, laryngotracheal groove appears
Digestive system	4th week, primitive gut forms
Foregut derivatives	4th week, formation of midgut derivatives begins
Pharynx and its derivatives	
Lower respiratory tract	
Esophagus, stomach, proximal duodenum (from stomach to entry of the common bile duct)	
Liver, biliary tract, gallbladder, pancreas	
Midgut derivatives	6th week, primordia appear, midgut elongates
Small intestine, except proximal duodenum	
Cecum, appendix	
Ascending colon and proximal half of transverse colon	
Hindgut derivatives	End of 7th week, anal canal has formed
Distal half of transverse colon	
Descending and sigmoid colon	
Rectum and upper portion of anal canal	
Part of the urogenital system	
Kidneys, urinary bladder, urethra	5th week, permanent adult kidney begins to develop
Adrenal glands	5th week, primordia of adrenal glands develop
Gonads, genital ducts, external genitalia	5th week, gonadal ridges form
Heart	3rd week, development of the heart begins
Atria	5th week, the atria are formed
Ventricles	5th week, the ventricles form
Fetal circulation	3rd week, embryonic blood vessels develop
Brain and spinal cord	End of 4th week, primary vesicles form and walls of the neural tube thicken to form the spinal cord
Pituitary	6th week, connection of Rathke's pouch with oral cavity disappears
Limbs	End of 4th week, limb buds appear
Skull	7th week, paired cartilages begin to fuse to form the cranium

Although the genetic makeup of the fetus principally determines its growth and development, other influences—both stimulatory and inhibitory—are superimposed on the genetic program. During the first half of pregnancy, the fetus's own genetic program is the primary determinant of growth, and thus constrains patterns of growth. During the second half of pregnancy, the patterns of growth and development are more variable. The four primary epigenetic factors at work during the second half of pregnancy are placental, hormonal, environmental (e.g., maternal nutrition), and metabolic (e.g., diabetes). We discuss the first two factors (placental and hormonal) in the next two sections.

Studies in both healthy and growth-restricted infants have identified the important determinants of newborn body mass (Fig. 57-1). The use of fetal ultrasonography now permits repetitive determination of measures of fetal growth, such as femur length, distance between the two parietal eminences of the head (biparietal diameter), head circumference, and abdominal circumference. For example, a healthy male infant gains 25 to 30 g/day during the last trimester of pregnancy. The ultrasound measurements provide valuable information about growth during gestation, whereas previously we made assumptions based solely on birth weight.

FIGURE 57-1 Relative importance of established factors with direct causal impacts on intrauterine growth retardation in developed countries. The sizes of the sectors do not reflect possible variations within countries related to sociodemographic factors. For discussion of growth restriction, see [Box 57-1](#). LBW, low birth weight. (Kramer MS: Determinants of low birth weight: Methodological assessment and meta-analysis. *Bull World Health Organ* 65[5]:663–737, 1987.)

The mother's contribution to the fetal environment includes maternal health and nutritional status, age (e.g., adolescents and older women have infants with lower birth weight), parity, prepregnancy weight and prenatal weight gain, height, and cigarette smoking, although factors vary in importance depending on the environment (e.g., maternal infection with malaria is a significant factor in endemic areas). The father contributes to birth weight only via the genes that he passes on to his child, with the correlation between father and infant being ~12%. The correlation with maternal weight is ~22%. From observations in cases of oocyte donation, it is apparent that newborn weight is related more to anthropometric measures of the mother than of the father. The paternal body size has a small influence on fetal lean mass, and fetal sex also has a small effect (males have somewhat higher lean body mass). Multiparity and premature birth both correlate with low birth weight, and both have become more common with artificial fertilization techniques.

Increases in placental mass parallel periods of rapid fetal growth

The placenta plays several important roles in fetal growth and development. In addition to serving transport and storage functions, the placenta is involved in numerous biosynthetic activities. These include the synthesis of steroids, such as estrogen and progesterone, and of protein hormones, such as human chorionic gonadotropin (hCG) and the human chorionic somatomammotropins (hCSs; see [p. 1139](#)).

Fetal growth closely correlates with placental weight and trophoblast surface area. During periods of rapid fetal growth, placental weight increases. As the placental mass increases, the total surface area of the placental villi (see [p. 1136](#)) increases to sustain gas transport and fetal nutrition. Moreover, maternal blood flow to the uterus and fetal blood flow to the placenta also increase in parallel with the increase in placental mass. Placental growth increases linearly until ~4 weeks before birth, and adequate placental reserve is particularly important during the third trimester, when fetal growth is very rapid. **Fetal growth**

restriction (Box 57-1) can occur as a result of decreased *placental reserve* caused by any insult. For example, mothers who smoke during pregnancy tend to have small placentas and are at high risk of delivering a low-birth-weight baby.

Box 57-1

Growth Restriction

Growth restriction is an important common pathway for many conditions that significantly increase infant morbidity and mortality, and it is also associated with many short- or long-term consequences. Some of the most important morbidities associated with growth restriction are birth asphyxia, neonatal hypoglycemia, necrotizing enterocolitis, hypocalcemia, meconium aspiration, persistent pulmonary hypertension of the newborn, pulmonary hemorrhage, thrombocytopenia, polycythemia, delayed neurological development, and hypothermia.

Two general terms describe an abnormality of fetal growth: (1) **small for gestational age**, which is based on birth weight; and (2) **intrauterine growth restriction (IUGR)**, which is based on the rate of fetal growth as detected by ultrasonography. Both terms describe infants who, for a variety of reasons, weigh much less than population-based norms (based on fetal growth curves); we will use the term IUGR.

IUGR has been variously defined as a birth weight lower than the 3rd, 5th, or 10th percentile for gestational age, or a birth weight that is more than two standard deviations lower than the mean for gestational age. Similar norms for body length and head circumference permit us to characterize growth restriction and determine whether it is symmetrical (i.e., anthropometric factors are uniformly decreased) or asymmetrical (e.g., weight is affected more than length, which is affected more than head growth). These distinctions are made by obtaining careful measurements at birth and then plotting length, weight, and head circumference on standard curves for the appropriate sex, gestational age, and comparable population.

The three general categories of IUGR are related to the time of onset of the pathological process as follows.

Symmetrical IUGR applies to infants whose length, weight, and abdominal and head circumferences are all less than the 10th percentile for gestational age. This type usually results from long-standing growth limitation that arises during early stages of fetal development (4 to 20 weeks' gestation). The result is fewer cells in the fetus. Causes include intrauterine infections (e.g., rubella, cytomegalovirus infection), chromosomal disorders, and congenital malformations. Maternal drug ingestion, excessive alcohol consumption, and smoking can also produce this pattern depending upon the length of exposure. Of fetuses with severe, early onset of growth restriction, ~25% have aneuploidy (i.e., abnormal number of chromosomes). The symmetrically diminished growth of these fetuses may result from inhibition of mitosis during early development.

Asymmetrical IUGR, which accounts for 70% to 80% of growth restriction in fetuses, is most frequently caused by uteroplacental insufficiency. Compared to symmetrical IUGR, this type of growth restriction results from an insult that occurs either later in gestation (usually after 28 weeks) or more briefly. Late in the second trimester, hypertrophy dominates as the means for growth and there is a rapid increase in cell size and increases in the formation of fat, muscle, bone, and other tissues. For fetuses with asymmetrical growth restriction, head growth is less impaired than weight gain. This form of IUGR is most often associated with small placentas and maternal conditions such as kidney disease, chronic hypertension, severe diabetes mellitus, or multiple gestation.

Intermediate IUGR is a combination of symmetrical and asymmetrical IUGR, accounting for 5% to 10% of all cases of fetal growth restriction. It probably occurs during the middle phase of fetal growth (20 to 28 weeks), between the hyperplastic and hypertrophic phases. During this middle period, mitotic rate decreases and overall cell size increases progressively. Chronic hypertension, lupus nephritis, or other vascular diseases in the mother that are severe and begin early in the second trimester may result in intermediate IUGR in the fetus, with symmetrical growth and no significant brain-sparing effect.

Insulin, the insulin-like growth factors, and thyroxine stimulate fetal growth

In [Chapter 48](#), we discussed several hormones—including glucocorticoids, insulin, growth hormone (GH), the insulin-like growth factors (IGFs), and thyroid hormones—that are important for achieving final adult mass.

Glucocorticoids and Insulin

As its major energy source, the growing fetus uses glucose, which moves across the placenta by facilitated diffusion via the glucose transporter GLUT1 (see [p. 114](#)). Unlike the adult, who uses sophisticated hormonal systems to control blood glucose levels ([pp. 1035–1050](#), [1050–1053](#), [1018–1026](#), and [1033](#)), the fetus is passive: the exchange of glucose across the placenta controls fetal blood glucose levels. The fetus normally has little need for gluconeogenesis, and the levels of gluconeogenic enzymes in the fetal liver are low. **Glucocorticoids** in the fetus promote the storage of glucose as glycogen in the fetal liver, a process that increases greatly during the final month of gestation in preparation for the increased glycolytic activity required during and immediately after delivery. Near term, when fetal glucose metabolism becomes sensitive to **insulin**, this hormone contributes to the storage of glucose as glycogen, as well as to the uptake and utilization of amino acids and lipogenesis (see [pp. 1035–1050](#)). In mice, knockout of the insulin receptor causes slight growth restriction in the fetus, whereas the additional knockout of the insulin gene severely reduces birth weight. Transient increases in maternal blood glucose levels after meals are closely mirrored by increases in fetal blood glucose levels. However, maternal insulin cannot cross the placenta, and this transient fetal hyperglycemia leads to increased fetal production of insulin.

Sustained hyperglycemia in mothers with poorly controlled diabetes (see [Box 51-5](#)) causes sustained fetal hyperglycemia, and therefore fetal hyperinsulinemia. The resulting high levels of fetal insulin, which is a growth factor (see [pp. 999–1000](#)), increase both the size of fetal organs (organomegaly) and fetal body mass (macrosomia; see [p. 999](#)). During the last half of the third trimester, fetal weight in pregnant women with poorly controlled diabetes generally exceeds that in normal pregnant women. In some cases, large fetal size leads to problems at delivery, prompting cesarean section. However, in mothers with severe diabetes, the placenta shows evidence of vascular insufficiency and the infants may be growth restricted.

Insulin-Like Growth Factors

Postnatally, **GH** acts by binding to the GH receptor (GHR; see [p. 994](#)), primarily in the liver, and triggering the production of somatomedin or IGF-1. IGF-2 is not so much under the control of GH. The IGF-1 receptor is similar, but not identical, to the insulin receptor and can bind both IGF-1 and IGF-2, as well as insulin (see [p. 996](#)). In the fetus, both IGF-1 and IGF-2, which are mitogenic peptides, are

extremely important for growth. IGF-1 and IGF-2 are present in the fetal circulation from the end of the first trimester, and their levels increase thereafter in both mother and fetus. Birth weight correlates positively with IGF levels. However, both relative levels of the IGFs and control of the IGFs are very different in the fetal stage than they are postnatally. First, fetal IGF-2 levels are much higher than IGF-1 levels; soon after birth, IGF-1 and IGF-2 levels resemble those in adults. Second, in the fetus, both IGF-1 and IGF-2 levels correlate poorly with GH levels. GH levels, which are much higher than postnatally, may have only a limited influence on fetal growth because GHRs are not as abundant (e.g., in liver) as they are after birth. This observation may explain why anencephalic fetuses (see [Box 10-2](#)), which have low GH levels, generally grow normally in utero. On the other hand, GH-deficient infants are often shorter than normal infants.

Epidermal Growth Factor

The fetus has abundant epidermal growth factor (EGF) receptors (see [p. 68](#)), and EGF is well known for its mitogenic properties, especially with regard to development of ectodermal and mesodermal structures. However, the fetus has no detectable mRNA encoding EGF. On the other hand, transforming growth factor- α (TGF- α), another potent mitogen that binds to EGF receptors on target cells, may act as a ligand for the EGF receptor; its mRNA is present widely in human fetal tissues.

Thyroid Hormones

The thyroid hormones are obligatory for normal growth and development (see [pp. 1013–1014](#)). Before the second trimester, most of the thyroxine (T_4) in the fetus is maternal. Fetal production of thyrotropin (or thyroid-stimulating hormone [TSH]) and T_4 begin to increase in the second trimester, concurrent with development of the hypothalamic-pituitary portal system. Hypothyroidism has adverse effects on fetal growth, generally reflected as a reduction in the size of organs such as the heart, kidney, liver, muscle, and spleen.

Peptide Hormones

Peptide hormones secreted by the placenta (see [Table 56-4](#)) can act via endocrine, paracrine, and autocrine mechanisms to stimulate growth and differentiation in several organ systems.

Many fetal tissues produce red blood cells early in gestation

During early gestation, islands of cells form within the yolk sac, some of which become primitive blood cells or hemocytoblasts. This phase of hematopoiesis ends by 6 weeks' gestation. Later, red blood cell (RBC) production (erythropoiesis; see [pp. 431–433](#)) occurs in many tissues not normally thought of as erythropoietic in the adult. At about the fourth week of gestation, the endothelium of blood vessels and the mesenchyme also begin to contribute to the pool of RBCs, followed shortly by the liver. The bone marrow, spleen, and other lymphoid tissues begin to produce RBCs only near the end of the first trimester. All these organ systems except bone marrow gradually lose their ability to manufacture blood cells, and by the third trimester, the bone marrow becomes the dominant source of blood cells.

RBCs formed early in gestation are nucleated, but as fetal development progresses, more and more of the circulatory RBCs are non-nucleated. The blood volume in the common circulation of the fetoplacental unit increases as the fetus grows. The fraction of total RBCs that are reticulocytes [N57-2](#) (immature, non-nucleated erythrocytes with residual polyribosomes) is high in the young fetus, but it decreases to

only ~5% at term. In the adult, the reticulocyte count is normally <1%. The life span of fetal RBCs depends on the age of the fetus; in a term fetus, it is ~80 days, or two thirds that in an adult (see [pp. 431–433](#)); it is shorter in the less mature fetus.

N57-2

Reticulocytes

Contributed by Emile Boulpaep, Walter Boron

As discussed on pages 431–433, **reticulocytes** are immature erythrocytes (also known as red blood cells, or RBCs). These cells are called reticulocytes—or “retics” in the slang—because certain stains (e.g., new methylene blue) reveal a mesh-like “reticular” network due to the presence of ribosomal RNA. In the adult, retics make up about 1% of all RBCs.

Embryonic **hemoglobin (Hb)** with different combinations of α -type chains (α and ζ) and β -type chains (ϵ and γ ; see [Table 29-1](#)) is present very early in gestation. Production of ζ and ϵ chains ceases by 8 weeks, and programmed development  [N4-5](#) governs increased synthesis of fetal Hb (HbF, $\alpha_2\gamma_2$), which predominates at birth. Adult Hb (HbA, $\alpha_2\beta_2$) and a small amount of HbA₂ ($\alpha_2\delta_2$) gradually replace HbF during the first 12 months of life until eventually the adult pattern of Hb expression is established (see [Table 29-2](#)). An exception is in certain genetic abnormalities of α - or β -chain production (e.g., thalassemia), in which HbF persists.

The Hb content ([Hb]) of fetal blood rises to ~15 g/dL by midgestation, equivalent to the level in normal men (see [p. 434](#)) and higher than [Hb] in maternal blood, which may be only ~12 g/dL. Fetal [Hb] increases near term and is ~17 g/dL in full-term infants and slightly less in premature infants. Postnatally, a substantial decrease in [Hb], with a nadir of ~11 g/dL near 2 months of age, is termed the *physiological anemia of infancy* because it does not respond to administration of iron or other hematinic agents. This level of anemia does not affect the well-being of an otherwise healthy infant. However, infants who are born prematurely (and therefore with a lower nadir) or who have other disturbances in O₂ transport (e.g., hypoxemia, impaired cardiac output) can exhibit irritability, failure to grow normally, or tissue hypoxia.

The fetal gastrointestinal and urinary systems excrete products into the amniotic fluid by midpregnancy

The fetus imbibes considerable quantities of amniotic fluid by 20 weeks' gestation. However, not until the final 12 weeks of gestation is fetal gastrointestinal function similar to that of the normal infant at term. The fetal gastrointestinal tract continuously excretes small amounts of meconium into the amniotic fluid.

Meconium consists of excretory products from the gastrointestinal mucosa and glands, along with unabsorbed residua from the imbibed amniotic fluid.

By the beginning of the second trimester, the fetus also begins to urinate. Fetal urine constitutes ~75% of amniotic-fluid production (see [p. 1137](#)). The fetal renal system does not acquire the capacity to regulate fluid, electrolyte, and acid-base balance until the beginning of the third trimester. Although the fetus has its final number of nephrons by 34 to 36 weeks' gestation, full development of renal function does not occur until several months following delivery, owing primarily to continued development of renal tubules and increased renal blood flow.

A surge in protein synthesis, with an increase in muscle mass, is a major factor in the rapid fetal weight gain during the third trimester

Fetal tissues constantly synthesize and break down proteins. Protein synthesis predominates throughout gestation, especially during the third trimester, when fetal protein synthesis—primarily in muscle and liver—increases 3- to 4-fold. The number of ribosomes per cell increases throughout gestation and early postnatal life. The efficiency of ribosomes at translating mRNA may also improve during gestation. Substrate availability (i.e., amino acids) and modulation of the synthetic apparatus by endocrine and other factors play important roles in regulating protein synthesis during gestation.

The formation of each peptide bond requires four molecules of ATP, so the energy cost of protein synthesis is 0.86 kcal/g. Protein synthesis comprises 15% to 20% of fetal metabolic expenditure in the third trimester. At equivalent phases of development, fetuses across several species invest similar fractions of total energy in protein synthesis. Because glucose is the major metabolic fuel, a shortfall of oxidized metabolic substrates (e.g., glucose and lactate) directly limits protein synthesis.

Increases in skeletal muscle mass account for 25% to 50% of fetal weight gain during the second half of gestation, when the number of muscle cells increases 8-fold and cell volume increases ~2.6-fold. Although skeletal muscle fibers are not differentiated in the first half of gestation, distinct type I and type II muscle fibers (see [pp. 249–250](#)) appear in equal amounts between 20 and 26 weeks of gestation.

Fetal lipid stores increase rapidly during the third trimester

Fetal fat stores account for only 1% of fetal body weight during the first trimester. By the third trimester, as much as 15% of fetal body weight is fat. At birth, humans have more fat than other warm-blooded animals (e.g., the newborn cat has 2%; the guinea pig, 9.5%; the rat, 11%), with the exception of hibernating mammals and migratory birds.

Approximately half the increase in body fat reflects increased lipid transport across the placenta, and the other half reflects increased fatty acid (FA) synthesis in the fetal liver. Blood levels of fetal lipids (i.e., triacylglycerols, FAs, and ketone bodies) remain low before 32 weeks' gestation. In the last 2 months, the fetus increases its lipid storage as triacylglycerols in white and brown adipose tissue as well as in liver. During this period, both subcutaneous fat (i.e., white fat) and deep fat (i.e., white and brown fat) increase exponentially. The stored fat ensures adequate fuel stores for postnatal survival, and it also provides thermal insulation to the newborn. In addition, brown fat is important for thermogenesis in the postnatal period.

Several factors are responsible for increased lipid stores in the near-term fetus. Increases in fetal albumin facilitate FA transfer across the placenta. Insulin acts on fetal hepatocytes to stimulate lipogenesis. Insulin also promotes the availability of substrates, including glucose and lactate, which in turn increase the synthesis of fat (see [pp. 1047–1050](#)).

Development and Maturation of the Cardiopulmonary System

Fetal lungs develop by repetitive branching of both bronchial and pulmonary arterial trees

Two critical factors make gas exchange in the infant lung as effective as that in the adult lung: (1) the structural growth and coincident branching of lung segments and blood vessels that creates an extensive alveolar-capillary interface for efficient diffusion of gases, and (2) the production of surfactant (see pp. 613–615), which permits lung expansion without excessive inspiratory effort. The fetal lung begins as an outpouching of the foregut at ~24 days' gestation. Several days later, this lung bud branches into two tubular structures, the precursors of the main bronchi. At 4 to 6 weeks' gestation, the bronchial tree begins to branch repetitively. The further maturation of the lungs occurs in four overlapping phases:

- 1. Pseudoglandular period (5 to 17 weeks).** The lung “airways” resemble branching exocrine glands, with acinar buds forming in the peripheral lung.
- 2. Canalicular period (16 to 26 weeks).** The creation of channels (canalization) within the airways is complete when ~17 generations of airways have formed, including the respiratory bronchioles. Each respiratory bronchiole gives rise to as many as six alveolar ducts, which give rise to the primitive alveoli during the second trimester. The branching of the pulmonary *arterial* tree, which begins during the pseudoglandular period, parallels both temporally and spatially the branching of the *bronchial* tree. However, at ~24 weeks' gestation, considerable interstitial tissue separates the capillaries from the respiratory epithelium.  N57-3
- 3. Saccular period (24 to 38 weeks).** The respiratory epithelium thins greatly, with loss of connective tissue, and the capillaries push into the alveolar sacs. The potential for gas exchange improves after ~24 weeks' gestation, when capillaries proliferate and come into closer proximity to the thin type I alveolar pneumocytes (see p. 599). During this period, surfactant synthesis and storage begin (although not extensively) in the differentiated type II cells.
- 4. Alveolar period (late fetal life through early childhood).** Alveoli-like structures are present at ~32 weeks' gestation, and at 34 to 36 weeks' gestation, 10% to 15% of the adult number of alveoli are present. Alveolar number continues to increase until as late as 8 years of age.

N57-3

Alveolar-Capillary Distances in the Fetus at 24 Weeks

Contributed by Henry Binder

If the fetus were born at 24 weeks of development, the premature infant would have a very low diffusing capacity (see pp. 663–664) owing to the great distance between the edge of the alveolar lumen and the edge of the capillary lumen.

An increase in cortisol, with other hormones, triggers surfactant production in the third trimester

Hormones play a major role in controlling fetal lung growth and development in preparation for ex utero function. A key target is surfactant (see [pp. 613–615](#)), which increases lung compliance (see [pp. 615–616](#)) and thereby reduces the effort of inspiration. Numerous hormones stimulate surfactant biosynthesis, including glucocorticoids, thyroid hormones, thyrotropin-releasing hormone, and prolactin, as well as growth factors such as EGF. Glucocorticoids, in particular, play an essential role in stimulating fetal lung maturation by increasing the number of both type II pneumocytes and lamellar bodies (see [pp. 614–615](#)) within these cells. Glucocorticoid receptors are probably present in lung tissue at midterm. Fetal cortisol levels rise steadily during the third trimester and surge just before birth. Two thirds of this cortisol is of fetal origin; the rest crosses the placenta from the mother.

The predominant phospholipid in surfactant is **dipalmitoylphosphatidylcholine (DPPC)** (see [pp. 613–614](#)). At ~32 weeks' gestation, increases in cortisol and the other hormones mentioned previously stimulate several regulatory enzymes. [N57-4](#) Thus, the net effect is vastly increased production of pulmonary surfactant late in gestation. Coincident with increased surfactant synthesis is a large increase in lung distensibility and stability on inflation. However, in infants born prematurely with insufficient surfactant and lungs that are not structurally mature, severe respiratory distress ([Box 57-2](#)) can result. Because of the surfactant deficiency, the infant must invest excessive work to create an adequate tidal volume with each breath and to maintain a normal functional residual capacity following expiration.

Box 57-2

Infant Respiratory Distress Syndrome

Infant respiratory distress syndrome (IRDS), which affects ~30,000 newborns annually in the United States, is characterized by increased work of breathing (nasal flaring, the use of accessory musculature, intercostal and subcostal retractions, tachypnea, and grunting) and impaired gas exchange (cyanosis).

Retractions occur because the lungs—with collapsed, fluid-filled, and poorly expanded alveoli—are less compliant than the chest wall, with nonossified ribs. The increased inspiratory effort to expand the noncompliant lungs creates a very negative intrapleural pressure. As a result, the chest wall becomes distorted, caving in between the ribs or beneath or above the rib cage, so that the increased inspiratory work does not much improve tidal volume. The more immature the infant, the more severe and life-threatening the lung disease and the more likely that signs of respiratory distress become apparent immediately after birth or within a few minutes. [N57-10](#)

In more mature preterm infants, the signs of IRDS may evolve over several hours. A chest radiograph reveals atelectasis with **air bronchograms** (i.e., air-filled bronchi standing out against the white background of collapsed lung tissue) and pulmonary edema. The edema and consolidation or collapse of alveoli can produce severe restrictive lung disease (see p. 611) and subsequent fatigue from the increased effort needed to breathe, contributing to respiratory failure that requires mechanical ventilation. Milder cases usually resolve spontaneously. IRDS occurs most commonly in premature infants, and the course is often confounded by the coexistence of a patent ductus arteriosus (see p. 1158), poor nutrition, and risk of infection. This combination of problems also raises the risk of short- and long-term complications, such as disruption of lung development (bronchopulmonary dysplasia), necrotizing enterocolitis, and intraventricular hemorrhage.

IRDS is usually caused by a deficiency of pulmonary surfactant owing to prematurity. Prematurity is by far the single most important risk factor for development of IRDS; others include male sex, delivery by cesarean section, perinatal asphyxia, second twin pregnancy, maternal diabetes, and deficiency of surfactant protein B or the ATP-binding cassette (ABC) protein ABCA3 (see p. 119). Surfactant insufficiency can result from abnormalities of surfactant synthesis, secretion, or recycling. Reduced surfactant lowers compliance directly (see pp. 615–616) and further lowers compliance indirectly because alveoli—with their propensity to collapse—tend to be on the lowest, flat part of the lung pressure-volume curve (stage 1 in Fig. 27-4B). Because of the tendency of alveoli to collapse, blood perfuses poorly ventilated or nonventilated alveoli, which results in hypoxemia (see pp. 692–693). In the extreme, when the alveoli are nonventilated, the result is venous admixture or shunt (see p. 693). In addition, capillary damage allows leakage into the alveolar space of plasma proteins, which may inactivate surfactant and thereby exacerbate the underlying condition.

The discovery that a deficiency of surfactant is the underlying problem in infants with IRDS prompted investigators to (1) develop means to assess fetal lung maturity and adequacy of surfactant production before delivery, (2) stimulate surfactant production in the fetus (by administration of corticosteroids to the mother prior to delivery), and (3) provide exogenous surfactant to the lungs until native synthesis occurs. As indicated in the following three paragraphs, each of these strategies has been a successful step in dramatically reducing the incidence and severity of IRDS.

Knowledge of lung maturity helps reduce complications in infants who are born prematurely or need to be delivered prematurely for specific medical indications related to the health of the mother or the infant. Clinical tests for assessing lung maturity exploit the knowledge that the major surfactant lipids are phosphatidylcholines (i.e., lecithins) and that phosphatidylglycerol (see pp. 613–614) is also overrepresented. A ratio of lecithin to sphingomyelin (L/S ratio) > 2.0 in the amniotic fluid is consistent with mature lungs, as is a positive result on phosphatidylglycerol assay.

Regarding surfactant production, the 2000 National Institutes of Health Consensus Development Conference *Antenatal Corticosteroids Revisited* recommended antenatal steroid therapy for pregnant women with fetuses between 24 and 34 weeks' gestational age who are at risk of preterm delivery within 7 days. This treatment accelerates lung maturation and surfactant production and diminishes the incidence of IRDS.

Finally, the postnatal administration of surfactant has dramatically reduced the mortality and improved the clinical course of IRDS, as illustrated for an experimental animal in Figure 57-2.

FIGURE 57-2 Effects of surfactant on the deflation limb of a static pulmonary pressure-volume diagram. These results are from experiments on normal rat lungs, lungs made surfactant deficient by saline lavage, and lavaged lungs subsequently treated with either DPPC or an extract from a calf-lung lavage (which also contains surfactant apoproteins SP-B and SP-C). TLC, total lung capacity. (Data from Hall SB, Venkitaraman AR, Whitsett JA, et al: Importance of hydrophobic apoproteins as constituents of clinical exogenous surfactants. *Am Rev Resp Dis* 145:24–30, 1995.)

Fetal Synthesis of Dipalmitoylphosphatidylcholine

Contributed by Ervin Jones

The predominant phospholipid in surfactant is **DPPC** (see pp. 613–614), which is synthesized as outlined in eFigure 57-1. Abundant glycogen stores in fetal type II pneumocytes serve as a primary energy and carbon source for the FAs involved in phospholipid synthesis. The condensation of diacylglycerol with cytosine diphosphate choline ultimately leads to the production of DPPC. At ~32 weeks' gestation, increases in cortisol and other hormones stimulate several regulatory enzymes, including **acetyl coenzyme A carboxylase**, **FA synthase**, and **CTP: phosphocholine cytidyl transferase**. The net effect is vastly increased production of pulmonary surfactant late in gestation. Coincident with increased surfactant synthesis is a large increase in lung distensibility and stability on inflation.

EFigure 57-1 Synthesis of DPPC. Before birth, cortisol upregulates several enzymes (highlighted in yellow) that are important for the synthesis of surfactant. CoA, coenzyme A; CDP, cytidine diphosphate; CMP, cytidine monophosphate; CTP, cytidine triphosphate; P_i , inorganic phosphate; PP_i , inorganic pyrophosphate.

N57-10

Respiratory Distress Syndrome of the Newborn

Contributed by Emile Boulpaep, Walter Boron

Two of the signs of infant respiratory distress described in Box 57-2—cyanosis and tachypnea—reflect central hypoxemia, that is, reduced oxygen content of the arterial blood. In this case, the hypoxemia is the result of poor alveolar ventilation. As described on page 652, **cyanosis** is the purplish color of poorly saturated Hb. As described in Box 32-2, **tachypnea** is an increase in respiratory rate, in this case probably caused by stimulation of both the central and peripheral chemoreceptors due to respiratory acidosis and hypoxia.

Several of the other signs described in Box 57-2—nasal flaring, intercostal and subcostal retractions, the use of accessory musculature, and grunting—are indications of low lung compliance. **Nasal flaring** (produced by cranial nerve VII; see Fig. 32-4) is a reflection of the increased inspiratory drive and is produced by one of the secondary muscles of inspiration (see point 4—upper respiratory tract muscles—on page 607). Other **accessory or secondary muscles of inspiration** also come into play. The **intercostal and subcostal retractions** are the result of the very negative intrapleural pressure (P_{IP}) generated by the young patient in an attempt to inflate its poorly compliant alveoli. **Grunting** is the sound made by closure of the glottis as the infant halts expiration at a lung volume (V_L) that is considerably higher than the true functional residual capacity (FRC) to which the lungs would deflate without grunting. This true FRC would be quite low, owing to the extremely high elastic recoil of these low-surfactant lungs. One might think of the relatively high V_L at the point of grunting as a “pseudo-FRC” from which the infant can begin the next inspiration with much less effort than if V_L had been allowed to fall all the way to the true FRC. The reason that the effort is so much less at the V_L of grunting is that the P_{TP} - V_L relationship (see Fig. 27-4B) is highly nonlinear, such that the compliance (i.e., the slope of the P_{TP} - V_L curve) is much higher at the V_L of grunting than at the V_L of the true FRC.

Fetal respiratory movements begin near the end of the first trimester but wane just before birth

Fetal breathing movements commence near the end of the first trimester, as confirmed in humans by studies using both Doppler ultrasonography and tocodynamometer (an external device that records uterine movements). It appears that hypoxia and tactile stimulation of the fetus promote these breathing movements, which occupy less than half of any 24-hour period. Near term, breathing movements are regular, similar to those found after birth. However, just before labor, fetal breathing decreases. In experimental animals, reducing breathing limits growth and expansion of the lungs.

The fetal lung undergoes many changes in preparation for birth. In utero, the alveoli and airways of the fetal lung are filled with a volume of fluid approximating the functional residual capacity (see p. 602) of the neonatal lung. The onset of labor is accompanied by increases in catecholamines and arginine

vasopressin, which decrease fluid production by the fetal lung and initiate active fluid reabsorption via epithelial Na^+ channels (ENaCs). The reabsorbed fluid moves out of the lung mainly via the pulmonary circulation and to a lesser extent via the pulmonary lymphatics. The small portion of remaining lung fluid is forced out of the trachea as the fetus passes through the birth canal (Box 57-3).

Box 57-3

Fetal Asphyxia

Any disturbance that abruptly interferes with the ability of the placenta to exchange O_2 and CO_2 between the maternal and fetal circulations can lead to *fetal asphyxia*—low P_{O_2} , high P_{CO_2} , and acidosis. Common causes include **maternal hypotension**, **abruptio placentae** (i.e., breaking away of a portion of the placenta from the uterine wall), a **prolapsed umbilical cord** (i.e., descent of the umbilical cord into the birth canal in front of the head or other part of the fetus so that it becomes compressed), and severe **anemia** or **polycythemia** (which can occur with twin-twin transfusion). A major consequence of the asphyxia is depressed myocardial function and reduced cardiac output, which further exacerbates the reduced O_2 delivery to the tissues.

In the brain, asphyxia produces substantial alterations in cerebral intracellular metabolism. As the brain is forced to shift from aerobic to anaerobic metabolism, high-energy phosphate compounds (e.g., ATP) decrease in concentration, and their breakdown products (e.g., ADP and inorganic phosphate) increase. The changes in metabolism disrupt the integrity of neurons and glia. Damage to the endothelium can cause hemorrhage with the brain parenchyma, ventricles, or choroid plexus.

Fetuses experiencing chronic O_2 deficiency in utero for a prolonged period are at increased risk after birth of metabolic derangements as well as cerebral and intraventricular hemorrhage.

The fetal circulation has four unique pathways—placenta, ductus venosus, foramen ovale, and ductus arteriosus—to facilitate gas and nutrient exchange

The circulatory system differentiates from the embryonic mesoderm, and the fetal heart begins to beat and circulate blood in the fourth week of gestation. The fundamental difference between the fetal and postnatal circulations is that the placenta performs for the fetus functions that—at least in part—are performed by four organ systems in extrauterine life: (1) the lungs (gas exchange), (2) the gastrointestinal tract (nutrition), (3) the liver (nutrition, waste removal), and (4) the kidneys (fluid and electrolyte balance, waste removal).

Just as in the mature circulation, the fetal right ventricle pumps most of its output to the gas-exchange organ (i.e., the placenta). The fetal left ventricle pumps most of its output to systemic tissues. The key principle governing the unique pattern of fetal blood flow is the presence of three **shunts** that allow blood to bypass future postnatal routes and instead direct a large fraction of deoxygenated blood to the placenta. Just as in the postnatal circulation, the relative vascular resistance of an organ determines the fraction of cardiac output distributed to that organ. Thus, the fetal heart pumps a large fraction of its output to the low-resistance placenta and smaller fractions to other organs that, in utero, have relatively high vascular resistance.

Figure 57-3 shows the placenta and the three shunts. Because the right and left fetal hearts largely pump

in *parallel* rather than in *series*, and because the inputs and outputs of these two sides mix, we define the **combined cardiac output (CCO)** as the sum of the outputs of the right and left ventricles. [Figure 57-3A](#) shows the fraction of the CCO that flows through the fetal circulatory system at important checkpoints. [Figure 57-3B](#) shows representative values for the O₂ saturation (S_{O_2}) of HbF and the P_{O_2} at these same checkpoints.

A BLOOD FLOW EXPRESSED AS PERCENT OF COMBINED CARDIAC OUTPUT

FIGURE 57-3 Fetal circulation. **A**, This schematic drawing is based on data that show the major elements of the fetal circulation obtained from studies on intact fetal lambs, with catheters inserted to measure blood flow, pressure, and O_2 content. The data serve as approximations for near-term human

fetuses, for which comparable data are not obtainable. Note that, in the main drawing, the heart is upside down for the sake of presenting the blood flow as simply as possible. The heart is right side up in the inset. Because the inputs and outputs of the right and left hearts mix, we define the CCO as the sum of the outputs of the right and left ventricles. The percent of the CCO that passes various checkpoints is represented as a number in a dark gray box. Note that the CCOs of the right ventricle (66%) and the left ventricle (34%) add up to 100%. The fetal circulation has four unique pathways: placenta, ductus venosus, foramen ovale, and ductus arteriosus. GI, gastrointestinal. **B**, This schematic drawing is the same as in **A** except that, at each checkpoint, we show the S_{O_2} of HbF against a black background and the P_{O_2} (in mm Hg) against a white background. The relationship between the S_{O_2} and P_{O_2} values is based on the O_2 saturation curve for HbF (similar to the curve labeled “Hb + CO_2 ” in Fig. 29-7). The S_{O_2} of blood at any point where two streams of blood merge is derived from the flow-weighted mixture of oxygen flows as follows: $(S_{O_2})_{\text{Merged}} = [(\text{flow} \times S_{O_2})_{\text{Stream-A}} + (\text{flow} \times S_{O_2})_{\text{Stream-B}}] / [\text{flow}_{\text{Stream-A}} + \text{flow}_{\text{Stream-B}}]$. The resultant P_{O_2} of that mixture is dictated by the HbF- O_2 dissociation curve, which shows the P_{O_2} for any S_{O_2} . The numerical values in this figure are reasonable *estimates* for a healthy near-term fetus.

Placenta

Of the CCO late in gestation, ~69% reaches the thoracic aorta (see Fig. 57-3A). About 50% of the CCO enters the placenta as deoxygenated blood through the *paired* umbilical arteries, which arise from the two common iliac arteries. This massive blood flow to the placenta not only shunts blood away from the lower trunk, but also lowers effective blood flow to all abdominal viscera, including the kidneys. The umbilical arteries branch repeatedly to form dense capillary networks within the villi (see p. 1136). As fetal blood enters the placenta, it has a lower P_{O_2} than maternal blood, so that O_2 passively diffuses from maternal to fetal blood. After O_2 equilibration across the placental membranes, the fetal blood has a higher O_2 content (see p. 650) than maternal blood because (1) HbF has a higher O_2 affinity than does HbA, and (2) fetal blood has a higher Hb content than maternal blood. The *single* umbilical vein returns well-oxygenated blood (S_{O_2} of 85%) from the placenta to the fetus.

Ductus Venosus

The relatively large volume of well-oxygenated umbilical venous blood (~50% of CCO) returns to the lower body from the placenta but bypasses the largely nonfunctional liver by shunting through the ductus venosus—the fetal first shunt. In addition, some blood from the portal circulation enters the ductus venosus. Blood from the ductus venosus then merges with blood from the inferior vena cava (~19% of CCO) that drains the lower limbs, kidneys, and splanchnic organs. Thus, ~69% of the CCO (S_{O_2} of 70%) enters the right atrium.

Foramen Ovale

The second major shunt is blood entering the right atrium and then crossing the foramen ovale—an oval hole between two flaps of tissue in the septum that divides the atria **N57-5**—to enter the *left* atrium. Of the 69% of the CCO that enters the right atrium via the inferior vena cava, ~27% of the CCO shunts through the foramen ovale directly into the left atrium. This movement represents a **right-to-left shunt**. Therefore, the left heart receives relatively well-oxygenated blood ($S_{O_2} \cong 70\%$) derived from the mixing of blood from the placenta and the caudal portion of the inferior vena cava. In addition, the left atrium

receives 7% of the CCO as poorly oxygenated blood ($S_{O_2} \cong 46\%$) from the nonfunctional lungs. Thus, the left ventricle pumps a total of $27\% + 7\% = 34\%$ of the CCO ($S_{O_2} \cong 65\%$). Because this blood enters the aorta upstream from the ductus arteriosus, it primarily flows to the coronary circulation, head, and forelimbs.

N57-5

Embryology of the Atrial Septum

Contributed by George Lister

Our understanding of atrial embryology informs us about fetal cardiac physiology. The **atrial septum primum** grows from superior to inferior to partition the atria into right and left. Before this septation is complete, small holes (foramina) develop in the midportion of the septum primum and begin to coalesce, creating an oval hole known as the **foramen ovale**. As this occurs, the **atrial septum secundum** begins to grow from superior to inferior and just to the right of the septum primum. Like a window shade, it grows down to cover the foramen ovale, but it does not grow completely to the center crux of the heart. As a result, and because the pressure in the right atrium minimally exceeds that in the left atrium in utero, the septum primum (the inferior portion of the atrial septum) is pushed away from the septum secundum and toward the left atrium, creating a “defect” in the atrial tissue that allows blood in the right atrium to move into the left atrium through the open foramen.

In the *right* atrium, $69\% - 27\% = 42\%$ of the CCO entering the right atrium from the inferior vena cava does not shunt through the foramen ovale. This relatively well-oxygenated blood ($S_{O_2} \cong 70\%$) joins the relatively poorly oxygenated 21% of the CCO ($S_{O_2} \cong 29\%$) that enters the right atrium from the superior vena cava and another 3% from the coronary vessels—a total of 24% of CCO. Because of the valve-like nature of the septum surrounding the foramen ovale, none of the incoming blood from the superior vena cava or coronary vessels shunts through the foramen ovale. Rather, it goes through the tricuspid valve to the right ventricle. Thus, the right ventricle receives $42\% + 21\% + 3\% = 66\%$ of the CCO ($S_{O_2} \cong 55\%$). The P_{O_2} in the fetal right ventricle is somewhat lower than that in the left ventricle. The blood from the right ventricle then enters the trunk of the pulmonary artery.

The right ventricle has a much larger stroke volume and pumps far more blood (66% of CCO) than the left (34% of CCO). Thus, the right ventricle has a relatively thick wall compared to its postnatal state and larger chamber volume in utero than the left ventricle. This difference is revealed in the electrocardiogram (ECG) of the newborn, which shows large right ventricular vectors and right-axis deviation compared with that of the older infant or adult. Despite the disparity in stroke volume, the two ventricles in utero pump at the same pressures because the low-resistance ductus arteriosus accepts nearly 90% of the output of the right ventricle.

Ductus Arteriosus

The third major shunt, also a right-to-left shunt, directs blood from the pulmonary artery to the aorta via the **ductus arteriosus**. The ductus arteriosus is a large vessel with substantial smooth muscle in its wall. The patency of this vessel is due to *active relaxation* of this smooth muscle, mediated by the low P_{O_2} of the perfusing blood and prostaglandins, particularly **prostaglandin E₂ (PGE₂)**. Note that the ductus

arteriosus exhibits hypoxic vasodilation, as do most systemic vessels (see [p. 478](#)). Fetal PGE_2 levels are much higher than adult levels. Administering prostaglandin inhibitors to an experimental fetal animal causes the ductus arteriosus to vasoconstrict.

Although 66% of the CCO enters the pulmonary artery, only 7% of the CCO perfuses the unventilated fetal lungs. This dichotomy reflects the high resistance of the fetal pulmonary, which is the result of hypoxic vasoconstriction (see [p. 687](#)) and acidosis, the collapsed state of the airways, and perhaps leukotrienes (particularly leukotriene D_4 [LTD_4]). The rest of the blood entering the pulmonary artery, $66\% - 7\% = 59\%$ of the CCO ($\text{S}_{\text{O}_2} \cong 55\%$), enters the descending aorta through the ductus arteriosus and mixes with the blood from the aortic arch, 10% of CCO, that did not perfuse the head and upper body ($\text{S}_{\text{O}_2} \cong 65\%$). Thus, the descending aorta receives $59\% + 10\% = 69\%$ of the CCO ($\text{S}_{\text{O}_2} \cong 60\%$), the overwhelming majority of which (50% of CCO) perfuses the placenta. While the blood is in the placenta, S_{O_2} rises from 60% to 85%.

Cardiopulmonary Adjustments at Birth

As the newborn exits the birth canal, it takes its first breath, which not only expands the lungs but also triggers a series of changes in the circulatory system. At the same time, the newborn loses its nutritional connection to the mother and confronts a cold new world. Three major challenges to metabolism accompany birth: *hypoxia*, *hypoglycemia*, and *hypothermia*. We discuss the adaptations of the respiratory and cardiovascular systems in this subchapter, and adjustments of other organ systems in the next.

Loss of the placental circulation requires the newborn to breathe on its own

Although separation of the placenta does not occur until several minutes after birth, vasoconstriction in the umbilical *arteries* terminates the ability of the placenta to deliver oxygenated blood to the newborn immediately upon birth. Thus, even though the newborn may remain attached to its placenta during the first few moments of life, it is essential that the baby begin to breathe immediately. Umbilical vasoconstriction has two origins. First, the stretching of the umbilical arteries during delivery stimulates them to constrict. Second, the sudden rise in the systemic arterial P_{O_2} in the newborn also stimulates and maintains vasoconstriction in the umbilical arteries. Birth may also be associated with an “autotransfusion” as blood in the placental circulation preferentially moves into the body of the emerging baby. Because the umbilical *veins* do not constrict as do the umbilical arteries, blood flows from placenta to newborn if the infant is held below the level of the placenta, and if the umbilical cord is not clamped. This autotransfusion may constitute 75 to 100 mL, which is a substantial fraction of the newborn's total blood volume of ~300 mL (90 mL/kg).

At birth, the newborn must transform its circulatory system from one that supports gas exchange in the placenta to one that supports O_2 and CO_2 exchange in the lungs. In addition, other circulatory adjustments must occur as the gastrointestinal tract, liver, and kidneys assume their normal roles. As the lungs become functional at birth, the pulmonary and systemic circulations shift from interconnected and *parallel* systems to separate entities that function in *series*.

Mild hypoxia and hypercapnia, as well as tactile stimuli and cold skin, trigger the first breath

The first breath is the defining event for the newborn. Not only does it inflate the lungs, but also—as discussed below—it triggers circulatory changes that convert the fetal pattern of blood flow to the adult pattern. The functional capabilities of the lungs depend on the surface area available for gas exchange, the ability of surfactant to maximize lung compliance, neural mechanisms that control breathing and the aforementioned circulatory changes.

The first breath is normally also the most difficult inspiration of a lifetime. A considerable negative pressure within the intrapleural space is necessary to overcome the effects of surface tension (stage 1 in [Fig. 27-4B](#)). The infant's first inspiratory effort requires a transpulmonary pressure (P_{TP})—the pressure difference between the intrapleural space and alveolar air spaces (see [p. 608](#))—of 60 cm H_2O to increase the lung volume by ~40 mL. In contrast, a typical adult only needs to change P_{TP} by ~2.5 cm H_2O during a

typical tidal volume of 500 mL (see [Fig. 27-5](#)). The newborn's first ventilatory effort creates an air-water interface for the first time, opening the alveoli. Breathing becomes far easier once the alveoli are open and the type II alveolar pneumocytes deliver surfactant to the air-water interface. Thus, the second inspiration may require a P_{TP} of only 40 cm H₂O. The newborn may not achieve the adult level of relative lung compliance until 1 hour after birth. Very immature neonates, who lack adequate surfactant (see [Box 57-2](#)), may have persistent difficulty expanding the lungs.

The rapid onset of breathing immediately after delivery appears to be induced by a temporary state of **hypoxia** and **hypercapnia**. In most normal deliveries, these changes in P_{O_2} and P_{CO_2} result from the partial occlusion of the umbilical cord. Tactile stimulation and decreased skin temperature also promote the onset of breathing. When newborns do not begin to breathe immediately, hypercapnia and hypoxia increase and provide further stimulation for the infant to breathe.

The peripheral and central chemoreceptors (see [pp. 709–717](#)) are responsible for sensing the blood-gas parameters (i.e., low P_{O_2} , high P_{CO_2} , and low pH), detecting asphyxia, and stimulating respiration. In addition, increased sympathetic tone may stimulate breathing at the time of birth by constricting vessels to the peripheral chemoreceptors (see [pp. 711–712](#)) and thereby lowering the local P_{O_2} in the microenvironment of the glomus cells and mimicking even more severe hypoxia. Finally, independent of the initial stimuli that trigger breathing, other central nervous system mechanisms may help to sustain breathing in the newborn. However, when asphyxia is severe, the changes in blood-gas concentrations may obtund rather than stimulate breathing, so that assisted ventilation and resuscitation are required.

The neonate's ability to control blood-gas parameters depends on the sensitivity of the lung's mechanical (i.e., stretch) reflexes, sensitivity of the central and peripheral chemoreceptors, gestational and postnatal age, ability of the respiratory muscles to resist fatigue, and effects of the sleep state. Variability in tidal volume (see [p. 601](#)) and timing of breathing as well as episodes of decreased arterial S_{O_2} (<90%) are common in healthy infants and are even more pronounced in premature infants. However, the variability decreases over the first few weeks, so that by ~1 month after normal term gestation (i.e., 44 weeks postconceptional age), periods with desaturation are rare, with no discernible differences between preterm and full-term infants.

Sleeping newborns, especially premature newborns, tend to have increased respiratory variability from breath to breath. For example, they exhibit **periodic breathing**, which consists of breaths with intermittent respiratory pauses (generally of a few to several seconds' duration) and varying tidal volumes. Periodic breathing and increased respiratory variability occur more frequently during rapid eye movement sleep than during quiet sleep, a state characterized by regular breathing, but the mechanisms underlying periodic breathing in the newborn remain unclear. [🔗N57-6](#)

N57-6

Apnea in the Newborn

Contributed by Gabriel Haddad

Apnea of prematurity or apnea in a full-term infant is defined in two ways:

1. **Statistically:** Based on the distribution of respiratory pauses in a population of infants. Using this definition, respiratory pauses >20 seconds in premature infants and >30 seconds in full-term infants during the first several months of life are too long to be normal and hence are termed apneas.

2. Physiologically: Based on the physiological consequences of respiratory pauses. For example, if a respiratory pause induces deleterious cardiovascular effects (e.g., bradycardia or cyanosis), that respiratory pause may also be termed apnea even if the duration of the apnea is <20 or 30 seconds as stated above. Hence, this latter definition is based on functional consequences and is therefore more clinically relevant.

At birth, removal of the placenta increases systemic vascular resistance, whereas lung expansion decreases pulmonary vascular resistance

As noted on [pages 1157–1158](#), the fetal circulation has four unique pathways for blood flow absent in the adult: the placental circulation, ductus venosus, foramen ovale, and ductus arteriosus. In this and the next three sections, we discuss the closure of each of these four pathways.

At birth, blood flow to the placenta ceases when the umbilical vessels are ligated, and the shunts progressively disappear over the ensuing hours to days. In addition, the pulmonary circulation, which received only ~7% of the CCO in the fetus, now accepts the entire cardiac output.

Removal of the Placental Circulation

The placental circulation, which receives ~50% of the CCO (see [Fig. 57-3A](#)), represents a major parallel path in the systemic circulation and accounts for the low vascular resistance of the fetal systemic circulation. When the placental circulation disappears at birth, the total peripheral resistance doubles. Because blood flow through the descending aorta is essentially unchanged, aortic and left ventricular systolic pressure must increase.

Increase in Pulmonary Blood Flow

During fetal life, hypoxic vasoconstriction (see [p. 687](#)) markedly limits pulmonary blood flow and thereby diverts right ventricular flow through the ductus arteriosus. At birth, pulmonary vascular resistance abruptly decreases >5-fold with breathing ([Fig. 57-4](#)), owing to lung expansion, an increase in alveolar P_{O_2} , a decrease in alveolar P_{CO_2} —each of which has discernible independent effects—and perhaps the release of PGI_2 (or prostacyclin). As a result, blood flow through the pulmonary vasculature increases by ~4-fold at birth, whereas pulmonary arterial and right ventricular pressure fall abruptly. These pressures continue to decline over the ensuing few months because of a regression of the pulmonary arterial musculature, growth of new pulmonary vessels, and, to some extent, the decline in blood viscosity as hematocrit falls.

FIGURE 57-4 Effect of birth on pulmonary vascular resistance, blood flow, and mean arterial pressure.

In the fetus, pulmonary vascular resistance is high, pulmonary blood flow is low, and mean pulmonary arterial pressure is high. At birth, each of these three situations rapidly reverses. The primary event is the fall in resistance, which occurs because (1) the pulmonary blood vessels are no longer being crushed; (2) breathing causes an increased P_{O_2} , which in turn causes vasodilation; and (3) local prostaglandins cause vasodilation. The reason that pressure falls after birth is that the fall in pulmonary vascular resistance is greater than the rise in blood flow. (Data from Rudolph AM: *Congenital Diseases of the Heart: Clinical-Physiological Considerations*. Armonk NY, Futura, 2001.)

Closure of the ductus venosus within the first days of life forces portal blood to perfuse the liver

Although blood flow through the umbilical vein ceases soon after birth, the majority of the portal blood continues to flow through the ductus venosus. Thus, immediately after birth, portal flow through the liver remains low. However, within a few days after term birth (longer after preterm birth), constriction of the vascular smooth muscle within the ductus venosus causes functional closure of this shunt pathway. As a result, pressure in the portal vein increases markedly, thereby diverting blood into the liver. The mechanisms underlying the contraction of the muscular walls of the ductus venosus remain unknown.

Closure of the foramen ovale occurs as left atrial pressure begins to exceed right atrial pressure

After birth, the decrease in the pulmonary vascular resistance permits increased blood flow through the lungs, which increases venous return to the left atrium and elevates **left atrial pressure**. At the same time, the increase in pulmonary blood flow, the closing of the ductus arteriosus, and the increase in systemic resistance (due to removal of the placenta) conspire to decrease blood flow down the descending aorta and thus the venous return to the right atrium. As a result, **right atrial pressure** falls. The net effect of the rise in left atrial pressure and the fall in right atrial pressure is a reversal of the pressure gradient across the atrial septum that pushes a flap of tissue—which previously protruded into the left atrium—back against the septum, functionally closing the foramen ovale (Fig. 57-5A). Closing the foramen usually prevents flow of blood from the left to the right atrium of the newborn.

FIGURE 57-5 Changes in the circulation at and around birth. **A**, The closure of the foramen ovale and ductus arteriosus establish separate right and left circulatory systems. As the pressure in the left atrium rises above the pressure in the right atrium—due to the large decrease in pulmonary vascular resistance—the flap of the foramen ovale pushes against the septum, preventing blood flow from the left to the right atrium. Eventually this flap seals shut. As aortic pressure exceeds the pressure of the pulmonary artery, blood flow through the ductus arteriosus reverses. Well-oxygenated aortic blood now flows through the

ductus arteriosus. This high P_{O_2} causes vasoconstriction, which functionally closes the ductus arteriosus within a few hours. Falling prostaglandin levels also contribute to the rapid closure. Eventually, the lumen of the ductus becomes anatomically obliterated. **B**, The elimination of the fetal shunts and the oxygenation of blood in the lungs lead to major increases in the O_2 saturation and P_{O_2} in the circulation.

The separation between the atria often becomes permanent as additional tissue grows over the foramen ovale in a few months. However, in some infants, the two flaps of atrial septal tissue that overlie the foramen [N57-5](#) do not completely adhere, so that a potential remnant pathway is left between the two

atria. About 15% to 25% of adults still have a patent foramen ovale that can permit blood to flow from the right to the left atrium if right atrial pressure exceeds left atrial pressure. Such a right-to-left shunt can occur pathologically in pulmonary hypertension or physiologically following heavy weightlifting. The shunt can also create a path by which a thrombus that develops in the systemic venous circulation can bypass the lungs and travel right to left into the systemic arterial circulation—a well-recognized mechanism for stroke in susceptible adults.

Closure of the ductus arteriosus completes the separation between the pulmonary and systemic circulations

Immediately after birth, the ductus arteriosus remains open but blood flow, which follows the path of least resistance, now begins to shunt (left to right) from the descending aorta to the pulmonary circulation because of the two events that change the relationship between pulmonary and systemic vascular resistance: (1) increased systemic resistance because of the removal of the placenta, and (2) decreased pulmonary resistance because of the expansion of the lungs.

Within a few hours after term birth, the ductus arteriosus closes *functionally* because its muscular wall constricts (see [Fig. 57-5A](#)). Usually, all blood flow through the ductus arteriosus ceases within 1 week after birth. Within a month or so, the lumen becomes obliterated *anatomically* because of thrombosis (i.e., blood clot within the lumen), intimal thickening, and loss of smooth-muscle cells.

The relatively rapid *functional* closure of the ductus arteriosus after birth is primarily the result of an increased P_{O_2} of the arterial blood (caused by breathing) that perfuses this vessel, a decrease in circulating PGE_2 (caused by placenta removal and increased pulmonary PGE_2 uptake), and a decrease in PGE_2 receptors in the ductus wall. As the P_{O_2} of blood flowing through the ductus arteriosus rises from 18 to 22 mm Hg in utero to ~60 mm Hg a few hours after birth, the smooth muscle in the wall of the ductus arteriosus contracts, which reduces or eliminates flow through the ductus. This contraction also constricts the vasa vasorum of the ductus, contributing to smooth-muscle apoptosis in the vessel wall. It is quite common, however, for the ductus arteriosus to remain patent in preterm infants, especially those who are most premature, and occasionally in the full-term infant. A patent ductus arteriosus allows a left-to-right shunt of blood from the aorta to the pulmonary artery because the aorta has a higher pressure. In the premature infant, reduced O_2 sensitivity and less smooth muscle contribute to prolonged patency. If the shunt is large, it has significant hemodynamic consequences because of the excess flow to the lungs and reduced flow to systemic organs. In such cases, administration of a cyclooxygenase (COX) inhibitor (see [Box 3-3](#)) such as indomethacin (which decreases levels of the vasodilator PGE_2 ; see [p. 1158](#)) or surgical ligation can close the ductus. In some newborns with congenital cardiac defects that block or severely decrease pulmonary blood flow, the ductus arteriosus may be the only route for getting blood to the lungs for gas exchange ([Box 57-4](#)).

Box 57-4

Congenital Cardiac Disease

Cardiac malformations are the most common significant congenital defects (~7 in 1000 live births). Many of the most severe defects still permit normal growth in utero but become life threatening when the infant is born. Despite progress in elucidating the genetic basis for these malformations, treatment of infants

still relies on early diagnosis and medical and surgical management. Application of the findings of basic laboratory studies has contributed to dramatic reversal of prognosis for malformations that were nearly universally fatal 50 years ago. Of those severe cardiac defects, some produce complete or nearly complete obstruction of blood flow from the right ventricle to the lungs (e.g., pulmonic valve atresia or severe pulmonary valve stenosis) and some cause obstruction of blood flow from the left ventricle to the systemic tissues (e.g., aortic valve atresia, severe aortic valve stenosis, or severe narrowing of the aortic arch).

The infants with obstruction to pulmonary blood flow experience extreme hypoxemia unless the ductus arteriosus remains sufficiently patent to permit blood from the aorta to flow to the lungs and exchange oxygen. For those infants, infusion of PGE_2 (to dilate the ductus) has become a life-saving therapy that permits adequate blood flow to the lungs and maintenance of a stable circulation for days until the valve is opened or bypassed in a surgical procedure. Indeed, the first major cardiac surgery in an infant was performed on a “blue baby” to create a connection (shunt) from the subclavian artery to the pulmonary artery—the Blalock-Taussig shunt—in 1944.

Infants with obstruction to systemic blood flow frequently present in circulatory shock with severe metabolic acidosis. When the ductus arteriosus is patent, blood flow can travel from the pulmonary artery to the aorta and perfuse the upper body (with retrograde flow) and the lower body. However, when the ductus narrows or closes as it usually does soon after birth, the situation becomes life threatening. Again, infusion of PGE_2 can nearly instantly improve systemic perfusion and ameliorate the shock-like state unless there has already been sustained damage to organs from inadequate circulation. Surgical management of some lesions—such as coarctation (narrowing) of the aorta—can result in a normal or near-normal life.

Other lesions—such as hypoplastic left heart syndrome, which includes aortic and mitral valve atresia and only a single right ventricle that is functional—present a much more complex surgical problem that require either a staged-management approach or even heart transplantation.

The closure of the ductus arteriosus completes the separation of the right and left circulations initiated with closure of the foramen ovale. Whereas the ventricles functioned in *parallel* in the fetus, now they function in *series* in the neonate. As a result, the O_2 saturation of the newborn's Hb is similar to that of the adult's (see [Fig. 57-5B](#)). Although intrapulmonary shunting and \dot{V}_A/\dot{Q} mismatch cause the arterial P_{O_2} in the infant to be lower than that in the adult, the leftward shift of the O_2 saturation curve of *HbF* (see [p. 654](#)) allows the newborn to achieve the same O_2 saturation as an adult. In the neonate, the sum of the ventricular outputs of the two ventricles (i.e., twice the cardiac output) is larger than the CCO in the fetus, a result primarily of a marked rise in the output of the left ventricle, which doubles its stroke volume. Compared with the adult, the newborn has a markedly lower systemic vascular resistance and thus can achieve a relatively high blood flow with a relatively low perfusion pressure (see [Box 57-4](#)).

Neonatal Physiology

In humans, the **neonatal period** is defined as the first 4 weeks after birth. The newborn's ability to survive during this period depends on the adequate development and maturation of various fetal organ systems, adaptations of these organ systems to extrauterine life, and nurturing by a mother or other caretaker because of the neonate's extreme dependence. As the newborn loses its nutritional link with the placenta, the infant must now rely on its own gastrointestinal tract. Moreover, other functions normally carried out by the placenta are now entrusted to the liver and kidneys. Finally, on exiting its uterine “incubator,” the newborn must stabilize body temperature.

Although the newborn is prone to hypothermia, nonshivering thermogenesis in brown fat helps to keep the neonate warm

The body loses heat to the environment by radiation, conduction, convection, and evaporation (see pp. 1196–1197). The relative importance of these processes depends on the circumstances. For instance, at birth the infant moves from a warm and liquid environment to cool and dry surroundings. Hence, evaporation is the main source of heat loss at delivery, and then when the newborn's skin is dry, body heat is lost primarily by other means. The newborn is particularly susceptible to thermal stress, owing to some important predisposing factors: (1) large skin surface area relative to small body mass (or volume), and particularly the large surface area and high blood flow of the head; (2) limited ability to generate heat via shivering thermogenesis; (3) poor thermal insulation from the environment by adipose tissue; and (4) lack of behavioral adjustments, such as changing clothing or moving to a more favorable environment (see pp. 1223–1225).

Despite these factors, the newborn has important mechanisms for resisting hypothermia, including vasomotor responses, which divert warmed blood to or from the skin surface, and **nonshivering thermogenesis**, a process that occurs primarily in liver, brain, and brown fat (Fig. 57-6). Cold stress triggers an increase in the levels of TSH and epinephrine. **TSH** stimulates the release of the thyroid hormones, predominantly T_4 (see p. 1006). Working in parallel, **epinephrine** activates, particularly in brown fat, the 5'/3'-monodeiodinase responsible for the peripheral conversion of circulating T_4 to the far more active triiodothyronine (T_3 ; see pp. 1009–1010). T_3 acts locally in brown fat to uncouple mitochondrial oxidation from phosphorylation and thereby to increase heat production.

FIGURE 57-6 Nonshivering thermogenesis in brown fat. AC, adenylyl cyclase; P_i , inorganic phosphate; PKA, protein kinase A; RXR, retinoid X receptor; THR, thyroid hormone receptor; TRE, thyroid response element.

Brown fat differs from white fat in having a high density of mitochondria; the cytochromes in these mitochondria give the brown fat cells their color. Newborns have particularly high levels of brown fat in the neck and midline of the upper back. In brown fat, the locally generated T_3 upregulates a protein called uncoupling protein 1 (**UCP1**; originally known as thermogenin). This protein is an H^+ channel located in the inner mitochondrial membrane. Normally, intracellular purine nucleotides (e.g., ATP, GDP) inhibit UCP1. However, epinephrine, acting via a cAMP pathway, activates the lipase that liberates FAs from triacylglycerols. These FAs relieve the inhibition of the H^+ channel and increase its conduction of protons. Consequently, the protons generated by electron transport enter the mitochondrion via UCP1, which dissipates the H^+ gradient needed by the H^+ -translocating ATP synthase (see [p. 118](#)). Thus, the mitochondria in brown fat can produce heat without producing useful energy in the form of ATP. The oxidation of FAs in brown fat generates ~27 kcal/kg of body weight each day, contributing a large fraction of the neonate's high metabolic rate per mass.

The neonate mobilizes glucose and FAs soon after delivery

Carbohydrate Metabolism

Elimination of the placental circulation at birth means that the newborn now has to ingest and digest its own food. However, the newborn may not start suckling for ~6 hours. During late fetal life, glucocorticoids promote rapid accumulation of glycogen via their action on glycogen synthase. In its first few hours, the neonate uses glycogenolysis to mobilize hepatic glycogen stores and thereby release glucose into the bloodstream. The two enzymes needed for breaking down hepatic glycogen, phosphorylase and glucose 6-phosphatase (see [p. 1182](#)), are present in the fetus but do not become active until soon after birth.

The newborn depletes hepatic glycogen stores in the first 12 hours of life and is susceptible to hypoglycemia if feeding is delayed. Stores of glycogen in cardiac muscle are 10 times those in the adult, and those in the skeletal muscle are 3 to 5 times those in the adult, but the fetus mainly uses the glycogen stored in these tissues to provide glucose for local use. The net effect is that during the first day of life, blood glucose levels may decline to 40 to 50 mg/dL, although they soon rise to near adult values once nutrition becomes adequate.

Infants born to **diabetic mothers** run a very high risk of having severe hypoglycemia (i.e., <40 mg/dL). The high maternal blood glucose levels translate to high fetal blood glucose levels, causing hyperplasia of β cells in the fetal pancreatic islets and hyperinsulinism in the fetus. Insulin levels remain high after birth, which produces extreme symptomatic hypoglycemia. Blood glucose levels tend to reach their low point within a few hours after birth and begin to recover spontaneously within 6 hours.

Even in the normal newborn, low levels of blood glucose in the immediately postnatal period lead to a decrease in blood levels of **insulin** (see [pp. 1035–1050](#)) and a reciprocal increase of **glucagon** (see [pp. 1050–1053](#)). This hormonal milieu promotes the net release of glucose by the liver. In the liver, glucagon acts via cAMP to stimulate glycogenolysis, inhibit glycogen synthesis, stimulate gluconeogenesis, and initiate synthesis of some gluconeogenic enzymes. All these actions promote formation of glucose for release into the bloodstream (see [Fig. 51-12](#)). In contrast to the adult, in whom phosphorylation is the main mechanism for regulating the enzymes involved in glycogen metabolism, in the fetus, the relative

concentration of the enzymes may be more important.

Epinephrine also promotes glucose mobilization (see Fig. 58-9) in the immediately postnatal period, and it uses the same cAMP pathway as glucagon. Hypoxia, hypoglycemia, and hypothermia all stimulate the release of epinephrine from the adrenal medulla.

Fat Metabolism

During the final 2 months of gestation, the fetus stores ~500 g of fat (i.e., ~15% of body weight), an important source of energy for the neonate. Decreased blood glucose just after birth raises levels of glucagon and epinephrine, which stimulate hormone-sensitive lipase in adipose tissue via cAMP (see p. 1182). This lipase breaks down triacylglycerols into glycerol and FAs, which enter the bloodstream. The liver can take up glycerol and ultimately synthesize glucose (i.e., gluconeogenesis).  **N57-7** The liver can also take up FAs and generate ketone bodies, which are important as the newborn deals with glycogen depletion.

N57-7

Gluconeogenesis with Glycerol as the Starting Material

Contributed by Emile Boulpaep, Walter Boron

As noted in the text, hepatocytes can take up glycerol and use it in gluconeogenesis. As outlined in Fig. 58-6B, after taking up glycerol, hepatocytes can use a three-step process to convert glycerol (highlighted by a rose-colored background in the left limb of the figure) to glyceraldehyde-3-phosphate. The first step is to use glycerol kinase to convert glycerol and ATP to **L-glycerol-3-phosphate** and ADP. The second step is to use glycerol-3-phosphate dehydrogenase (plus oxidized nicotinamide adenine dinucleotide [NAD⁺]) to oxidize L-glycerol-3-phosphate to **dihydroxyacetone phosphate** (plus reduced NAD [NADH] + H⁺). The third step is to use triose phosphate isomerase to isomerize the dihydroxyacetone phosphate to **glyceraldehyde-3-phosphate**.

Hepatocytes can use the glyceraldehyde-3-phosphate to generate glucose. The first step is to use aldolase to combine glyceraldehyde-3-phosphate and dihydroxyacetone phosphate (generated in the second step of glyceraldehyde-3-phosphate) to generate **fructose-1,6-bisphosphate**. The second step is to bypass the phosphofructokinase reaction of glycolysis by using fructose-1,6-bisphosphatase to generate **fructose-6-phosphate**. The third step is to use phosphoglucosomerase to isomerize the fructose-6-phosphate to **glucose-6-phosphate**. Finally, glucose-6-phosphatase in the endoplasmic reticulum bypasses the glucokinase reaction of glycolysis by converting glucose-6-phosphate to **glucose**. Glucagon stimulates production of both fructose-1,6-bisphosphatase and glucose-6-phosphatase.

Metabolic Rate

The neonate's metabolic rate—expressed per kilogram of body weight—is much higher than that of the adult. Through the first year of life, the growing infant has a daily resting metabolic rate of ~55 kcal/kg,

which is nearly double the value of ~30 kcal/kg for a healthy young adult. At birth, the growing infant has a daily caloric requirement of 100 to 120 kcal/kg, which will fall to 90 to 100 kcal/kg by the end of the first year. The difference between the caloric requirement and resting metabolic rate represents the calories expended in physical activity and growth.

Breast milk from a mother with a balanced diet satisfies all of the infant's nutritional requirements during the first several months of life

Provided the mother's diet is adequate during pregnancy, the newborn is in complete nutritional balance at birth. The newborn's natural nutrition for the first few days of life is **colostrum** (a milk-like substance secreted by the mammary glands), and thereafter it is **breast milk** (see [Table 56-7](#) for the composition of these substances), both of which the newborn's gastrointestinal tract can readily digest. The American Academy of Pediatrics recommends exclusive breast-feeding for the first 6 months, and then breast-feeding complemented with consumption of other foods until at least 1 year of age. If the infant is breast-fed, and if the mother's nutritional status is good, colostrum and breast milk meet all of the newborn's nutritional needs. Moreover, colostrum and breast milk make important contributions to the newborn's immune status. Both contain high concentrations of immunoglobulin A (or secretory) antibodies directed against bacteria and viruses, and they also contain macrophages. Breast milk contains factors that promote the growth of lactobacilli, which colonize the colon and may protect the infant from some virulent strains of *Escherichia coli*.

If the mother's dietary intake of iron is adequate during pregnancy, the infant's hepatic stores of **iron** will be adequate for hematopoiesis for 6 to 9 months following delivery.

The **calcium** in breast milk can meet the infant's needs for the rapid calcification of bones and teeth. Although the supply of calcium per se is unlikely to be a problem, **vitamin D** is necessary for the proper absorption of calcium by the intestines (see [pp. 1065–1067](#)). Vitamin D supplementation may be necessary if the newborn or the mother is not exposed to sufficient sunlight to generate vitamin D in the skin (see [p. 1064](#)). Supplementation may also be required in formula-fed infants and in infants born prematurely. **Rickets** (see [Box 52-2](#)) can develop rapidly in a vitamin D–deficient infant. 🍌[N57-8](#)

N57-8

Scurvy in Infants

Contributed by Ervin Jones

Vitamin C (ascorbic acid; see [Table 45-3](#)) is necessary for the synthesis of hydroxyproline in collagen and chondroitin sulfate in cartilage, bone, and other connective tissues. The neonate is normally born with sufficient stores of vitamin C and receives adequate amounts of this vitamin in breast milk. If the breast milk or formula is vitamin C deficient, the infant may develop scurvy, which can be prevented by administering vitamin C supplements to the mother or infant. **Scurvy** is a disease manifest by lesions on the skin and mucous membranes.

The neonate is at special risk of developing fluid and acid-

base imbalances

The newborn normally loses 6% to 10% of body weight during the first week of life, which reflects a decrease in interstitial and intravascular volume. After ~1 week, the rate of fluid intake begins to exceed that rate of loss, and term infants return close to birth weight by $1\frac{1}{2}$ weeks.

The newborn's total-body water is ~75% of body weight compared with 60% for men and 50% for women (see [Table 5-1](#)). Once the newborn is in a steady state, daily turnover of body water is 100 to 120 mL/kg (i.e., 3- to 4-fold higher than in adults). About one third of this fluid loss occurs via skin and respiration, whereas the other two thirds occurs via urine and stool. Large variations in newborn fluid loss may go undetected because of the environment, the neonate's large ratio of surface area to mass, and the inability to seek access to water. Thus, small changes in the balance between fluid intake and loss can lead to rapid and profound disturbances in body fluid compartments, which requires very careful management.

The immaturity of the neonate's **kidneys** further complicates matters. For example, the glomerular filtration rate (GFR; see [p. 739](#)), which is extremely low at birth, increases rapidly during the first 2 weeks of life. However, even when normalized for body surface area, GFR does not reach adult levels until ~1 year of age, in part because renal blood flow during that time increases from ~5% to 20% of cardiac output. Moreover, the dehydrated newborn has limited capacity to conserve fluid because the concentrating ability of the kidney (i.e., a maximal urine osmolality of ~450 mOsm) is substantially less than that of an adult (~1200 mOsm). This difference reflects shorter loops of Henle and low urea concentrations in the medullary interstitium until the newborn ingests protein.

Because of the newborn's relatively high metabolic rate, the neonate generates a greater load of nonvolatile acids (see [p. 821](#)) than the adult. Moreover, the immature state of neonatal kidneys with respect to acid excretion puts the neonate at risk of developing metabolic acidosis (see [p. 635](#)).

Humoral and cellular immune responses begin at early stages of development in the fetus

Maternal **antibodies** play a key role in protecting the infant from infection both in utero and during the first several months after birth.

Fetus

The placenta actively transports the small immunoglobulin G (IgG) antibodies from mother to fetus, so that fetal IgG levels are even higher than those in the mother. These maternal IgG antibodies ward off infection by viruses and some bacteria. However, maternal IgA (which is primarily present in secretions), IgE, and IgM antibodies generally do not cross the placenta in appreciable amounts, and the baby is generally born with very low levels of these other immunoglobulins.

The fetus begins to develop its own immune capabilities at very early stages of development. However, because the fetus is isolated from antigens, the fetal immune system normally does not make large amounts of antibodies. Nevertheless, the fetus can respond to intrauterine infections by generating IgM antibodies. In addition, the fetus also begins to produce other proteins that help to protect against bacterial and viral infections. Among these are the following: (1) the components of the **complement** pathway; (2) **lysozyme**, an enzyme found in secretions such as tears and mucus, which digests the cell walls of bacteria and fungi; and (3) **interferon- γ** , which is produced by T lymphocytes and which activates B lymphocytes,

macrophages, and endothelial cells.

Neonate

Not only does the fetus have high prenatal levels of maternal IgG, but the newborn receives copious amounts of secretory IgA antibodies in colostrum and breast milk. However, the blood levels of *maternal* IgG antibodies progressively fall, and IgG levels in the infant's blood reach a nadir at ~3 months of age. After that time, the infant's own production of IgG antibodies causes total IgG levels to increase gradually. However, even at 1 year of age, IgG levels—as well as the levels of IgA, IgM, and IgE—are only half of adult levels.

Antibodies obtained in utero from the mother protect the fetus against most childhood diseases, including **diphtheria**, **measles**, and **poliomyelitis**. The persistence of antibodies at levels high enough for protection varies considerably from one disease to another. For example, maternal measles antibodies are so persistent that vaccinations against measles often fail if attempted before the infant is 15 months of age. In contrast, maternal antibodies against **whooping cough** (pertussis) are generally inadequate to protect the infant beyond 1 to 2 months. The infant normally receives a first DTaP immunization (diphtheria, tetanus, and acellular pertussis), as well as a first poliomyelitis immunization, at 2 months of age.

In premature newborns, immaturity of organ systems and fragility of homeostatic mechanisms exacerbate postnatal risks

The World Health Organization defines a **premature infant** as one born sooner than 37 weeks after the mother's last menstrual period, compared with the normal 40 weeks (see [p. 1142](#)). Virtually all the challenges to the health of the neonate are made more severe by prematurity or intrauterine growth restriction (see [Box 57-1](#)), conditions that are therefore associated with reduced chances of survival. These problems generally reflect immaturity either of certain organ systems (e.g., lungs, intestines, liver, kidneys) or of homeostatic mechanisms (e.g., thermoregulation). 🍌N57-9

N57-9

Problems of Prematurity

Contributed by Ervin Jones

Blood Plasma Parameters

Because both the respiratory and the renal systems regulate **blood pH** (see Equation 28-27), variations in one or both of these systems can lead to substantial fluctuations in blood pH in the premature infant. In addition, prematurity is often associated with hypoglycemia, hypocalcemia, hyperbilirubinemia, and hypoproteinemia (reflecting an immature liver).

Respiration

Large numbers of mature alveoli begin to appear only relatively late in gestation (see [p. 1156](#)). Similarly, the type II alveolar pneumocytes begin to produce substantial amounts of surfactant only just before the normal term of gestation. As a result, premature infants have a reduced vital capacity and functional

residual capacity. The greater the degree of prematurity, the greater the incidence of—and mortality from—**infant respiratory distress syndrome** (see Box 57-2). In addition to having these problems with pulmonary mechanics, premature newborns are also prone to difficulties with ventilatory control. For example, infants with a birth weight of <1500 g have a high incidence of **recurrent apnea** (i.e., cessation of breathing for >20 seconds, or long enough to produce either cyanosis or bradycardia; see Fig. 23-6A for the mechanism by which hypoxia can produce bradycardia).

Gastrointestinal Function

Prematurity predisposes the newborn to **necrotizing enterocolitis**, in which intestinal ischemia leads to the inflammation and death of the mucosa or even the entire intestinal wall. Stresses such as asphyxia or hypothermia may trigger this condition. In addition, the digestive and absorptive systems—especially for lipids—may be inadequate in the premature infant. Because vitamin D is a fat-soluble vitamin required for the absorption of Ca^{2+} (see discussion beginning on page 1065), premature infants are at special risk of developing **rickets**.

Liver

The immature infant is born with inadequate stores of hepatic glycogen, stores that are essential for maintaining adequate plasma glucose levels in the first hours of extrauterine life. Inadequate hepatic synthesis of coagulation factors (see Table 18-4) can increase the risk of hemorrhage.

Kidneys

Immaturity leads to across-the-board impairment of renal function. Renal blood flow, GFR, and tubular function are all affected. Impaired concentrating ability leads to high urinary water losses. In addition, low gestational age is associated with high levels of **insensible water loss** because the skin is thin, the subcutaneous tissue is inadequate, and the surface-to-volume ratio is so large. Thus, fluid balance is a major problem for the premature infant. The premature infant is also at a greater risk than the term infant for developing acidosis.

Hematopoiesis

The premature infant is at increased risk of **anemia**. The baby born at term has a relatively high Hb concentration (14 to 20 g/dL) and hematocrit (43% to 63%). The Hb level normally falls slowly during the first few months of life due to a decreased rate of hematopoiesis and then rises gradually during childhood. The nadir in Hb concentration is more marked in the premature infant for two reasons. First, the premature infant is born with approximately 2 g/dL less Hb than its term counterpart. Second, it has a reduced hematopoietic capacity, due at least in part to decreased iron stores.

Body Temperature

Premature newborns have difficulty maintaining an adequate temperature, so that body temperature tends to approach the ambient temperature. In a relatively cool room, the body temperature of a premature infant can fall to 30°C. For this reason, a pediatrician treating a premature newborn places it in an **incubator**, which provides a neutral thermal environment (see p. 1196) and keeps the infant's body core temperature (see pp. 1193–1194) near 37°C. The more immature the newborn (i.e., the smaller the body and the higher the surface-to-volume ratio), the higher must be the temperature of the incubator to maintain the proper body core temperature in the infant.

Metabolism

Gerald I. Shulman, Kitt Falk Petersen

Metabolism encompasses all chemical reactions in the body's cells, necessary to sustain life. These chemical processes allow the body to grow, reproduce, maintain structure, and respond to changes in its environment. These processes can be **anabolic**, in which energy is used in the formation of substances such as proteins or nucleic acids, or **catabolic**, in which organic substances are broken down during cellular respiration to harvest energy to support cellular processes such as biosynthesis, transport of molecules or ions across cell membranes, or locomotion. A healthy, sedentary young man weighing 70 kg requires 2100 kcal (~30 kcal/kg body weight) [N58-1](#) to sustain resting metabolism for 1 day, an amount known as the **resting metabolic rate (RMR)**. The number of calories increases with increased activity, illness, or other stress. For example, the metabolic rate can rise 2- to 3-fold with exposure to a cold environment, or up to 10-fold during heavy exercise. The **basal metabolic rate (BMR)** is a clinical term for metabolism that is measured under standardized conditions in which the subject (1) has had a full night of restful sleep, (2) has been fasting for 12 hours, (3) is in a neutral thermal environment (see [p. 1196](#)), (4) has been resting physically for 1 hour, and (5) is free of psychic and physical stimuli. In adults the BMR (*units*: kilocalories per hour and per square meter of body surface area) is ~5% higher for males than for females and falls with age. The BMR is less than the RMR.

N58-1

Kleiber's Law

Contributed by Edward Masoro, Emile Boulpaep, Walter Boron

One gram of tissue from a small mammal has a higher resting metabolic rate (RMR; see p. 1170) than the same mass of tissue from a larger mammal (e.g., a human). By plotting heat production versus body weight for animals over a range of five orders of magnitude, Max Kleiber showed that metabolic rate (in kcal/day) is not proportional to body weight (in kg) but to body weight raised to the power $\frac{3}{4}$.

Allometry is the study of how body size relates to various biological parameters (e.g., metabolic rate, anatomic parameters).

Regulation of energy metabolism in humans involves a complex interplay among ingested nutrients, hormones, and interorgan exchanges of substrates to maintain a constant and adequate supply of fuel for all organs of the body. Because energy acquisition by the body is intermittent, whereas energy expenditure is continuous, the body needs to store and then parcel out energy in a carefully coordinated fashion.

Insulin (see pp. 1035–1050) is the key hormone that orchestrates this exchange and distribution of substrates between tissues under fed and fasting conditions. Glucagon (see pp. 1050–1053), catecholamines (see pp. 1030–1031), cortisol (see pp. 1018–1026), and growth hormone (see pp. 990–995) play major roles in energy regulation at times of acute energy needs, which occur during exercise, under conditions of stress, or in response to hypoglycemia. The major organs involved in fuel homeostasis are (1) the liver, which is normally the major producer of glucose;  **N58-2** (2) the brain, which in the fasted state is the major utilizer of glucose; and (3) the muscle and adipose tissue, which respond to insulin and store energy in the form of glycogen and fat, respectively.

N58-2

Role of the Kidneys in Fuel Homeostasis

Contributed by Kitt Petersen, Gerald Shulman

Although the kidneys can also produce glucose by gluconeogenesis, their net contribution to whole-body glucose production is typically <10% except under conditions of prolonged fasting, when they can contribute up to 30% to 40%.

The purpose of this chapter is to review how humans utilize energy and the means by which the body manages its energy stores during times of feeding, fasting, and exercise.

Forms of Energy

Virtually all energy that sustains humans derives, directly or indirectly, from breaking and releasing the energy stored in carbon-carbon bonds that were created in plants during photosynthesis. Cellulose, the principal form of this stored energy in the biosphere, consists of polymers of glucose joined by β -1,4 linkages that humans cannot digest (see [pp. 914–915](#)). However, ruminants can degrade cellulose to glucose because they have cellulase-producing bacteria in their digestive tracts. Humans obtain their energy from food in three forms: (1) carbohydrates, (2) proteins, and (3) lipids. Moreover, each form consists of building blocks: monosaccharides (glucose, fructose, and galactose) for carbohydrates, amino acids for proteins, and fatty acids for lipids.

Carbohydrates, which exist in the body mainly in the form of glucose, contain 4.1 kcal/g of energy. The major storage form is **glycogen**, a polymer of glucose (10^6 to 10^8 Da) that consists of glucose molecules linked together by α -1,4 linkages in the straight portions of the polymer ([Fig. 58-1](#)) and by α -1,6 linkages at the frequent branch points (see [Fig. 45-3](#)). Virtually all cells of the body store glycogen; the highest concentrations occur in liver and muscle. Cells store glycogen in cytoplasmic granules that also contain the enzymes needed for glycogen synthesis and degradation. Glycogen is highly hydrophilic, containing 1 to 2 g of water per gram of glycogen, and thus provides a handy storage depot for glucose without affecting the osmotic pressure of the intracellular space. However, this packaging of glycogen with water makes glycogen a relatively inefficient means of storing energy because it yields only 1 to 2 kcal for each gram of *hydrated* glycogen instead of the theoretical 4.1 kcal/g of *dry* carbohydrate. In contrast to the other potential stored forms of energy (lipid and protein), the liver can quickly break down glycogen by glycogenolysis to provide glucose for the brain during hypoglycemia. Similarly, muscle can quickly break down glycogen to glucose-6-phosphate (G6P) to provide the energy necessary to run a high-intensity anaerobic sprint.

FIGURE 58-1 Glycogen synthesis and glycogenolysis. After entering a liver or skeletal muscle cell, glucose is immediately phosphorylated to G6P, which can have three fates: glycolysis, breakdown via the pentose phosphate shunt,  **N58-16** or glycogen synthesis. Glycogenolysis directly yields G1P and is thus not simply the reverse of glycogen synthesis. UDP, uridine diphosphate; UTP, uridine triphosphate.

N58-16

The Pentose Phosphate Pathway (or Hexose Monophosphate Shunt)

Contributed by Emile Boulpaep, Walter Boron

Figure 58-1 mentions that glucose-6-phosphate can have three major fates. The *anabolic* series of reactions summarized in this figure convert G6P to glycogen. The glycolytic pathway summarized in Figure 58-6A is a *catabolic* pathway that converts G6P to pyruvate. The third fate—the **pentose phosphate pathway**—is another catabolic series of reactions that converts G6P to ribose-5-phosphate.

The pentose phosphate pathway has two major products, NADPH and ribose-5-phosphate. The cell can use the reducing equivalents in **NADPH** (i.e., energy “currency”) to reduce double bonds in the energy-consuming synthesis of FAs and steroids. These reactions are particularly important in such tissues as liver, adipose tissue, mammary gland, and adrenal cortex. Note that the cell cannot use NADH to create NADPH. Thus, the pentose phosphate pathway is critical. The second product of the pathway, **ribose-5-phosphate**, is important for the synthesis of ribonucleotides, which is particularly important in growing and regenerating tissues. The pentose phosphate pathway involves four reactions, the first and third of which involve the conversion of NADP^+ to NADPH and H^+ .

If the cell does not use the ribose-5-phosphate to generate ribonucleotides, the cell can use a complex series of reactions to convert the ribose-5-phosphate to **fructose-6-phosphate**. This sequence of reactions (i.e., from G6P to ribose-5-phosphate to fructose-6-phosphate) bypasses or “shunts” the conversion of G6P to fructose-6-phosphate, which would otherwise be catalyzed by phosphoglucose isomerase (see Fig. 58-6A). For this reason, the pentose phosphate pathway is also called the **hexose monophosphate shunt**.^{*} However, the reader should be reassured that the shunt does not permit the cell to generate two NADPH molecules for free. Three G6P molecules ($3 \times 6 = 18$ carbons) must traverse the hexose monophosphate shunt to generate six NADPH molecules ($3 \times 2 = 6$) plus two fructose-6-phosphate ($2 \times 6 = 12$ carbons) molecules, a single glyceraldehyde-3-phosphate ($1 \times 3 = 3$ carbons), and three CO_2 molecules that arise from a decarboxylation reaction in the pentose phosphate pathway ($3 \times 1 = 3$ carbons). If those three glucose molecules had gone through the classical glycolytic pathway, they would have generated $3 \times 2 = 6$ net ATPs and 6 NADHs (see Table 58-3). However, if those same three glucose molecules all go through the pentose phosphate pathway, the net result is only five ATPs, only five NADHs, but six NADPHs. Thus, the cell gives up only one ATP and one NADH for the sake of generating six NADPHs—not a bad deal for the cell!

- Nelson DL, Cox MM. *Lehninger Principles of Biochemistry*. 3rd ed. Worth Publishers: New York; 2000.
- Voet D, Voet JG. *Biochemistry*. 2nd ed. Wiley: New York; 1995.

*Note that the term *shunt* is a bit of a misnomer, inasmuch as the “shunt” is not a *shortcut* from glucose-6-phosphate to fructose-6-phosphate (normally catalyzed in one step by phosphoglucose isomerase), but rather a *lengthy* detour!

The liver normally contains 75 to 100 g of glycogen but can store up to 120 g (8% of its weight) as glycogen. Muscle stores glycogen at much lower concentrations (1% to 2% of its weight). However, because of its larger mass, skeletal muscle has the largest store of glycogen in the body (300 to 400 g). **N58-3** A typical 70-kg human has up to ~700 g of glycogen (~1% of body weight). Thus, the total energy stored in the body in the form of glycogen can be nearly 3000 kcal ([Table 58-1](#)); this is still only a tiny fraction of that stored in the form of lipid, enough to supply resting metabolism for less than a day and a half, assuming 100% efficiency. Nonetheless, carbohydrate stores are essential because certain tissues, particularly the brain, rely heavily on carbohydrates for their fuel. Whereas muscle contains the largest store of glycogen in the body, this pool of glycogen cannot contribute directly to blood glucose in response to hypoglycemia because muscles lack glucose-6-phosphatase (G6Pase), which is necessary to convert G6P derived from glycogenolysis to glucose. Instead, the primary role of muscle glycogen is to supply energy locally for muscle contraction during intense exercise.

TABLE 58-1
Energy of Body Stores

CHEMICAL	WEIGHT (kg)	ENERGY DENSITY (kcal/g)	ENERGY (kcal)
Glycogen	0.7	1.5*	1,050
Protein	9.8/2 = 4.9†	4.3	21,000
Lipid	14	9.4	131,600

*Approximate energy density of hydrated glycogen.
†Because only half of this protein can be mobilized as a fuel source, the total yield is only ~21,000 kcal.

N58-3

Glycogen Supercompensation

Contributed by Kitt Petersen, Gerald Shulman

Exercise induces an increase in GLUT4 expression in skeletal muscle, which leads to an increase in insulin-stimulated glucose uptake and glycogen accumulation. The effect wears off ~40 hours after exercise. Thus, after glycogen has been depleted by exercise, carbohydrate feeding results in enhanced glycogen accumulation, known as **supercompensation**. Under conditions of supercompensation (i.e., high-carbohydrate feeding following intense exercise), athletes can increase muscle glycogen content to up to 3% of body weight (rather than the usual 1% stated in the text).
If, after intense exercise, supercompensation of rats is prevented by feeding a carbohydrate-poor diet, the increase in GLUT4 expression is substantially prolonged (i.e., 66 versus only 40 hours following exercise).

Proteins are linear polymers of L-amino acids (Fig. 58-2), which have the general molecular structure $^+H_3N-HC(R)-COO^-$. Different functional R groups distinguish the 20 amino acids incorporated into nascent proteins during mRNA translation. In addition, four other amino acids are present in mature proteins: γ -carboxyglutamic acid, hydroxylysine, 4-hydroxyproline, and 3-hydroxyproline. However, these amino acids result from post-translational modification of amino acids that are already in the polypeptide chain. In α -amino acids, the amino group ($-NH_3^+$), the carboxyl group ($-COO^-$), and R all attach to the central or α -carbon atom. In proteins, the amino acids are linked together by peptide bonds that join the α -amino group of one amino acid with the α -carboxyl group of another. Nine of the amino acids are termed **essential amino acids** (Table 58-2) because the body cannot synthesize them at rates sufficient to sustain growth and normal functions. Thus, we must obtain these amino acids in our diet.

FIGURE 58-2 Structure of proteins. The chemistry of R determines the identity of the amino acid.

TABLE 58-2

Essential and Nonessential α -Amino Acids

ESSENTIAL	NONESSENTIAL
Histidine	Alanine
Isoleucine	Arginine
Leucine	Asparagine
Lysine	Aspartate
Methionine	Cysteine
Phenylalanine	Glutamate
Threonine	Glutamine
Tryptophan	Glycine
Valine	Proline
	Serine
	Tyrosine

Proteins contain 4.3 kcal/g, about the same as carbohydrates. A typical 70-kg human with 14% protein (9.8 kg)—only about half of which is available as a fuel source—can thus store ~21,000 kcal (see Table 58-1) in the form of available protein—which could potentially provide ~10 days' worth of energy. Unlike carbohydrate, protein is not a primary energy reserve in humans. Instead, proteins serve other

important structural and functional roles. Structural proteins make up skin, collagen, ligaments, and tendons. Functional proteins include enzymes that catalyze reactions, muscle filaments such as myosin and actin, and various hormones. The body constantly breaks down proteins to amino acids, and vice versa, which allows cells to change their protein makeup as demands change. Thus, it is not surprising that protein catabolism makes only a small contribution—much less than 5%—to normal resting energy requirements. In contrast, during starvation, when carbohydrate reserves are exhausted, protein catabolism can contribute as much as 15% of the energy necessary to sustain the resting metabolic requirements by acting as major substrates for gluconeogenesis (see [p. 1176](#)).

In the healthy human adult who is eating a weight-maintaining diet, amino acids derived from ingested protein replenish those proteins that have been oxidized in normal daily protein turnover. Once these protein requirements have been met, the body first oxidizes excess protein to CO_2 and then converts the remainder to glycogen or **triacylglycerols (TAGs)**.

Lipids are the most concentrated form of energy storage because they represent, on average, 9.4 kcal/g. Lipids are dietary substances that are soluble in organic solvents but not in water and typically occur in the form of TAGs ([Fig. 58-3A](#)). The gastrointestinal (GI) tract breaks down ingested TAGs (see [pp. 925–927](#)) into **fatty acids (FAs)** and *sn*2-monoacylglycerols (see [Fig. 58-3B](#)). FAs are composed of long carbon chains (14 to 24 carbon atoms) with a carboxyl terminus, and can be either *saturated* with hydrogen atoms or *unsaturated* (i.e., double bonds may connect one or more pairs of carbon atoms). When fully saturated, FAs have the general form $\text{CH}_3-(\text{CH}_2)_n-\text{COOH}$ (see [Fig. 58-3C](#)).

FIGURE 58-3 Structures of TAGs and FAs.

In contrast to glycogen and protein, fat is stored in a nonaqueous environment and therefore yields energy very close to its theoretical 9.4 kcal/g of TAGs. This greater efficiency of energy storage provided by fat is crucial for human existence in that it allows for greater mobility and promotes survival during famine. Therefore, although humans have two large storage depots of potential energy (protein and fat), fat serves as the major expendable fuel source. Most of the body's fat depots exist in the subcutaneous

adipose tissue layers, although fat also exists to a small extent in muscle and in visceral (deeper) depots in obese individuals. A typical 70-kg human with 20% fat (14 kg) thus carries 131,600 kcal of energy stored in adipose tissue (see [Table 58-1](#)). Assuming an RMR of 2100 kcal/day and 100% efficiency of converting the fat to energy, mobilization and subsequent oxidation of this entire depot could theoretically sustain the body's entire resting metabolic requirement for several weeks.

Energy Balance

Energy input to the body is the sum of energy output and storage

The **first law of thermodynamics** states that energy can be neither created nor destroyed; in a closed system, total energy is constant. This concept is illustrated in [Figure 58-4](#). Humans acquire all of their energy from ingested food, store it in different forms, and expend it in different ways. In the steady state, energy intake must equal energy output.

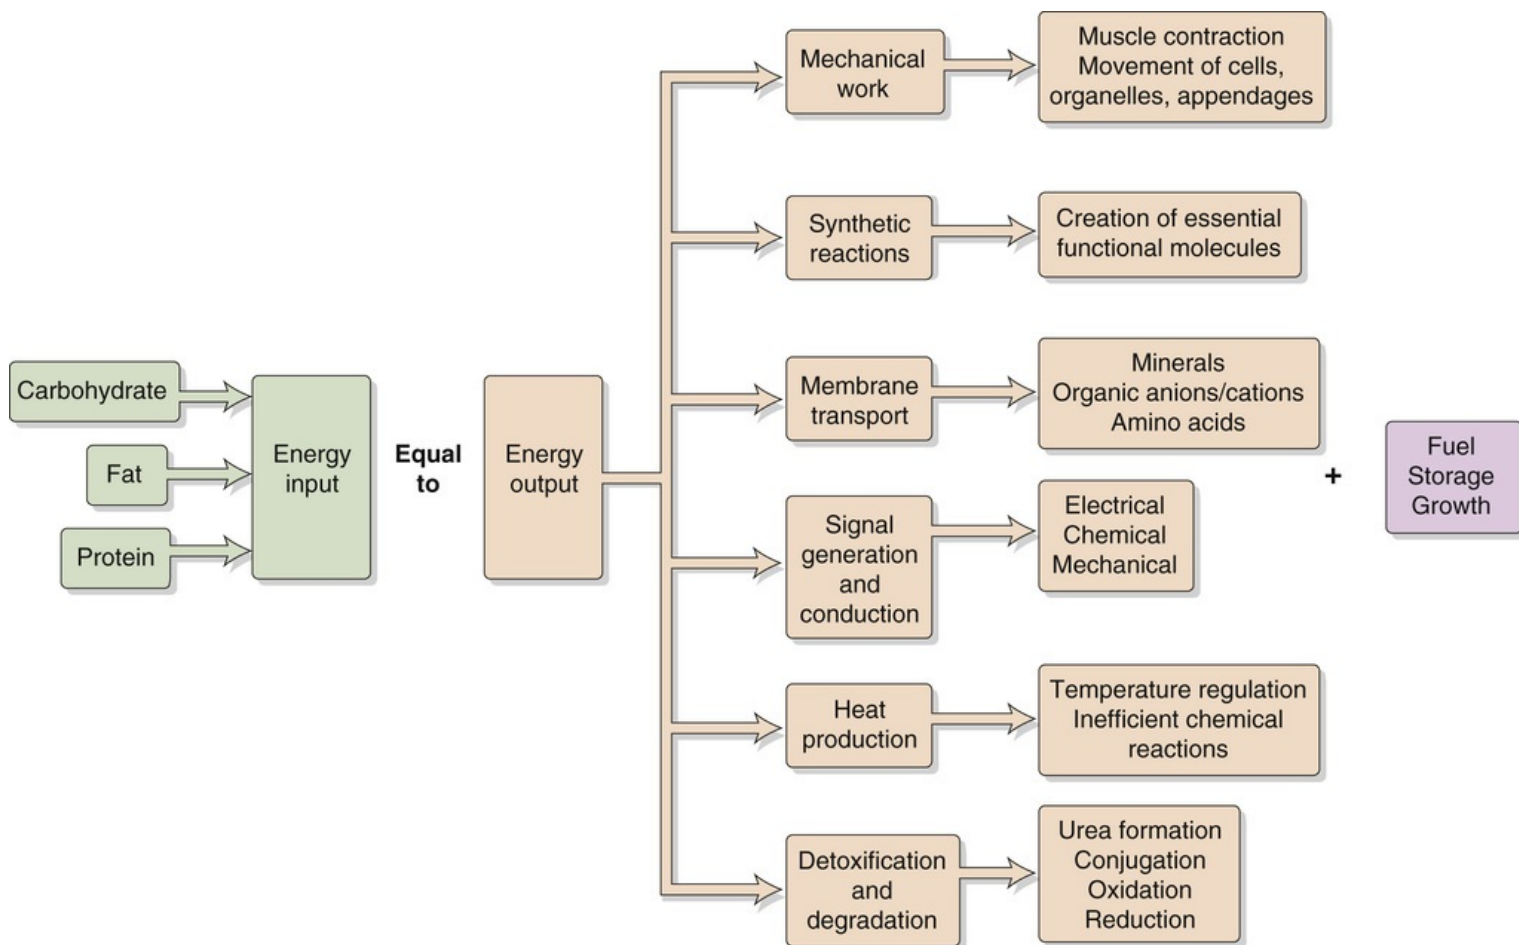

FIGURE 58-4 Energy balance.

The GI tract breaks down ingested carbohydrates (see [pp. 914–915](#)), proteins (see [pp. 920–921](#)), and lipids (see [p. 925](#)) into smaller components and then absorbs them into the bloodstream for transport to sites of metabolism. For example, the GI tract reduces ingested carbohydrates to simple sugars (e.g., glucose, fructose), which are then transported to liver and muscle cells and either oxidized to release energy or converted to glycogen and fat for storage. Oxidation of fuels generates not only free energy but also waste products and heat (thermal energy).

The body's energy *inputs* must balance the sum of its energy *outputs* and the energy *stored*. When the body takes in more energy than it expends, the person is in **positive energy balance** and gains weight. In the case of adults, this gain is mostly in the form of fat. In healthy children during growth periods, this gain is mostly in the form of muscle, organ, and bone growth. Conversely, when energy intake is less than

expenditure, this **negative energy balance** leads to weight loss, mostly from fat and, to a lesser extent, from protein in muscle.

A person can gain or lose weight by manipulating energy intake or output. An optimal strategy to encourage weight loss involves both increasing energy output and reducing energy intake. In most people, a substantial decrease in energy intake alone leads to inadequate nutrient intake, which can compromise bodily function.

Nitrogen balance—the algebraic sum of whole-body protein *degradation* and protein *synthesis*—is an indication of the *change* in whole-body protein stores. It is estimated from dietary protein intake and urinary nitrogen (i.e., urea) excretion. Children eating a balanced diet are in positive nitrogen balance because they store amino acids as protein in the process of growth. Patients who have suffered burns or trauma are usually in negative nitrogen balance because of the loss of lean (mostly muscle) body mass.

The inefficiency of chemical reactions leads to loss of the energy available for metabolic processes

The **second law of thermodynamics** states that chemical transformations always result in a loss of the energy available to drive metabolic processes—the **Gibbs free energy (G)**. The total internal energy (E) of the human body is the sum of the disposable or free energy (G) plus the unavailable or wasted energy, which ends up as heat (i.e., the product of absolute temperature, T, and entropy, S):

$$E = G + TS$$

(58-1)

For example when you ingest glucose, the total internal energy increases by a small amount (ΔE). Some of this energy will be stored as glycogen (ΔG), and some will be wasted as heat ($T \cdot \Delta S$). According to [Equation 58-1](#), as long as the temperature is constant, the change in total internal energy will have two components:

$$\underbrace{\Delta E}_{\text{Energy of ingested glucose}} = \underbrace{\Delta G}_{\text{Energy stored as glycogen}} + \underbrace{T \cdot \Delta S}_{\text{Energy wasted as heat}}$$

(58-2)

Thus, some of the increased total energy (ΔE) will be stored as glycogen (ΔG). However, because of the inefficiencies of the chemical reactions that convert glucose to glycogen, some of the ΔE is wasted as heat ($T \cdot \Delta S$). Another way of stating the second law is that $T \cdot \Delta S$ can never be zero or negative, and chemical reactions can never be 100% efficient.

If we add *no energy* to the body (i.e., ΔE is zero), the body's total free energy must decline (i.e., ΔG is negative). This decline in G matches the rise in $T \cdot S$, reflecting inefficiencies inherent in chemical transformations. Consider, for example, what would happen if you took 1 mole of glucose (180 g), put it into a bomb calorimeter with O_2 , and completely burned the glucose to CO_2 and H_2O . This combustion would yield 686 kcal in the form of heat but would conserve no usable energy. Now consider what happens if your body burns this same 1 mole of glucose. In contrast to the bomb calorimeter, your

mitochondria not only would oxidize glucose to CO_2 and H_2O but also would conserve part of the free energy in the form of ATP. Each of the many chemical conversion steps from glucose to CO_2 and H_2O makes available a small amount of the total energy contained in glucose. Converting 1 mole of ADP and inorganic phosphate (P_i) to 1 mole of ATP under the conditions prevailing in a cell consumes ~ 11.5 kcal/mole. Therefore, if a particular step in glucose oxidation releases *at least* 11.5 kcal/mole, it can be coupled to ATP synthesis. The conversion of the lower-energy ADP to the higher-energy ATP traps energy in the system, thus conserving it for later use. The cellular oxidation of 1 mole of glucose conserves ~ 400 kcal of the potential 686 kcal/mole; the remaining 286 kcal/mole is liberated as heat.

Free energy, conserved as high-energy bonds in ATP, provides the energy for cellular functions

ATP consists of a nitrogenous ring (adenine), a 5-carbon sugar (ribose), and three phosphate groups (Fig. 58-5). The last two phosphates are connected to the rest of the molecule by high-energy bonds. The same is true for a related nucleotide, GTP. If we compare the free energies of phosphate bonds of various molecules, we see that the high-energy phosphate bonds of ATP lie toward the middle of the free-energy scale. Thus, in the presence of P_i , ADP can accept energy from compounds that are higher on the free-energy scale (e.g., phosphocreatine), whereas ATP can release energy in the formation of compounds that are lower on the free-energy scale (e.g., G6P). ATP can therefore *store* energy derived from energy-releasing reactions and *release* energy needed to drive other chemical reactions.

FIGURE 58-5 Hydrolysis of ATP to ADP, P_i , and H^+ .

Examples of the chemical reactions fueled by converting ATP to ADP and P_i include the formation of bridges between actin and myosin during muscle contraction and the pumping of Ca^{2+} against its electrochemical gradient during muscle relaxation. 🔥N58-4

Hydrolysis of ATP

Contributed by Kitt Petersen, Gerald Shulman

Although the conversion of ATP to ADP and P_i is often referred to as a *hydrolysis reaction*, because the traditional representation is $ATP + H_2O \rightarrow ADP + P_i + H^+$, the reaction actually occurs in two steps. The first typically involves transfer of a part of the phosphate group to an intermediate molecule, thus increasing the intermediate's free-energy content. The second step involves displacing the phosphate moiety, which releases P_i and energy. In contrast, true hydrolysis reactions merely release heat, which cannot be trapped to drive chemical processes.

Energy Interconversion From Cycling between 6-Carbon and 3-Carbon Molecules

Some metabolic reactions are neither uniquely anabolic nor catabolic, but they serve to interconvert the carbon skeletons of the building blocks of the three major energy forms—carbohydrates, proteins, and lipids. In this subchapter, we focus on two major pathways of interconversion: glycolysis and gluconeogenesis.

Glycolysis converts the 6-carbon glucose molecule to two 3-carbon pyruvate molecules

The breakdown of glucose to pyruvate ([Fig. 58-6A](#)) can occur in the presence of O_2 (aerobic glycolysis) or the absence of O_2 (anaerobic glycolysis). This process yields 47 kcal of free energy per mole of glucose. Of this energy, the cell can trap enough to yield directly 2 moles of ATP per mole of glucose ([Table 58-3](#)), even under the relatively inefficient anaerobic conditions. Under *aerobic* conditions, the mitochondria can generate an additional three or five ATP molecules per glucose molecule from two **reduced nicotinamide adenine dinucleotide (NADH)** molecules. 🍌[N58-5](#) Cells that contain few mitochondria (e.g., fast-twitch muscle fibers; see [pp. 249–250](#)) or no mitochondria (i.e., erythrocytes 🍌[N58-6](#)) rely exclusively on anaerobic glycolysis for energy.

FIGURE 58-6 Glycolysis and gluconeogenesis. **A**, Highlighted in green are the three enzymes that catalyze reactions in glycolysis that are essentially irreversible. These enzymes are subject to allosteric regulation. **B**, Highlighted in blue are the three gluconeogenic bypasses, which circumvent the three irreversible steps of glycolysis. The precursors for gluconeogenesis include amino acids (illustrated here for alanine), pyruvate, and lactate. Green arrow indicates stimulation. NAD^+/NADH , oxidized and reduced forms of nicotinamide adenine dinucleotide, respectively.

TABLE 58-3

Generation of ATP from Glycolysis*

REACTION	ATP CHANGE PER GLUCOSE
Glucose \rightarrow G6P	-1
Fructose-6-phosphate \rightarrow Fructose-1,6-bisphosphate	-1
$2 \times (1,3\text{-Bisphosphoglycerate}) \rightarrow 2 \times (3\text{-Phosphoglycerate})$	+2
$2 \times \text{Phosphoenolpyruvate} \rightarrow 2 \times \text{Pyruvate}$	+2
	Net +2

*Under anaerobic conditions, glycolysis—which takes place in the cytosol—yields two lactate molecules plus two ATP molecules per glucose molecule. Under aerobic conditions, the metabolism of glucose does not proceed to lactate and thus yields a net gain of two NADH molecules per glucose molecule. The oxidative phosphorylation of each NADH molecule will yield 1.5 or 2.5 ATP molecules, depending on which shuttle system the cell uses to transfer the reducing equivalents from the cytosol into the mitochondria. **N58-15** Therefore, under aerobic conditions, glycolysis of one glucose molecule generates two ATP molecules directly plus three or five ATP molecules via the oxidative phosphorylation of the two NADH molecules, for a total of five or seven ATP molecules per glucose molecule. This yield is summarized in the first two rows of [Table 58-4](#).

N58-5

NADH/ NAD^+ versus NADPH/ NADP^+

Contributed by Alisha Bouzaher

NADH and NAD^+ are, respectively, the reduced and oxidized forms of nicotinamide adenine dinucleotide (NAD) and their close analogs are NADPH and NADP^+ , the reduced and oxidized forms of nicotinamide adenine dinucleotide phosphate (NADP). The coenzymes NADH and NADPH each consist of two nucleotides joined at their phosphate groups by a phosphoanhydride bond. NADPH is structurally distinguishable from NADH by the additional phosphate group residing on the ribose ring of the nucleotide, which allows enzymes to preferentially interact with either molecule.

Total concentrations of NAD^+/NADH (10^{-5}M) are higher in the cell by ~ 10 -fold compared to $\text{NADP}^+/\text{NADPH}$ (10^{-6}M). Ratios of the oxidized and reduced forms of these coenzymes offer perspective into the metabolic activity of the cell. The high NAD^+/NADH ratio favors the transfer of a hydride from a substrate to NAD^+ to form NADH, the reduced form of the molecule and oxidizing agent. Therefore, NAD^+ is highly prevalent within catabolic reaction pathways where reducing equivalents (carbohydrate, fats, and proteins) transfer protons and electrons to NAD^+ . NADH acts as an energy carrier, transferring electrons from one reaction to another. Conversely, the $\text{NADP}^+/\text{NADPH}$ ratio is low, favoring the transfer of a hydride to a substrate oxidizing NADPH to NADP^+ . Thus, NADPH is utilized as a reducing agent within anabolic reactions, particularly the biosynthesis of fatty acids.

Red Blood Cells

Contributed by Emile Boulpaep, Walter Boron

As noted on pages 434–435 of the text, mature erythrocytes lack all organelles, including mitochondria. Of the glucose that they take up, 90% undergoes **glycolysis** to provide ATP. The remaining 10% follows the **pentose phosphate pathway** (see Fig. 58-1)—also known as the hexose monophosphate shunt or the phosphogluconate pathway—to produce NADPH (i.e., reducing equivalents) as well as 5-carbon sugars.

About a century and a half ago, Pasteur recognized that glycolysis by yeast occurs faster in anaerobic conditions than in aerobic conditions.  **N58-7** This **Pasteur effect** reflects the cell's attempt to maintain a constant $[ATP]_i$ by controlling the rate at which glycolysis breaks down glucose to generate ATP. The key is the **allosteric regulation** of enzymes that catalyze the three reactions in the glycolytic pathway that are essentially irreversible: **hexokinase** (or glucokinase in liver and pancreas), **phosphofructokinase (PFK)**, and **pyruvate kinase** (highlighted in green in Fig. 58-6A). In each case, either the direct reaction product (i.e., G6P in the case of hexokinase) or downstream metabolic products (e.g., ATP in the case of the other two) inhibits the enzyme. If glycolysis should temporarily outstrip the cell's need for ATP, the buildup of products slows glycolysis. Thus, introducing O_2 activates the citric acid cycle (see p. 1185), which raises $[ATP]_i$, inhibits PFK and pyruvate kinase, and slows glycolysis.

N58-7

Allosteric Regulation of Glycolytic Enzymes by Metabolic Products (Pasteur Effect)

Contributed by Ethan Nadel, Emile Boulpaep, Walter Boron

As pointed out on page 1176, the three enzymes of the glycolytic pathway that catalyze reactions that are essentially irreversible are also all under allosteric control.

Hexokinase in muscle (the comparable enzyme in liver is glucokinase) catalyzes the essentially irreversible conversion of free glucose to **G6P** (see Fig. 58-6A) and thereby traps the sugar inside the cell and enables it to enter the glycolytic pathway. Hexokinase is *inhibited* by increased concentrations of its reaction product, G6P. Thus, when the concentration of G6P increases excessively, hexokinase is temporarily inhibited (negative feedback), which reduces the rate of G6P production and enables it to match once again the rate of consumption in the steady state.

The enzyme **phosphofructokinase (PFK)** catalyzes the essentially irreversible conversion of fructose-6-phosphate to fructose-1,6-bisphosphate (see Fig. 58-6A). The activity of PFK is allosterically regulated by the cellular energy status, increasing with decreases in $[ATP]_i$ (or with increases in ATP breakdown products), and vice versa. Further, an increased concentration of **citrate**—which indicates that pyruvate is being provided to the citric acid cycle faster than it can be used—increases the inhibitory

influence of ATP on PFK, attenuating the rate of glycolysis further and thus signaling that the cell's energy needs are being met.

Pyruvate kinase catalyzes the final step of glycolysis, the essentially irreversible transfer of the phosphate group from phosphoenolpyruvate (PEP) to ADP, yielding ATP and pyruvate (see Fig. 58-6A). A high $[ATP]_i$ decreases the affinity of pyruvate kinase for PEP, reducing the rate of reaction at the $[PEP]_i$ normally prevailing. Pyruvate kinase is also inhibited by **acetyl CoA**, which is the entry molecule to the citric acid cycle, a source of high ATP production.

The allosteric inhibitors (indicated above in **bold italics**) of the aforementioned three enzymes are responsible for the observation by Pasteur (the so-called **Pasteur effect**) that glycolysis is slower under aerobic conditions, when these allosteric inhibitors are present at higher concentrations.

Under anaerobic conditions, cells convert pyruvate to lactate, which is accompanied by the accumulation of H^+ —**lactic acidosis**. This acidosis, in turn, can impede muscle contraction by decreasing muscle cell pH, which can result in muscle cramps and inhibition of key glycolytic enzymes needed for ATP synthesis. Thus, sustained skeletal muscle activity depends on the aerobic metabolism of pyruvate as well as FAs.

Gluconeogenesis converts nonhexose precursors to the 6-carbon glucose molecule

Gluconeogenesis is essential for life because the brain and **anaerobic tissues**—formed elements of blood (erythrocytes, leukocytes), bone marrow, and the renal medulla—normally depend on glucose as the primary fuel source. The daily glucose requirement of the brain in an adult is ~120 g, which accounts for most of the 180 g of glucose produced by the liver. The major site for gluconeogenesis is the liver, with the renal cortex making a much smaller contribution. During prolonged fasting (2 to 3 months), the kidney can account for up to 40% of total glucose production.

Although glycolysis converts glucose to pyruvate (see Fig. 58-6A) and gluconeogenesis converts pyruvate to glucose (see Fig. 58-6B), gluconeogenesis is not simply glycolysis in reverse. The thermodynamic equilibrium of glycolysis lies strongly on the side of pyruvate formation (i.e., the ΔG is very negative). Thus, in contrast to glycolysis, gluconeogenesis requires energy, consuming four ATP, two GTP, and two NADH molecules for every glucose molecule formed. Most of the ΔG decrease in glycolysis occurs in the three essentially irreversible steps indicated by single arrows in Figure 58-6A. Gluconeogenesis bypasses these three irreversible, high- ΔG glycolytic reactions by using four enzymes: **pyruvate carboxylase**, **phosphoenolpyruvate carboxykinase (PEPCK)**, **fructose-1,6-bisphosphatase (FBPase)**, and **G6Pase** (see Fig. 58-6B). The enzymes of gluconeogenesis and glycolysis are present in separate cellular compartments to minimize futile cycling of substrates between glycolysis and gluconeogenesis; the glycolytic enzymes reside in the cytosolic compartment, whereas the gluconeogenic enzymes are present in the mitochondria (pyruvate carboxylase) or in the lumen of the endoplasmic reticulum (G6P).

The liver accomplishes gluconeogenesis by taking up, and converting to glucose, several nonhexose precursors (see Fig. 58-6B). These include two breakdown products of glycolysis (lactate and pyruvate), all the intermediates of the citric acid cycle, 18 of the 20 amino acids, and glycerol. Regardless of the precursor—except for glycerol—all pathways go through **oxaloacetate (OA)**. Thus, the liver can convert **lactate** to pyruvate, and then convert **pyruvate** to OA via **pyruvate carboxylase**, consuming one ATP.

Similarly, the citric acid cycle can convert all its intermediates to OA. Finally, the liver can deaminate all amino acids—except leucine and lysine—to form pyruvate, OA, or three other intermediates of the citric acid cycle (α -ketoglutarate, succinyl coenzyme A [CoA], or fumarate). The major gluconeogenic amino acids are **alanine** and **glutamine**. 🟡N58-8 Leucine and lysine are not gluconeogenic because their deamination leads to acetyl CoA, which cannot generate net OA (see [p. 1185](#)). Similarly, FAs are not gluconeogenic because their breakdown products are almost exclusively acetyl CoA. In contrast, leucine and lysine are **ketogenic** because cells can convert acetyl CoA to FAs ([Fig. 58-7](#)) or ketone bodies (see [p. 1185](#)).

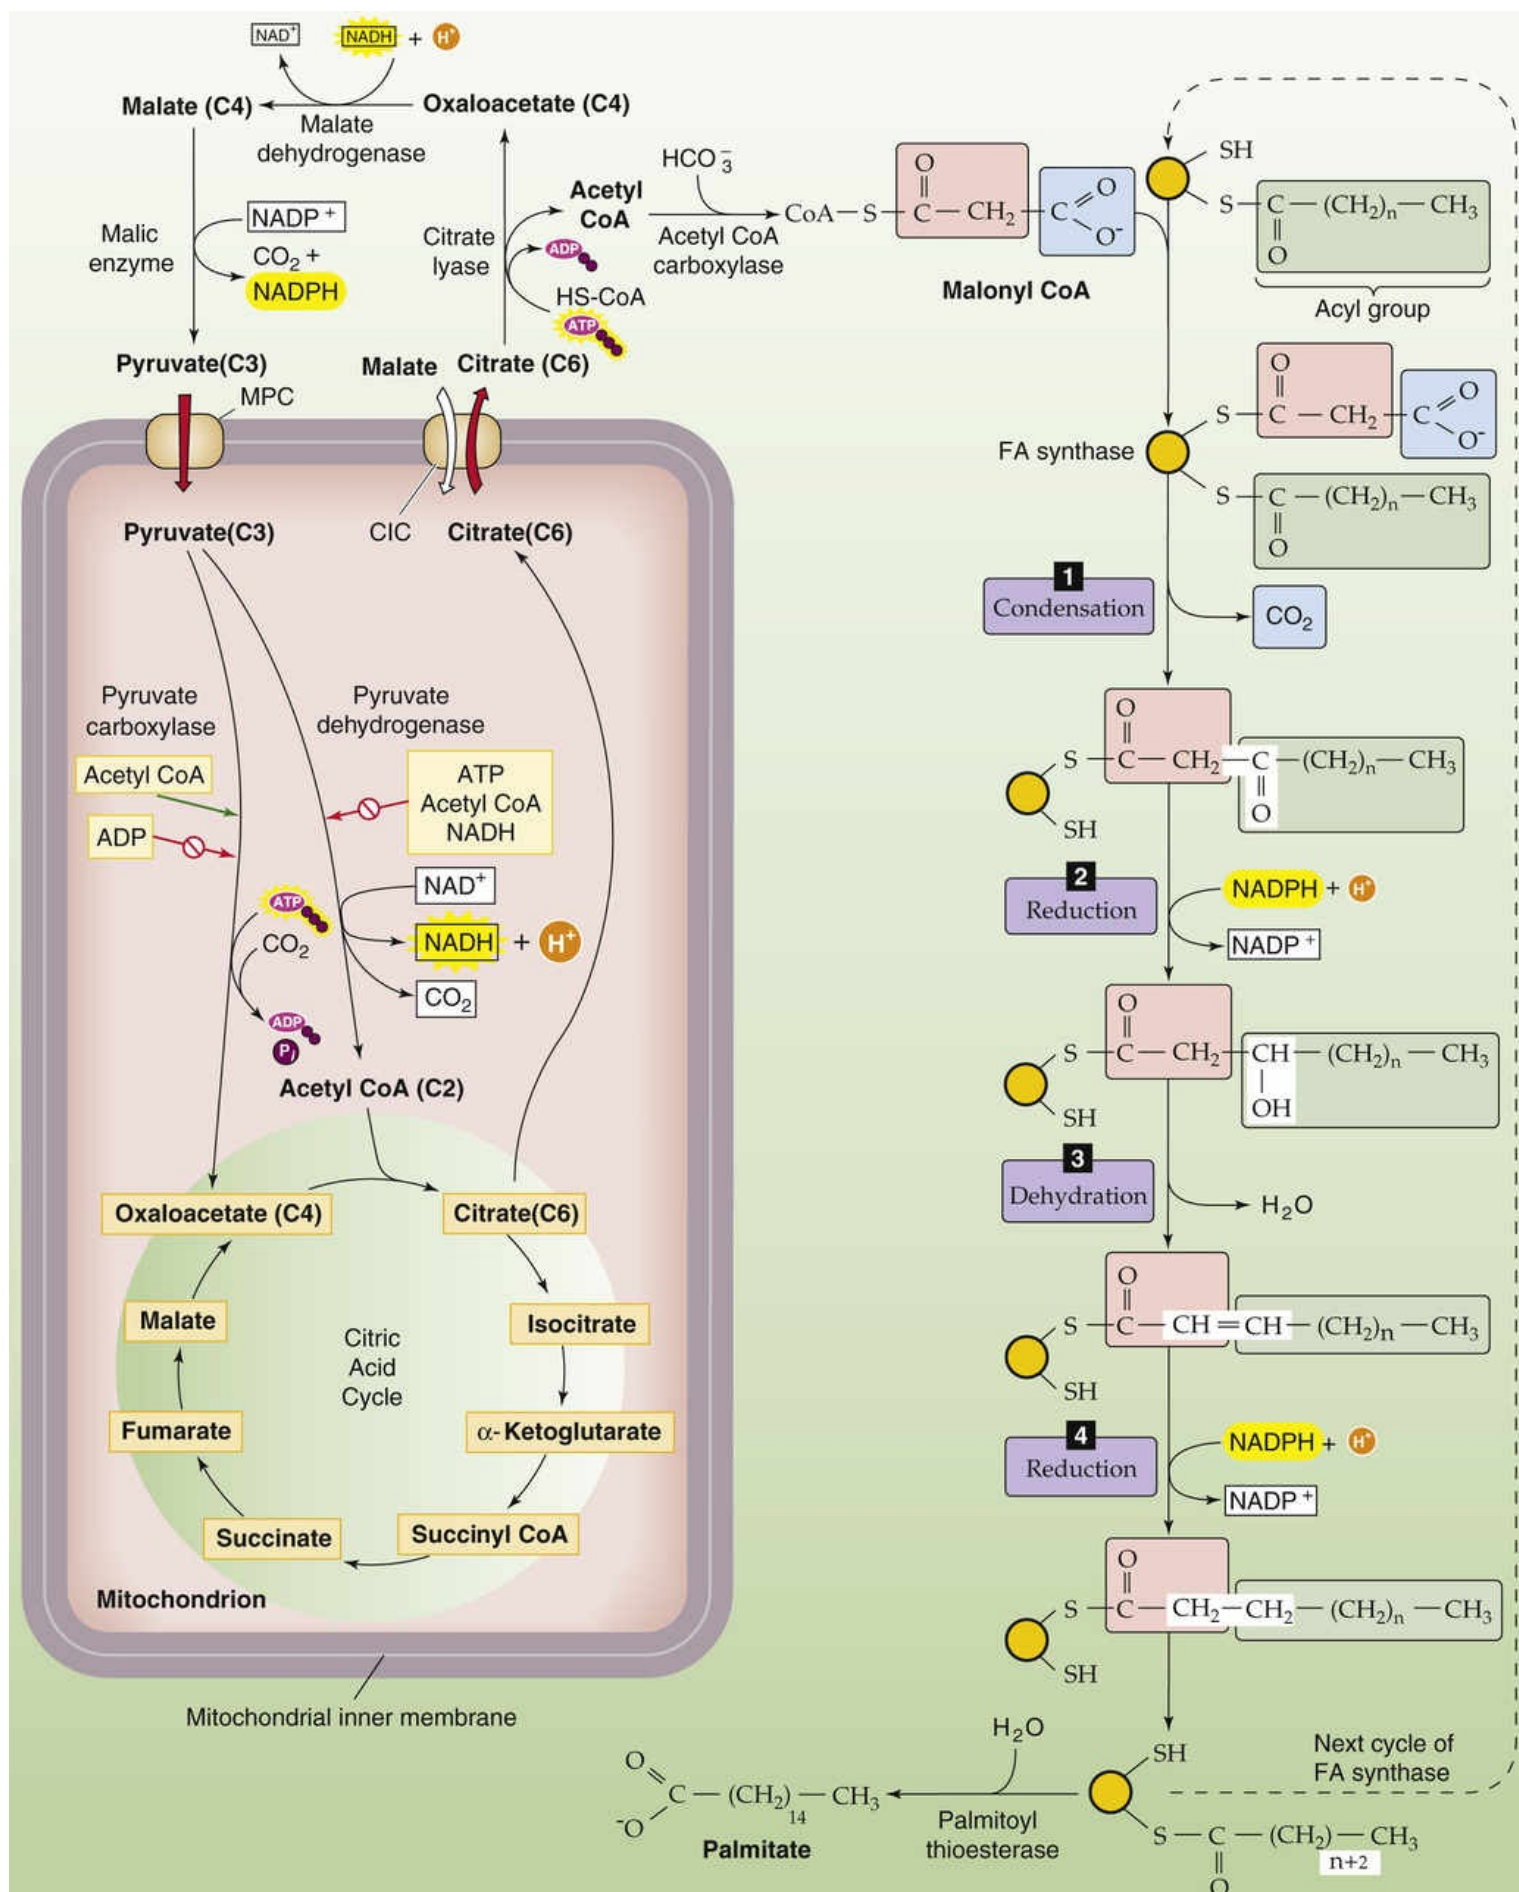

FIGURE 58-7 FA synthesis. The left side of the figure shows how the cell effectively transports acetyl CoA from the inside of the mitochondrion to the cytoplasm—exporting citrate and then taking up pyruvate. The key enzyme is citrate lyase. The right side of the figure shows how the cell generates FAs, two carbons at a time. Glucose can feed into the system via pyruvate. Amino acids can feed into the system via acetyl CoA (ketogenic amino acids), pyruvate, or intermediates of the citric acid cycle. NAD⁺/NADH,

N58-8

Gluconeogenic and Ketogenic Amino Acids

Contributed by Emile Boulpaep, Walter Boron

The **18 gluconeogenic amino acids** enter the citric acid cycle at various sites as indicated below. The **7 ketogenic amino acids** are converted into acetyl CoA or acetoacetate, as indicated below. Finally, **5 amino acids are both gluconeogenic and ketogenic** and are indicated in red below.

Gluconeogenic amino acids (18):

Enter at pyruvate: Ala, Cys, Gly, Ser, Thr, Trp

Enter at oxaloacetate: Asp, Asn

Enter at fumarate: Asp, Phe, Tyr

Enter at succinyl CoA: Ile, Met, Val

Enter at α -ketoglutarate: Arg, Glu, Gln, His, Pro

Ketogenic amino acids (7):

Enter at acetyl CoA: Ile, Leu, Thr

Enter at acetoacetate (converts to acetyl CoA): Leu, Lys, Phe, Trp, Tyr

Both gluconeogenic and ketogenic (5):

Ile, Phe, Thr, Trp, Tyr

Once the liver has converted the precursor to OA, the next step is the conversion of OA to phosphoenolpyruvate (PEP) by **PEPCK**, which consumes one GTP molecule (see Fig. 58-6B). The liver can convert PEP to fructose-1,6-bisphosphate (F-1,6-BP) by using the glycolytic enzymes in reverse. The gluconeogenic precursor **glycerol** enters the pathway at dihydroxyacetone phosphate. **FBPase** converts F-1,6-BP to fructose-6-phosphate, and **G6Pase** completes gluconeogenesis by converting G6P to glucose.

The major gluconeogenic precursors are (1) lactate, which is derived from glycolysis in muscle and anaerobic tissues; (2) alanine, which is mostly derived from glycolysis and transamination of pyruvate in skeletal muscle; and (3) glycerol, which is derived from lipolysis in adipocytes.

Reciprocal regulation of glycolysis and gluconeogenesis

minimizes futile cycling

We already noted that key glycolytic and gluconeogenic enzymes are located in separate compartments. The liver also reciprocally and coordinately *regulates* these processes so that when one pathway is active the other pathway is relatively inactive. This regulation is important because both glycolysis and gluconeogenesis are highly exergonic, and therefore no thermodynamic barrier prevents futile cycling of substrates between these two pathways. Because glycolysis creates two ATP molecules and gluconeogenesis consumes four ATP and two GTP molecules, a full cycle from one glucose to two pyruvates and back again would have a net cost of two ATP and two GTP molecules. The liver regulates flux through these pathways in the short term mostly by allosteric regulation of enzyme activity, and in the long term by transcriptional regulation of gene expression.

Allosteric Regulation

PFK (glycolysis) is stimulated by AMP, whereas it is inhibited by citrate and ATP (see [Fig. 58-6A](#)). **FBPase** (gluconeogenesis) is inhibited by AMP and is activated by citrate (see [Fig. 58-6B](#)). In addition, **fructose-2,6-bisphosphate (F-2,6-BP)**,  [N58-9](#) which is under the reciprocal control of glucagon and insulin, reciprocally regulates these two enzymes, stimulating PFK and inhibiting FBPase. In the fed state, when the glucagon level is low (see [pp. 1050–1051](#)) and the insulin level is high (see [p. 1041](#)), [F-2,6-BP] is high, which promotes consumption of glucose. Conversely, in the fasted state, [F-2,6-BP] is low, which promotes gluconeogenesis.

N58-9

Fructose-2,6-Bisphosphate

Contributed by Emile Boulpaep, Walter Boron

Although structurally very similar to fructose-1,6-bisphosphate, **fructose-2,6-bisphosphate (F-2,6-BP)** is neither a substrate nor a product in either glycolysis or gluconeogenesis. However, it is an allosteric regulator of both glycogenolysis and gluconeogenesis.

The enzyme **phosphofructokinase 2 (PFK-2)** phosphorylates fructose-6-phosphate to yield F-2,6-BP. Conversely, the enzyme **fructose-2,6-bisphosphatase 2 (FBPase-2)** removes one phosphate from F-2,6-BP to yield fructose-6-phosphate. Interestingly, a single bifunctional protein mediates both the PFK-2 and FBPase-2 activities. These two enzymes are distinct from phosphofructokinase 1 (PFK in [Fig. 58-6A](#)) and fructose-1,6-bisphosphatase (FBPase-1; see [Fig. 58-6B](#)).

Fructose-6-phosphate is an important allosteric regulator of both glycolysis and gluconeogenesis. By modulating the two enzymes noted above, **insulin** raises but **glucagon** lowers cytosolic [F-2,6-BP]. Thus, in the fed state (high insulin/low glucagon), [F-2,6-BP] rises, thereby stimulating glycolysis but inhibiting gluconeogenesis.

Reference

Nelson DL, Cox MM. *Lehninger Principles of Biochemistry*. 3rd ed. Worth Publishers: New York; 2000 [pp; 732; 733].

Similarly, the liver reciprocally regulates **pyruvate kinase** (glycolysis) and **pyruvate carboxylase/PEPCK** (gluconeogenesis). High concentrations of ATP and alanine inhibit pyruvate kinase, whereas ADP inhibits pyruvate carboxylase. Furthermore, acetyl CoA inhibits pyruvate kinase but activates pyruvate carboxylase.

In this way, high concentrations of biosynthetic precursors and ATP favor gluconeogenesis and suppress glycolysis. Conversely, high concentrations of AMP, reflecting a low energy charge of the liver, suppress gluconeogenesis and favor glycolysis.

Transcriptional Regulation

More long-term regulation of gluconeogenesis and glycolysis occurs by hormonal regulation of gene expression. The major hormones involved in this process are insulin, glucagon, epinephrine, and cortisol. In contrast to allosteric regulation, which occurs in seconds to minutes, transcriptional regulation occurs over hours to days. Insulin, which increases following a meal (see [p. 1041](#)), stimulates the expression of the glycolytic enzymes **PFK** and pyruvate kinase, as well as the enzyme that makes F-2,6-BP. [N58-9](#) In addition, as noted in [Figure 51-8](#), insulin suppresses the expression of the key gluconeogenic enzymes PEPCK, FBPase, and G6Pase. Insulin leads to the phosphorylation of the FOXO1 transcription factor, which prevents FOXO1 from entering the nucleus and activating transcription of genes that encode these enzymes.

Conversely, glucagon, the levels of which increase during starvation, inhibits the expression of the glycolytic enzymes PFK and pyruvate kinase, as well as the enzyme that makes F-2,6-BP. Epinephrine and norepinephrine, released under conditions of stress, have actions similar to those of glucagon. At the same time, these hormones stimulate the expression of the gluconeogenic enzymes PEPCK and G6Pase via cAMP and protein kinase A (PKA). Phosphorylation of the transcriptional factor CREB (cAMP response element-binding protein; see [p. 89](#)) directly promotes both increased transcription of gluconeogenic genes (e.g., PEPCK) and increased transcription of the transcriptional cofactor **PGC-1 α** (peroxisome proliferator-activated receptor- γ coactivator-1 α). PGC-1 α then binds and activates the transcription factors HNF4 and FOXO1, which further promote the transcription of these key gluconeogenic enzymes.

Cells can convert glucose or amino acids into FAs

The body—principally the liver—can convert glucose to FAs. As shown in [Figure 58-6A](#), glycolysis converts glucose to pyruvate, which can enter the mitochondrion via the **mitochondrial pyruvate carrier**, or **MPC** (see [Fig. 58-7](#)). When ATP demand is low, high levels of ATP, acetyl CoA, and NADH inside the mitochondria inhibit pyruvate dehydrogenase, which converts pyruvate to acetyl CoA—the normal entry point into the citric acid cycle (see [p. 1185](#)). Conversely, high levels of ATP and acetyl CoA stimulate pyruvate carboxylase, which instead converts pyruvate to OA, the last element in the citric acid cycle. The mitochondrion then converts the OA and acetyl CoA to citrate, which it exports to the cytosol via an exchanger called the **citrate carrier**, or **CIC** (SLC25A1). A cytosolic enzyme called **citrate lyase** converts the citrate back to OA and acetyl CoA. The hepatocyte converts the cytosolic OA to malate or pyruvate, each of which can re-enter the mitochondrion. Thus, the net effect is to make acetyl CoA disappear from the mitochondrion and appear in the cytosol for FA synthesis.

As noted above, the breakdown of ketogenic amino acids [N58-8](#) yields acetyl CoA (see [p. 1176](#)). This acetyl CoA can also contribute to FA synthesis. In addition, the breakdown of other amino acids yields pyruvate or intermediates of the citric acid cycle, which again can contribute to FA synthesis.

The synthesis of FAs from acetyl CoA takes place in the cytosol, whereas the oxidation of FAs to acetyl

CoA occurs in the mitochondrion (see below, [pp. 1183–1185](#)). The first committed step—and the rate-limiting step—in FA synthesis is the ATP-dependent carboxylation of acetyl CoA (2 carbons) to form **malonyl CoA** (3 carbons), catalyzed by **acetyl CoA carboxylase (ACC)**.  **N58-10** The next step is the sequential addition of 2-carbon units to a growing acyl chain, shown as $-\text{CO}-(\text{CH}_2)_n-\text{CH}_3$ in [Figure 58-7](#), to produce an FA. With each round of elongation, a malonyl CoA molecule reacts with **FA synthase**, which then decarboxylates the malonyl moiety and condenses the growing acyl chain to the remaining 2-carbon malonyl fragment. The subsequent reduction, dehydration, and reduction steps—all catalyzed by the same multifunctional peptide—complete one round of elongation. Starting from a priming acetyl group (which comes from acetyl CoA), seven rounds of addition—in addition to a hydrolysis step to remove the acyl chain from the enzyme—are required to produce palmitate:

N58-10

Acetyl CoA Carboxylase Isoforms

Contributed by Emile Boulpaep, Walter Boron

The two isoforms of ACC, encoded by different genes, are the following:

ACC1:

265 kDa

Cytosolic

Highly expressed in lipogenic tissues: liver, adipocytes, lung, mammary gland

Involved in FA synthesis

ACC2:

280 kDa

Has a unique 144-amino-acid sequence at the amino terminus; amino acids 1 to 20 may be a leader sequence

Membrane protein, associated with mitochondria, thought to face the cytosol

Expressed in heart, skeletal muscle more than liver

Regulates β -oxidation by producing malonyl CoA; carnitine acyltransferase I is the committed step

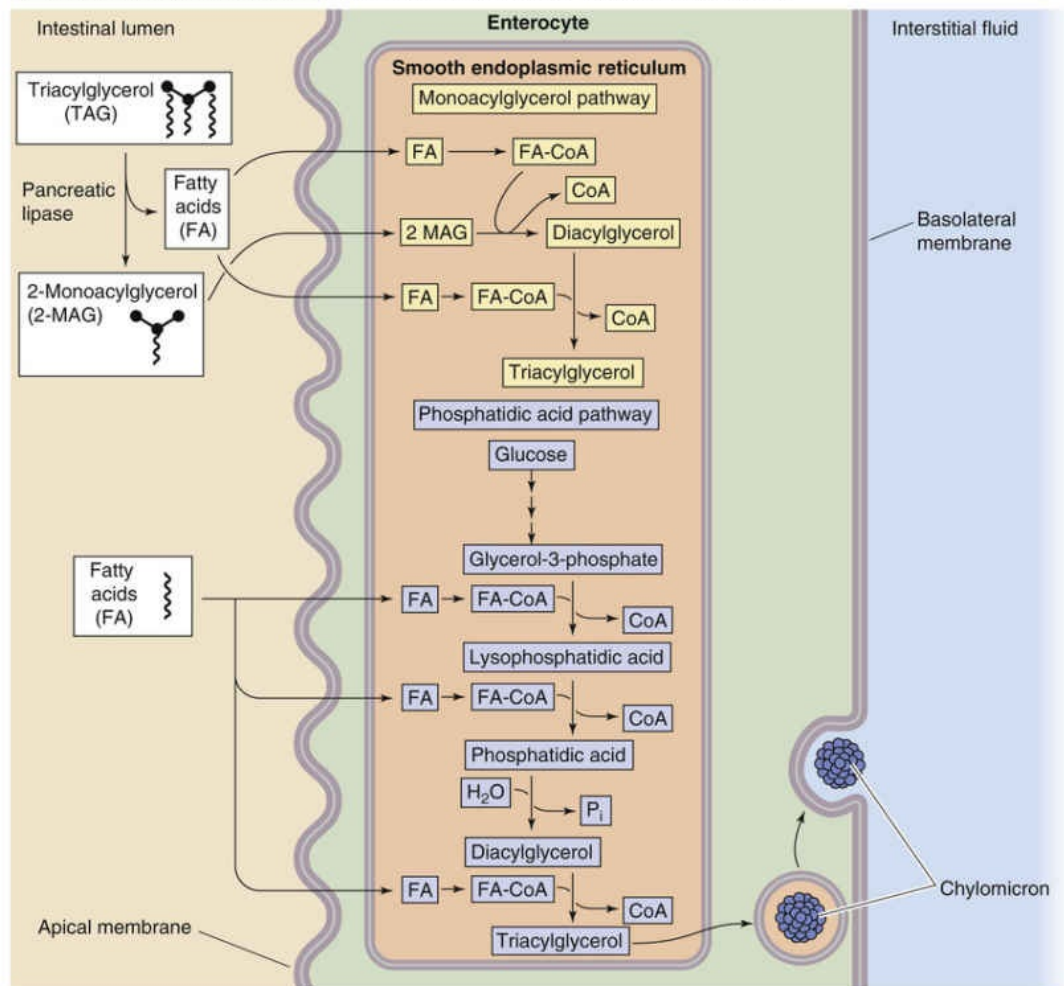

where NADPH and NADP⁺ are the reduced and oxidized forms of nicotinamide adenine dinucleotide phosphate, respectively. The cell esterifies the FAs to glycerol to make **TAGs** (see [Fig. 58-3A](#)). **N58-11** The liver can package TAGs as **very-low-density lipoproteins (VLDLs)**; see [p. 968](#)) for export to the blood.

N58-11

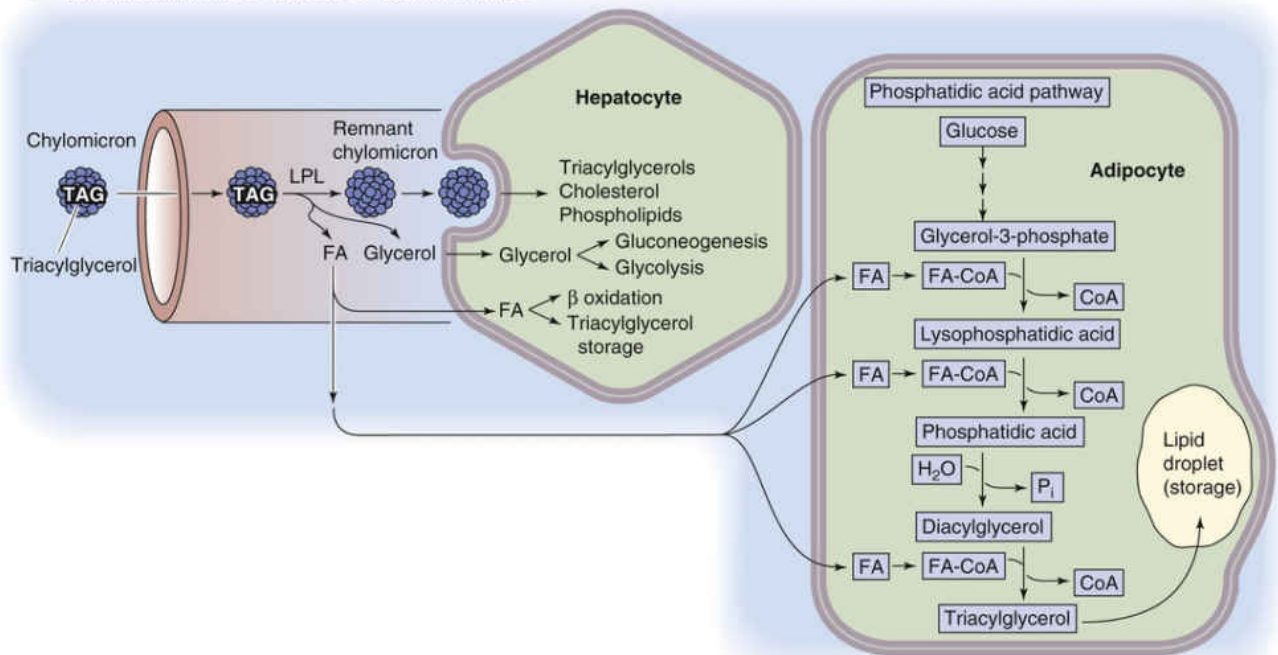

Digestion, Absorption, and Storage of Triacylglycerols

Contributed by Ethan Nadel

A INTestinal absorption and re-esterification of triacylglycerols

B BREAKDOWN AND STORAGE OF DIETARY LIPIDS

EFigure 58-1 **A**, Pancreatic lipase breaks down TAGs into FAs and 2-MAGs in the lumen of the small intestine. These products enter the enterocyte, which uses either the MAG or the phosphatidic acid pathway to re-esterify them. The resulting TAGs are packaged into chylomicrons, which enter the lymph and, ultimately, the blood. **B**, Lipoprotein lipase (LPL) in capillaries hydrolyzes TAGs in chylomicrons to FA and glycerol. Adipocytes re-esterify the FAs to TAGs for storage in fat droplets. Hepatocytes take up remnant chylomicrons (by receptor-mediated endocytosis), glycerol, and some FA.

The body permits only certain energy interconversions

The body has a hierarchy for energy interconversion. As discussed above, the body can convert amino acids to glucose (gluconeogenesis) and fat, glucose to fat, and glucose to certain amino acids. However, the body cannot convert fat to either glucose or amino acids. Fats can only be stored or oxidized. The reason is that cells oxidize FAs two carbons at a time to acetyl CoA (a 2-carbon molecule; see [pp. 1183–1185](#)), which they cannot convert into pyruvate (a 3-carbon molecule) or OA (a 4-carbon molecule). The only exceptions are the uncommon FAs that have an odd number of carbon atoms, and even with these, only the terminal 3-carbon unit escapes oxidation to acetyl CoA. Thus, almost all carbon atoms in FAs end up as acetyl CoA, which enters the citric acid cycle (see [p. 1185](#)). There, isocitrate dehydrogenase and α -ketoglutarate dehydrogenase release the two carbon atoms of acetyl CoA as two CO_2 molecules, which thus yields no net production of OA or pyruvate. In contrast, plants have two additional enzymes (the glyoxylate cycle) that allow them to convert two molecules of acetyl CoA to OA and glucose.

Energy Capture (Anabolism)

During feeding, when the energy ingested as food exceeds the energy released by oxidation, the body stores excess calories as glycogen or fat. However, storing energy has a cost, although it is relatively inexpensive from a total-energy standpoint. The process of digesting a mixed meal in the GI tract elevates the whole-body metabolic rate 20% to 25% higher than the RMR for ~90 minutes following a meal. In addition to this cost of digesting and absorbing, the energy cost of *storing* dietary carbohydrate as glycogen or dietary lipid as TAGs is 3% to 7% of the energy taken in. The cost of storing amino acids as protein is nearly 25% of the energy taken in. Moreover, storage after *interconversions* among dietary categories is particularly expensive. The cost of storing dietary carbohydrate as TAGs, or of storing amino acids as glycogen, is nearly 25% of the intake energy.

After a carbohydrate meal, the body burns some ingested glucose and incorporates the rest into glycogen or TAGs

Three mechanisms maintain normoglycemia following carbohydrate ingestion: (1) suppression of hepatic glucose production; (2) stimulation of hepatic glucose uptake; and (3) stimulation of glucose uptake by peripheral tissues, predominantly muscle. Insulin is the primary signal, which orchestrates the storage and metabolism of glucose via the insulin receptor (see Fig. 51-5). Glucose is the dominant signal for insulin secretion. However, with meals, other signals converge on the β cells of the pancreatic islets to coordinate insulin secretion, as becomes apparent when one compares the insulin responses to identical amounts of glucose loads given intravenously versus orally (see Fig. 51-3A). Viewed differently, for similar plasma glucose levels, oral glucose raises plasma [insulin] several-fold higher than does intravenous glucose. This differential insulin response is due to the secretion of multiple incretins (see p. 1041)—especially glucagon-like peptide 1 (GLP-1) and gastric inhibitory peptide (GIP)—as well as from parasympathetic innervation of the pancreatic β cells. The incretins and neural signals prime the β cells, magnifying insulin release following meal-induced increases in blood glucose. This priming is absent when blood glucose increases as a result of increased hepatic glycogenolysis in response to stress, and thus minimizes the potentially detrimental hyperinsulinemia during stress.

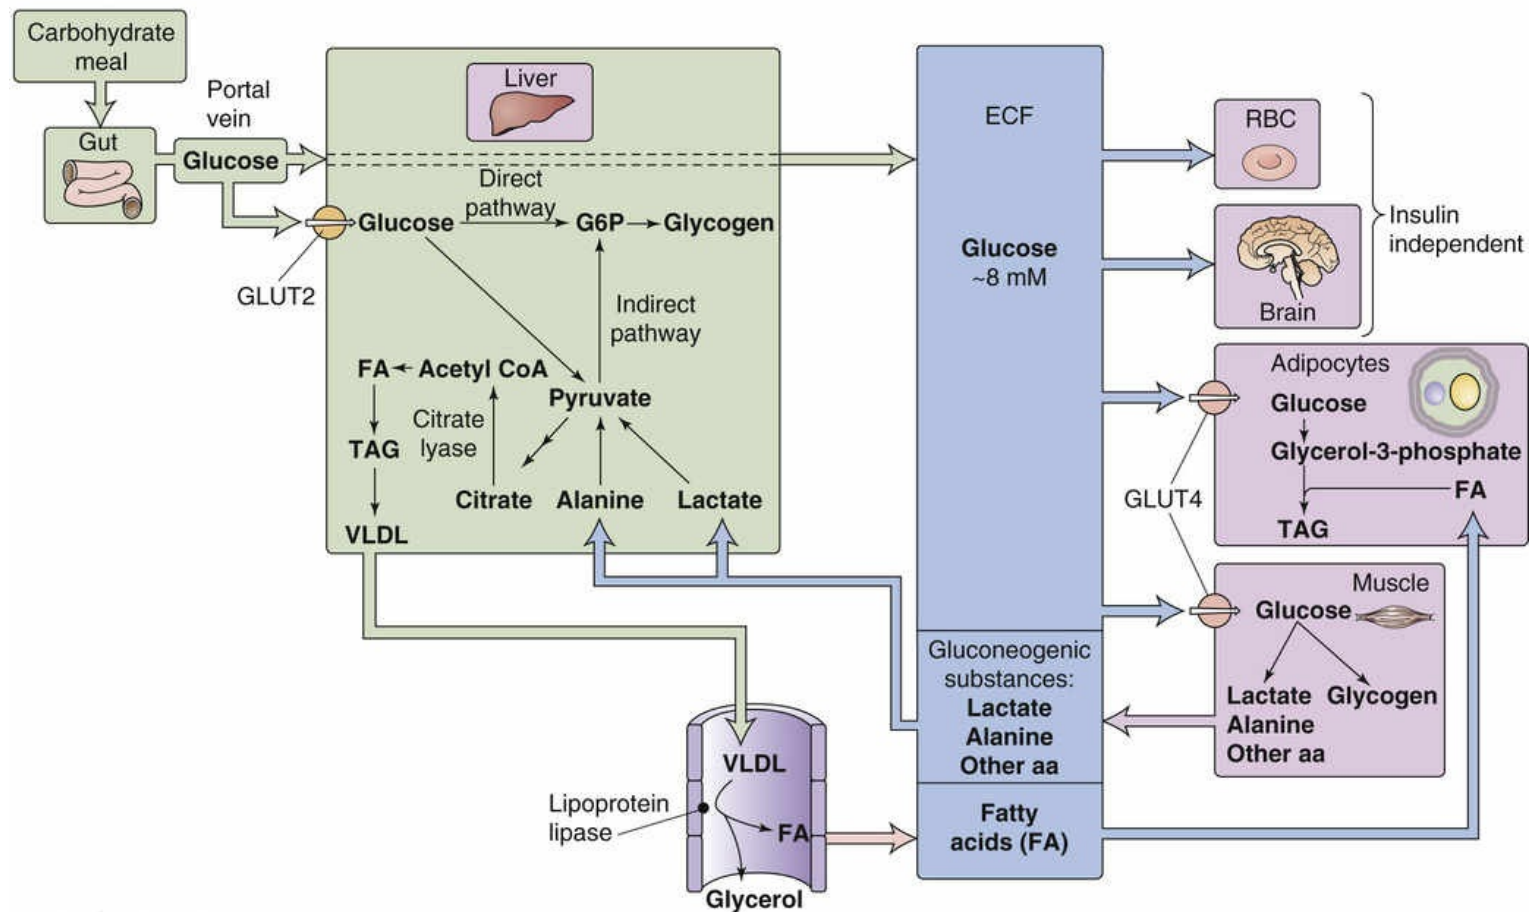

Liver

Following a carbohydrate meal, levels of insulin and glucose rise in the portal vein (similar to the situation shown in Fig. 51-3A), whereas glucagon levels fall. These changes suppress hepatic glucose production and promote net hepatic glucose uptake. Thus, the liver buffers the entry of glucose from the portal vein into the systemic circulation, thereby minimizing fluctuations in plasma [glucose] while promoting glucose storage. Once plasma [glucose] returns to baseline, the liver resumes net glucose production to maintain normoglycemia. Depending on the size of the carbohydrate load, the liver may take up one fourth to one third of the ingested exogenous glucose load. Because the liver not only decreases its *production* of glucose but also takes up a significant amount of glucose, the contribution of the liver to postprandial glucose homeostasis is substantial and approaches that of muscle.

Glucose taken up by the liver during the meal is predominantly stored as **glycogen**. The liver synthesizes glycogen by both a **direct pathway** from exogenous glucose and an **indirect pathway** from gluconeogenesis (Fig. 58-8A). When we ingest a meal following an overnight fast, these pathways

contribute roughly equally to hepatic glycogen synthesis. However, the relative contributions of these pathways depends on the composition of the diet, the level of glycemia achieved during the meal, and the relative concentrations of insulin and glucagon. A high-carbohydrate diet, hyperglycemia, and insulin promote the direct pathway, whereas reduced carbohydrate intake, lower plasma [glucose], and elevations in circulating [glucagon] stimulate the indirect pathway.

A CARBOHYDRATE MEAL

B PROTEIN MEAL

C FATTY MEAL

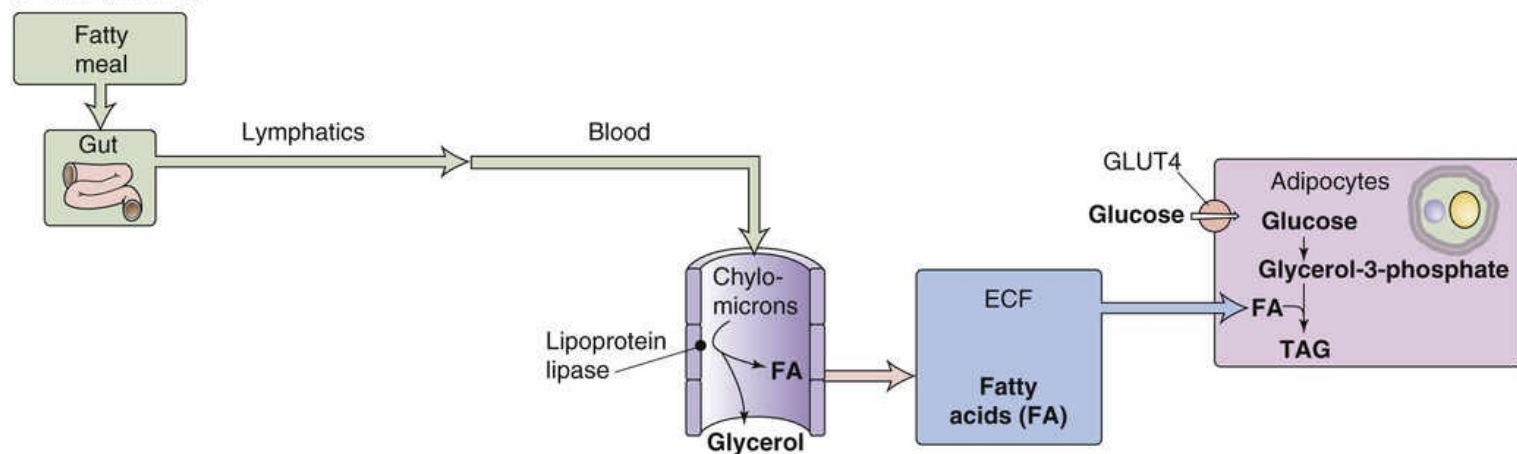

FIGURE 58-8 Energy storage following meals. **A**, Three major organs handle the glucose assimilated by the small intestine. Liver stores some glucose as glycogen, and converts some to FAs—packaged as

VLDLs—for export to adipocytes. Muscle stores some glucose as glycogen and converts some to lactate and gluconeogenic amino acids for export to the liver. Adipocytes convert glucose to glycerol-3-phosphate, a precursor of TAGs. **B**, Two major organs handle the amino acids assimilated by the small intestine. Liver converts gluconeogenic amino acids to glycogen. Muscle converts amino acids to glycogen. **C**, Chylomicrons from the small intestine undergo hydrolysis in systemic blood vessels. Adipocytes re-esterify the resulting FAs (together with glycerol-3-phosphate generated from glucose) for storage as TAGs. ECF, extracellular fluid; RBC, red blood cell.

Hepatic glycogen stores peak 4 to 6 hours following a meal. Thus, when we ingest three meals per day at 4- to 6-hour intervals, hepatic glycogen stores increase throughout the day in a staircase fashion. During this time, most of the glucose required for metabolism comes from exogenous glucose (see dashed arrow in [Fig. 58-8A](#)). Glycogen stores reach their peak around midnight, after which hepatic glycogenolysis contributes ~50% to whole-body glucose production and the other 50% derives from hepatic gluconeogenesis.

Because the liver has citrate lyase, it can also convert glucose that it takes up following a meal to FAs (see [Fig. 58-8A](#)) via reactions summarized in [Figure 58-7](#). The hepatocyte esterifies these FAs to glycerol to make **TAGs**, which it packages as **VLDLs** for export to the blood.

Muscle

Glucose escaping the liver is cleared predominantly by striated muscle, which stores most of this glucose as glycogen (see [Fig. 58-8A](#)). Muscle metabolizes the remaining glucose via the glycolytic pathway and then either oxidizes the products or recycles them to the liver, mostly as lactate and alanine.

The uptake of glucose into muscle—as well as adipose tissue—is regulated predominantly by a rise in [insulin] and, to a lesser extent, by the hyperglycemia per se. Insulin, via the **phosphatidylinositol 3-kinase (PI3K)** pathway (see [p. 1042](#)), promotes translocation of the **GLUT4** glucose transporter (see [p. 1047](#)) to the plasma membrane, and thus stimulates glucose uptake by muscle and fat. In addition, insulin modulates the subsequent metabolism of glucose by increasing the activity of glycogen synthase, thereby promoting glucose storage, and by increasing the activity of pyruvate dehydrogenase, thereby increasing glucose oxidation as well.

Adipose Tissue

Although adipose tissue typically represents a large component of the peripheral mass (10% to 15% of body weight in men, 25% to 30% in women), adipocytes metabolize only a minor fraction of ingested glucose (see [Fig. 58-8C](#)). The reason is that, in contrast to the liver, human adipocytes have a relatively low metabolic rate and contain relatively little citrate lyase, and thus have a low capability of converting glucose into FAs. However, adipocytes use glucose as the starting material for generating glycerol-3-phosphate, [N58-12](#) which serves as the backbone for TAG synthesis (see [Fig. 58-8A](#)). As we saw above, in times of caloric and carbohydrate excess, the liver (which has an abundance of citrate lyase) synthesizes FAs de novo from glucose and esterifies the FAs to generate TAGs, which it then exports in the form of VLDL particles (see [Fig. 46-15](#)). Lipoprotein lipase (LPL; see [p. 1050](#)) on the luminal surface of endothelial cells hydrolyzes the TAGs in VLDLs and chylomicrons to FAs. Subsequently the FAs enter adipocytes, which re-esterify them to form TAGs for storage. These adipocytes are mostly in the subcutaneous and visceral tissues and, to a much smaller extent, around muscle.

sn-Glycerol-3-Phosphate

Contributed by Kitt Petersen, Gerald Shulman

Glycerol has no asymmetric carbon atoms. However, adding a phosphate group at either end makes the middle carbon atom asymmetric. Depending on whether you assign the appellation carbon 1 to one end of the molecule or the other, the same compound is known either as **L-glycerol-3-phosphate** or **D-glycerol-1-phosphate**. Another synonym is **α -glycerol phosphate**. When stereospecific numbering (sn) is used, the compound is unambiguously known as **sn-glycerol-3-phosphate**. For the sake of simplicity in the text, we simply refer to it as **glycerol-3-phosphate**.

The larger the meal, the greater the rate of glucose uptake by liver, muscle, and adipose tissue—because of higher levels of circulating insulin and glucose. In contrast, the brain uses glucose, its major oxidative fuel, at a constant rate, despite these fluctuations in plasma glucose during feeding. GLUT1 facilitates glucose uptake across the blood-brain barrier, and GLUT3 mediates glucose uptake into neurons, independent of insulin ([Box 58-1](#)).

Box 58-1

Fructose Ingestion

The hepatic metabolism of *fructose* differs from that of glucose in ways that are important to human health. Hepatic glucose metabolism is tightly regulated by PFK (see p. 1176), which is inhibited by ATP and citrate. Thus, a sufficient energy status signals hepatocytes to reduce uptake of dietary glucose, much of which now bypasses the liver to reach the systemic circulation. In contrast, dietary fructose is metabolized to fructose-1-phosphate by fructokinase, which is independent of hepatic energy status and the inhibitory effects of high $[\text{ATP}]_i$ and $[\text{citrate}]_i$. Thus, fructose uptake and metabolism by the liver is unregulated, and relatively little ingested fructose reaches the systemic circulation. In the liver, a large fructose load—as from soft drinks sweetened with inexpensive high-fructose corn syrup—can result in increased *de novo* lipogenesis and inhibition of FA oxidation. This process contributes to the development of hepatic insulin resistance and **nonalcoholic fatty liver disease (NAFLD)**. Owing to the current epidemic of obesity, NAFLD is now the most common liver disorder in adults and children. (*Contributed by Fred Suchy.*)

After a protein meal, the body burns some ingested amino acids and incorporates the rest into proteins

Following a protein meal, the amino acids absorbed by the GI tract (see [pp. 922–925](#)) have two major fates: they can either be oxidized to yield energy or be incorporated into protein. The liver removes a large fraction of amino acids that enter portal blood following a meal, particularly the gluconeogenic amino acids (see [Fig. 58-8B](#)). In contrast, the liver less avidly removes the branched-chain amino acids (leucine, isoleucine, and valine), which muscle predominantly captures. Indeed, branched-chain amino acids are critical for the immediate repletion of muscle protein because they have a unique capacity to promote net protein accumulation, predominantly by inhibiting protein breakdown and to some extent by stimulating protein synthesis.

Insulin plays a major role in orchestrating protein anabolism, mostly by suppressing protein

degradation. Therefore, the combination of the hyperinsulinemia and hyperaminoacidemia that follows a protein meal not only blocks proteolysis but also stimulates protein synthesis, resulting in net protein accumulation. Because some amino acids (e.g., arginine, leucine) are weak insulin secretagogues (see [p. 1139](#)), a protein meal stimulates insulin release even when the meal lacks carbohydrate. Under such conditions, glucagon plays a critical role in preventing potential hypoglycemia by maintaining hepatic glucose production in the face of hyperinsulinemia. In a *mixed* meal, the presence of carbohydrates augments insulin secretion beyond the effect of protein alone and further enhances protein anabolism.

After a fatty meal, the body burns some ingested FAs and incorporates the rest into TAGs

Following a fat-containing meal (see [Fig. 58-8C](#)), lipases in the duodenum hydrolyze the TAGs to FAs and glycerol, which enterocytes in the small intestine take up, re-esterify into TAGs, and secrete as chylomicrons. [N58-11](#) The chylomicrons enter the lymphatics and then the systemic circulation.

Insulin, secreted in response to the carbohydrate or protein components of the meal, has three major effects on lipid metabolism. First, insulin induces synthesis of **LPL** (see [p. 1050](#)), which—at the luminal membrane of endothelial cells—promotes hydrolysis of TAGs to FAs and glycerol. The breakdown products enter the adipocytes for re-esterification into TAGs. Insulin promotes storage in muscle and adipose tissue of both *exogenous* TAGs (derived from a meal and carried in chylomicrons; see [p. 930](#)), as shown in [Figure 58-8C](#), and *endogenous* TAGs (produced by the liver and carried in VLDLs; see [p. 968](#)), as shown in [Figure 58-8A](#).

Second, insulin stimulates glucose uptake into adipocytes by stimulating **GLUT4**. The adipocytes transform the glucose to glycerol-3-phosphate, as discussed above (see [p. 1181](#)), which is the backbone required for the re-esterification of FAs into TAGs. Adipocytes lack glycerol kinase and therefore, unlike liver and kidney, are unable to phosphorylate glycerol directly.

Third, in fat cells, insulin inhibits **adipose triacylglycerol lipase (ATGL; see p. 1050)**, which releases an FA from a TAG to form a diacylglycerol (DAG; TAG → DAG + FA), and **hormone-sensitive lipase (HSL)**, which releases an FA from a DAG to form a monoacylglycerol (MAG; DAG → MAG + FA). These enzymes—not to be confused with LPL—catalyze the hydrolysis of *stored* TAGs in adipocytes. By suppressing lipolysis, insulin markedly decreases plasma [FA] and promotes net storage of absorbed fat into the adipocyte.

In a mixed meal—when glucose, amino acids, and FAs are all available—an increase in plasma [insulin] augments the incorporation of these substances into glycogen, protein, and fat. This is accomplished by inhibiting glycogenolysis, proteolysis, and lipolysis as well as by promoting the opposite of these three processes. Because of the dose-response relationships, low levels of insulin preferentially inhibit the breakdown of energy stores, whereas high levels preferentially stimulate energy accumulation. Thus, small meals (associated with smaller insulin responses) mainly conserve depots by reducing breakdown, whereas larger meals (and concomitant greater insulin responses) increase depots by stimulating storage.

Energy Liberation (Catabolism)

The general principle in energy catabolism is that the body first breaks down a complex storage polymer (e.g., glycogen or TAGs) to simpler compounds (e.g., glucose, FAs, lactate) that the cells can then metabolize to provide energy, mostly in the form of ATP, for cellular function.

The first step in energy catabolism is to break down glycogen or TAGs to simpler compounds

Skeletal Muscle

Glycogenolysis in skeletal muscle is catalyzed by glycogen phosphorylase (GP; Fig. 58-9A). In three ways, muscle contraction activates GP. First, **epinephrine** binds to a β -adrenergic receptor and thereby promotes the formation of cAMP (see p. 53). The cAMP activates PKA, which in turn phosphorylates glycogen phosphorylase kinase (PK). In parallel, PKA inactivates phosphoprotein phosphatase 1 (see Fig. 3-7), thereby stabilizing the phosphorylated state of PK. The now active form of PK converts the inactive glycogen phosphorylase *b* (GPb) to the active **GPa**. Second, muscle activity increases the turnover of ATP, thereby raising $[AMP]_i$; the binding of AMP allosterically activates GPb. Conversely, at rest, ATP competes with AMP for this nucleotide-binding site on GPb and thus inhibits GPb. Third, intense activity of skeletal muscle causes $[Ca^{2+}]_i$ to rise; the binding of Ca^{2+} to PK allosterically activates this enzyme, **N58-13** and converts GPb to the active GPa. Skeletal muscle converts the product of glycogenolysis, glucose-1-phosphate (G1P), to G6P, which enters the glycolytic pathway within the muscle cell.

FIGURE 58-9 Mobilization of energy stores by epinephrine and glucagon. **A**, In muscle, epinephrine promotes glycogenolysis and glycolysis, thereby producing ATP (for muscle contraction) and lactate. See Figure 3-7 for a representation of how PKA inactivates phosphoprotein phosphatase 1 (PP1). **B**, In liver, primarily glucagon and also epinephrine trigger glucose production in the short term via glycogenolysis, and over the long term via gluconeogenesis. Because they have G6Pase, hepatocytes can generate glucose and export it to the blood. **C**, In adipocytes, epinephrine triggers production of FAs and glycerol, which leave the adipocytes and enter the blood. GS, glycogen synthase; HSL, hormone-sensitive triacylglycerol lipase; UDP, uridine diphosphate. Yellow halos surround the active forms of enzymes.

PK has the subunit structure $(\alpha\beta\gamma\delta)_4$. The α and β subunits are substrates for PKA. The δ subunits are in fact **calmodulin (CaM)**. In other words, PK is a Ca^{2+} -CaM-dependent kinase (i.e., a CaM kinase). Thus, an increase in $[\text{Ca}^{2+}]_i$ can activate PK allosterically and thereby promote the conversion of **phosphorylase b** to **phosphorylase a**, which favors glycogenolysis.

Liver

As is the case in muscle, GP_a in hepatocytes converts glycogen to G1P. The signaling pathways that establish the GP_a/GP_b ratio are the same as in muscle, except that in the liver, it is mainly **glucagon** (see pp. 1050–1053) in the portal blood—and, to a lesser extent, epinephrine—that triggers the increase in $[\text{cAMP}]_i$ (see Fig. 58-9B). The liver then converts G1P to G6P, as in muscle. However, unlike muscle, liver contains the enzyme **G6Pase**; G6Pase cleaves the phosphate from G6P to yield glucose, which is free to enter the bloodstream. Thus, whereas glycogenolysis in skeletal muscle serves to meet *local* energy demands by releasing G6P, glycogenolysis in the liver serves to meet whole-body energy demands—mainly those of the central nervous system (CNS)—by releasing glucose to the *blood*.

Adipocytes

In adipocytes, HSL catalyzes **lipolysis**, the hydrolysis of the ester linkages of TAGS to release FAs and glycerol. Nearly all (95%) of the available energy of TAGS resides in the FA moieties. Two hormones can stimulate lipolysis: **epinephrine**, which the adrenal medulla secretes under conditions of low blood glucose or stress, and **growth hormone** (see pp. 990–995). As in skeletal muscle and hepatocytes, epinephrine acts through cAMP (see Fig. 58-9C). The result is activation of HSL and release of FAs, which exit the adipocytes into the bloodstream. There, the poorly soluble FAs bind to circulating **albumin**, which releases them at the sites of energy demand.

The second step in TAG catabolism is β -oxidation of FAs

In carbohydrate catabolism, after the breakdown of glycogen, the second step is glycolysis. In TAG metabolism, after the breakdown to FAs, the second step is the β -oxidation of FAs, which takes place in the mitochondrial matrix. (Recall that FA synthesis takes place in the cytoplasm; see p. 1178.) Before β -oxidation, the hepatocyte uses **FA transport protein 5 (FATP5 or SLC27A5)** to transport the FA from the extracellular fluid into the cytosol (Fig. 58-10), where **acyl CoA synthase** activates the FA to **acyl CoA** (i.e., the FA chain coupled to CoA). To deliver acyl CoA to the mitochondrial matrix, the cell uses **carnitine acyltransferase I (CAT I)** on the cytosolic side of the mitochondrial outer membrane to transfer the acyl group to carnitine. The resulting acylcarnitine moves through a **porin** (see p. 109) in the mitochondrial outer membrane to enter the intermembrane space. The **carnitine/acylcarnitine transporter (CAC, SLC25A20)** on the mitochondrial inner membrane moves acylcarnitine into the mitochondrial matrix. There, **CAT II** transfers the acyl group back to CoA to form acyl CoA and carnitine. The carnitine recycles to the cytosol via CAC and the porin, whereas acyl CoA undergoes β -oxidation.

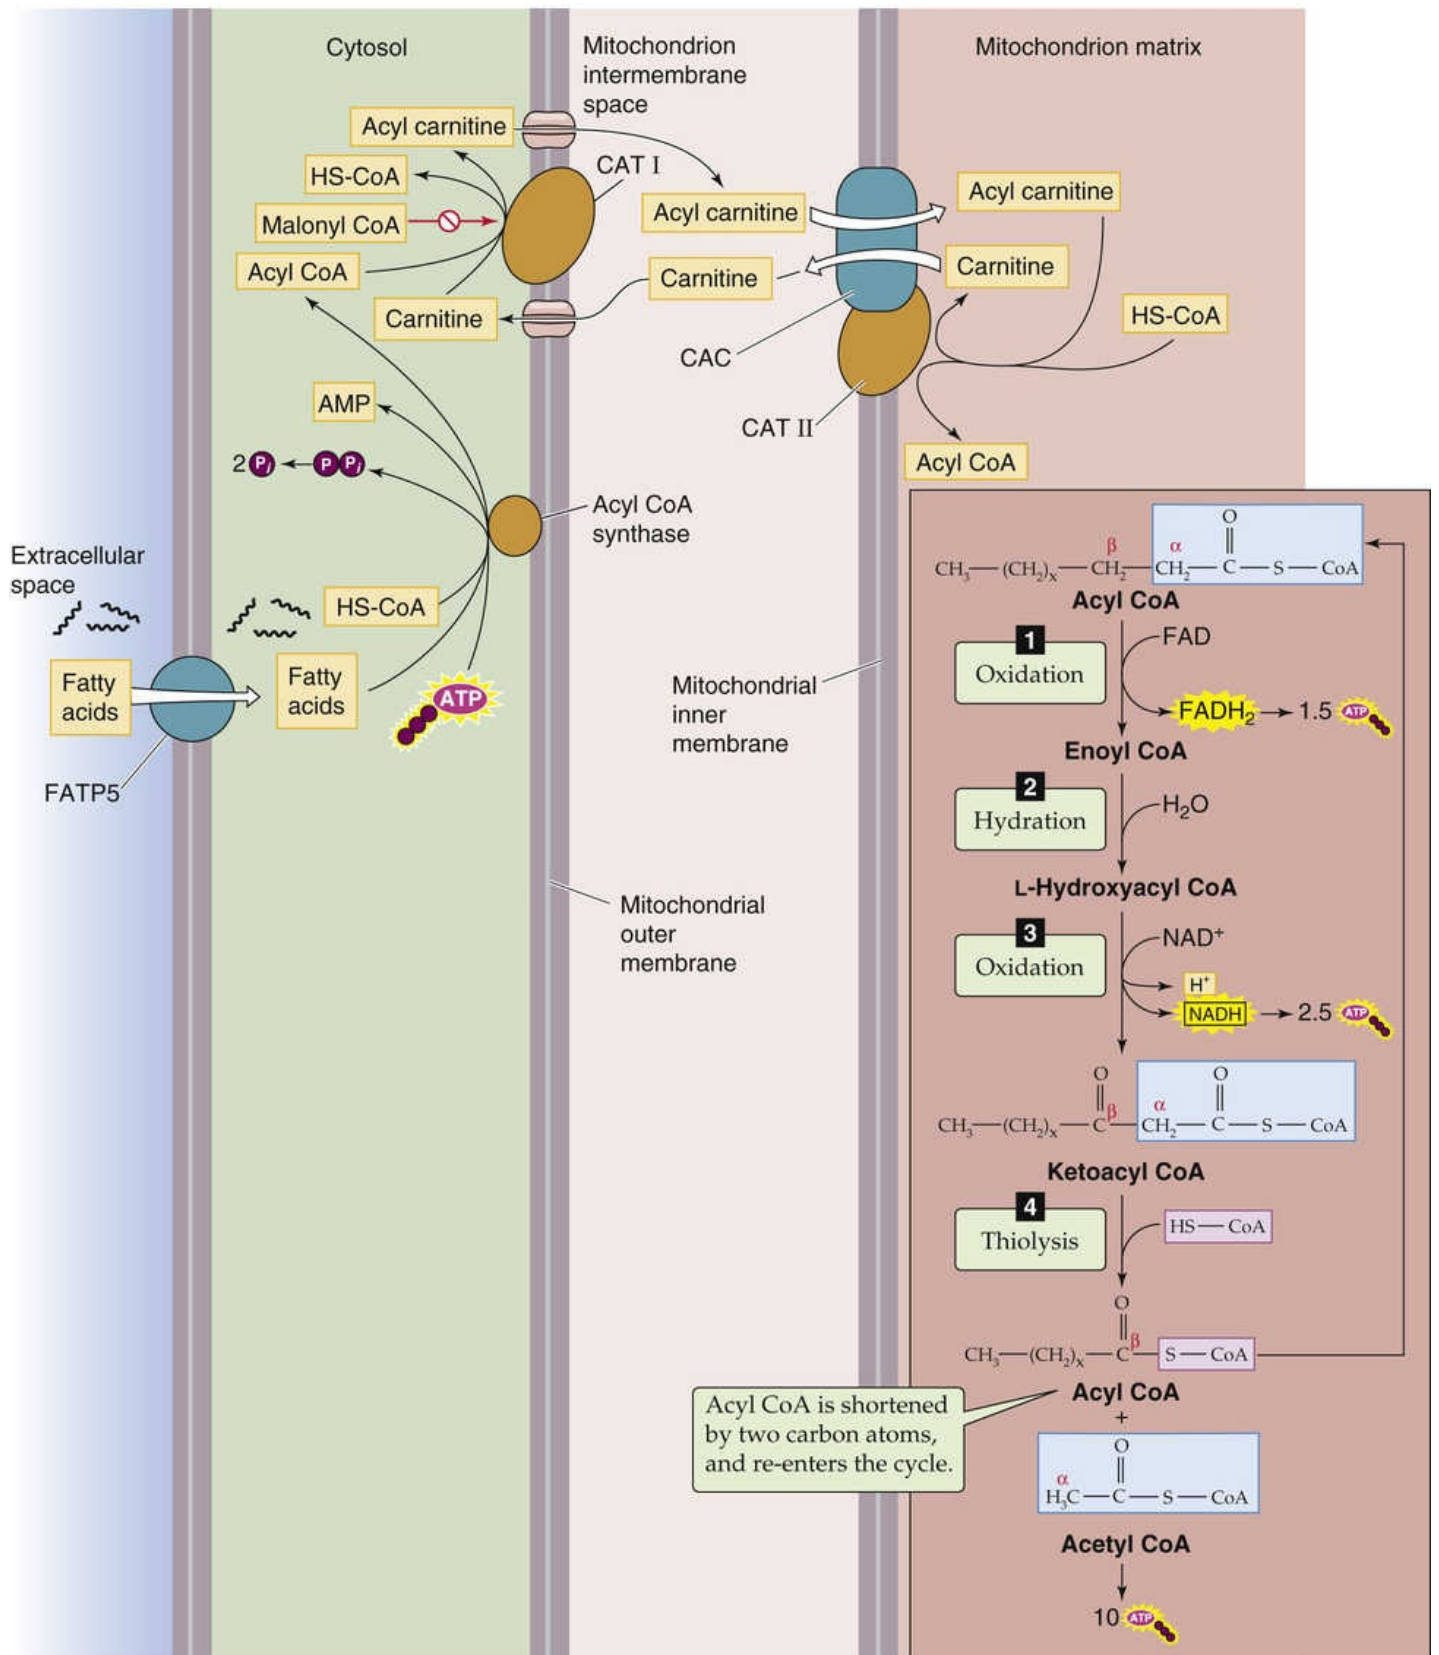

FIGURE 58-10 FA transport into mitochondrion and β -oxidation. FAD/FADH₂, oxidized and reduced forms of flavin adenine dinucleotide, respectively; NAD⁺/NADH, oxidized and reduced forms of nicotinamide adenine dinucleotide, respectively.

β -oxidation is a multistep process that removes a 2-carbon fragment from the end of an acyl CoA and releases the fragment as an acetyl CoA (see [Fig. 58-10](#)). The process also releases one **reduced flavin adenine dinucleotide** (FADH₂), one NADH, and the remainder of the acyl chain (beginning with the original β carbon), which serves as the starting point for the next cycle. β -oxidation continues until it consumes the entire FA chain. For an FA chain containing n carbons, the number of cycles is $([n/2] - 1)$. The final cycle generates two acetyl CoA molecules. Unlike the breakdown of glucose, which can yield ATP even in the absence of O₂ (via glycolysis), the catabolism of FAs to yield energy in the form of ATP can occur only in the presence of O₂.

Malonyl CoA plays a central role in regulating the balance between FA synthesis and β -oxidation. When energy levels are high, the enzyme ACC generates malonyl CoA from acetyl CoA, as shown in [Figure 58-7](#). In turn, malonyl CoA provides the 2-carbon building blocks for FA synthesis. In contrast, malonyl inhibits CAT I and thereby inhibits β -oxidation (see [Fig. 58-10](#)).

The final common steps in oxidizing carbohydrates, TAGs, and proteins to CO₂ are the citric acid cycle and oxidative phosphorylation

Under aerobic conditions, cells containing mitochondria typically convert most of the pyruvate they generate from carbohydrate metabolism to acetyl CoA, rather than to lactate. Pyruvate—a 3-carbon piece of glucose's carbon skeleton—moves from the cytoplasm into the mitochondrial matrix ([Fig. 58-11](#)). There, pyruvate is oxidatively decarboxylated to acetyl CoA, which releases CO₂ as well as an NADH. Acetyl CoA also forms in the mitochondria as the end product of the β -oxidation of FAs as well as amino-acid breakdown. The metabolism of the acetate moiety of acetyl CoA, as well as the oxidation of NADH and FADH₂, is the final common pathway of **aerobic catabolism**, which releases CO₂, H₂O, ATP, and heat.

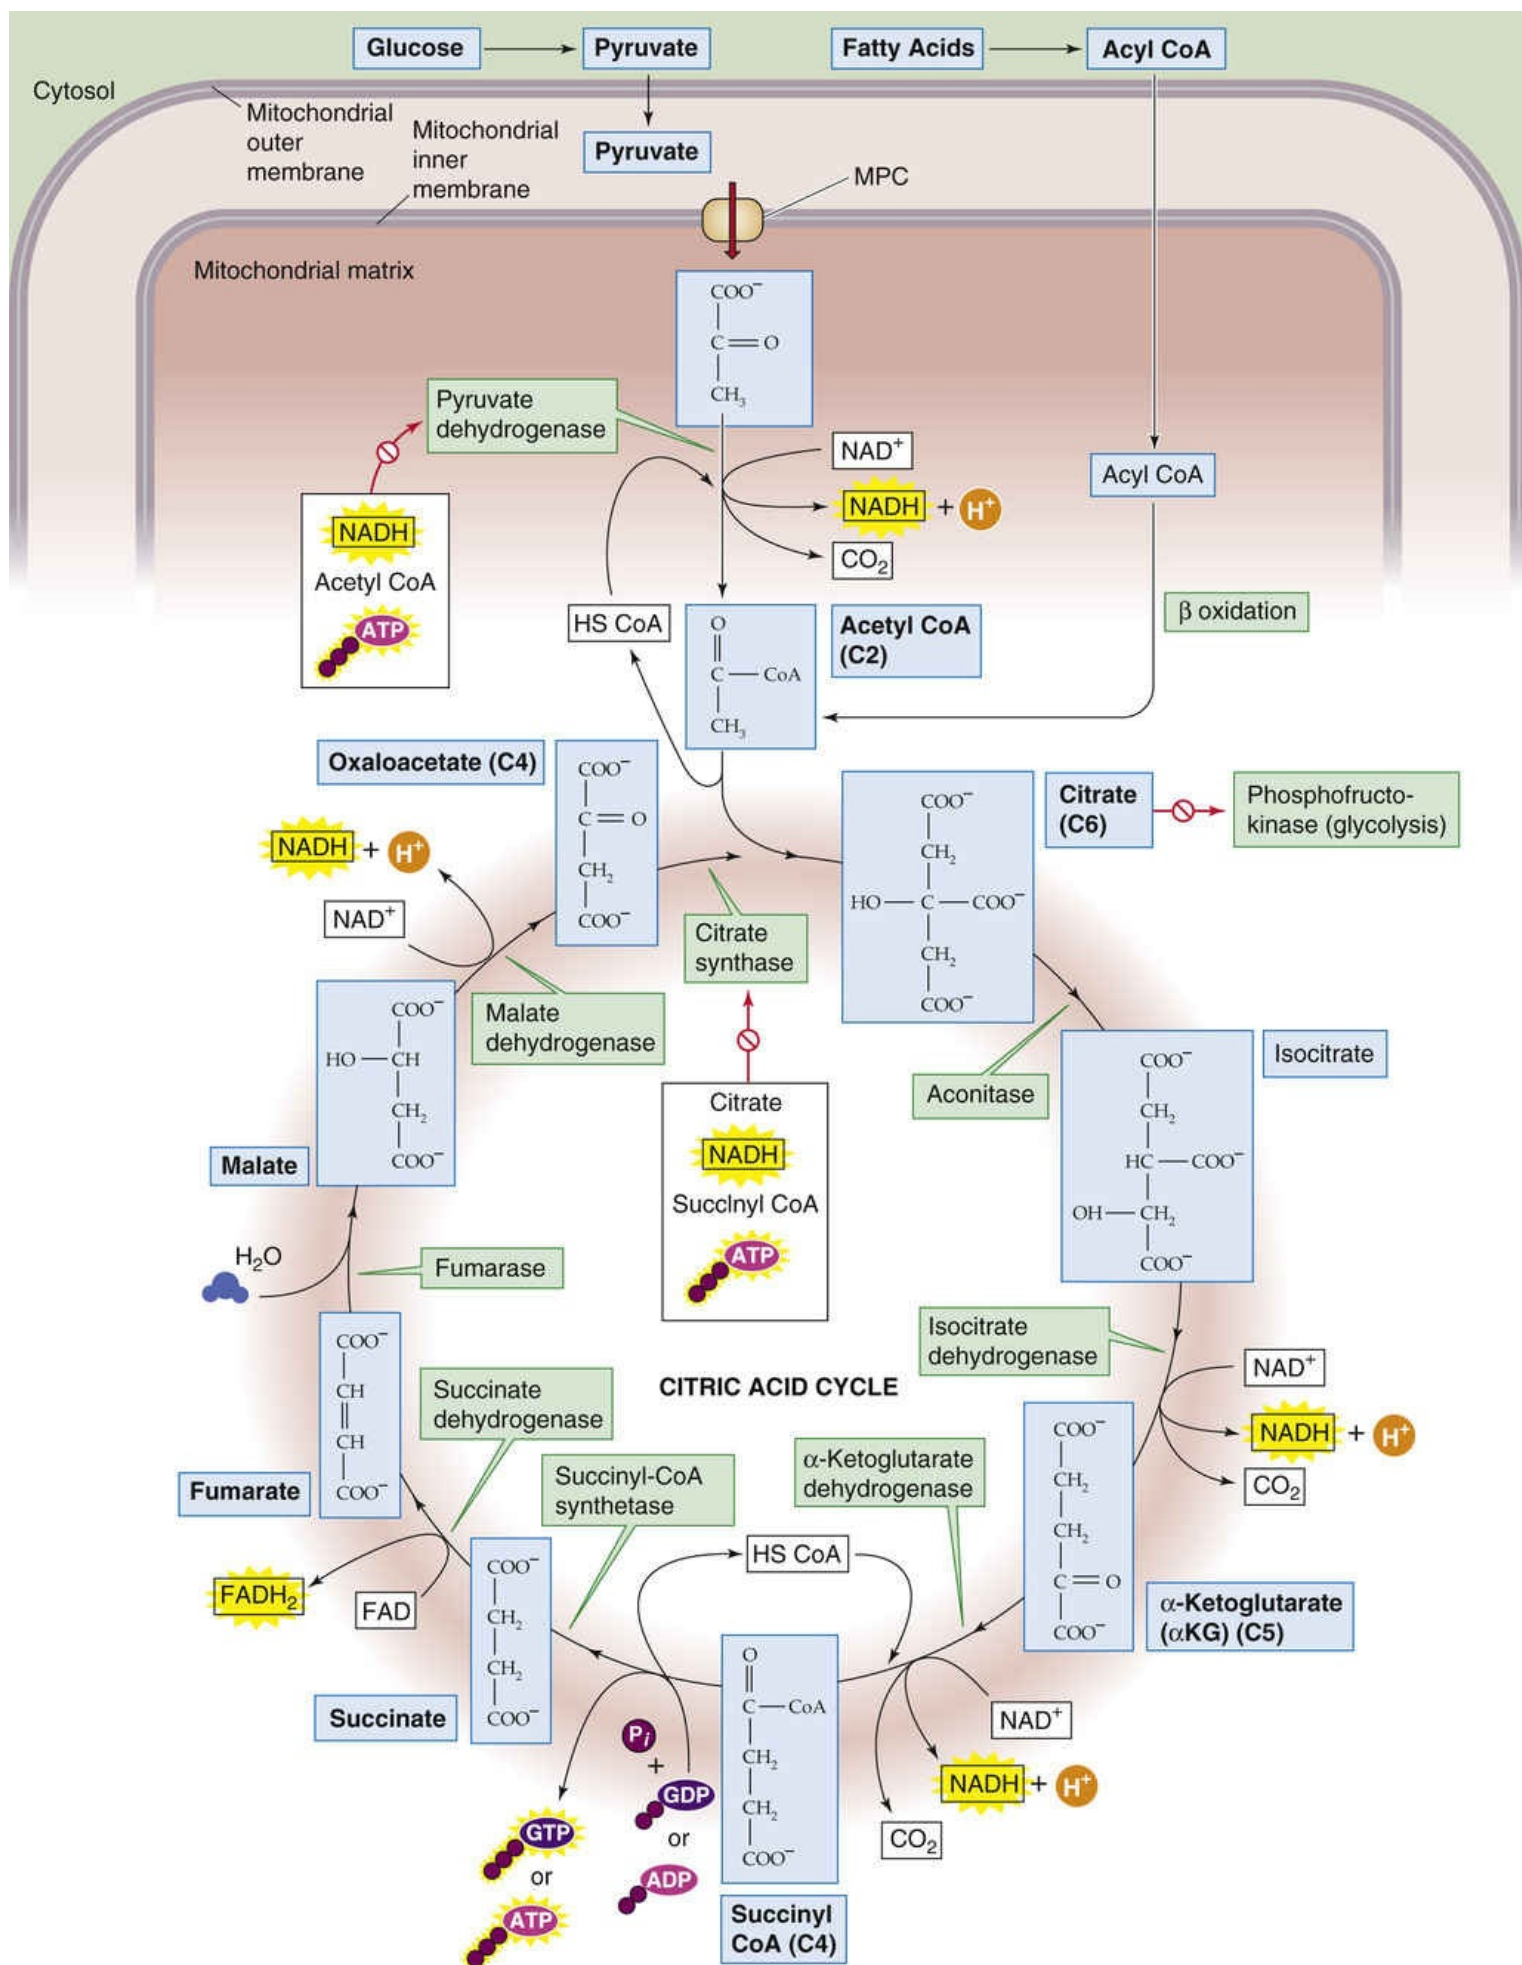

FIGURE 58-11 Citric acid cycle. FAD/FADH₂, oxidized and reduced forms of flavin adenine dinucleotide, respectively; NAD⁺/NADH oxidized and reduced forms of nicotinamide adenine dinucleotide, respectively.

Citric Acid Cycle

A 2-carbon fragment—acetyl CoA—derived from glucose, FA, or amino-acid metabolism enters the phase of catabolism known as the citric acid cycle, also called *internal respiration* (see p. 590) or *oxidative decarboxylation* because the 2-carbon fragment ends up as two CO₂ molecules (see Fig. 58-11). The citric acid cycle conserves the liberated energy as GTP and the reduced electron carriers NADH and FADH₂.

Cells tightly control the citric acid cycle by three *mechanisms* that limit substrate flux through the citric acid cycle: substrate availability, product accumulation, and feedback inhibition of key enzymes. Cells regulate the citric acid cycle at four *sites*. The two entry-point enzymes, pyruvate dehydrogenase and citrate synthase, are the most important. **Pyruvate dehydrogenase (PDH)** N58-14 is inhibited allosterically by two of its immediate products (NADH and acetyl CoA) and one downstream product (ATP). The second primary site of regulation in the citric acid cycle is **citrate synthase**, which is under feedback inhibition of several immediate and downstream products (citrate, NADH, succinyl CoA, ATP). The citrate produced in this reaction feeds back negatively on PFK (see p. 1178), which effectively couples glycolysis and oxidative metabolism (see Fig. 58-6). Two other enzymes, isocitrate dehydrogenase and α-ketoglutarate dehydrogenase, may also be rate limiting for the citric acid cycle under the right conditions.

N58-14

Regulation of Pyruvate Dehydrogenase

Contributed by Ethan Nadel

The **PDH enzyme complex** is a massive assembly of three different enzymes (a total of 132 monomers) that catalyzes the conversion of pyruvate to acetyl CoA. It is inhibited allosterically by two of its immediate products (NADH and acetyl CoA) and one downstream product (ATP). The PDH reaction is also regulated by phosphorylation/dephosphorylation reactions that are catalyzed by kinases and phosphatases that are additional components of the enzyme complex. When [ATP]_i is high, a protein kinase phosphorylates one of the proteins in the complex, thereby inactivating it and stopping the reaction. Conversely, when [ATP]_i is low, a phosphatase hydrolyzes a phosphate group from this same enzyme, activating it and allowing the PDH enzyme complex reaction to proceed.

Oxidative Phosphorylation

The process by which mitochondria retrieve energy from FADH₂ and NADH is oxidative phosphorylation. These reduced nucleotides are products of glycolysis (see Fig. 58-6), β-oxidation (see Fig. 58-10) conversion of pyruvate to acetyl CoA (see Fig. 58-11), and the citric acid cycle. Oxidative phosphorylation involves the transfer of electrons along a chain of molecules, and it ultimately traps the releasing energy in the formation of 1.5 ATP molecules per FADH₂ and 2.5 ATP molecules per NADH (see Fig. 5-9B). N58-15

N58-15

Shuttle Systems for Moving Reducing Equivalents

Contributed by Emile Boulpaep, Walter Boron

As outlined in Figure 5-9B in the text, the electron transport chain of the mitochondrion uses the energy stored in the reducing equivalents NADH (and FADH₂)—which themselves must be within the mitochondrial matrix—to pump H⁺ from the mitochondrial matrix to the mitochondrial intermembrane space (i.e., the space between the inner and outer mitochondrial membranes). Later, these H⁺ flow back into the mitochondrial matrix “downhill” through ATP synthase, which uses the recovered energy to convert ADP and P_i to ATP.

As outlined in Figure 58-11 and Table 58-4, most of these reducing equivalents (i.e., NADH and FADH₂) originate in the mitochondrial matrix. In other words, they are created on the same side of the mitochondrial inner membrane on which they will be used. However, the two molecules of NADH that arise from the *glycolysis* of one glucose molecule (see Fig. 58-6A) are created in the cytoplasm. Thus, the cell must somehow move these reducing equivalents across the mitochondrial inner membrane and into the mitochondrial matrix before the mitochondrion can use them to generate ATP. However, the cell cannot move the reducing equivalents *directly* across the mitochondrial inner membrane. Instead, it must use one of two complicated **shuttle systems** to do the job. One is called the malate-aspartate shuttle, and the other is called the glycerol-3-phosphate shuttle. The efficiency of the two shuttle systems is quite different. The malate-aspartate shuttle is the more efficient of the two, ultimately yielding 2.5 ATPs per NADH. The glycerol-3-phosphate shuttle yields only 1.5 ATPs per NADH.

Malate-Aspartate Shuttle

Most cells—particularly heart, kidney, and liver—use the malate-aspartate shuttle system. The first step is catalyzed by **malate dehydrogenase** in the intermembrane space (IS):

Next, the **malate- α -ketoglutarate exchanger** in the mitochondrial inner membrane moves the malate into the mitochondrial matrix (MM) in exchange for α -ketoglutarate (α KG):

Next, **malate dehydrogenase** in the mitochondrial matrix regenerates the NADH:

This NADH can now enter the electron-transport chain. However, several more steps are required to complete the shuttle. Next, **aspartate aminotransferase** in the mitochondrial matrix consumes the oxaloacetate generated in Equation NE 58-3:

This is the α KG that exchanges for malate in Equation NE 58-2. In the meantime, the **glutamate-aspartate exchanger** in the mitochondrial inner membrane moves the newly formed aspartate out of the mitochondrion in exchange for glutamate:

This imported glutamate is the substrate in Equation NE 58-4. Finally, the enzyme **aspartate aminotransferase** in the intermembrane space catalyzes the following reaction:

Equation NE 58-6 (which takes place in the intermembrane space) is the inverse of Equation NE 58-4 (which takes place in the mitochondrial matrix).

Summing these six reactions, you will see that the net effect is to transfer NADH from the intermembrane space to the mitochondrial matrix. Because the NADH enters the electron transport chain at complex I (see Fig. 5-9B), the electron transport chain can use the energy stored in the NADH molecule to pump 10 H^+ ions out of the mitochondrion across the mitochondrial inner membrane. Because the net stoichiometry of ATP synthesis is one ATP for every four H^+ , the NADH that passes through the glycerol-3-phosphate shuttle generates 10/4 or 2.5 ATPs.

Glycerol-3-Phosphate Shuttle

The brain and skeletal muscle use a shuttle system that—in terms of the number of ATPs generated per NADH—is only 60% as efficient as the malate-aspartate shuttle. In the first step, the cytosolic enzyme **glycerol-3-phosphate dehydrogenase** simultaneously converts $\text{NADH} + \text{H}^+$ to NAD^+ and converts dihydroxyacetone phosphate (DHAP, an intermediate of glycolysis; see Fig. 58-6B) to glycerol-3-phosphate:

Next, another **glycerol-3-phosphate dehydrogenase**—present on the outer surface of the mitochondrial inner membrane—converts the glycerol-3-phosphate back to DHAP while simultaneously transferring two H to an FAD to form FADH_2 :

This FADH_2 can then transfer a pair of electrons that eventually pass through complexes III and IV (see

Fig. 5-9B), which can pump six H^+ ions out of the mitochondrion across the mitochondrial inner membrane. Because the net stoichiometry of ATP synthesis is one ATP for every four H^+ , the NADH that passes through the glycerol-3-phosphate shuttle generates only 6/4 or 1.5 ATPs.

Ketogenesis

Conditions such as prolonged fasting, consumption of a low-carbohydrate diet, or untreated diabetes mellitus lead to the production of three water-soluble byproducts of incomplete FA oxidation, substances collectively known as **ketone bodies**: acetoacetate, β -hydroxybutyrate, and acetone. What the conditions have in common is the accelerated β -oxidation of FAs, which produces acetyl CoA faster than the citric acid cycle can consume it. In addition, accelerated gluconeogenesis steals the OA (see Fig. 58-6B) that would be the entry point for acetyl CoA to enter the citric acid cycle (see Fig. 58-11). As a result, excess acetyl CoA spills over into the production of the three ketone bodies, primarily by liver mitochondria. As indicated by the downward orange arrows in Figure 58-12, the first three reactions in ketogenesis have the net effect of condensing two molecules of acetyl CoA and one H_2O into one molecule of **acetoacetate**, two molecules of HS CoA, and one H^+ . Thus, uncontrolled ketogenesis, which occurs in the absence of insulin (e.g., diabetic ketoacidosis), causes a metabolic acidosis (see p. 635). The second and third reactions are essentially irreversible. Next, the liver can either reduce acetoacetate to **D- β -hydroxybutyrate** or decarboxylate the acetoacetate to **acetone**. The body rids itself of the volatile acetone and CO_2 molecules in the expired air. The acetone gives the breath a fruity odor that can be useful in the physical diagnosis of diabetic ketoacidosis.

Extrahepatic tissues—especially the CNS and striated muscle—can consume either one D- β -hydroxybutyrate or one acetoacetate molecule, as shown by the upward red arrows in [Figure 58-12](#), to produce two acetyl CoA molecules that can then enter the citric acid cycle (see [Fig. 58-11](#)). The key reaction—catalyzed by **β -ketoacyl CoA transferase**—bypasses the two irreversible ketogenic reactions by transferring a CoA from succinyl CoA to acetoacetate. This reaction is itself essentially irreversible. The reason that ketone bodies flow from the liver to extrahepatic tissues is that β -ketoacyl CoA transferase is not present in hepatocytes.

Oxidizing different fuels yields similar amounts of energy per unit O₂ consumed

The source with the greatest energy density (kcal/g) is saturated FAs (see [Table 58-1](#)), which have a high density of carbon and hydrogen that can be oxidized to CO₂ and H₂O. Accordingly, the complete combustion of 1 g of an energy-rich fuel (i.e., lipid) requires more O₂. However, the energy yield per O₂ is similar among fuels, because about the same amount of O₂ is needed to oxidize each carbon and hydrogen. The **energy yield per unit of O₂** is only slightly greater for carbohydrate (5.0 kcal/L of O₂) than for lipid (4.7 kcal/L O₂). Carbohydrate, with its greater energy yield per O₂, is the body's preferred fuel for combustion during maximal exercise when O₂ availability is limited. However, fat is the preferred fuel during prolonged activity, when O₂ is available and fuel sources are abundant.

The metabolism of glucose by *aerobic* glycolysis and the citric acid cycle is far more efficient in providing energy in the form of ATP than *anaerobic* glycolysis in that complete oxidation of 1 molecule of glucose to CO₂ and H₂O via oxidative metabolism provides 30 to 32 molecules of ATP, whereas metabolism of 1 molecule of glucose to lactate by anaerobic glycolysis yields only ~2 molecules of ATP ([Table 58-4](#)). However, anaerobic glycolysis has the major advantage of being able to supply much more ATP *per unit time* than oxidative metabolism of glucose or fat. In this way, energy from glycogen supplies energy for muscle contraction during intense activities, such as sprinting. Responsible for this intense work are fast-twitch type 2 fibers, which have a much greater glycolytic capability but much lower mitochondrial density than slow-twitch type 1 fibers. Unfortunately, muscle can support this type of activity only for several minutes before lactate accumulates and the muscle cramps, or the muscle exhausts its stored glycogen. In contrast, oxidative metabolism of FAs is the major mechanism for supporting exercising muscle during prolonged activity, such as running a marathon, which is mostly the work of the slow-twitch type 1 muscle fibers (see [pp. 1209–1212](#)).

TABLE 58-4
Generation of ATP from the Complete Oxidation of Glucose*

Glycolysis $\xrightarrow{\text{direct}}$	2 ATP
Glycolysis $\rightarrow 2 \times 1 \text{ NADH} \xrightarrow{\text{ox. phos.}}$	3 or 5 ATP
$2 \times (\text{Pyruvate} \rightarrow \text{acetyl CoA}) \rightarrow 2 \text{ NADH} \xrightarrow{\text{ox. phos.}}$	5 ATP
Citric acid cycle $\rightarrow 2 \times 1 \text{ GTP} \xrightarrow{\text{direct}}$	2 ATP
Citric acid cycle $\rightarrow 2 \times 3 = 6 \text{ NADH} \xrightarrow{\text{ox. phos.}}$	15 ATP
Citric acid cycle $\rightarrow 2 \times 1 = 2 \text{ FADH} \xrightarrow{\text{ox. phos.}}$	3 ATP
<div>2</div>	
Total	30 or 32 ATP per glucose

*The calculations in this table assume that the oxidative phosphorylation of each NADH molecule produced in the cytosol (row 2) will yield 1.5 or 2.5 ATP molecules, depending on which shuttle system the cell uses to transfer the reducing equivalents from the cytosol into the mitochondria. The calculations also assume that the oxidative phosphorylation of each NADH produced in the mitochondria (rows 3 and 5) yields 2.5 ATPs, and the oxidative phosphorylation of each FADH₂ produced in the mitochondria (row 6) yields 1.5 ATPs. **N58-15**

ox. phos., oxidative phosphorylation.

In the case of FA metabolism (see Fig. 58-10), each cycle of β-oxidation yields a total of 14 ATP molecules (Table 58-5). The total number of ATP molecules generated from the FA depends on the number of carbon atoms in the FA chain. For example, palmitic acid, a 16-carbon FA, needs seven β-oxidation cycles to form eight acetyl CoA molecules. The seven cycles generate 7 × 14 = 98 ATPs. The leftover acetyl CoA represents an additional 10 ATPs, for a total of 108 ATPs. Because the initial activation of the palmitate to palmitoyl CoA involves converting an ATP to AMP plus pyrophosphate—and regenerating ATP from AMP requires forming two high-energy phosphate bonds—the net ATP production is 108 – 2 = 106 ATPs per palmitate oxidized.

TABLE 58-5
Generation of ATP in One Cycle of β-Oxidation of a Fatty Acid*

*The above calculations assume that oxidative phosphorylation generates 2.5 ATP per NADH, and 1.5 ATP per FADH₂. **N58-15**

(Acyl CoA → Enoyl CoA) → 1 FADH ₂ $\xrightarrow{\text{ox. phos.}}$		1.5 ATP
(L-Hydroxyacyl CoA → Ketoacyl CoA) → 1 NADH $\xrightarrow{\text{ox. phos.}}$		2.5 ATP
1 Acetyl CoA → {	Citric acid cycle $\xrightarrow{\text{direct}}$ → 1 GTP $\xrightarrow{\text{ox. phos.}}$	1 ATP
	Citric acid cycle → 3 NADH $\xrightarrow{\text{ox. phos.}}$	7.5 ATP
	Citric acid cycle → 1 FADH ₂ $\xrightarrow{\text{ox. phos.}}$	1.5 ATP
Total		14 ATP per cycle
ox. phos., oxidative phosphorylation.		

For each primary fuel source, [Table 58-6](#) provides the **respiratory quotient (RQ; see p. 681)** or ratio of moles of CO₂ produced per mole of O₂ consumed at the tissue level. The RQ reflects the density of oxygen atoms in the fuel source. For example, with carbohydrates, the cell needs to supply only enough external O₂ to oxidize the carbon atoms to CO₂. The H₂O is already built into the carbohydrate molecule, which has an H-to-O ratio of 2 : 1.

TABLE 58-6
Respiratory Quotients of the Major Foodstuffs

	ENERGY DENSITY (kcal/g)	RQ
Carbohydrate	4.1	1.00
Protein	4.3	0.80–0.85
Lipid	9.4	0.70

For **carbohydrate oxidation**,

Because lipids contain so many fewer oxygen atoms, lipid oxidation requires more external O₂.
For **lipid oxidation**,

The RQ for protein oxidation is 0.80 to 0.85.

Protein oxidation constitutes a very minor fraction of the total fuel oxidation in any tissue. The brain and anaerobic tissues normally use carbohydrate nearly exclusively and have an RQ of ~1.0. Most tissues oxidize both carbohydrate and fat, and the RQ reflects this mixture. The whole-body RQ following an overnight fast is ~0.8 for people eating a typical Western diet; individuals with lower lipid intake have a higher RQ (i.e., approaching the value of 1 for carbohydrates).

Integrative Metabolism During Fasting

The human body has two main priorities for energy liberation during fasting.

The first priority is to maintain a stable supply of energy for CNS function. The brain has little stored energy in the form of glycogen or TAGs and therefore depends on the liver (and under some circumstances the kidney) for a constant supply of energy in the form of glucose or ketone bodies (see [p. 1185](#)). In the fed state and early in the fasting state, the brain derives essentially all its energy from oxidation of glucose because ketone bodies are not present and the blood-brain barrier is mostly impermeable to FAs. Because a continuous supply of glucose is required to meet the energy demands of the CNS, humans have evolved elaborate, redundant mechanisms to maintain plasma [glucose] within a very narrow range, between 60 and 140 mg/dL (3.3 to 7.8 mM), between fasting and fed states. Lower [glucose] impairs brain function, whereas elevated plasma [glucose] exceeds the renal glucose threshold, results in polyuria, and leads to the multiple complications associated with poorly controlled diabetes mellitus (retinopathy, neuropathy, and nephropathy).

Most other major organs of the body (liver, skeletal muscle, heart, kidney) fill their energy needs at this time by oxidizing FAs. In contrast to the well-regulated plasma [glucose], the concentrations of FAs and ketone bodies can vary by 10- and 100-fold, respectively, depending on the fed and fasted conditions. During prolonged fasting (>2 days), the liver metabolizes FAs to raise plasma levels of ketone bodies (see [p. 1185](#)) sufficiently to supply much of the brain's oxidative fuel needs and diminish the need for gluconeogenic substrate supply by proteolysis.

The second priority for the body is to maintain its protein reserves (i.e., contractile proteins, enzymes, nervous tissue, etc.) in times of fasting.

The body also has two main priorities for energy repletion after fasting. First, following a meal, liver and muscle replenish their limited glycogen reserves. Once these stores are full, liver and muscle convert any excess energy in the form of carbohydrate and protein to fat. Muscle glycogen is the most readily available form of energy for muscle contraction, especially when intense bursts of physical activity are required. Therefore, maintaining an adequate supply of muscle glycogen at all times has obvious survival benefits in times of fight or flight. The second priority during feeding is to replenish protein reserves.

During an overnight fast, glycogenolysis and gluconeogenesis maintain plasma glucose levels

The period after an overnight fast serves as a useful reference point because it represents the period before the transition from the fasted to the fed state. At this time, the concentrations of insulin, glucagon, and metabolic substrates that were altered by meal ingestion during the preceding day have returned to their basal levels. Moreover, the body is in a relative steady state in which the rate of release of endogenous fuels from storage depots closely matches fuel consumption.

Requirement for Glucose

After an overnight fast, the decline in circulating insulin leads to a marked decrease in glucose uptake by insulin-sensitive tissues (e.g., muscle) and a shift toward the use by these tissues of FAs mobilized from fat stores. Nevertheless, the average adult continues to metabolize glucose at a rate of 7 to 10 g/hr. Total-body stores of free glucose, which exists mostly in the extracellular space, amount to only 15 to 20 g or

~2 hours' worth of glucose fuel. However, the useful glucose store is even less if we consider that the plasma [glucose]—normally ~90 mg/dL (5.0 mM) after an overnight fast—may not fall to less than ~55 mg/dL (3.0 mM) before brain function becomes abnormal. Thus, maintaining plasma [glucose] in the presence of this ongoing glucose use, particularly by the brain, requires that the body produce glucose at rates sufficient to match its ongoing consumption.

Gluconeogenesis versus Glycogenolysis

Four to 5 hours after a meal (perhaps longer for a very large meal), a fall in plasma [insulin] (see [pp. 1035–1050](#)) and a rise in [glucagon] (see [pp. 1050–1053](#)) cause the liver to begin breaking down its stores of glycogen and releasing it as glucose. Moreover, both the liver and, to a lesser extent, the kidney generate glucose by gluconeogenesis. The release of glucose by these two organs is possible because they are the only two with significant amounts of pyruvate carboxylase (see [p. 1176](#)) and PEPCK (see [p. 1176](#)), as well as G6Pase (see [p. 1182](#)), which catalyzes the conversion of G6P to glucose. Net hepatic glycogenolysis and gluconeogenesis each contribute ~50% of whole-body glucose production during the first several hours of a fast.

Gluconeogenesis: The Cori Cycle

In the first several hours of a fast, the brain consumes glucose at the rate of 4 to 5 g/hr, which is two thirds the rate of hepatic glucose production (~180 g/day). Obligate anaerobic tissues also metabolize glucose but convert it primarily to lactate and pyruvate. The liver takes up these products and uses gluconeogenesis to regenerate glucose at the expense of energy. The liver releases the glucose for uptake by the glucose-requiring tissues, thus completing the **Cori cycle** ([Fig. 58-13](#)).

FIGURE 58-13 Metabolism during an overnight fast. αAA, α-amino acid; αKA, α-keto acid; αKG, α-ketoglutarate; AQP9, aquaporin 9; ECF, extracellular fluid; RBC, red blood cell.

Gluconeogenesis: The Glucose-Alanine Cycle

After an overnight fast, the body as a whole is in negative nitrogen balance, with muscle and splanchnic tissues being the principal sites of protein degradation and release of amino acids into the blood. **Alanine** and **glutamine**, which are particularly important, represent ~50% of total amino acid released by muscle, even though these amino acids represent only 10% to 13% of total amino acids in muscle protein. The reason that alanine and glutamine are overrepresented is that muscle synthesizes them (see Fig 58-13). During fasting, breakdown of muscle protein yields amino acids, which subsequently transfer their amino groups to α-ketoglutarate (supplied by the citric acid cycle) to form glutamate. Glutamine synthase can then add a second amino group to glutamate, thereby producing glutamine. Alternatively, alanine aminotransferase can transfer the amino group of glutamate to pyruvate (the product of glucose breakdown), generating alanine and α-ketoglutarate. Both glutamine and alanine enter the blood. The intestine uses some of the glutamine as an oxidative fuel and releases the amino groups into portal blood as either alanine or ammonia.

The amino acids taken up by the liver provide carbon for gluconeogenesis. On a molar basis, alanine is the principal amino acid taken up by the liver. In the first several hours of fasting, the liver principally uses alanine for gluconeogenesis (see p. 1176). Because the carbon backbone of alanine came from

glucose metabolism in muscle, and the liver regenerates glucose from this alanine, the net effect is a **glucose-alanine cycle** between muscle and liver, analogous to the Cori cycle.

In addition to playing a role in gluconeogenesis, the glucose-alanine cycle is critical for **nitrogen metabolism** and thus provides a nontoxic alternative to ammonia for transferring amino groups—derived from muscle amino-acid catabolism—to the liver (see [Fig. 58-13](#)). The hepatocytes now detoxify the amino groups on alanine and other amino acids by generating urea (see [Fig. 46-14](#)), which the kidney then excretes (see [Fig. 36-1](#)). Another key amino acid in nitrogen metabolism is glutamine, which muscle releases into the blood for uptake by the gut and liver as well as the kidney. The kidney uses the carbon skeleton of glutamine for renal gluconeogenesis and converts the amino group to ammonia, which it excretes (see [pp. 829–831](#)). This ammonia excretion is particularly important in maintaining body acid-base balance during fasting. Combined, alanine and glutamine account for >40% of the amino-acid carbon used by liver and kidneys in gluconeogenesis.

Neither the Cori cycle nor the glucose-alanine cycle in muscle yields new carbon skeletons. Rather, both cycles transfer energy—and the glucose-alanine cycle also transfers nitrogen—between muscle and liver. The energy for hepatic glucose synthesis comes from oxidation of fat in the liver.

Lipolysis

Finally, the fall in plasma [insulin] after an overnight fast permits the release of FAs and glycerol from fat stores (see [Fig. 51-10](#)). This response appears to be more pronounced in visceral than peripheral fat depots. The decline in [insulin] and the ensuing lipolysis are sufficient to supply FAs to extracerebral tissues (e.g., muscle, heart, liver) for fuel and glycerol to the liver for gluconeogenesis. However, these changes are not sufficient to stimulate the hepatic conversion of FA to ketone bodies (see [pp. 1185–1187](#)).

The body never completely suppresses gluconeogenesis. When an individual ingests a meal, gluconeogenic flux provides glucose for hepatic glycogen stores (*indirect pathway*; see [p. 1179](#)). During fasting, the liver redirects the gluconeogenic flux to provide glucose for delivery to the circulation.

Starvation beyond an overnight fast enhances gluconeogenesis and lipolysis

We have just seen that, during an overnight fast, glycogenolysis and gluconeogenesis contribute about equally to maintain a fasting plasma [glucose] of ~90 mg/dL (5.0 mM). What happens if we extend our fast for 1 or 2 days? Because the glucose utilization rate is 7 to 10 g/hr, if half of this were provided by *glycogenolysis* (as is true for an overnight fast; see [p. 1189](#)), the hepatic glycogen stores of ~70 g that remain after an overnight fast would be sufficient to last only an additional day. However, in the early stages of starvation, the body compensates by accelerating *gluconeogenesis*.

Orchestrating the metabolic adaptations in the early stages of starvation—increased gluconeogenesis, but also increased proteolysis and lipolysis—are a decline in [insulin] to a level lower than that seen after an overnight fast and a modest increase in portal vein [glucagon]. Insulin deficiency promotes all aspects of the metabolic response, whereas the effect of glucagon is mostly confined to the liver (see [pp. 1050–1053](#)).

Enhanced Gluconeogenesis

Adaptations in both liver and muscle are responsible for increasing gluconeogenesis (see [Fig. 58-13](#)). In muscle, acceleration of proteolysis leads to the release of alanine and other glycogenic amino acids,

whereas the liver accelerates its conversion of gluconeogenic amino acids into glucose. This enhanced gluconeogenesis, however, is not the result of increased availability of substrates, because plasma levels of alanine and other glycogenic amino acids decline. Instead, fasting increases transport of alanine into the liver and upregulates key gluconeogenic enzymes (see [p. 1176](#)), which makes gluconeogenesis *more efficient*.

The dependence of gluconeogenesis on proteolysis is reflected by an increase in urinary nitrogen excretion in the early phase of starvation. During the first 24 hours of a fast, the average 70-kg person excretes 7 to 12 g of elemental nitrogen in the urine, equivalent to 50 to 75 g of protein. Because tissue protein content does not exceed 20% by weight for any tissue, 50 to 75 g of protein translates to 250 to 375 g of lean body mass lost on the first day of a fast.

Enhanced Lipolysis

The activation of HSL and ATGL (see [p. 1182](#)) increases release of FAs and glycerol from TAG stores in adipose tissue and muscle (see [Fig. 58-13](#)). The increased availability of glycerol provides the liver with an additional substrate for gluconeogenesis (see [p. 1176](#)) that contributes to glucose homeostasis. Moreover, the increased availability of FAs to muscle and other peripheral tissues limits their use of glucose, which preserves glucose for the CNS and other obligate glucose-utilizing tissues and diminishes the demands for gluconeogenesis and proteolysis.

Elevated levels of FAs cause **insulin resistance** in skeletal muscle by directly interfering with insulin activation of GLUT4 (see [Fig. 58-13](#)). Intracellular lipid intermediates (e.g., DAGs, ceramides) activate a serine/threonine kinase cascade that involves protein kinase C θ , which leads to increased *serine* phosphorylation of insulin-receptor substrate 1 (IRS-1; see [p. 1042](#)). This serine phosphorylation, in turn, leads to decreased *tyrosine* phosphorylation of IRS-1, and thus to a decrease in PI3K activity, which diminishes GLUT4 translocation to the plasma membrane of muscle. This FA-induced decrease in insulin-stimulated glucose uptake by muscle, and the parallel increased availability of FAs as a fuel for muscle, spare glucose for other tissues (e.g., brain, renal medulla, erythrocytes) under fasting conditions. However, this adaptation may play an important pathological role in mediating the insulin resistance associated with obesity and type 2 diabetes.

FAs not only have effects on muscle, but also enter the liver, where they undergo β -oxidation (see [pp. 1183–1185](#)) and generate energy. A fall in the insulin-glucagon ratio inhibits ACC (see [pp. 1178–1179](#) and [Fig. 58-7](#)), thereby reducing levels of malonyl CoA and promoting mitochondrial FA oxidation. Thus, the hormonal changes both increase the supply of FAs and activate the enzymes necessary for FA oxidation. This β -oxidation furnishes the energy and reducing power required for gluconeogenesis. If the availability of FAs outstrips the ability of the citric acid cycle to oxidize the resulting acetyl CoA, the result may be the accumulation of ketone bodies (see [p. 1185](#)), which can serve as a fuel for the CNS as well as for cardiac and skeletal muscle.

Prolonged starvation moderates proteolysis but accelerates lipolysis, thereby releasing ketone bodies

As the duration of fasting increases, the body shifts from using its limited protein stores for gluconeogenesis to using its relatively large energy depots in fat for ketogenesis ([Fig. 58-14](#)). Moreover, the brain shifts from oxidizing glucose to oxidizing two ketone bodies (see [p. 1185](#)), β -hydroxybutyrate and acetoacetate, to meet most of its energy requirements.

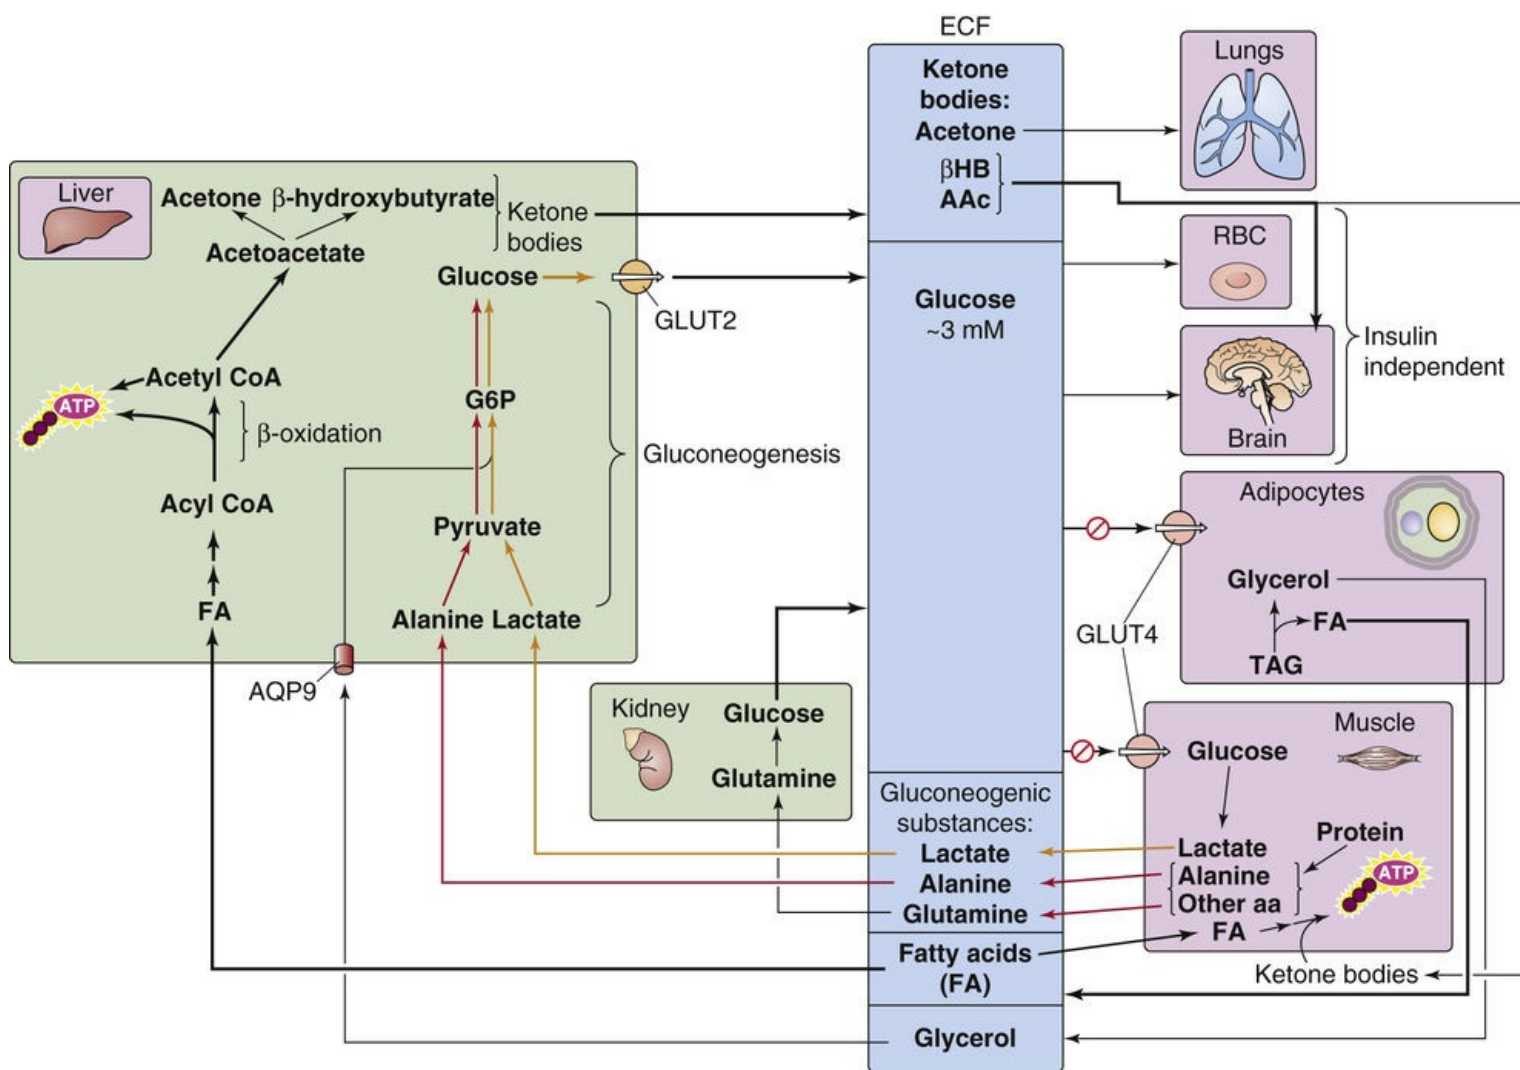

FIGURE 58-14 Metabolism during prolonged starvation. aa, amino acids; AAc, acetoacetyl CoA; AQP9, aquaporin 9; ECF, extracellular fluid; β HB, β -hydroxybutyrate; RBC, red blood cell. **N58-2**

Decreased Proteolysis

A fasting human could survive for only ~10 days if totally dependent on protein utilization to meet whole-body energy requirements. Thus, prolonged survival during starvation requires a major reduction in proteolysis. Indeed, urea excretion decreases from 10 to 15 g/day during the initial days of a fast to <1 g/day after 6 weeks of fasting. Because urea is the major obligatory osmolyte in the urine (see pp. 811–813), this reduced urea production lessens obligatory water excretion and therefore the daily water requirement. Ammonium excretion also decreases.

Decreased Hepatic Gluconeogenesis

The transition from protein to lipid degradation permits humans to extend their survival time during a prolonged fast from weeks to months, as long as fat stores are available and water intake is adequate. During this transition, hepatic gluconeogenesis decreases (see Fig. 58-14), mostly because of diminished substrate delivery. During the first few weeks of a fast, muscle releases less alanine, the principal substrate for hepatic gluconeogenesis, so that plasma [alanine] falls markedly, to less than one third of the concentrations seen after the absorption of a meal. Indeed, during a prolonged fast, infusing a small amount of alanine causes plasma [glucose] to rise.

Increased Renal Gluconeogenesis

Whereas hepatic gluconeogenesis falls, renal gluconeogenesis rises (see [Fig. 58-14](#)) to reach as much as 40% of whole-body glucose production. Renal gluconeogenesis, which consumes H^+ (see [Fig. 39-5A](#)), most likely is an adaptation to the acidosis that accompanies ketogenesis (see [p. 1185](#)). Indeed, acidosis stimulates renal ammoniagenesis in parallel with renal gluconeogenesis.

Increased Lipolysis and Ketogenesis

During the first 3 to 7 days of fasting, hypoinsulinemia accelerates the mobilization of FAs from adipose tissue. As a result, plasma FA levels double and remain stable thereafter. The combination of low insulin and high glucagon levels also increases hepatic oxidation of FAs, leading to a marked increase of hepatic ketogenesis (see [Fig. 58-14](#) and [pp. 1051–1053](#)) or *ketogenic capacity*. The liver achieves peak rates of ketone body production (~ 100 g/day) by the third day and maintains them thereafter. Low insulin levels also progressively reduce the extraction of ketone bodies by peripheral tissues. Thus, despite relatively stable rates of ketone body production, circulating levels of ketone bodies continue to rise throughout the next few weeks. As a result, the CNS receives an increasing supply of these water-soluble substrates, which eventually account for more than one half of the brain's energy requirements. In this way, ketone bodies ultimately supplant the brain's dependency on glucose. Thus, by limiting the brain's gluconeogenic demands, the body preserves protein stores. Besides the CNS, other body tissues, especially the heart and skeletal muscle, can use ketone bodies to cover a significant proportion of their energy demands.

As the fast progresses and fat stores are depleted, levels of leptin (see [pp. 1001–1002](#)) decrease. This decrease in leptin levels is a protective signal that profoundly affects the hypothalamic-pituitary-gonadal axis, reducing the oscillations of luteinizing hormone and follicle-stimulating hormone and causing anovulation. In times of famine, this mechanism protects fertile women from the additional nutritional demands associated with pregnancy.

In summary, the body has evolved powerful adaptive mechanisms that ensure adequate substrate supply in the form of glucose and ketone bodies during a prolonged fast to maintain adequate CNS function. Even during a prolonged fast, humans do not lose consciousness because of decreased substrate supply to the brain. Instead, death under these conditions typically occurs when fat stores are depleted and severe protein wasting causes failure of respiratory muscles, which in turn leads to atelectasis and terminal pneumonia.

Regulation of Body Temperature

Shaun F. Morrison

Heat and Temperature: Advantages of Homeothermy

Homeotherms maintain their activities over a wide range of environmental temperatures

The ability to regulate internal body temperature has provided higher organisms independence from the environment. Because the rates of most physical and chemical reactions depend on temperature, most physiological functions are sensitive to temperature changes. Thus, the activity levels of **poikilotherms** (species that do not regulate internal body temperature) generally depend on environmental temperature, whereas **homeotherms** (species that do regulate internal body temperature) can engage in most normal activities independent of ambient temperature. A lizard, for example, is capable of relatively less movement away from its lair on a cold, overcast day than on a hot, sunny day, whereas a prairie dog may be equally mobile on either day. An arctic fox acclimatizes to the extreme cold of winter by maintaining a thick, insulating coat that enables it to resist body cooling and minimizes the necessity to increase metabolic heat generation, which would require increased food intake.

The stable body temperature of homeotherms is the consequence of designated neural networks that incorporate both anticipatory and negative-feedback controls. This arrangement creates an internal environment in which chemical reaction rates are relatively high and optimal and avoids the pathological consequences of wide fluctuations in body temperature (Table 59-1). The fundamental thermoregulatory system includes (1) thermal sensors; (2) thermosensory afferent pathways; (3) an integration system in the central nervous system (CNS); (4) efferent pathways; and (5) thermal effectors capable of heat generation (i.e., thermogenesis), such as brown adipose tissue and skeletal muscle (shivering), or effectors that modulate heat transfer, such as the circulation to the skin (which dissipates heat) and the sweat glands (which augment heat loss).

TABLE 59-1
Consequences of Deviations in Body Temperature

TEMPERATURE (°C)	CONSEQUENCE
40–44	Heat stroke with multiple organ failure and brain lesions
38–40	Hyperthermia (as a result of fever or exercise)
36–38	Normal range
34–36	Mild hypothermia
30–34	Impairment of temperature regulation
27–29	Cardiac fibrillation

In this chapter, we describe the physical aspects of heat transfer both within the homeotherm's body and between the body and the environment. We also provide a framework for understanding the major integrative role played by the CNS in regulating body temperature and consider the physiological mechanisms involved in altering rates of heat transfer and in producing extra heat in a cold environment or during fever. Finally, we look at the consequences of extreme challenges to the thermoregulatory mechanism, such as hypothermia, hyperthermia, and dehydration.

Body core temperature depends on time of day, physical activity, time in the menstrual cycle, and age

Temperature is a measure of heat content. The “normal” body temperature of an adult human is $\sim 37^{\circ}\text{C}$ (98.6°F) but it may be as low as 36°C or as high as 37.5°C in active, healthy people. *Body temperature* usually refers to the temperature of the internal body *core*,  **N59-1** measured under the tongue (sublingually), in the ear canal, or in the rectum. For clinical purposes, the most reliable (although the least practical) among these three is the last, because it is least influenced by ambient (air) temperature. Measurement devices range from traditional mercury-in-glass thermometers to electronic digital-read-out thermistors. Nearly all such instruments are accurate to 0.1°C . The least invasive approach uses an infrared thermometer to measure the radiant temperature (see [p. 1196](#)) over the temporal artery.  **N59-1**

N59-1

Body Core Temperature

Contributed by Ethan Nadel

As noted in the text, the term *body temperature* usually refers to the temperature of the body *core*. Like effective circulating volume, **body core temperature** is a concept that is difficult to define with precision. The body core is generally understood to refer to internal organs, including the central blood volume that equilibrates with the core. Thus, the core includes the brain (the location of the central temperature sensors, which are in the hypothalamus), the heart, and other organs that are insulated from the environment and that produce heat at a relatively constant rate. However, the body core clearly excludes potential heat generators whose heat output varies with time, such as skeletal muscle and liver. Likewise, the body core also excludes the skin and portions of the upper airways (see p. 600), which are at the mercy of the environment.

Body core temperature (T_{core}) depends on many factors that alter either the activity of the CNS thermoregulatory network or the level of metabolism and heat content of the body, including the time of day, the stage of the menstrual cycle in women, and the individual's age.

All homeotherms maintain a circadian rhythm (~ 24 -hour cycle) of body temperature, with variations of $\sim 1^{\circ}\text{C}$. In humans, body temperature is usually lowest between 3:00 and 6:00 AM and peaks at 3:00 to 6:00 PM. The circadian rhythmicity in physiological variables is governed by groups of neurons in the suprachiasmatic nucleus in the anterior hypothalamus, whose activity is entrained by light-dark cues to a ~ 24 -hour cycle but is independent of the sleep-wake cycle. The influence of these neurons on the CNS thermoregulatory network produces the circadian rhythmicity in body temperature.

Reproductive hormones, and the CNS circuits that govern their production, influence the CNS thermoregulatory network. Indeed, in many women, body temperature increases $\sim 0.5^{\circ}\text{C}$ during the postovulatory phase of the menstrual cycle (see [pp. 1110–1111](#)). An abrupt increase in body temperature of 0.3°C to 0.5°C accompanies ovulation and may be useful as a fertility guide.

Infants and older people are less able than other age groups to maintain a stable normal body temperature, particularly in the face of external challenges. Newborns do not readily shiver or sweat and have a high surface-to-mass ratio, which renders them more susceptible to fluctuations in core temperature when exposed to hot or cold environments. However, they have large deposits of brown adipose tissue, which the sympathetic nervous system can stimulate to generate heat for cold defense. Moreover, newborns can implement a modest degree of sympathetic vasoconstriction of the skin to reduce heat loss in the cold.

Older people are also subject to greater fluctuations in core temperature. Aging is associated with a

progressive deficit in the ability to sense heat and cold (see [p. 1244](#)), as well as reduced ability to generate heat (reduced metabolic rate and metabolic potential because of lower muscle mass) and to dissipate heat (reduced cardiovascular reserve and sweat gland atrophy from disuse).

The body's rate of heat production can vary from ~70 kcal/hr at rest to 600 kcal/hr during exercise

Because the chemical reactions are inefficient, cellular functions produce heat (see [p. 1173](#)). The body's rate of heat production depends on the rate of energy consumption and thus of O_2 consumption (\dot{V}_{O_2}) because nearly all energy substrates derived from food are oxidized. Minor variations occur, depending on the mixture of fuels (foods) being oxidized, a process that determines the respiratory quotient (RQ; see [p. 681](#) and [Table 58-6](#)).

The body's metabolic rate, and thus its rate of heat production, is not constant. The **resting metabolic rate (RMR; see [p. 1170](#))** is the energy consumption necessary to maintain the basal functions of resting cells, such as active solute transport across membranes as well as the activity of cardiac and respiratory muscles necessary for organismal survival. RMR is influenced by age, sex, circadian phase, season, digestive state, phylogeny, body size, and habitat. Voluntary or involuntary (e.g., postural and shivering) muscular activity adds to the overall metabolic heat production. Even digesting a meal increases the metabolic rate (see [p. 1179](#)). An increase in tissue temperature itself raises the metabolic rate, according to the van't Hoff relation (i.e., a 10°C increase in tissue temperature more than doubles the metabolic rate). Furthermore, certain hormones, notably thyroxine and epinephrine, increase the cellular metabolic rate. At an RQ of 0.8 (see [p. 681](#) and [Table 58-6](#)), the average person under sedentary (i.e., RMR) conditions has a resting \dot{V}_{O_2} of 250 mL/min, which corresponds to an energy production of 72 kcal/hr (~85 watts). Because the body at RMR, by definition, performs no work on the environment, all of this energy production ultimately is dissipated as heat—as if the body were a zero-efficiency, 85-watt incandescent light bulb.

During physical exercise, the rate of energy consumption—and hence, heat generation—increases in proportion to the intensity of exercise. An average adult can comfortably sustain an energy-consumption rate of 400 to 600 kcal/hr (e.g., a fast walk or a modest jog) for extended periods. Nearly all increased heat generation during exercise occurs in active skeletal muscle, although a portion arises from increased activity of cardiac and respiratory muscles. A thermal load of this magnitude would raise core temperature by 1.0°C every 8 to 10 minutes if the extra heat could not escape the body. Physical activity would be limited to 25 to 30 minutes, at which time the effects of excessive hyperthermia ($>40^\circ\text{C}$) would begin to impair body function. This impairment, of course, does not usually occur, primarily because of the effectiveness of the thermoregulatory heat-defense system. Within a relatively short period, the increase in body temperature resulting from exercise leads to an increased rate of heat dissipation from the skin and the respiratory system commensurate with the rate of heat production. Thereafter, the body maintains a new, but slightly elevated, steady temperature. When exercise ceases, body temperature gradually decreases to its pre-exercise level.

Modes of Heat Transfer

Maintaining a relatively constant body temperature requires a fine balance between heat production and heat losses

If body temperature is to remain unchanged, increases or decreases in heat production must be balanced by increases or decreases in heat loss, resulting in negligible heat storage within the body. If the body is at constant mass, the whole-body **heat-balance equation** expresses this concept as follows:

Metabolism
(M)

–

Work
done on
environment
(W)

–

Radiative
heat
loss
(R)

+

Convective

loss
(E)

=

Storage
of
heat
(S)

Heat production (H)

Heat losses

(59-1)

All terms in the foregoing equation have the units kcal/hr.

Several physiological processes contribute to temperature homeostasis, including modulation of metabolic heat production, physical heat transfer, and elimination of heat. These processes operate at the level of cells, tissues, and organ systems. Let us discuss in order the terms in [Equation 59-1](#).

Metabolism (M) is the consumption of energy from the cellular oxidation of carbohydrates, fats, and proteins. For an athlete, the **useful work on the environment (W)** might be the energy imparted to an iron ball during the shot put event. However, because of a long list of inefficiencies—the inherent inefficiency of metabolic transformations (see [pp. 1173–1174](#)) as well as frictional losses (e.g., blood flowing through vessels, air flowing through airways, tissues sliding passed one another)—most metabolic energy consumption ends up as **heat production (H = M – W)**. [Table 59-2](#) shows the fractional contributions of different body systems to total heat production under sedentary, resting conditions.

TABLE 59-2
Contribution of Body Systems to Resting Metabolism

CNS and nerves	20
Musculature (at rest)	20
Abdominal viscera	45
Resting metabolic rate	100 (~70 kcal/hr)

Under conditions of maximal exercise, $\dot{V}_{O_{2max}}$ (see [pp. 1213–1215](#)) may correspond to a total energy expenditure (M in [Equation 59-1](#)) of 1300 kcal/hr for an endurance athlete. If 60% of this energy evolves as heat—so that the athlete does ~500 kcal/hr of useful work on the environment—the rate of heat production will be 1300 – 500 = 800 kcal/hr (~960 watts) for a brief period of time. This change is equivalent to changing from an 85-watt light bulb to a 1000-watt space heater. Unless the body can dissipate this heat, death from hyperthermia and heat stroke ([Box 59-1](#)) would ensue rapidly.

Box 59-1

Heat Stroke

As body core temperature rises, excessive cutaneous vasodilation can lead to a fall in arterial pressure (see p. 576) and, therefore, to a decrease in brain perfusion. As T_{core} approaches 41°C , confusion and, ultimately, loss of consciousness occur. Excessive hyperthermia ($>41^{\circ}\text{C}$) leads to the clinical condition known as **heat stroke**. High temperature can cause fibrinolysis and consumption of clotting factors and thus disseminated intravascular coagulation (DIC), which results in uncontrolled vascular thrombosis and hemorrhage. Heat-induced damage to the cell membranes of skeletal and myocardial muscle leads to rhabdomyolysis (in which disrupted muscle cells release their intracellular contents, including myoglobin, into the circulation) and myocardial necrosis. Cell damage may also cause acute hepatic insufficiency and pancreatitis. Renal function, already compromised by low renal blood flow, may be further disrupted by the high plasma levels of myoglobin. Ultimately, CNS function is affected by the combination of high brain temperature, DIC, and metabolic disturbances.

Virtually all heat leaving the body must exit through the skin surface. In the following three sections, we consider the three major routes of heat elimination: **radiation (R)**, **convection (C)**, and **evaporation (E)**. As the heat-balance equation shows, the difference between heat production ($M - W$) and heat losses ($R + C + E$) is the **rate of heat storage (S)** within the body. The value of S may be positive or negative, depending on whether $(M - W) > (R + C + E)$ or vice versa. A positive value of S results in a rise of T_{core} , such as during exercise, whereas a negative value of S results in a fall in T_{core} , as would occur shortly after entering very cold water.

Heat moves from the body core to the skin, primarily by convection

Generally, all heat production occurs within the body's tissues, and all heat elimination occurs at the body surface. [Figure 59-1](#) illustrates a **passive system** in which heat flows depend on the size, shape, and composition of the body, as well as on the laws of physics. The circulating blood carries heat away from active tissues, such as muscle, to the body core—represented by the heart, lungs, and their central circulating blood volume. [N59-2](#) How does the body prevent its core from overheating? The answer is that the core transfers this heat to a dissipating heat sink. The organ serving as the body's greatest potential heat sink is the relatively cool **skin**, which is the largest organ in the body. Only a minor amount of the body's generated heat flows *directly* from the underlying body core to the skin by **conduction** across the body tissues. Most of the generated body heat flows in the blood—by **convection**—to the skin, and blood flow to the skin can increase markedly during heat defense. There, nearly all heat transferred to the skin will flow to the environment, as discussed in the next section.

FIGURE 59-1 Passive or unregulated heat transfer. In the steady state, the rate of heat production by the body core must match the flow of heat from the core to the skin, and from the skin to the environment. Certain CNS commands that are not directly involved in temperature regulation can affect heat flow. Examples include CNS signals that initiate sweating in response to hypoglycemia, changes in blood flow patterns in response to a fall in blood pressure, and changes in metabolism in response to alterations in thyroid metabolism.

N59-2

Heat Transfer from Muscle to Body Core

Contributed by Ethan Nadel

In the simplest analysis, the rate of heat transfer from any tissue to the blood depends on (1) the rate of tissue energy production, (2) the temperature of the tissue, (3) the temperature of the incoming blood, and (4) blood flow through the tissue.

Inactive skeletal muscle, for example, has a low blood flow and a correspondingly low rate of metabolism. The rate of O_2 consumption (\dot{V}_{O_2})—a measure of metabolic rate—averages 1.5 to 2.0 mL of O_2 consumed per minute for each kilogram of muscle tissue. Because the temperature of resting muscle (33°C to 35°C) is lower than that of the body core (37°C), heat flows from arterial blood to inactive skeletal muscle. A similar analysis shows that heat moves from a highly active tissue such as the liver (38°C) to the blood, which distributes the heat to the other tissues of the body core.

The body's greatest *potential* heat source is skeletal muscle, which has a relatively large mass and can increase its rate of heat production >100-fold. Because skeletal muscle has such potential, it is useful for modeling heat transfer and changes in tissue temperature (eFig. 59-1). The **energy balance equation** for skeletal muscle is as follows:

$$\begin{aligned}
 & \left[\begin{array}{c} \text{Heat} \\ \text{generated by} \\ \text{muscle} \\ \text{metabolism} \end{array} \right] - \left[\begin{array}{c} \text{Heat convected} \\ \text{from} \\ \text{muscle to} \\ \text{blood} \end{array} \right] - \left[\begin{array}{c} \text{Heat} \\ \text{conducted} \\ \text{from muscle} \\ \text{to skin} \end{array} \right] \\
 & = \left[\begin{array}{c} \text{Heat} \\ \text{excess that} \\ \text{produces an} \\ \text{increase in} \\ \text{muscle} \\ \text{temperature} \end{array} \right]
 \end{aligned}$$

The three terms on the left describe all the heat that the muscle gains or loses. If they add up to a positive number, muscle temperature increases. In the steady state, these three terms add up to zero, and muscle temperature is stable.

During the onset of exercise, the heat produced by metabolism increases rapidly. If the three terms on the left side of Equation NE 59-1 sum to a very positive number (which implies a large energy excess), muscle temperature rises rapidly. However, the dramatic increase in the rate of warming is relatively short-lived because of two factors: (1) The increase in muscle temperature reverses the temperature gradient between muscle and the blood perfusing it, so that heat now flows from muscle to blood. (2) Muscle vascular resistance decreases and cardiac output increases rapidly (see p. 581), so that blood flow through the muscle increases proportionally with the intensity of exercise. These adjustments are relatively complete within a few minutes. Increases of up to 30-fold in blood flow account for a proportional increase in heat transfer from active muscle to blood.

As exercise continues, muscle temperature increases to a new steady-state level, which causes more heat transfer from muscle to blood. The result is an increase in core temperature as warm venous blood leaving the muscles enters the body core.

FIGURE 59-1 Energy flows in muscle.

The transfer of heat from core to skin occurs by two routes:

$$\left[\begin{array}{c} \text{Heat} \\ \text{transfer} \\ \text{from core} \\ \text{to skin} \end{array} \right] = \left[\begin{array}{c} \text{Heat} \\ \text{passively conducted} \\ \text{from core to} \\ \text{skin} \end{array} \right] + \left[\begin{array}{c} \text{Heat} \\ \text{convected by blood} \\ \text{from core to} \\ \text{skin} \end{array} \right]$$

(59-2)

Both the conduction and convection terms in the previous equation are proportional to the temperature

gradient from core to skin ($T_{\text{core}} - \bar{T}_{\text{skin}}$), where \bar{T}_{skin} is the average skin temperature, usually obtained from at least four skin sites. The *proportionality constant* for passive conduction across the subcutaneous fat (the body's insulation) is relatively fixed. However, the proportionality constant for heat convection by blood is a variable term, reflecting the variability of the blood flow to the skin. The ability to alter skin blood flow, under autonomic control, is therefore the primary determinant of heat flow from core to skin. The capacity to *limit* blood flow to the skin is an essential defense against body cooling (hypothermia) in the cold. A side effect, however, is that skin temperature falls. Conversely, the capacity to *elevate* skin blood flow is an essential defense against hyperthermia. On very hot days when skin temperature may be very high and close to T_{core} , even high skin blood flow may not be adequate to transfer sufficient heat to allow T_{core} to stabilize because the temperature gradient ($T_{\text{core}} - \bar{T}_{\text{skin}}$) is too small.

Although most of the heat leaving the core moves to the skin, a small amount also leaves the body core by the evaporation of water from the respiratory tract. The evaporative rate is primarily a function of the rate of ventilation (see [p. 675](#)), which in turn increases linearly with the metabolic rate over a wide range of exercise intensities.

Heat moves from the skin to the environment by radiation, conduction, convection, and evaporation

[Figure 59-2](#) is a graphic summary of the heat-balance equation (see [Equation 59-1](#)) for an athlete exercising in an outdoor environment. This illustration depicts the movement of heat within the body, its delivery to the skin surface, and its subsequent elimination to the environment by radiation, convection, and evaporation.

FIGURE 59-2 Model of energy transfer between the body and the environment.

Radiation

Heat transfer by radiation occurs between the skin and solid bodies in the environment. The infrared portion of the electromagnetic energy spectrum carries this energy, which is why infrared cameras can detect warm bodies at night. The exchange (gain or loss) of body heat with another object by radiation occurs at a rate that is proportional to the temperature difference between the skin and the object:

Rate of radiative heat loss	<i>Radiative</i> heat- transfer coefficient	Mean skin temp	Radiant temp of another object	Body surface area available for <i>radiative</i> heat exchange
--------------------------------------	--	----------------------	---	--

$$\underbrace{\frac{R}{\frac{kcal}{hr}}}_{\text{Rate of radiative heat loss}} = \underbrace{\frac{h_{\text{radiative}}}{\frac{kcal}{hr \times ^\circ C \times m^2}}}_{\text{Radiative heat-transfer coefficient}} \cdot \underbrace{(\bar{T}_{\text{skin}} - T_{\text{radiant}})}_{^\circ C} \cdot \underbrace{\frac{A_{\text{radiative}}}{m^2}}_{\text{Body surface area available for radiative heat exchange}}$$

(59-3)

R is positive when the body loses heat and negative when it gains heat.

One may not be very aware of radiative heat fluxes to and from the body, particularly when the T_{radiant} differs from the ambient environmental temperature (T_{ambient}), which tends to dominate our attention. Indoors, T_{radiant} is the same as T_{ambient} because surrounding objects thermally equilibrate with one another. Outdoors, radiating bodies may be at widely different temperatures. The **radiant heat load** from the sun to the body on a cloudless summer day may exceed the RMR by a considerable amount. The radiant heat load from a fire or a radiant lamp can provide substantial warming of bodies in the radiant field. Conversely, on a winter evening, the **radiant heat loss** from the body to a cloudless, dark sky—which has a low radiant temperature—may exceed RMR. Thus, one may feel a sudden chill when walking past an uncurtained window. This chill is caused by the sudden fall in skin temperature owing to increased radiant heat loss. Radiation of heat from the body accounts for ~60% of heat lost when the body is at rest in a neutral thermal indoor environment. A **neutral thermal environment** is a set of conditions (air temperature, airflow and humidity, and temperatures of surrounding radiating surfaces) in which the temperature of the body does not change when the subject is at rest (i.e., RMR) and is not shivering.

Conduction

Heat transfer by conduction occurs when the body touches a solid material of different temperature. For example, lying on the hot sand causes one to gain heat by conduction. Conversely, placing an ice pack on a sore muscle causes heat loss by conduction. However, under most normal circumstances (e.g., when one is standing and wearing shoes or recumbent and wearing clothes), the heat gain or loss by conduction is minimal.

Convection

Heat transfer by convection occurs when a medium such as air or water carries the heat between the body and the environment. The convective heat loss is proportional to the difference between skin and ambient temperature:

Rate of convective heat loss	Convective heat- transfer coefficient	Mean skin temp	Ambient temp	Body surface area available for convective heat exchange
---------------------------------------	--	----------------------	-----------------	---

$$\underbrace{\frac{C}{\frac{kcal}{hr}}}_{\frac{kcal}{hr \times ^\circ C \times m^2}} = \underbrace{h_{\text{convective}}}_{\frac{kcal}{hr \times ^\circ C \times m^2}} \cdot \underbrace{(\bar{T}_{\text{skin}} - T_{\text{ambient}})}_{^\circ C} \cdot \underbrace{A_{\text{convective}}}_{m^2}$$

(59-4)

C is positive when the body loses heat, and negative when it gains heat.

Whereas the radiative heat-transfer coefficient ($h_{\text{radiative}}$) is constant, the convective coefficient ($h_{\text{convective}}$)

is variable and can increase up to 5-fold when air velocity is high. Thus, even when ($\bar{T}_{\text{skin}} - T_{\text{ambient}}$) is fixed, convective heat loss increases markedly as wind speed increases. In the absence of air movement, the air immediately overlying the skin warms as heat leaves the skin. As this warmer and lighter air rises off the skin, cooler ambient air replaces it and, in turn, is warmed by the skin. This is the process of **natural convection**. However, with forced air movement, such as by wind or a fan, the cooler “ambient” air replaces the warmer air overlying the skin more rapidly. This change increases the effective convective heat transfer from the skin, even though the temperature of the ambient air is unchanged. This is a process of **forced convection**, which underlies the **wind chill factor**.

Evaporation

Humans can dissipate nearly all the heat produced during exercise by evaporating sweat (see pp. 1215–1216) from the skin surface. The evaporative rate is independent of the temperature gradient between skin and environment. Instead, it is proportional to the water vapor-pressure gradient between skin and environment:

Rate of evaporative heat loss	Evaporative heat- transfer coefficient	H ₂ O vapor pressure of skin	H ₂ O vapor pressure of environment	Body surface area available for <i>evaporative</i> heat exchange
--	---	--	---	---

$$\underbrace{\frac{E}{\frac{kcal}{hr}}}_{\frac{kcal}{hr \times mm \text{ Hg} \times m^2}} = \underbrace{h_{\text{evaporative}}}_{\frac{kcal}{hr \times mm \text{ Hg} \times m^2}} \cdot \underbrace{(P_{\text{skin}} - P_{\text{ambient}})}_{mm \text{ Hg}} \cdot \underbrace{A_{\text{evaporative}}}_{m^2}$$

(59-5)

E is positive when the body loses heat by evaporation and negative when it gains heat by condensation.

The evaporation of 1 g of water removes ~0.58 kcal from the body. Because the body's sweat glands can deliver up to 30 g fluid/min or 1.8 L/hr to the skin surface, evaporation can remove 0.58 kcal/g × 1800 g/hr or ~1000 kcal/hr. Thus, under ideal conditions (i.e., when ambient humidity is sufficiently low to allow efficient evaporation), evaporation could theoretically remove nearly all the heat produced during heavy exercise (see p. 1195). As with convection, increased air velocity over the skin increases the effective vapor-pressure gradient between skin and the overlying air because of the faster movement of water vapor away from the skin.

The efficiency of heat transfer from the skin to the environment depends on both physiological and environmental factors. If ambient humidity is high, the gradient of water vapor pressure between skin and air will be low, thereby slowing evaporation and increasing the body's tendency to accumulate excess heat during exercise. This phenomenon underlies the temperature-humidity index—or **heat index**. Conversely, if ambient humidity is low, as in the desert, net heat loss from the body by evaporation will occur readily, even when ambient temperature exceeds skin temperature and the body is gaining heat by radiation and convection.

When the body is immersed in water, nearly all heat exchange occurs by convection, because essentially no exchanges can occur by radiation or evaporation. Because of the high conductivity and thermal capacity of water, the heat-transfer coefficient ($h_{\text{convective}}$) is ~100 times greater than that of air, so that the rate of body heat exchange is much greater in water than it is in air. It is therefore not surprising that nearly all the deaths in the *Titanic* shipwreck disaster resulted from hypothermia in the cold Atlantic waters, rather than from drowning.

When heat gain exceeds heat loss, body core temperature rises

With a knowledge of the transfer coefficients— $h_{\text{radiative}}$ (see [Equation 59-3](#)), $h_{\text{convective}}$ (see [Equation 59-4](#)), and $h_{\text{evaporative}}$ (see [Equation 59-5](#))—and the gradients of temperature and water vapor pressure between the skin and environment, we can calculate the body heat fluxes (R, C, and E). Knowing M (computed from \dot{V}_{O_2} by indirect calorimetry, see [pp. 1011– 1012](#)) and W (if any), we can use the heat-balance equation (see [Equation 59-1](#)) to calculate the **rate of heat storage**. From this value, we can predict the rate of change in mean body temperature:

$$\frac{\Delta \bar{T}_{\text{body}}}{\Delta t} = \frac{\text{Rate of heat storage}}{\text{Specific heat of body tissues} \cdot \text{Body weight}}$$

$\frac{\text{°C}}{\text{hr}}$

$\frac{\text{kcal/hr}}{[\text{kcal}/(\text{kg}^\circ\text{C})] \times \text{kg}}$

(59-6)

We can verify the accuracy of this predicted rate of change in \bar{T}_{body} ● **N59-3** by comparing it to the \bar{T}_{body} measured by direct thermometry, using a weighted average of the measured T_{core} and average T_{skin} .

N59-3
Mean Body Temperature

Contributed by Ethan Nadel

It is difficult to make an accurate determination of *mean* body temperature (\bar{T}_{body}). An approximation is

that mean body temperature is $0.67 T_{\text{core}} + 0.33 \bar{T}_{\text{skin}}$ in cold conditions, and $0.9 T_{\text{core}} + 0.1 \bar{T}_{\text{skin}}$ in warm conditions. T_{core} is measured directly from the rectum (or esophagus), and \bar{T}_{skin} is the average skin temperature.

The body has to deal with two types of heat load that tend to make its temperature rise. In the heat-balance equation (see [Equation 59-1](#)), the term $(M - W)$ constitutes an **internal heat load**. Although the term $(R + C + E)$ normally reflects a net heat *loss* from the body, it can also be a net heat *gain* by the body—an **external heat load**, which can occur if either the radiation (R) or convection (C) terms are heat *gains* rather than heat *losses*. Thus, if we stand in the sun and T_{radiant} exceeds \bar{T}_{skin} (see [Equation 59-3](#)), we experience a radiant heat load. If we stand in a hot sauna and T_{ambient} exceeds \bar{T}_{skin} (see [Equation 59-4](#)), we experience a convective heat load. Clearly, both internal and external heat loads can result in net heat storage and thus a rise in body temperature. Changes in environmental temperature (T_{radiant} and T_{ambient}) exert their influence from the *outside*, through the body surface. If, starting from relatively low values, T_{radiant} or T_{ambient} rises, at first the rate at which heat leaves the body decreases, so core temperature tends to rise. Further increases in environmental temperature produce a frank heat load rather than a loss.

For the athlete, *all* the terms of the heat-balance equation are important because dissipating the thermal load is essential for prolonging exercise. The clinician must understand these principles to treat thermally related illnesses. For example, excessive heat exposure can lead to **heat exhaustion**, in which T_{core} rises to as high as 39°C if the body cannot dissipate the heat load. Failure of the body's heat-defense mechanisms arises principally from dehydration (which reduces sweating) and hypovolemia (which reduces blood flow from muscle to core to skin). Heat exhaustion is the most common temperature-related abnormality in athletes. In more severe cases, excessive heat can lead to **heat stroke** (see [Box 59-1](#)), in which T_{core} rises to 41°C or more, due to impaired thermoregulatory mechanisms.

Clothing insulates the body from the environment and limits heat transfer from the body to the environment

Placing one or more layers of clothing between the skin and the environment insulates the body and retards heat transfer between the core and the environment. In the presence of clothing, heat transfer from a warmer body to a cooler environment occurs by the same means as without clothing (i.e., radiation, conduction, convection, and evaporation), but from the clothing surface rather than from the skin surface. The insulating effect of clothing is described by the **clo unit**. By definition, 1 clo is the insulation necessary to maintain a resting person at a thermal steady state in comfort at 21°C with minimal air movement. Obviously, clo units increase with a greater area of skin coverage by clothing, or with thicker clothing.

Active Regulation of Body Temperature by the Central Nervous System

Dedicated neural circuits in the CNS actively regulate body temperature. The central thermoregulatory network includes the following:

1. Afferent neurons that are the skin and visceral thermoreceptors
2. Thermal afferent pathways within the CNS
3. The thermoregulatory integration center in the preoptic anterior hypothalamus  [N59-4](#)
4. Efferent pathways providing autonomic and somatomotor inputs to effectors
5. Thermal effectors that control heat transfer between the body and environment, and that control heat production by the body

N59-4

Preoptic Area and Anterior Hypothalamus

Contributed by Shaun Morrison, edited by Alisha Bouzaher

Inconsistent findings have led to debate among anatomists regarding the exact anatomical location of the preoptic area. Overall, the literature tends to suggest that the preoptic area is located *in* the anterior hypothalamus rather than *anterior to* the hypothalamus. A neutral view would be that the **preoptic area** lies immediately anterior to the optic chiasm.

This central thermoregulatory network is an **active system** that is superimposed on, and regulates, the *passive poikilothermic system* described on [pages 1194–1198](#), in which the circulatory system and the laws of physics determine heat transfer between the body core and the environment.

Thermoreceptors in the skin and temperature-sensitive neurons in the hypothalamus respond to changes in their local temperature

Skin-temperature receptors, although ideal for sensing changes in environmental temperature, do not serve well during exercise because internal temperatures would rise to intolerably high levels before the skin temperature rose to allow them to detect this excess heat. Temperature-sensitive neurons in the brain, in contrast, although ideal for detecting changes in T_{core} , are inadequate for sensing changes in the environmental temperature. Because of the thermal inertia of the body's mass, the lag time in using sensors of T_{core} to detect externally induced changes in temperature would be too great to achieve effective regulation. Not surprisingly, then, the body is endowed with temperature sensing neurons in both the periphery and in the CNS. The integration of their signals within the CNS central thermoregulatory

network permits a rapid and effective balance of heat loss and heat production that normally maintains T_{core} within relatively narrow limits.

Skin Thermoreceptors

The body has specialized sensory neurons (thermoreceptors) that provide the CNS with information about the thermal condition of the skin. The thermosensitive elements of thermoreceptors are free nerve endings that are distributed over the entire skin surface and contain cation channels that alter their conductance as the environmental temperature rises (TRPV1 to TRPV4 channels; see p. 386) or falls (TRPM8 channels; see p. 386). Peripheral thermoreceptors fall into two categories—**warmth** receptors and **cold** receptors (Fig. 59-3). Each type is anatomically distinct and each innervates definable warmth- or cold-sensitive spots on the skin surface (see p. 386). Thermal discrimination varies over the surface of the body; it is coarsest on the body trunk and limbs, and finest on the face, lips, and fingers. **Warmth receptors** increase their steady firing rate as local skin temperature increases from $\sim 32^{\circ}\text{C}$ up to $\sim 45^{\circ}\text{C}$ (see Fig. 59-3). **Cold receptors**, which are the predominant type of skin thermoreceptor, characteristically increase their steady firing rate as local temperature decreases from $\sim 40^{\circ}\text{C}$ down to 26°C . Both receptors respond to step changes in temperature with an initial, temporary change (i.e., *phasic* or dynamic response), followed by a stable change in the sensor's firing rate (i.e., *tonic* or static response; see Fig. 15-28).

FIGURE 59-3 Response of warmth and cold receptors to temperature change.

Because of their location, skin thermoreceptors primarily provide the hypothalamic thermoregulatory center with information about *ambient temperature* (Fig. 59-4), although their discharge rate also depends on the temperature of the blood perfusing the skin. As discussed on page 1200, skin thermoreceptors provide an anticipatory (feed-forward) signal, relaying information on changes in ambient temperature to the central thermoregulatory network, which drives **reflex thermoregulation** and thereby minimizes changes in T_{core} . Information from skin thermoreceptors also travels through thalamic pathways to the cerebral cortex, thus providing the basis for conscious perception of the thermal environment. Therefore, we can localize thermal stimuli on the skin surface and have an appreciation of thermal comfort. This thalamocortical pathway may be responsible for triggering **behavioral**

thermoregulation; for example, moving from the sun to the shade when we feel too hot (see [p. 1224](#)).

FIGURE 59-4 Overall model of temperature regulation. C, cold receptor; W, warmth receptor.

Hypothalamic Temperature-Sensitive Neurons

The principal mechanism through which the central thermoregulatory network senses changes in T_{core} is via temperature-sensitive neurons in the preoptic area of the anterior hypothalamus (see [Fig. 47-3](#)), [N59-4](#) where ~10% of neurons are warmth sensitive (i.e., their discharge rate increases as local temperature rises). As in skin thermoreceptors, TRPV channels endow preoptic temperature-sensitive neurons with the ability to change their discharge rate as the temperature of their local environment changes. The temperature-sensitive neurons in the preoptic area play the major role in detecting changes

in deep body temperature (see Fig. 59-4). Sensing of T_{core} by preoptic temperature-sensitive neurons is especially important during exercise, intake of hot fluids, or the resolution of a fever. In these conditions, heat storage increases more rapidly than heat dissipation, a situation calling for a prompt increase in heat loss to avoid a significant increase in T_{core} .

The CNS thermoregulatory network integrates thermal information and directs changes in efferent activity to modify rates of heat transfer and production

Warming or cooling of the skin—via skin thermoreceptors—alters both the tonic and the phasic components of afferent neuronal activity (see Fig. 59-4). The cell bodies of the warmth receptors and cold receptors are in the dorsal root ganglia and their axons synapse in the dorsal horn on *second-order* thermal sensory neurons, which project rostrally to two integration sites: (1) In the thalamus, they synapse on *third-order* neurons that provide somatosensory information to the cerebral cortex for conscious perception of skin-temperature changes and their localization to particular areas of the skin. (2) In the parabrachial nucleus of the pons, they synapse on *third-order* neurons that provide autonomic sensory information to the preoptic hypothalamus. Here, *fourth-order* neurons integrate cutaneous-temperature information with T_{core} information encoded in the discharge rates of the preoptic warmth-sensitive neurons.

Cutaneous warmth thermoreceptors—upon exposure to a warm environment—increase the activity of warmth sensory neurons in the thermal afferent pathway and thereby *stimulate* the discharge of the preoptic warmth-sensitive neurons. Conversely, cutaneous cold sensory signals *inhibit* the discharge of the preoptic warmth-sensitive neurons. Thus, the input from the warmth and cold sensory neurons, which report T_{skin} , shifts the discharge rate of the preoptic warmth-sensitive neurons away from the level otherwise determined by T_{core} .  **N59-7**

N59-7

Effect of Skin Temperature on the Response to Hypothalamic Drive

Contributed by John Stitt

In the experiments on rabbits (see eFigure 59-4), the investigators implanted water-perfused thermodes to control the temperature of the **preoptic area/anterior hypothalamus (POAH)**, shown on the x-axis. Metabolic rate, shown on the y-axis, was calculated from \dot{V}_{O_2} , and the animals were placed in a temperature-controlled chamber. Mean skin temperature (three different symbols) was also measured. eFigure 59-4 demonstrates how changes in ambient (skin) temperatures (T_{skin}) affects the POAH gain (the slope of a fitted line). This gain was determined by plotting the metabolic responses to brief step changes in the POAH temperature away from its normal level of 39.2°C (vertical dashed line in the figure). The POAH gain is flattest at the warmest skin temperature ($T_{\text{skin}} = 34.3^\circ\text{C}$) and it is steepest at the coldest skin temperature ($T_{\text{skin}} = 30.5^\circ\text{C}$). It can also be seen that when hypothalamic temperature is left undisturbed at its normal level of 39.2°C, the metabolic rate is at resting level (3.0 watt/kg) when T_{skin} is

34.3°C (i.e., with the subject in a relatively warm room). On the other hand, when T_{skin} is 30.5°C (i.e., with the subject in a cooler room), the metabolic rate rises to >6.0 watt/kg, due to the shivering thermogenesis induced by the low skin temperatures.

FIGURE 59-4 Thermoeffector responses. These results are from experiments in rabbits **ON59-7** in which the investigators implanted water-perfused thermodes to control the temperature of the preoptic/anterior hypothalamic area **ON59-4** (x-axis) at three different skin temperatures (T_{skin}).

The preoptic warmth-sensitive neurons provide a variable level of *inhibition* to descending efferent pathways that otherwise would excite two types of spinal neurons: (1) sympathetic preganglionic neurons that promote cutaneous vasoconstriction (limiting heat transfer within and from the body) and brown adipose tissue thermogenesis, and (2) α motor neurons that cause shivering in skeletal muscle (generating heat). For example, a fall in T_{skin} would disinhibit the activity of the efferent pathways to the cold-defense effectors and thereby tend to increase T_{core} .

The efferent pathways from the preoptic area are different for each of the thermal effectors, consistent with the variety of thermal effectors and their interchangeable roles in other functions (e.g., muscles that shiver also produce net movement). Moreover, nonthermal inputs have unique effects on different efferent pathways. For instance, **dehydration** increases plasma osmolality, which stimulates CNS osmoreceptors

(see Fig. 40-8) that can strongly inhibit the efferent pathway for sweating, so that the body conserves free water at the expense of cooling. Similarly, **hypoxia** (e.g., ascent to high altitude, late stages of emphysema) stimulates the arterial chemoreceptor reflex, which strongly inhibits the efferent pathways for thermogenesis in brown adipose tissue and skeletal muscle, tissues with high rates of O_2 consumption.

The skin receptors provide information mainly about environmental temperature, which affects the body's heat-loss rate and could ultimately cause T_{core} to change if the body did not initiate the appropriate thermoregulatory responses to skin cooling or warming. Thus, reflex responses driven by changes in the average skin temperature may be thought of as **anticipatory** or feed-forward, inasmuch as these responses do not bring skin temperature to a regulated level because of the skin's exposure to the ambient environment. However, these anticipatory reflexes are essential elements for an effective thermoregulatory system because the body's thermal inertia is too great to rely on central receptors alone. For example, low skin temperature, which is lowered still further by cutaneous vasoconstriction in the cold, ensures a rapid and continuous cold signal that maintains a drive for cutaneous vasoconstriction, brown adipose thermogenesis, and shivering. Conversely, thermoregulatory responses to changes in core (i.e., hypothalamic) temperature exhibit **negative feedback**.  **N1-1** For example, during exercise, the increase in T_{core} directly increases the discharge of the preoptic warmth-sensitive neurons; this increased discharge causes them to decrease the intensity of heat retention and heat generation, and thereby promotes a return of T_{core} to the regulated level.

In conclusion, T_{core} depends upon the balance between the *active* thermoregulatory system (i.e., the network from sensors to effectors) and the *passive* thermal elements (i.e., the overall metabolic heat load and the physical exchange of heat between the body and the environment). Presumably, human evolution of warmth-sensitive preoptic neurons has conferred the particular membrane properties and sensitivities to peripheral inputs that produce a T_{core} of $\sim 37^\circ\text{C}$, which is optimal for cellular chemical machinery.

Thermal effectors include behavior, cutaneous circulation, sweat glands, and skeletal muscles responsible for shivering

Humans have become quite adept at devising behavioral adaptations that permit survival in a wide range of environmental temperatures. As a thermal effector, **behavior** (from simply moving out of the hot sun, to building a fire, to designing a suit for space walks) is usually the central thermoregulatory system's first response to a change in environmental temperature, as sensed by skin thermoreceptors (see p. 1224). Behavior is also an essential anticipatory mechanism (e.g., putting on heavy clothing before going outside in a snowstorm) that is so habitual we do not even recognize it as part of our thermoregulatory repertoire.

The thermal effectors that modulate heat transfer are under the control of the sympathetic nervous system. Adjusting the smooth-muscle tone of cutaneous arterioles and of arteriovenous anastomoses (shunts) controls **cutaneous blood flow** (see pp. 570–571)—and therefore heat flow—from the core to the skin surface, the primary site of heat dissipation to the environment. Over most of the skin, the sympathetic nervous system controls blood flow. When it is necessary to increase heat dissipation, active vasodilation can increase cutaneous blood flow up to 10-fold above the resting level. Conversely, when it is necessary to conserve heat in a cold environment, cutaneous blood flow falls, partly by inhibition of active vasodilation and also by increased sympathetically mediated cutaneous vasoconstriction. As vasoconstriction increases, the reduced flow of warm blood through the cutaneous circulation causes skin temperature to fall even closer to ambient temperature, which results in further activation of the skin cold thermoreceptors. Even with maximal vasoconstriction in effect, heat losses to a very cold environment do

not fall to zero because of a small thermal conductance of the body's tissues to the skin surface and a temperature difference between the skin and the environment.

Piloerection reduces the rate of heat loss by retaining a layer of warm air next to the skin and occurs by activation of the sympathetic input to smooth muscles in the hair follicles. Although the thermoregulatory benefit of piloerection waned as humans lost their thick fur, the central thermoregulatory circuits and sympathetic innervation of hair follicles maintain this vestigial reflex response to cold.

With a moderate heat load, the autonomic response primarily increases heat transfer from core to skin by elevating cutaneous blood flow. However, when the heat load is sufficiently great, the preoptic warmth-sensitive neurons also drive activation of the **eccrine sweat glands** (see pp. 1215–1216), which secrete sweat onto the skin surface. Sweating elevates the partial pressure of water vapor at the skin surface and promotes increased evaporation, which takes heat from the skin. The innervation of the secretory segment of the sweat gland is sympathetic, but it is unusual in that acetylcholine is the neurotransmitter (see p. 342). Because sweating can lead to the loss of large amounts of water (>1 L/hr) and electrolytes, adequate hydration in hot environments is essential to prevent circulatory collapse and fatal hyperthermia (see Box 59-1).

As cold stress increases, cutaneous vasoconstriction is supplemented with heat production—**thermogenesis**—initially in brown adipose tissue and subsequently through shivering. The sympathetic nervous system heavily innervates **brown adipocytes** (see pp. 1164–1166), releasing norepinephrine onto β_3 -adrenergic receptors. The subsequent oxidation of fatty acids leads to the production not of ATP but of heat by virtue of the **uncoupling protein UCP1** (see pp. 1013 and 1166) and the abundant mitochondria. This thermogenesis depends on the size of the brown adipose tissue depots and the sympathetic input. Substantial brown adipose tissue depots have long been recognized in small rodents, hibernating animals, and human infants. However, the demonstration of brown adipose tissue in adult humans—and, in particular, its relative absence in the obese—has stimulated research into its potential role in metabolic homeostasis.

Shivering begins with an often-unrecognized increase in basal skeletal muscle tone, followed by the familiar involuntary, clonic, rhythmic contractions and relaxations of skeletal muscles. Shivering can triple or quadruple the metabolic rate for brief intervals and double the metabolic rate for extended periods (hours) before fatigue occurs. The same α motor neurons that innervate skeletal muscle for normal body movement and posture also drive shivering, but the mechanism underlying the rhythmic activations of α motor neurons during shivering is unknown.

Hypothermia, Hyperthermia, and Fever

Hypothermia or hyperthermia occurs when heat transfer to or from the environment overwhelms the body's thermoregulatory capacity

Although the body's temperature-regulating machinery is impressive, its capabilities are not limitless. Any factor that causes sufficiently large shifts—either negative or positive—in the rate of heat storage (see [Equation 59-1](#)) could result in progressive hypothermia or hyperthermia (see [Equation 59-6](#)). Because humans must operate within a fairly narrow core-temperature range, such temperature changes could become life-threatening.

The most common environmental condition causing excessive **hypothermia** is prolonged immersion in cold water. Water has a specific heat per unit volume that is ~ 4000 times that of air and a thermal conductivity that is ~ 25 times that of air. Both properties contribute to a convective heat-transfer coefficient ($h_{\text{convective}}$ in [Equation 59-4](#)) that is ~ 100 -fold greater in water than it is in air. The $h_{\text{convective}}$ is $\sim 200 \text{ kcal}/(\text{hr} \cdot ^\circ\text{C} \cdot \text{m}^2)$ at rest in still water but $\sim 500 \text{ kcal}/(\text{hr} \cdot ^\circ\text{C} \cdot \text{m}^2)$ while swimming. The body's physiological defenses against hypothermia include peripheral vasoconstriction (which increased insulation) and shivering (which increases heat production), but even these measures do not prevent hypothermia during prolonged exposure because of water's high thermal conductivity. A thick layer of insulating fat retards heat loss to the water and postpones or even prevents hypothermia during prolonged exposures. Endurance swimmers have used this knowledge to protect themselves by applying a thick layer of grease to the skin surface before an event (now, more commonly, they don a wetsuit). Herman Melville noted this principle in 1851, when he referred to the low thermal conductivity of fat:

For the whale is indeed wrapt up in his blubber as in a real blanket. ... It is by reason of this cozy blanketing that the whale is enabled to keep himself comfortable in all seas. ... this great monster, to whom corporeal warmth is as indispensable as it is to man.

—*Moby Dick*

Like blubber, clothing adds insulation between skin and environment and thus reduces heat loss during exposure to the cold. The more skin one covers, the more one reduces the surface area for direct heat loss from skin to environment by convection and radiation. Adding *layers* of clothing increases the resistance of heat flow by trapping air, which is an excellent insulator. During heat exposure, the major avenue for heat loss is evaporation of sweat. Because evaporation also depends on the surface area available, the amount of clothing should be minimized. Wetting the clothing increases the rate of heat loss from the skin because water is a better conductor than air. Water also can evaporate from the clothing surface, which removes heat from the outer layers and increases the temperature gradient (and rate of heat loss) from skin to clothing.

The most common environmental condition that results in excessive **hyperthermia** is prolonged simultaneous exposure to heat and high ambient humidity, particularly when accompanied by physical activity (i.e., elevated heat-production rate). The ability to dissipate heat by *radiation* falls as the radiant temperature of nearby objects increases (see [Equation 59-3](#)), and the ability to dissipate heat by *convection* falls as ambient temperature increases (see [Equation 59-4](#)). When ambient temperature

reaches the mid-30s (°C), evaporation becomes the only effective avenue for heat dissipation. However, high ambient humidity reduces the skin-to-environment gradient for water vapor pressure, which reduces *evaporation* (see [Equation 59-5](#)). The combined reduction of heat loss by these three pathways can markedly increase the rate of heat storage (see [Equation 59-6](#)), causing progressive hyperthermia.

It is uncommon for radiative or convective heat gain to cause hyperthermia under conditions of low ambient humidity, because the body has a high capacity for dissipating the absorbed heat by evaporation. Radiative heat gain can be excessively high during full exposure to the desert sun or during exposure to heat sources such as large furnaces. The most obvious protections against radiative hyperthermia are avoiding radiant sources (e.g., sitting in the shade) and covering the skin with loose clothing. The latter screens the radiation while allowing air circulation underneath the clothing and thereby maintaining evaporative and convective losses.

Exercise raises heat production, which is followed by a matching rise in heat loss, but at the cost of a steady-state hyperthermia of exercise

At the onset of muscular exercise, the rate of heat production increases in proportion to exercise intensity and exceeds the current rate of heat dissipation; thus, heat storage occurs and core temperature rises ([Fig. 59-5](#)). This rise in the temperature of the local environment of the preoptic warmth-sensitive neurons increases their discharge rate, which increases the neural output that activates heat dissipation (see [Fig. 59-4](#)). As a result, skin blood flow and sweating increase as T_{core} rises, promoting an increase in the rate of heat transfer from core to environment and slowing the rate at which T_{core} rises. However, heat dissipation during exercise does not increase enough both to eliminate the already-acquired heat storage and to balance the ongoing heat production. Thus, the mildly elevated steady-state T_{core} persists as long as exercise continues.

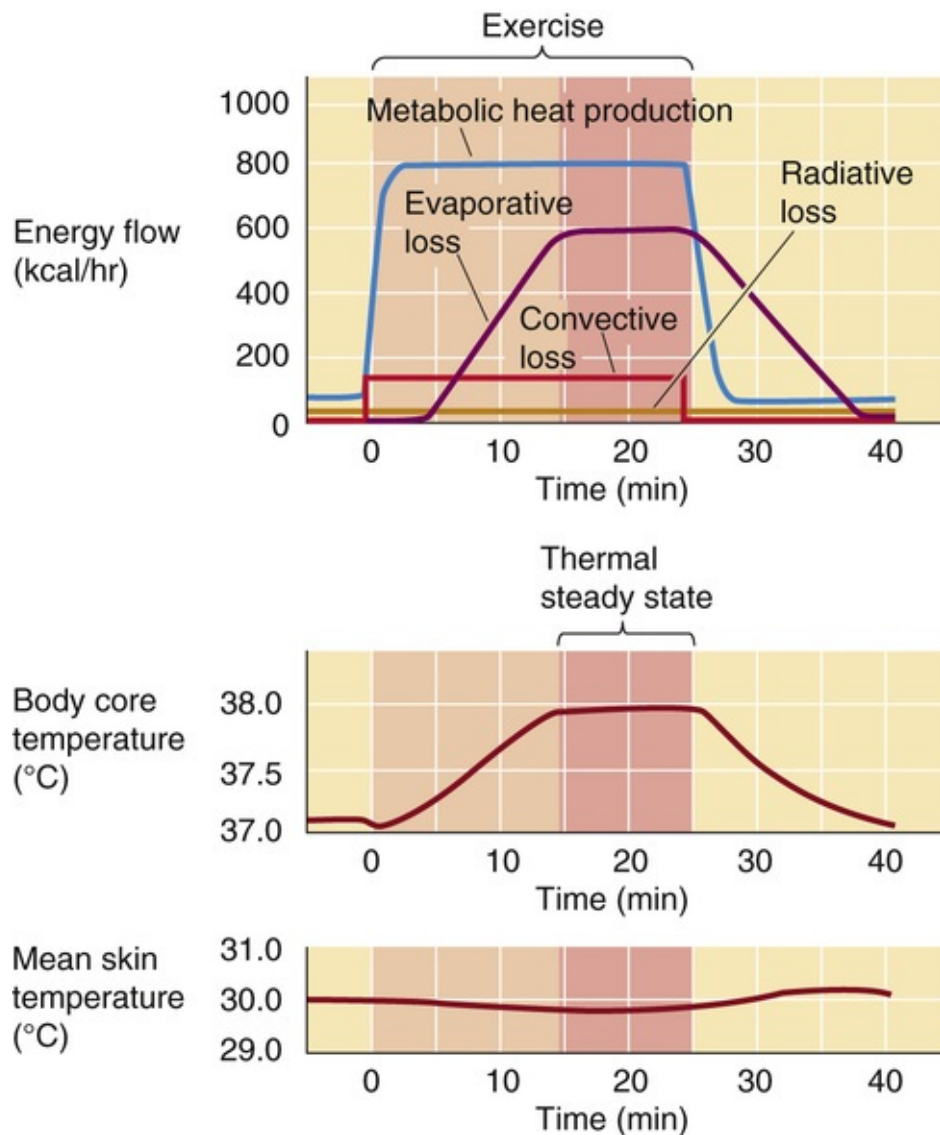

FIGURE 59-5 Whole-body heat balance during exercise.

The elevated T_{core} during exercise may be one aspect of the body's "central command" for exercise and is necessary to maintain the elevated discharge of the preoptic warmth-sensitive neurons in order to sustain increased activity of the thermal effectors for heat dissipation. In the example illustrated in [Figure 59-5](#), metabolic heat production rises rapidly to its maximal level for the particular level of exercise underway. However, evaporative heat loss increases only after a delay and then rises slowly to its maximal level, driven by increasing body temperature. In this example, the result is net storage during the first 15 minutes. The slight initial drop in T_{core} at the onset of exercise is caused by flushing out of blood from the cooler peripheral circulation when the muscle and skin beds vasodilate in response to the onset of exercise. Note also that mean skin temperature *decreases* during exercise because of the increased evaporative cooling of the skin caused by sweating. 🟡N59-5

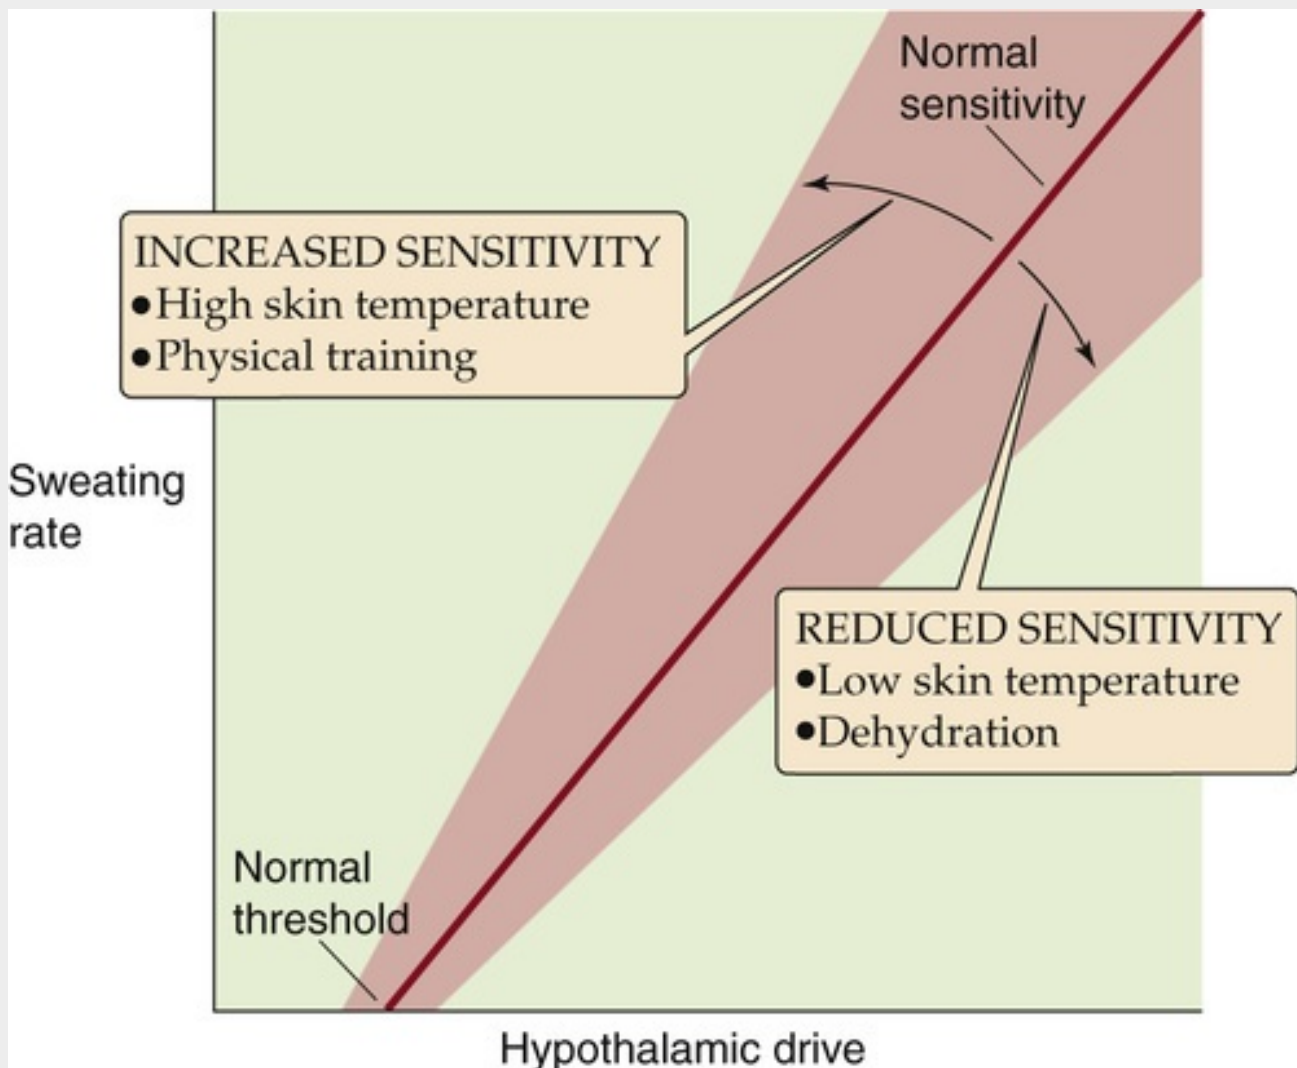

N59-5

Effect of Training on the Hyperthermia of Exercise

Contributed by Ethan Nadel

Physical training reduces the hyperthermia of exercise by reducing the threshold for sweating (so that sweating begins earlier) and increasing sweating sensitivity (so that a given hypothalamic drive produces

more sweating); it thus provides a greater margin of safety between operating and limiting temperatures for exercise (eFig. 59-2). To the extent that training enhances sweat gland function (evaporative heat loss), reliance on cutaneous circulation (convective heat loss) falls, while preserving blood flow to muscle. The relative dehydration caused by continuous water losses during prolonged exercise elevates the temperature threshold for sweating and reduces the sensitivity (see eFig. 59-2). The result is a higher core temperature during exercise.

EFigure 59-2 Thermoeffector responses with physical training.

Fever is a regulated hyperthermia

Whereas hyperthermias such as that resulting from exercise in a hot environment arise from incomplete compensation by the thermoregulatory system for an imposed heat load, fever is a *regulated* elevation of core temperature induced by the central thermoregulatory system itself.

In response to a variety of infectious and inflammatory stimuli, macrophages and, to a lesser extent, lymphocytes release cytokines into the circulation (Fig. 59-6). Cytokines (see p. 68) are a diverse group of peptides and proteins involved in numerous tasks, among which are serving as the messenger molecules of the immune system. The first step in the host defense response is the **immune response** to foreign substances, including stimulation of T-lymphocyte proliferation, of natural killer cells, and of antibody production. The second is the **acute-phase response**, a diffuse collection of host reactions,

including fever production, lethargy, and hyperalgesia, which apparently support the immunological response to, and the body's recovery from, infection or trauma. Finally, cytokines such as interleukin-1 β (IL-1 β) act as endogenous pyrogens ([Table 59-3](#)) in a signaling cascade that induces peripheral (e.g., in liver) and CNS production of **prostaglandin E₂** (PGE₂; see [Fig. 3-11](#)). IL-1 β , for example, could interact with the endothelial cells in a leaky portion of the blood-brain barrier (see [pp. 284–287](#)) located in the capillary bed of the *organum vasculosum laminae terminalis* (OVLT; see [pp. 284–285](#)). The OVLT is highly vascular tissue that lies in the wall of the third ventricle (above the optic chiasm) in the brain. IL-1 β triggers endothelial cells within the OVLT to release PGE₂, which then diffuses into the adjacent preoptic hypothalamus to drive the febrile response.

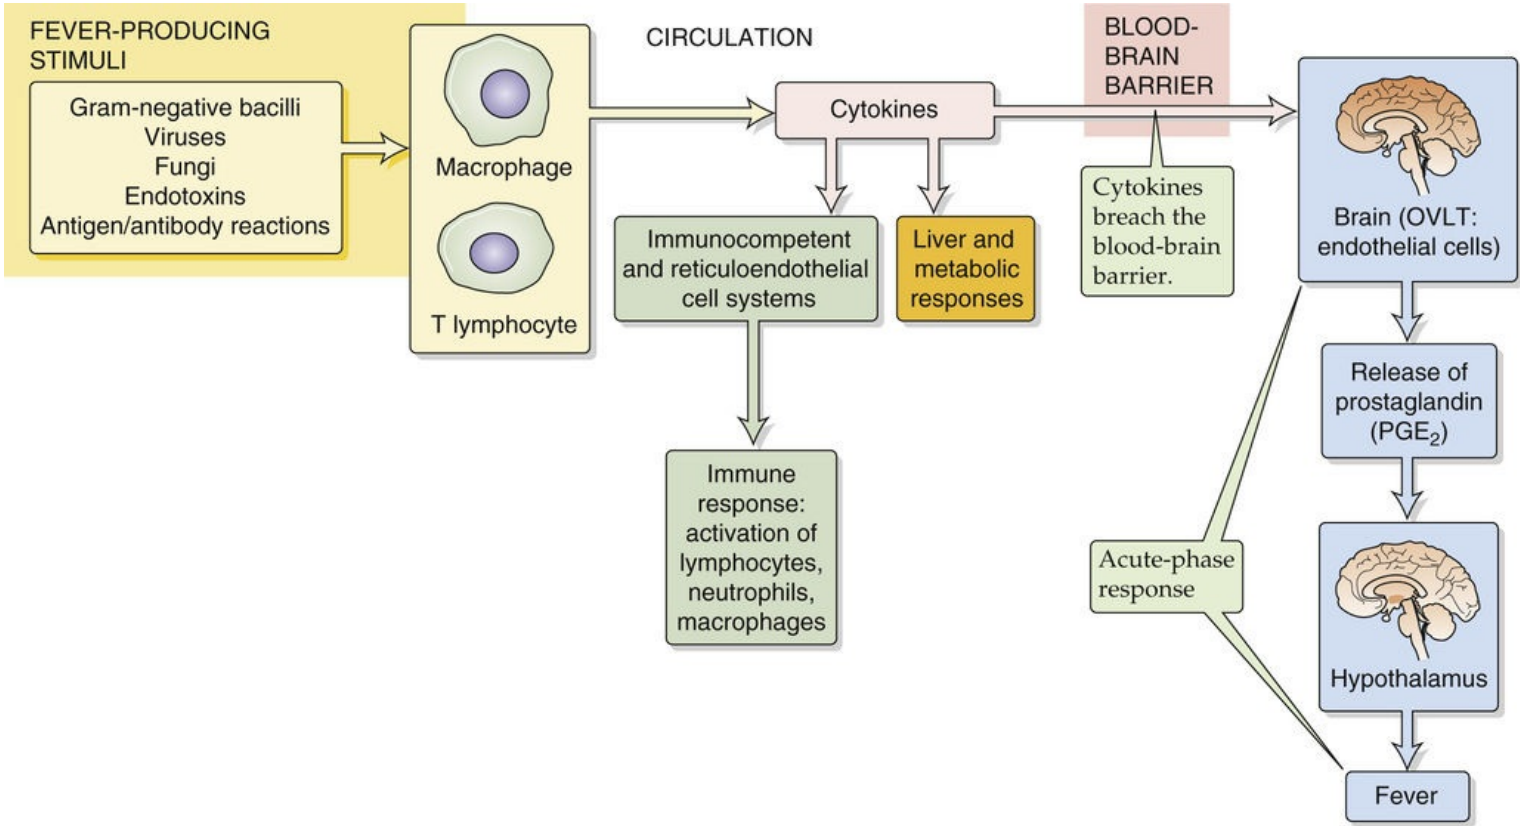

FIGURE 59-6 Host defense response.

Interferon- γ	INF- γ

PGE₂ inhibits warmth-sensitive neurons in the preoptic area—akin to the action of stimulated skin cold

thermoreceptors—and activates the thermal effectors (see [pp. 1200–1201](#)) for heat retention (cutaneous vasoconstriction) and heat production (brown adipose tissue thermogenesis, and shivering or “chills”), which results in an increase in T_{core} . This sequence is in sharp contrast to the hyperthermia of exercise, in which the rise in T_{core} due to muscle heat production provides a strong and unimpeded stimulus for the preoptic warmth-sensitive neurons to increase the activity of the thermal effectors for *heat defense*. In contrast, in fever, the excitatory effect of the elevated T_{core} cannot compete with the strong inhibition of the preoptic warmth-sensitive neurons elicited by the local increase in PGE_2 , and activation (via disinhibition) of the thermal effectors for *cold defense* prevails. 🍌[N59-6](#)

N59-6

Exercise Hyperthermia versus Fever

Contributed by Ethan Nadel

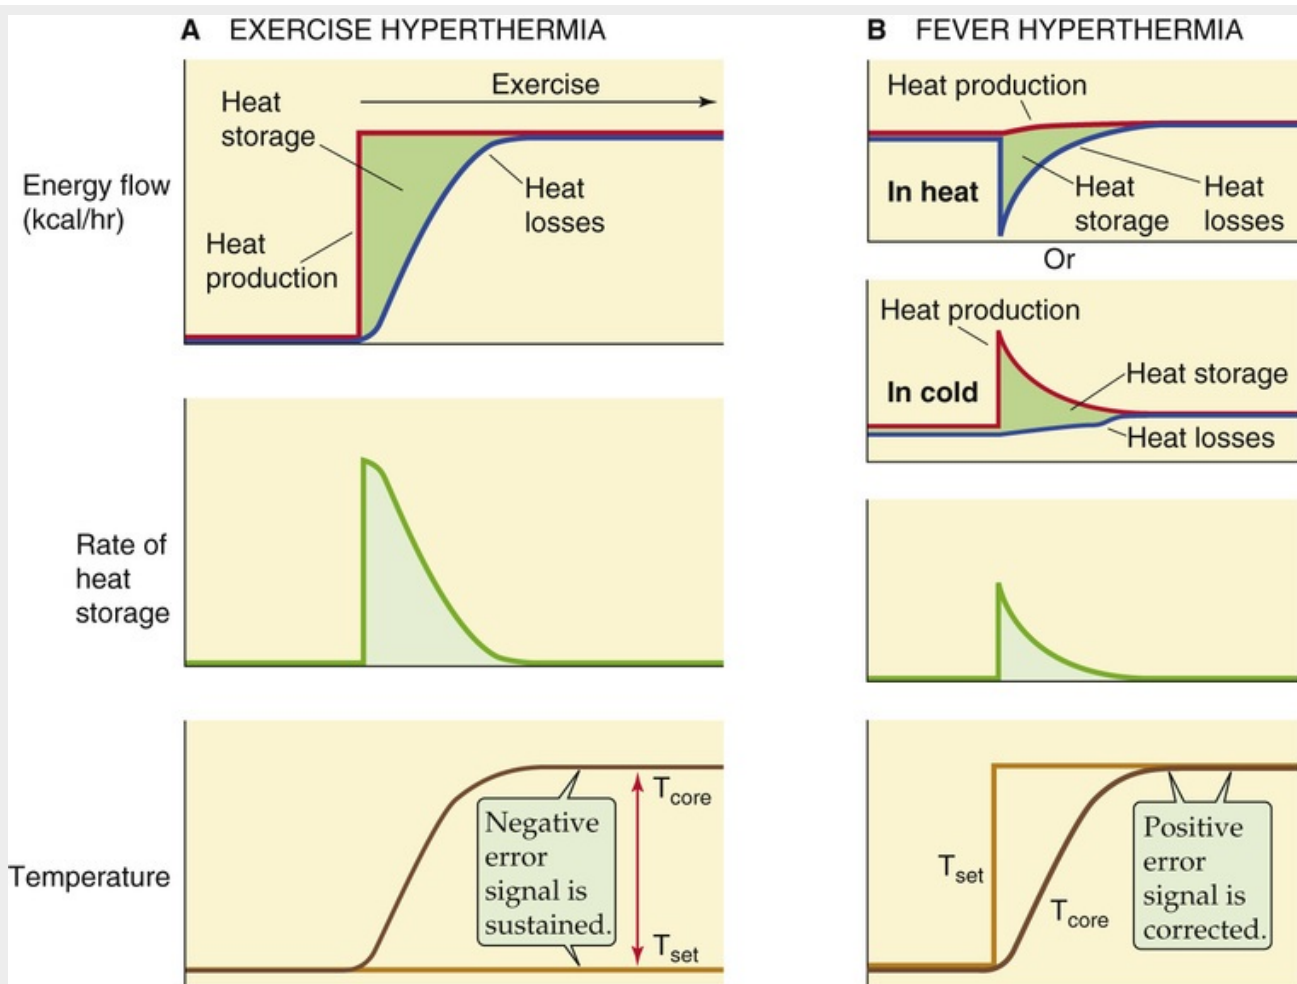

FIGURE 59-3 Exercise hyperthermia versus fever. **A**, The top panel shows how, during exercise, heat production temporarily exceeds heat loss, which results in net heat storage. The middle panel shows that the rate of heat storage is highest initially and falls to zero in the new steady state. Finally, the bottom panel shows that as body core temperature rises away from the set-point (T_{set}), the error signal gradually increases. In the new steady state, the error signal is maximal and sustained. **B**, The top pair of panels show how, during fever, net heat storage can occur because of either reduced heat loss or increased heat production. The third panel shows that, as in exercise, the rate of heat storage is highest initially. The bottom panel shows that as body core temperature rises, it approaches the new elevated set point. Thus, the error signal is initially maximal and gradually decreases to zero in the new steady state.

Once the PGE_2 production falls—perhaps due to administration of an anti-inflammatory drug that inhibits PGE_2 synthesis (see [Box 3-3](#))—the elevated T_{core} can now produce a marked stimulation of the preoptic warmth-sensitive neurons, resulting in an inhibition of the thermal effectors for heat production and a strong stimulation of those for heat loss, and the fever “breaks.”

In both exercise and fever, behavioral thermoregulatory responses support those autonomic and shivering responses being directed by the neurons in the preoptic area. During exercise, one *feels warm*, and this deviation from thermal comfort drives behaviors such as removing clothing or splashing cold water on the body to cool it. In contrast, during the onset of a fever, one *feels cold* and may choose to put on additional clothing or blankets to warm the body. If fever strikes when the patient is in a hot environment in which the cutaneous vessels are dilated, cutaneous vasoconstriction will occur to reduce heat loss. In contrast, if the patient is in a cool environment in which the cutaneous vessels are already constricted, increased thermogenesis will occur in brown adipose tissue and through shivering (chills). However, because the thermal effectors activated in cold defense are the same as those activated during fever, it may be difficult to produce a significant febrile elevation of T_{core} in a fairly cold environment.

The value of fever in fighting infection is still debated. A popular hypothesis is that the elevated temperature enhances the host's response to infection. This view is supported by the observation that, in vitro, the rate of T-lymphocyte proliferation in response to interleukins is many-fold higher at 39°C than it is at 37°C.

Exercise Physiology and Sports Science

Steven S. Segal

Physical exercise is often the greatest stress that the body encounters in the course of daily life. Skeletal muscle typically accounts for 30% to 50% of the total body mass. Thus, with each bout of muscular activity, the body must make rapid, integrated adjustments at the level of cells and organ systems—and must tune these adjustments over time. The subdiscipline of exercise physiology and sports science focuses on the integrated responses that enable the body to convert chemical energy into mechanical work. To understand these interdependent processes, one must appreciate where regulation occurs, the factors that determine physical performance, and the adaptations that take place with repetitive use.

The cross-bridge cycle that underlies contraction of skeletal muscle requires energy in the form of ATP (see [pp. 234–236](#)). Skeletal muscle converts only ~25% of the energy stored in carbon-carbon bonds (see [p. 1170](#)) into mechanical work. The rest appears as heat, due to the inefficiencies of the biochemical reactions (see [pp. 1173–1174](#)). Thus, the dissipation of this heat is central to cardiovascular function, fluid balance, and the ability to sustain physical effort—an example of an integrated organ-system response. Moreover, because muscle stores of ATP, phosphocreatine, and glycogen are limited, the ability to sustain physical activity requires another set of integrated cellular and organ-system responses to supply O₂ and energy sources to active muscles.

Motor Units and Muscle Function

[Chapter 9](#) deals with the cellular and molecular physiology of skeletal muscle contraction. In this subchapter, we examine the integration of these cellular and molecular elements into the contraction of a whole muscle.

The motor unit is the functional element of muscle contraction

The **motor unit** (see [pp. 228–229](#)) is the functional unit of skeletal muscle and consists of a single motor neuron and all the muscle fibers that it activates. A typical skeletal muscle such as the biceps brachii receives innervation from ~750 somatic motor neurons.

When the motor neuron generates an action potential, all fibers in the motor unit fire simultaneously. Thus, the fineness of control for movement varies with the **innervation ratio** (see [pp. 228–229](#))—the number of muscle fibers per motor neuron.  **N60-1** The small motor units that are recruited during sustained activity contain a high proportion of **type I** muscle fibers (see [p. 249](#)), which are highly oxidative and resistant to fatigue. The **type IIa** motor units (see [p. 249](#)) have larger innervation ratios, contract faster, and have less oxidative capacity and fatigue resistance than type I units. Still larger motor units—recruited for brief periods for rapid, powerful activity—typically consist of **type IIx** muscle fibers; these have less oxidative capacity (i.e., are more glycolytic) and are much more susceptible to fatigue than type IIa muscle. In practice, it may be best to view muscle fiber types and motor units as a continuum rather than distinct entities.

N60-1

Innervation Ratio

Contributed by Steven Segal, Emile Boulpaep, Walter Boron

A **motor unit** is a motor neuron and all of the muscle fibers that it innervates (see [pp. 228–229](#)). The innervation ratio quantifies the motor unit. The **innervation ratio** is the number of muscle fibers innervated by a single motor neuron. Thus, large motor units have high innervation ratios.

Muscles controlling the very fine movements of the eye (e.g., rectus lateralis) have innervation ratios of only a few muscle fibers. At the other extreme, motor units in the thigh (e.g., quadriceps muscle) and calf (e.g., gastrocnemius muscle) often contain thousands of muscle fibers and are involved in such powerful activities as sprinting and jumping. In the muscles involved in hand movements, motor units have innervation ratios that vary from <100 fibers (e.g., interosseous muscles controlling fine movements of the fingers) to >1000 fibers (e.g., forearm muscles controlling such coarse movements as grasping).

Within a whole muscle, muscle fibers of each motor unit intermingle with those of other motor units so extensively that a volume of muscle containing 100 muscle fibers is innervated by terminals from perhaps 50 different motor neurons. However, each muscle fiber is innervated by only one motor neuron. Within some muscles, the fibers of a motor unit are constrained to discrete compartments. This anatomical organization enables different regions of a muscle to exert force in somewhat different directions, which

enables more precise control of movement.

Muscle force rises with the recruitment of motor units and an increase in their firing frequency

During contraction, the force exerted by a muscle depends on (1) how many motor units are recruited, and (2) how frequently each of the active motor neurons fires action potentials. Motor units are recruited in a progressive order, from the smallest (i.e., fewest number of muscle fibers) and therefore the weakest motor units to the largest and strongest. This intrinsic behavior of motor-unit recruitment is known as the **size principle** and reflects inherent differences in the biophysical properties of respective motor neurons. For a given amount of excitatory input (i.e., depolarizing synaptic current; I_{syn} in [Fig. 60-1](#)), a neuronal cell body with smaller volume and surface area has a higher membrane input resistance. Therefore, the depolarizing voltage rises to threshold more quickly in a neuron with a smaller neuronal cell body than in a neuron with a larger cell body (see [Fig. 60-1](#)). Because the neurons with the small cell bodies tend to innervate a small number of slow-twitch (type I) muscle fibers, the motor units with the greatest resistance to fatigue are the first to be recruited. Conversely, the neurons with the larger cell bodies tend to innervate a larger number of fast-twitch (type II) fibers, so the largest and most fatigable motor units (type IIx) are the last to be recruited (e.g., during peak levels of force production). Because the relative timing of action potentials in different motor units is asynchronous, the force developed by individual motor units integrates into a smooth contraction. As a muscle relaxes, the firing of respective motor units diminishes in reverse order.

FIGURE 60-1 Size principle for motor units. Small motor neurons are more excitable, conduct action potentials more slowly, and excite fewer fibers that tend to be slow twitch (type I). Conversely, large motor neurons are less excitable, conduct action potentials more rapidly, and excite many fibers that tend to be fast twitch (type II). EPSP, excitatory postsynaptic potential; R_m , membrane resistance; V_m , membrane potential. (Adapted from Kandel ER, Schwartz JH, Jessell TM: Principles of Neural Science, 4th ed. New York, McGraw-Hill, 2000.)

At levels of force production lower than the upper limit of recruitment, gradations in force are accomplished via concurrent changes in the number of active motor units and the firing rate of those that have been recruited—**rate coding**. Once all the motor units in a muscle have been recruited, any further increase in force results from an increase in firing rate. The relative contribution of motor-unit recruitment and rate coding varies among muscles. In some cases, recruitment is maximal by the time muscle force reaches ~50% of maximum, whereas in others, recruitment continues until the muscle reaches nearly 90% of maximal force.

Not only do the intrinsic membrane properties of motor neurons (i.e., the size principle) affect motor neuron firing, but other neurons that originate in the brainstem project to the motor neurons and release the neuromodulatory neurotransmitters serotonin and norepinephrine (see Fig. 13-7A and B). For example, this neuromodulatory input, acting on the motor neurons of small, slow-twitch motor units, can promote self-sustained levels of firing of the motor neurons during the maintenance of posture. In contrast, the

withdrawal of this excitatory neuromodulatory input during sleep promotes muscle relaxation. Thus, the brainstem can control the overall gain of a pool of motor neurons.

Compared with type I motor units, type II units are faster and stronger but more fatigable

Within a given motor unit, each muscle fiber is of the same **muscle fiber type**. As summarized in [Tables 9-1](#) and [9-2](#), the three human muscle fiber types—type I, type IIa, and type IIx—differ in contractile and regulatory proteins, the content of myoglobin (and thus color) and of mitochondria and glycogen, and the metabolic pathways used to generate ATP (i.e., oxidative versus glycolytic metabolism). Physical training can modify these biochemical properties, which determine a range of functional parameters, including (1) speeds of contraction and relaxation, (2) maximal force, and (3) susceptibility to fatigue ([Fig. 60-2](#)).

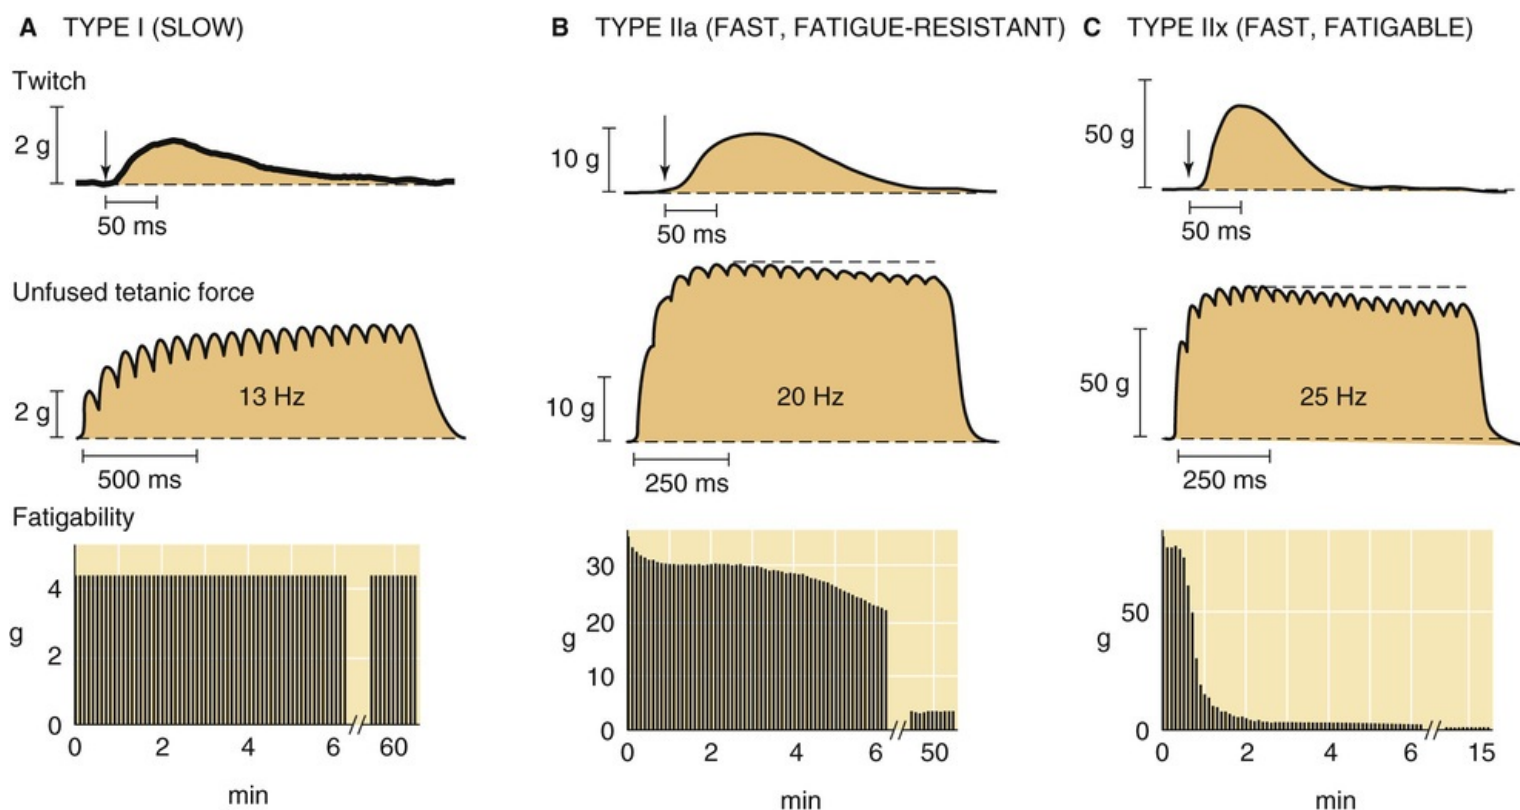

FIGURE 60-2 Properties of fiber types. The top row shows the tension developed during single twitches for each of the muscle types; the arrows indicate the time of the electrical stimulus. The middle row shows the tension developed during an unfused tetanus. The bottom row shows the degree to which each fiber type can sustain force during continuous stimulation. Note that the time scales become progressively larger from the top to bottom rows, with a break in the bottom row. Also, the tension scales become progressively larger from left (fewer fibers per motor unit) to right (more fibers per motor unit). These results are from experiments performed on cat gastrocnemius muscle, which has type IIb fibers (instead of type IIx fibers as in humans). (Data from Burke RE, Levine DN, Tsairis P, et al: *J Physiol* 234:723–748, 1977.)

In response to an action potential evoked through the motor axon, **slow-twitch** (type I) motor units (see [Fig. 60-2A](#), top) require relatively long times to develop moderate levels of force and return to rest. In contrast, **fast-twitch** (types IIa and IIx) motor units exhibit relatively short contraction and relaxation times and develop higher levels of force (see [Fig. 60-2B and C](#), top). Accordingly, during repetitive stimulation (middle row of [Fig. 60-2](#)), slow-twitch motor units summate to a fused tetanus at lower stimulation frequencies than do fast-twitch motor units. Indeed, the α motor neurons in the spinal cord that

drive slow motor units fire at frequencies of 10 to 50 Hz, whereas those that drive fast motor units fire at 30 Hz to >100 Hz.

The maximal force that can develop per cross-sectional area of muscle tissue is constant across fiber types ($\sim 25 \text{ N/cm}^2$). Therefore, the ability of different motor units to develop active force is directly proportional to the number and diameter of fibers each motor unit contains. In accord with the innervation ratios of motor units, peak force production (middle row of [Fig. 60-2](#)) increases from type I motor units (used for fine control of movement) to type II motor units (recruited during more intense activities).

The susceptibility to fatigue of a motor unit depends on the metabolic profile of its muscle fibers. The red type I muscle fibers have a greater mitochondrial density and can rely largely on the aerobic metabolism of carbohydrate and lipid as fuel because they are well supplied with capillaries for delivery of O_2 and nutrients. Type I motor units, although smaller in size (and innervation ratio), are recruited during sustained activity of moderate intensity and are highly resistant to fatigue (see [Fig. 60-2A](#), bottom). In contrast, the larger type II motor units are recruited less often—during brief periods of intense activity—and rely to a greater extent on short-term energy stores (e.g., glycogen stored within the muscle fiber). Among type II motor units, **type IIa** motor units have intermediate innervation ratios, a greater mitochondrial density, a larger capacity for aerobic energy metabolism, a greater O_2 supply, and a higher endurance capacity, and hence are classified as **fast fatigue-resistant** (bottom of [Fig. 60-2B](#)). In contrast, **type IIx** motor units have the highest innervation ratios and a greater capacity for rapid energy production through nonoxidative (i.e., anaerobic) glycolysis, and thus can produce rapid and powerful contractions. However, type IIx units tire more rapidly and are therefore classified as **fast fatigable** (see [Fig. 60-2C](#), bottom).

As external forces stretch muscle, series elastic elements contribute a larger fraction of total tension

As sarcomeres contract, some of their force acts laterally—through membrane-associated and transmembrane proteins—on the extracellular matrix and connective tissue that surrounds each muscle fiber. Ultimately, the force is transmitted to bone, typically (but not always) through a tendinous insertion. The structural elements that transmit force from the cross-bridges to the skeleton comprise the **series elastic elements** of the muscle and behave as a spring with a characteristic stiffness. Stretching resting muscle causes **passive tension** to increase exponentially with length (see [Fig. 9-9C](#)). Thus, muscle stiffness increases with length. During an **isometric contraction** (see [pp. 237–238](#)), when the external length of a muscle (or muscle fiber) is held constant, the sarcomeres shorten at the expense of stretching the series elastic elements. An isometric contraction can occur at modest levels of force development, such as holding a cup of coffee, as well as during maximal force development, such as when opposing wrestlers push and pull against each other, with neither gaining ground. Physical activity typically involves contractions in which muscles are shortening and lengthening, as well as periods during which muscle fibers are contracting isometrically.

During cyclic activity such as running, muscles undergo a stretch-shorten cycle that may increase total tension while decreasing active tension. For example, as the calf muscles relax as the foot lands and decelerates, the series elastic elements of the calf muscles (e.g., the Achilles tendon, connective tissue within muscles) are stretched and develop increased passive tension (see [Fig. 9-9C](#)). Thus, when the calf muscles contract to begin the next cycle, they start from a higher *passive* tension and therefore use a smaller increment in *active* tension to reach a higher *total* tension. 🟡N60-2 This increased force helps to

propel the runner forward.

N60-2

Effect of Stretch on the Active Tension of Skeletal Muscle

Contributed by Emile Boulpaep, Walter Boron

As shown in Figure 9-9D, the **active tension** of skeletal muscle is maximal at a sarcomere length with an optimal overlap of the thin and thick filaments. At relatively low initial lengths of the muscle (e.g., at 70 on the x-axis of Fig. 9-9C, D), the active tension is relatively low. Prestretching the muscle to a greater initial length produces a greater active tension ... up to a point (i.e., 100 on the x-axis). Further increases in passive length actually produce a decrease in active tension (e.g., 130 on the x-axis). Of course, the **total tension** increases continuously from the lowest to the highest muscle lengths.

In a **concentric** contraction (e.g., climbing stairs), the force developed by the cross-bridges exceeds the external load, and the sarcomeres shorten. During a concentric contraction, a muscle performs **positive work** (force \times distance) and produces power (work/time; see [p. 240](#)). As shown in [Figure 9-9E](#), the muscle achieves peak power at relatively moderate loads (30% to 40% of isometric tension) and velocities (30% to 40% of maximum shortening velocity). The capacity of a muscle to perform positive work determines physical performance. For example, a stronger muscle can shorten more rapidly against a given load, and a muscle that is metabolically adapted to a particular activity can sustain performance for a longer period of time before succumbing to fatigue.

In an **eccentric** contraction (e.g., descending stairs), the force developed by the cross-bridges is less than the imposed load, and the sarcomeres lengthen. During an eccentric contraction, the muscle performs **negative work**, thereby providing a brake to decelerate the applied force being applied, and absorbs power. Eccentric contractions can occur with light loads, such as lowering a cup of coffee to the table, as well as with much heavier loads, such as decelerating after jumping off a bench onto the floor. At the same absolute level of *total* force production, eccentric contractions—with increasingly stretched sarcomeres—develop less active tension than do concentric or isometric contractions. Conversely, the passive tension developed by the series elastic elements makes a greater contribution to total tension. As a result, the maximum tension generated eccentrically can be greater than that generated isometrically. When the external force stretches the muscle sufficiently, all the tension is passive and the limit is the breaking point (see [Fig. 19-9B](#)) of the series elastic elements. Thus, eccentric contractions are much more likely than isometric or isotonic contractions to damage muscle fibers and connective tissue, as occurs with the common injury of a ruptured Achilles tendon.

The action of a muscle depends on the axis of its fibers and its origin and insertion on the skeleton

In addition to the contractile and metabolic properties of muscle fibers discussed above, two anatomical features determine the characteristics of the force produced by a muscle.

The first anatomical determinant of muscle function is the arrangement of fibers with respect to the axis of force production (i.e., the angle of pennation). With other determinants of performance (e.g., fiber type and muscle mass) being equal, muscles that have a relatively small number of long fibers oriented parallel to the axis of shortening (e.g., the sartorius muscle of the thigh; [Fig. 60-3A](#), top) shorten more

rapidly. Indeed, the more sarcomeres are arranged in *series*, the more rapidly the two ends of the muscle will approach each other. In contrast, muscles that have many short fibers at an angle to the axis (e.g., the gastrocnemius muscle of the calf; [Fig. 60-3A](#), bottom) develop more force. Indeed, the greater the number of fibers (and sarcomeres) in *parallel* with each other, the greater the total cross-sectional area for developing force.

A AXIS OF MUSCLE FIBERS

B ORIGIN AND INSERTION OF A MUSCLE

The second anatomical determinant of limb movement consists of the locations of the origin and insertion of the muscle to the skeleton. Consider, for example, the action of the brachialis muscle on the elbow joint. The distance between the insertion of the muscle on the ulna and the joint's center of rotation is D , which may be 5 cm. The **torque** that the muscle produces on the joint is the *component* of total muscle force that is perpendicular to the ulna, multiplied by D (see Fig. 60-3B). An equivalent definition is that *torque* is the product of the total muscle force multiplied by the **moment arm**, which is the length of the line segment that runs perpendicular to the muscle and through the center of rotation (see Fig. 60-3B). As we flex the elbow, the moment arm is constantly changing and muscle force changes as well. For this joint, we achieve maximum torque at 60 degrees of flexion.

Fluid and energetically efficient movements require learning

To perform a desired movement—whether playing the piano or serving a tennis ball—the nervous system must activate a combination of muscles with the appropriate contractile properties, recruit motor units in defined patterns, and thereby create suitable mechanical interactions among body segments. When we perform movements with uncertainty—as in learning a new skill—actions tend to be stiff because of concurrent recruitment of motor units in antagonistic muscles that produce force in opposite directions. Such superfluous muscle fiber activity also increases the energy requirements for the activity. Even in someone who is skilled, the fatigue of small motor units leads to the recruitment of larger motor units in the attempt to maintain activity, but with loss of fine control and greater energy expenditure. With learning, recruitment patterns become refined and coordinated, and muscle fibers adapt to the task. Thus, movements become fluid and more energetically efficient, as exemplified by the movements of highly trained musicians and athletes, who can make difficult maneuvers appear almost effortless.

Strength versus endurance training differentially alters the properties of motor units N60-3

N60-3

Endurance (“Aerobic”) versus Strength (“Anaerobic”) Training

Contributed by Emile Boulpaep, Walter Boron

The distinction between **endurance training** (e.g., long-distance running) and **strength training** (e.g., weightlifting) refers to the manner of exercise. Endurance training involves performing a lower-intensity activity for a longer period. Strength training, in contrast, involves performing a high-intensity activity for shorter periods.

The distinction between **aerobic** and **anaerobic** refers to the metabolic pathway that the muscles primarily use to regenerate ATP. Thus, in aerobic exercise, the cells regenerate ATP primarily by using oxidative phosphorylation. In anaerobic exercise—of course, no one exercises in the absence of oxygen!—the cells regenerate ATP primarily by using anaerobic glycolysis, generating lactic acid in the bargain.

The firing pattern of the α motor neuron—over time—ultimately determines the contractile and metabolic properties of the muscle fibers in the corresponding motor unit. This principle was demonstrated by cross-innervation experiments in which investigators cut the motor nerve to a muscle composed primarily of *fast* motor units and switched it with the motor nerve of a muscle composed primarily of *slow* motor units.  **N60-4** As the axons regenerate and the muscles recover contractile function over several weeks, the fast muscle becomes progressively slower and more fatigue resistant whereas the slow muscle becomes faster and more susceptible to fatigue. Varying the pattern of efferent nerve impulses via long-term stimulation of implanted electrodes elicits similar changes in muscle properties. A corollary of this principle is that physical activity leads to adaptation only in those motor units that are actually recruited during the activity.

N60-4

Cross-Innervation Experiments

Contributed by Steven Segal

The principle described in the text—that it is the type of motor neuron that determines the properties of the muscle fibers the neuron innervates—was demonstrated in experiments reported by Buller, Eccles, and Eccles in a classic paper published in 1960.

The effects of physical activity on motor-unit physiology depend on the intensity and duration of the exercise. In general, sustained periods of activity of low to moderate intensity performed several times per week—**endurance (aerobic) training**—result in a greater oxidative capacity of muscle fibers and are manifested by increases in O₂ delivery, capillary supply, and mitochondrial content (see [pp. 1219–1222](#)). These adaptations reduce the susceptibility of the affected muscle fibers to fatigue (see [pp. 1212–1213](#)). The lean and slender build of long-distance (i.e., endurance) runners reflects the abundance of highly oxidative type I and IIa muscle fibers of relatively small diameter, promoting O₂ and CO₂ diffusion between capillaries and mitochondria for high levels of aerobic energy production. Further, the high ratio of surface area to volume of the slender body also facilitates cooling of the body during prolonged activity and in hot environments.

In contrast, brief sets of high-intensity contractions performed several times per week—**strength (anaerobic) training**—result in type IIx motor units that can produce more force and can shorten against a given load at greater velocity by increasing the amount of contractile protein. The hypertrophied muscles of sprinters and weightlifters exemplify this type of adaptation, which relies more on rapid, *anaerobic* sources of energy production (see [p. 1209](#)).

Conversion of Chemical Energy to Mechanical Work

At rest, skeletal muscle has a low metabolic rate. In response to contractile activity, the energy consumption of skeletal muscle can easily rise >100-fold. The body meets this increased energy demand by mobilizing energy stores both locally from muscle glycogen and triacylglycerols, and systemically from liver glycogen and adipose tissue triacylglycerols. The integrated physiological response to exercise involves the delivery of sufficient O₂ and fuel to ensure that the rate of **ATP** synthesis rises in parallel with the rate of ATP breakdown. Indeed, skeletal muscle precisely regulates the ratio of ATP to ADP even with these large increases in ATP turnover.

Physical performance can be defined in terms of power (work/time), speed, or endurance. Skeletal muscle has three energy systems, each designed to support a particular type of performance (Fig. 60-4). For power events, which typically last a few seconds or less (e.g., hitting a ball with a bat), the immediate energy sources include ATP and **phosphocreatine (PCr)**. For spurts of activity that last several seconds to a minute (e.g., sprinting 100 m), muscles rely primarily on the rapid nonoxidative breakdown of carbohydrate stored as muscle glycogen to form ATP. For activities that last 2 minutes or longer but have low power requirements (e.g., jogging several kilometers), the generation of ATP through the oxidation of fat and glucose derived from the circulation becomes increasingly important. We now consider the key metabolic pathways for producing the energy that enables skeletal muscle to have such a tremendous dynamic range of activity.

FIGURE 60-4 Energy sources for muscle contraction. (Modified from Edington DW, Edgerton VR: The Biology of Physical Activity. Boston, Houghton Mifflin, 1976.)

ATP and PCr provide immediate but limited energy

At the onset of exercise, or during the transition to a higher intensity of contractile activity, the immediate energy sources are ATP and PCr. As for any other cell, muscle cells break down ATP to ADP and inorganic phosphate (P_i), releasing ~ 11.5 kcal/mole of free energy (ΔG) under physiological conditions (see p. 1174):

Muscle cells rapidly regenerate ATP from PCr in a reaction that is catalyzed by **creatine kinase**:

Resting skeletal muscle cells contain 5 to 6 mmol/kg of ATP but 25 to 30 mmol/kg of PCr—representing nearly 5-fold more energy. These two energy stores are sufficient to support intense contractile activity for only a few seconds. When rates of ATP breakdown (see Equation 60-1) are high, ADP levels (normally very low) increase and can actually interfere with muscle contraction. Under such conditions, **adenylate kinase** (also known as **myokinase**) transfers the second phosphate group from one ADP to another, thereby regenerating ATP:

The foregoing reaction is limited by the initial pool of ADP, which is small. In contrast, creatine kinase (see Equation 60-2) so effectively buffers ATP that $[\text{ATP}]_i$ changes very little. Although changes in $[\text{ATP}]_i$ cannot provide an effective signal to stimulate metabolic pathways of energy production, the products of ATP hydrolysis— P_i , ADP, and AMP—are powerful signals.

The high-energy phosphates ATP + PCr are historically referred to as **phosphagens** and are recognized as the immediate energy supply because they are readily available, albeit for only several seconds (see Fig. 60-4, red curve). This role is of particular importance at the onset of exercise and during transitions to more intense activity, before other metabolic pathways have time to respond.

Anaerobic glycolysis provides a rapid but self-limited source of ATP

When high-intensity exercise continues for more than several seconds, the breakdown of ATP and PCr is followed almost instantly by the accelerated breakdown of intramuscular glycogen to glucose and then to lactate. This anaerobic metabolism of glucose has the major advantage of providing energy quickly to meet the increased metabolic demands of an intense workload, even before O_2 , glucose, or fatty-acid delivery from blood increases. However, because of the low ATP yield of this pathway, muscle rapidly

depletes its glycogen stores, which so that intense activity is limited to durations of ~1 minute (see Fig. 60-4, purple curve).

Muscle fibers store 300 to 400 g of carbohydrate in the form of glycogen (see p. 1171) and, particularly in the case of type II fibers, are rich in the enzymes required for glycogenolysis and glycolysis. In **glycogenolysis** (see p. 1182), phosphorylase breaks down glycogen to glucose-1-phosphate. Activation of the sympathetic nervous system during exercise elevates levels of epinephrine and—by activating β -adrenergic receptors on muscle fibers—promotes the breakdown of muscle glycogen. Subsequently, phosphoglucomutase converts glucose-1-phosphate to glucose-6-phosphate (G6P). Muscle fibers can also take up blood-borne glucose using GLUT4 transporters (see p. 1047) and use hexokinase to phosphorylate it to G6P. During nonoxidative generation of ATP (see Fig. 60-4, purple curve), intracellular glycogen is more important than blood-borne glucose in rapidly contributing G6P for entry into **glycolysis**—breakdown of glucose to pyruvate (see Fig. 58-6A).

In the absence of O_2 , or when glycolysis generates pyruvate more rapidly than the mitochondria can oxidize it (see below), muscle cells can divert pyruvate to lactic acid, which readily dissociates into H^+ and lactate. The overall process generates two ATP molecules per glucose molecule:

This anaerobic regeneration of ATP from ADP through breakdown of intramuscular glycogen, although faster than oxidative metabolism, captures only a fraction of the energy stored in glucose. Moreover, the process is self-limiting because the H^+ generated from the dissociation of lactic acid can lower pH_i from 7.1 to nearly 6.2; the lower pH inhibits glycolysis and impairs the contractile process, which contributes to muscle fatigue (see p. 1213).

Oxidation of glucose, lactate, and fatty acids provides a slower but long-term source of ATP

The body stores only a small amount of O_2 in the blood, and the cardiovascular and respiratory systems require 1 to 2 minutes to increase O_2 delivery to muscle to support oxidative metabolism. Endurance training accelerates these adjustments. Nevertheless, before the increase in O_2 delivery is complete, skeletal muscle must rely on the immediate release of energy from ATP and PCr, as well as anaerobic glycolysis, as just discussed. As blood flow and O_2 delivery increase over the first 1 to 2 minutes, the contribution of aerobic ATP production reduces the dependence on short-term sources of ATP. Thus, in order to sustain light and intermediate physical activity for longer than ~1 minute, muscle regenerates ATP through oxidative metabolism in the mitochondria of type I and type IIa muscle fibers (see Fig. 60-4, blue curve). Muscle also uses oxidative metabolism to recover from intense activities of short duration that relied on the immediate and nonoxidative systems of energy supply.

The nonoxidative metabolism of glucose provides nearly 100-fold more energy than is available via the immediate breakdown of ATP and PCr. However, oxidative metabolism of the same amount of glucose provides 15-fold more energy than the nonoxidative metabolism of glucose.

Oxidation of Nonmuscle Glucose

The aerobic metabolism of glucose, although slower than anaerobic glycolysis (see [Equation 60-4](#)), provides nearly 15-fold more ATP molecules per glucose molecule (see [Table 58-4](#)):  **N58-15**

The majority of glucose that contracting skeletal muscle oxidizes during aerobic energy production comes from circulating glucose, which in turn originates primarily from the breakdown of the hepatic glycogen stores of 75 to 100 g (see [p. 1171](#)). Exercising muscle can increase its uptake of circulating glucose by 7- to 40-fold; this uptake is balanced by enhanced hepatic glucose release, so that blood [glucose] is stabilized. An increase in portal vein levels of **glucagon**, in particular (see [Fig. 51-12](#)), and a decrease in **insulin**—together with an increase in **epinephrine** (see [Fig. 58-9B](#))—are the main signals for this elevated hepatic glucose output during exercise.

Contracting skeletal muscle is an important sink for blood-borne glucose ([Fig. 60-5](#)). Moreover, contractile activity triggers the translocation of additional GLUT4 transporters (see [p. 114](#)) from the cytosol to the plasma membrane. This process, which is insulin independent and is likely mediated by activation of AMP kinase, supports increased glucose uptake. Because exercise-induced translocation of GLUT4 does not depend on insulin, endurance exercise is an important adjunct in controlling elevated levels of blood [glucose] in patients with diabetes.

FIGURE 60-5 Steady-state energy supply to muscle from energy stores in muscle, liver, and adipose tissue. CoA, coenzyme A.

Oxidation of Lactate

During the first minutes of exercise, active muscle fibers use glycogenolysis to liberate glucose and then use glycolysis to form either pyruvate or lactate, depending on the relative activities of glycolysis and mitochondrial respiration. Indeed, lactate production occurs even in fully aerobic contracting muscles with high oxidative capacity. As blood flow and O₂ delivery increase during the initial minutes of the cardiovascular and respiratory adjustments to exercise, types I and IIa oxidative muscle fibers convert lactate back to pyruvate for uptake and subsequent oxidation by the mitochondria. In addition, glycolytic (type IIx) muscle fibers release lactate that can diffuse to nearby oxidative muscle fibers for aerobic production of ATP (see [Fig. 60-5](#)). The lactate that escapes into the bloodstream can enter other skeletal muscles or the heart for oxidation (see [Fig. 60-5](#)), or the liver for gluconeogenesis (discussed in next paragraph). This shuttling of lactate provides a metabolic link between anaerobic and oxidative cells. After the initial few minutes of moderate-intensity exercise—and after the cardiovascular and respiratory adjustments have stabilized—exercising muscle takes up and oxidizes *blood-borne* glucose and simultaneously diminishes its release of lactic acid.

Gluconeogenesis

Hepatic gluconeogenesis (see [p. 1176](#)) becomes increasingly important as exercise is prolonged beyond an hour and hepatic glycogen stores become depleted. The most important substrates for hepatic gluconeogenesis are lactate and alanine. During prolonged exercise, the key substrate is lactate released into the circulation by contracting skeletal muscle (see below) for uptake by the liver, which resynthesizes glucose for uptake by the muscle—the **Cori cycle** (see [p. 1189](#)).

At workloads exceeding 65% of maximal O₂ uptake by the lungs ($\dot{V}_{O_{2max}}$; discussed on [pages 1213–1214](#)), lactate production rises faster than removal and causes an exponential increase in blood [lactate]. Endurance training increases the rate of lactate clearance from the blood at any given [lactate]. Oxidation is responsible for ~75% of lactate removal, and hepatic gluconeogenesis is responsible for the remainder.

Also during prolonged exercise, the oxidation of branched-chain amino acids by skeletal muscle leads to the release of alanine into the circulation for uptake by the liver, followed by hepatic gluconeogenesis and the release of glucose into the blood for uptake by muscle—the **glucose-alanine cycle** (see [p. 1189](#)).

The Cori and glucose-alanine cycles play an important role in redistributing glycogen from resting muscle to exercising muscle during prolonged exercise and during recovery from exercise. For example, after prolonged arm exercise, lactate release from leg muscle is 6- to 7-fold greater than in the pre-exercise basal state. [N60-5](#) Similarly, after leg exercise, lactate release from forearm muscle increases. The signal for this lactate release is the elevated circulating epinephrine level (see [p. 1210](#)), which stimulates β -adrenergic receptors in nonexercising muscle as well, leading to glycogen breakdown. Thus, the Cori cycle redistributes glycogen from resting muscle to fuel muscles undergoing prolonged exercise. During recovery, muscle glycogenolysis and lactate release from nonexercising muscle continue, and lactate enters the liver for conversion to glucose, followed by release into the circulation. The subsequent glucose uptake by previously exercising muscles thereby helps to replenish their glycogen stores. In this way, the body ensures an adequate supply of fuel for the next fight-or-flight response.

N60-5

Reallocation of Glycogen from Resting to Exercising Muscle

Contributed by Steven Segal

What is the stimulus for a nonexercising muscle (e.g., leg) to release lactate in response to exercise by another muscle (e.g., arm)? During exercise, enhanced sympathetic nerve activity causes the adrenal medulla to release epinephrine (see p. 583). The degree to which epinephrine release rises depends on exercise intensity, duration, and the mass of muscle engaged in activity. The epinephrine, acting on β_2 -adrenergic receptors on all (including inactive) muscle fibers, stimulates glycogenolysis. Following the reduction of pyruvate by lactate dehydrogenase, lactate enters the blood (see Fig. 60-5). This effect of circulating epinephrine is the primary reason for the release of lactate from inactive muscle, which contributes to the **Cori cycle**.

The inactive muscle also releases alanine. One explanation is that, with prolonged physical stress (and certainly with starvation), the release of adrenocorticotrophic hormone stimulates the adrenal cortex to release cortisol. In turn, circulating cortisol would enhance proteolysis in all skeletal muscle (see p. 1022), whether active or inactive. The amino acids liberated would include alanine. Probably more significant for exercise is the transamination of pyruvate to alanine as glutamate (derived from other amino acids through the action of transaminases) is converted to α -ketoglutarate (see Fig. 58-13). Thus, whether liberated directly from protein breakdown or synthesized from pyruvate, alanine would enter the circulation. As blood glucose falls and blood alanine rises, the pancreatic α cells release more glucagon, which promotes hepatic gluconeogenesis—the **alanine-glucose cycle**.

Oxidation of Nonmuscle Lipid

Most stored energy is in the form of triacylglycerols. In the prototypical 70-kg person, adipocytes store ~132,000 kcal of potential energy (see Table 58-1). The mobilization of lipid from adipocytes (see p. 1182) during exercise is largely under the control of the sympathetic nervous system, complemented by the release of growth hormone during exercise lasting >30 to 40 minutes. The result of this mobilization is an increase in circulating levels of fatty acids, which can enter skeletal muscle—especially type I and IIa fibers (see Fig. 60-5).

Not only do fatty acids released from adipocytes enter muscle via the circulation, but skeletal muscle itself stores several thousand kilocalories of potential energy as intracellular triacylglycerols, which contribute to fatty-acid oxidation.

In the presence of adequate O_2 , fatty acids provide up to 60% of the oxidized fuel supply of muscle during prolonged exercise. The oxidation of fatty acids (see pp. 1183–1185), such as palmitate in the following example, has a very high yield of ATP:

Lipids are an important source of energy when O_2 is available; that is, during prolonged low- to moderate-intensity activity and during recovery following exercise.

Choice of Fuel Sources

For sustained activity of moderate intensity, fat is the preferred substrate, given ample O_2 availability. For

example, at 50% of $\dot{V}_{O_{2max}}$, fatty-acid oxidation accounts for more than half of muscle energy production, with glucose accounting for the remainder. As the *duration* of exercise further lengthens, glucose utilization progressively declines and fatty-acid oxidation increases, with fatty acids becoming the dominant oxidative fuel. However, as exercise *intensity* increases, active muscle relies increasingly on glucose derived from intramuscular glycogen as well as on blood-borne glucose. This crossover from lipid to carbohydrate metabolism has the advantage that, per liter of O_2 consumed, carbohydrate provides slightly more energy than lipid (see [p. 1187](#)). Conversely, as muscle depletes its glycogen stores, it loses its ability to consume O_2 at high rates.

At a given metabolic demand, the increased availability and utilization of fatty acids translate to lower rates of glucose oxidation and muscle glycogenolysis, which prolongs the ability to sustain activity. Endurance training promotes these adaptations of skeletal muscle by increasing capillarity (which promotes O_2 delivery) and mitochondrial content (which promotes oxidative ATP production). Under conditions of carbohydrate deprivation (e.g., starvation), extremely prolonged exercise (e.g., ultramarathon), and impaired glucose utilization (e.g., diabetes), muscle can also oxidize ketone bodies as their plasma levels rise.

Muscle Fatigue

Fatigued muscle produces less force and has a reduced velocity of shortening

Muscle fatigue is defined as the inability to maintain a desired power output—resulting from muscle contraction against a load—with a decline in both force and velocity of shortening. A decline in maximal force production with fatigue results from a reduction in the number of active cross-bridges as well as in the force produced per cross-bridge.  **N9-6** As fatigue develops, the production of force usually declines earlier and to a greater extent than shortening velocity. Other characteristics of fatigued skeletal muscle are lower rates of both force production and relaxation, owing to impaired release and reuptake of Ca^{2+} from the sarcoplasmic reticulum (SR). As a result, fast movements become difficult or impossible, and athletic performance suffers accordingly. Nevertheless, fatigue may serve an important protective role in allowing contractions at reduced rates and lower forces while preventing extreme changes in cell composition that could cause damage. Muscle fatigue is reversible with rest, which contrasts with muscle damage or weakness, in which even muscles that are well rested are compromised in their ability to develop force. For example, muscle damage induced by eccentric contractions (see [p. 1207](#)) can easily be mistaken for fatigue, except the recovery period can last for days.

Factors contributing to fatigue include motivation, physical fitness, nutritional status, and the types of motor units (i.e., fibers) recruited as governed by the intensity and duration of activity. Fatigue during *prolonged* activity of *moderate* intensity involving relatively *low* frequencies of motor-unit activation (see [p. 1212](#)) is caused by different factors than fatigue during *bursts* of *high* intensity involving *high* frequencies of motor-unit activation (see [p. 1212](#)). Moreover, fatigue can result from events occurring in the central nervous system (CNS; central fatigue) as well as from changes within the muscle (peripheral fatigue).

Changes in the CNS produce central fatigue

Central fatigue reflects changes in the CNS and may involve altered input from muscle sensory nerve fibers, reduced excitatory input to motor control centers of the brain and spinal cord, and altered excitability of α and γ motor neurons (see [Fig. 15-30](#)). The contributions of these factors vary with the individual and with the nature of the activity. For example, central fatigue is likely to play only a minor role in limiting performance of highly trained athletes who have learned to pace themselves according to the task and are mentally conditioned to discomfort and stress. In contrast, central fatigue is likely of greater importance in novice athletes and during repetitive (i.e., boring) tasks. The identification of specific sites involved in central fatigue is difficult because of the complexity of the CNS. Nevertheless, external sensory input, such as shouting and cheering, can often increase muscle force production and physical performance, which indicates that pathways proximal to corticospinal outputs can oppose central fatigue.

Impaired excitability and impaired Ca^{2+} release can produce peripheral fatigue

Under normal conditions, transmission block at the neuromuscular junction does not cause muscle fatigue, even though the release of neurotransmitter can decline. Thus, **peripheral fatigue** reflects a spectrum of events at the level of the muscle fiber, including impairments in the initiation and propagation of muscle action potentials, the release and handling of intracellular Ca^{2+} for cross-bridge activation, depletion of substrates for energy metabolism, and the accumulation of metabolic byproducts. The nature of fatigue and the time required for recovery vary with the recruitment pattern of motor units and the metabolic properties of their constitutive muscle fibers (see [Fig. 60-2](#)).

High-Frequency Fatigue

With continuous firing of action potentials during intense exercise, Na^+ entry and K^+ exit exceed the ability of the Na-K pump (see [pp. 115–117](#)) to restore and maintain normal resting ion concentration gradients. As a result, $[\text{K}^+]_o$ and $[\text{Na}^+]_i$ increase, so that the resting membrane potential of muscle fibers is more positive by 10 to 20 mV. This depolarization inactivates voltage-gated Na^+ channels, which makes it more difficult to initiate and propagate action potentials. Within the T tubule, such depolarization impairs the ability of L-type Ca^{2+} channels to activate Ca^{2+} -release channels in the SR (see [Fig. 9-3](#)). Fatigue resulting from *impaired membrane excitability* is particularly apparent at high frequencies of stimulation during recruitment of *type II* motor units—**high-frequency fatigue**. On cessation of contractile activity, ionic and ATP homeostasis recovers within 30 minutes; thus, the recovery from high-frequency fatigue occurs relatively quickly.

Low-Frequency Fatigue

In prolonged moderate-intensity exercise, the release of Ca^{2+} from the SR falls, which apparently reflects changes in the Ca^{2+} -release channel or its associated proteins along with inhibition of the SERCA pump (sarcoplasmic and endoplasmic reticulum Ca-ATPase; see [p. 118](#)) and thus diminished SR Ca^{2+} stores; this decrease in Ca^{2+} release leads to a depression in the amplitude of the $[\text{Ca}^{2+}]_i$ transient that accompanies the muscle twitch. A diminution of Ca^{2+} release is apparent at all stimulation frequencies. However, the effect on force development is most apparent at low stimulation frequencies. Indeed, during unfused tetani (see [Fig. 9-10C](#)), $[\text{Ca}^{2+}]_i$ does not continuously remain at high enough levels to saturate troponin C (see [p. 233](#)). As a result, cross-bridge formation is highly sensitive to the amount of Ca^{2+} released from the SR with each stimulus. In contrast, with high frequencies of stimulation that produce fused tetani (see [Fig. 9-10D](#)), $[\text{Ca}^{2+}]_i$ is at such high levels that Ca^{2+} continuously saturates troponin C and thereby maximizes cross-bridge interactions, which masks the effects of impaired Ca^{2+} release with each stimulus. Fatigue resulting from *impaired Ca^{2+} release* is thus particularly apparent at low frequencies of stimulation during recruitment of *type I* motor units—**low-frequency fatigue**. Recovery requires several hours.

Fatigue can result from ATP depletion, lactic acid accumulation, and glycogen depletion

ATP Depletion

As outlined in [Chapter 9](#), muscle fibers require ATP for contraction (see [pp. 234–236](#)), relaxation (see [p. 237](#)), and the activity of the membrane pumps that maintain ionic homeostasis. Therefore, the cells must maintain $[\text{ATP}]_i$ to avoid fatigue.

Intense stimulation of muscle fibers (particularly type IIx) requires high rates of ATP utilization, with PCr initially buffering $[ATP]_i$ (see pp. 1208–1209). As fatigue develops and $[PCr]_i$ diminishes, $[ATP]_i$ can fall from 5 mM to <2 mM, particularly at sites of cross-bridge interaction and in the vicinity of membrane pumps, so that respective ATPase activities are impaired. Simultaneously, P_i , ADP, Mg^{2+} , lactate, and H^+ accumulate in the sarcoplasm. Impairment of SERCA (see p. 118) at the SR prolongs the Ca^{2+} transient while reducing the electrochemical driving force for Ca^{2+} release from the SR. Independently, the fall in $[ATP]_i$ and increase in $[Mg^{2+}]$ can also inhibit Ca^{2+} release via the ryanodine receptor (see p. 230).

Lactic Acid Accumulation

Intense activity also activates glycolysis (see pp. 1174–1176)—again, particularly in type IIx fibers—which results in a high rate of lactic acid production and thus reduces pH_i to as low as 6.2 (see Equation 60-4). This fall in pH_i inhibits myosin ATPase activity, and thereby reduces the velocity of shortening. The fall in pH_i also inhibits cross-bridge interaction, the binding of Ca^{2+} to troponin, the Na-K pump, as well as phosphofructokinase (the rate-limiting step of muscle glycolysis; see p. 1176). The combined effects of low pH_i and high P_i interact to impair the peak force production of muscle fibers more than either agent alone. The mechanisms are reductions in the number of cross-bridges and in the force per cross-bridge by impairment of the transition from weak to strong binding states between actin and myosin (see p. 235). In addition, both H^+ and P_i reduce Ca^{2+} sensitivity of contractile proteins, so that higher free $[Ca^{2+}]_i$ is required for a given level of force production.

Glycogen Depletion

During prolonged exercise of moderate intensity (~50% of maximal aerobic power), and with well-maintained O_2 delivery, the eventual decrease in glycogen stores in oxidative (type I and IIa) muscle fibers decreases power output. Long-distance runners describe this phenomenon as “hitting the wall.” Muscle glycogen stores are critical because the combination of blood-borne delivery of substrates and the availability of intramuscular fatty acids is inadequate to accommodate the energy requirements.  N60-6 In long-distance running, endurance depends on the absolute amount of glycogen stored in the leg muscles before exercise. To postpone hitting the wall, the athlete must either begin the event with an elevated level of muscle glycogen or race more slowly. Because glycogen storage is primarily a function of diet, carbohydrate loading can increase resting muscle glycogen stores and postpone the onset of fatigue. Low-carbohydrate diets have the opposite effect. Although physical training has little effect on the capacity for glycolysis, it can promote glycogen storage, particularly if combined with a carbohydrate-rich diet. Aerobic training can spare muscle glycogen by adaptations such as mitochondrial proliferation (see pp. 1220–1222) that shift the mix of oxidized fuels toward fatty acids. Indeed, well-trained athletes can maintain moderate-intensity exercise for hours.

N60-6

Mechanism of Fatigue During Prolonged Exercise

Contributed by Steven Segal

The onset of fatigue under conditions of prolonged exercise of moderate intensity may be attributable to

the leakage of intermediates (e.g., α -ketoglutarate) from the citric acid cycle (see Fig. 58-11), which impairs aerobic energy production. Until the concentrations of these intermediates fall below critical levels, glycogen breakdown can restore these intermediates through anaplerotic additions and thereby serve to maintain power output.

During exercise at *relatively high* intensities (>65% of maximal aerobic power), fatigue develops in the order of tens of minutes. One explanation for this decrement in performance is that type IIx muscle fibers fatigue when their glycogen supplies become exhausted, which results in a decline in whole-muscle power output.

Determinants of Maximal O₂ Uptake and Consumption

The O₂ required for oxidative metabolism by exercising muscle travels from the atmosphere to the muscle mitochondria in three discrete steps:

1. Uptake of O₂ by the lungs, which depends on pulmonary ventilation
2. O₂ delivery to muscle, which depends on blood flow and O₂ content
3. Extraction of O₂ from blood by muscle, which depends on O₂ delivery and the P_{O_2} gradient between blood and mitochondria

Maximal O₂ uptake by the lungs can exceed resting O₂ uptake by more than 20-fold

The respiratory and cardiovascular systems can readily deliver O₂ to active skeletal muscle at mild and moderate exercise intensities. As power output increases, the body eventually reaches a point at which the capacity of O₂ transport systems can no longer keep pace with demand, so the rate of O₂ uptake by the lungs (\dot{V}_{O_2}) plateaus (Fig. 60-6). At rest, \dot{V}_{O_2} is typically 250 mL/min for a 70-kg person (see p. 647), which corresponds to 3.6 mL of O₂ consumed per minute for each kilogram of body mass (mL O₂/[min × kg]). **Maximal oxygen uptake measured at the lungs ($\dot{V}_{O_{2max}}$)** is an objective index of the functional capacity of the body's ability to generate aerobic power. In people who have a deficiency in any part of the O₂ transport system (e.g., chronic obstructive pulmonary disease or advanced heart disease), $\dot{V}_{O_{2max}}$ can be as low as 10 to 20 mL O₂/(min × kg). The range for mildly active middle-aged adults is 30 to 40 mL O₂/(min × kg); for people in this category, a 3-month program of aerobic conditioning can increase $\dot{V}_{O_{2max}}$ by >20%. In elite endurance athletes, $\dot{V}_{O_{2max}}$ may be as high as 80 to 90 mL O₂/(min × kg), more than a 20-fold elevation above the resting \dot{V}_{O_2} . Lowering of the O₂ content of the blood by hemorrhage or high altitude decreases $\dot{V}_{O_{2max}}$, whereas blood transfusion or aerobic conditioning increases it.

FIGURE 60-6 Dependence of O_2 consumption on mechanical power output. Aerobic training increases the maximal O_2 uptake by the lungs ($\dot{V}_{\text{O}_2\text{max}}$).

The typical method for determining $\dot{V}_{\text{O}_2\text{max}}$ is an incremental exercise test on a stationary cycle ergometer or treadmill. Such tests assess training status, predict performance in athletes, and provide an index of functional impairment in patients. During the test, the technician monitors the P_{O_2} and P_{CO_2} of the subject's expired air, as well as total ventilation. The criteria for achieving $\dot{V}_{\text{O}_2\text{max}}$ include (1) an inability to continue the pace at the prescribed power requirement, (2) a leveling off of \dot{V}_{O_2} as the power requirement increases (see Fig. 60-6), and (3) a **respiratory exchange ratio** ($\dot{V}_{\text{CO}_2}/\dot{V}_{\text{O}_2}$) > 1.15 . Such a high $\dot{V}_{\text{CO}_2}/\dot{V}_{\text{O}_2}$ is a transient/non-steady-state occurrence (i.e., not a real respiratory quotient; see p. 681) and indicates that a significant hyperventilation, triggered by low blood pH (see p. 710), is reducing the body's CO_2 stores.

O_2 uptake by muscle is the product of muscle blood flow and O_2 extraction

The body's total store of O_2 is ~ 1 L (mainly in the form of O_2 bound to hemoglobin), a volume that (if used completely) could support moderate aerobic exercise for 30 seconds at best, heavy aerobic exercise for not more than 15 seconds, and maximal aerobic exercise for less than 10 seconds. If activity is to persist, the body must continually transport O_2 from the ambient air to the muscle mitochondria at a rate that is equivalent to the O_2 utilization by the muscle. This increased O_2 transport is accomplished by increasing alveolar ventilation to maintain alveolar P_{O_2} levels that are sufficient to saturate arterial blood fully with O_2 (see p. 681) and by increasing cardiac output to ensure a sufficiently high flow of oxygenated blood to the active muscles (see p. 464). The integrated organ-system response to the new, elevated metabolic load involves the close coupling of the pulmonary and the cardiovascular O_2 -delivery systems to the O_2 -

acceptor mechanisms in the muscle; the response includes sophisticated reflexes to ensure matching of the two processes.

The convective O₂-delivery rate is the product of cardiac output (i.e., heart rate × stroke volume) and arterial O₂ content:

$$\begin{array}{ccccccc}
 \text{Arterial O}_2 & & \text{Heart} & & \text{Cardiac} & & \text{Arterial} \\
 \text{delivery rate} & & \text{rate} & & \text{stroke} & & \text{O}_2 \\
 \text{to whole body} & & & & \text{volume} & & \text{content} \\
 \\
 \underbrace{\dot{V}_{aO_2}}_{\substack{\text{mL O}_2 \\ \text{min}}} & = & \underbrace{\text{HR}}_{\substack{\text{beats} \\ \text{min}}} & \cdot & \underbrace{\text{SV}}_{\substack{\text{mL blood} \\ \text{beat}}} & \cdot & \underbrace{\text{CaO}_2}_{\substack{\text{mL O}_2 \\ \text{mL blood}}} \\
 & & & & & & (60-7)
 \end{array}$$

The rate of O₂ uptake by skeletal muscle depends on both the O₂ delivery to skeletal muscle and the **extraction** of O₂ by the muscle. According to the Fick equation (see p. 423), \dot{V}_{O_2} is the product of blood flow to muscle (F) and the arteriovenous (a-v) difference for O₂:

$$\begin{array}{ccccc}
 \text{Rate of O}_2 & & \text{Blood flow} & & \text{a - v} \\
 \text{uptake by} & & \text{to} & & \text{difference of} \\
 \text{skeletal muscle} & & \text{skeletal muscle} & & \text{O}_2 \text{ content} \\
 \\
 \underbrace{\dot{V}_{O_2}}_{\substack{\text{mL O}_2 \\ \text{min}}} & = & \underbrace{F}_{\substack{\text{mL blood} \\ \text{min}}} & \cdot & \underbrace{(\text{CaO}_2 - \text{CvO}_2)}_{\substack{\text{mL O}_2 \\ \text{mL blood}}} \\
 & & & & (60-8)
 \end{array}$$

The \dot{V}_{O_2} , established by the rate of oxidative phosphorylation in muscle mitochondria, requires an adequate rate of O₂ delivery to the active muscle. Exercise triggers a complicated series of changes in the cardiovascular system that has the net effect of increasing F and redistributing cardiac output away from the splanchnic and renal vascular beds as well as from inactive muscle to better supply the active musculature (see p. 581). Increased O₂ extraction from the blood by active skeletal muscle occurs at the onset of exercise in response to elevated mitochondrial respiration and the attendant fall in intracellular P_{O₂}, which increases the gradient for O₂ diffusion from blood within the microcirculation (see Fig. 24-5) to mitochondria within active muscle fibers.

At the onset of exercise, the content of O₂ in the arterial blood (CaO_2 ; see Fig. 29-3) actually increases slightly (e.g., from 20.0 to 20.4 mL O₂/mL blood) secondary to the increase in alveolar ventilation triggered by the CNS (see p. 350). Also as a consequence of the anticipatory hyperventilation, P_{CO₂} actually falls with the onset of exercise. Possible mechanisms of this ventilatory increase include a response to mechanoreceptors in joints and muscles, descending cortical input, and resetting of peripheral chemoreceptors by a reduction in their blood supply (see pp. 711–712). The increase in ventilation in anticipation of future needs is enhanced in well-trained athletes.

O₂ delivery by the cardiovascular system is the limiting step for maximal O₂ utilization

For years, exercise and sports scientists have debated over the factors that limit $\dot{V}_{O_{2max}}$ and thus contribute to performance limitations. As noted above, the transport of O₂ from atmosphere to muscle mitochondria occurs in three steps: uptake, delivery, and extraction. A limitation in any step could be rate limiting for maximal O₂ utilization by muscle.

Limited O₂ Uptake by the Lungs

One view is that the lungs limit $\dot{V}_{O_{2max}}$. An inability of alveolar O₂ diffusion to saturate arterial blood fully (see Fig. 30-10C) occurs in a subset of elite athletes (including race horses). Thus, a decrease in Ca_{O_2} occurs at maximal effort on an incremental test. The inability of the lungs to saturate arterial blood in athletes could be the consequence of a ventilation-perfusion mismatch at very high cardiac outputs (see p. 698).  N60-7

N60-7

Exercise-Induced Arterial Hypoxemia in Women

Contributed by Emile Boulpaep, Walter Boron

It has been well established that young male athletes can develop arterial hypoxemia when exercising near their maximal rate of O₂ consumption ($\dot{V}_{O_{2max}}$). Thoroughbred horses can also exhibit **exercise-induced arterial hypoxemia (EIAH)**. The study cited below shows that many healthy and active young women experience a significant EIAH, even when well below $\dot{V}_{O_{2max}}$. The alveolar-arterial (A-a) gradient (see Box 31-1) rises with \dot{V}_{O_2} , reaching values 3- to 10-fold higher than the resting value when \dot{V}_{O_2} is at $\dot{V}_{O_{2max}}$. The anatomical basis of this effect may be smaller lung volumes (corrected for height and age), reduced diffusing capacity (D_L ; see p. 668), smaller-caliber airways, and reduced hematocrit. Physiologically, the mechanism could involve a significant \dot{V}_A/\dot{Q} mismatch.

Limited O₂ Delivery by the Cardiovascular System

According to the prevalent view, a limitation in O₂ transport by the cardiovascular system determines $\dot{V}_{O_{2max}}$. That is, **maximal cardiac output**, and hence O₂ delivery, is the limiting step according to the **convective flow model**. Support for this view comes from the observation that training can considerably augment maximal cardiac output and muscle blood flow (see the following section). Moreover, $\dot{V}_{O_{2max}}$ largely increases in parallel with these adaptations (Fig. 60-7).

FIGURE 60-7 Dependence of maximal oxygen utilization on oxygen delivery. The graph illustrates the relationship between maximal O_2 delivery to the peripheral tissues ($\dot{V}_{aO_2 \max}$) and maximal O_2 uptake by lungs ($\dot{V}_{O_2 \max}$) for five individuals with different lifestyles. Training increases both O_2 delivery and O_2 uptake. (Data from Saltin B, Strange S: Maximal oxygen uptake: old and new arguments for a cardiovascular limitation. Med Sci Sports Exerc 24:30–37, 1992.)

Limited O_2 Extraction by Muscle

A third point of view is that, with increasing demand, O_2 extraction by muscle from blood becomes inadequate despite adequate O_2 delivery. According to this **diffusive flow model**, a major limitation in O_2 transport is the kinetics of O_2 diffusion from hemoglobin in the red blood cell to the muscle mitochondrial matrix. Thus, anything that lowers either the muscle's diffusing capacity for O_2 or the P_{O_2} gradient between hemoglobin and mitochondria reduces $\dot{V}_{O_2 \max}$.

Effective circulating volume takes priority over cutaneous blood flow for thermoregulation

When we exercise in the heat, our circulatory systems must simultaneously support a large blood flow to both the skin (see p. 1195) and contracting muscles, which taxes the cardiac output and effective circulating volume (see pp. 554–555). During exercise, the ability to maintain both arterial blood pressure and body core temperature (T_{core}) within acceptable physiological limits depends on maintaining an adequate effective circulating volume. Effective circulating volume depends on total blood volume, which in turn relies on extracellular fluid (ECF) volume and overall vasomotor (primarily venomotor) tone, which is important for distributing blood between central and peripheral blood vessels.

Effective circulating volume tends to fall during prolonged exercise, especially exercise in the heat, for three reasons (Fig. 60-8).

FIGURE 60-8 Effect of exercise on central blood volume.

First, exercise causes a **shift in plasma water** from the intravascular to the interstitial space. This transcapillary movement of fluid during exercise primarily reflects increased capillary hydrostatic pressure as arterioles dilate (see p. 469). In addition, increased osmolality within muscle cells removes water from the extracellular space. When exercise intensity exceeds 40% of $\dot{V}_{O_{2max}}$, this loss of plasma water is proportional to the exercise intensity. In extreme conditions, the loss of plasma water can amount to >500 mL, or ~15% of the total plasma volume.

Second, exercise causes a loss of total-body water through **sweating** (discussed in the next subchapter). If exercise is prolonged without concomitant water intake, sweat loss will cost the body an important fraction of its total water. A loss of body water in excess of 3% of body weight is associated with early signs of heat-related illness, including lightheadedness and disorientation, and it constitutes

clinical dehydration. 🟡N40-10

Third, exercise causes a **redistribution of blood volume** to the skin because of the increase in cutaneous blood flow in response to body heating (see [Fig. 60-8](#)). Venous volume *in the skin* increases as a result of the increased pressure in the compliant veins as blood flow to the skin rises. No compensatory venoconstriction occurs in the skin because of the overriding action of the temperature-control system.

In response to this decrease in effective circulating volume that occurs during exercise, the cardiopulmonary low-pressure baroreceptors (see [pp. 546–547](#)) initiate compensatory responses to increase total vascular resistance (see [Fig. 60-8](#)). The sympathetic nervous system increases this resistance by (1) increasing the splanchnic vascular resistance, which directs cardiac output away from the gut; (2) offsetting some of the thermoregulatory system's vasodilatory drive to the skin; and (3) offsetting some of the vasodilatory drive to the active skeletal muscles.

With heavy heat loads, the restriction of peripheral blood flow has the benefit of helping to maintain arterial blood pressure and effective circulating volume, but it carries two liabilities. First, it reduces convective heat transfer from the core to the skin because of the reduced skin blood flow (see [p. 1195](#)), which contributes to excessive heat storage and, in the extreme, heat stroke (see [Box 59-1](#)). Second, the limitation of blood flow to active muscle may compromise O₂ delivery and hence aerobic performance.

With low thermal and metabolic demand, no serious conflict arises among the systems that regulate effective circulating volume, arterial blood pressure, and body temperature. The cutaneous circulation is capable of handling the heat-transfer requirements of the temperature-regulatory mechanism without impairing muscle blood flow or cardiac filling pressure.

Sweating

Eccrine, but not apocrine, sweat glands contribute to temperature regulation

Sweat glands are exocrine glands of the skin, formed by specialized infoldings of the epidermis into the underlying dermis. Sweat glands are of two types, apocrine and eccrine ([Fig. 60-9A](#)). The **apocrine** sweat glands, located in the axillary and anogenital regions of the body, are relatively few in number (~100,000) and large in diameter (2 to 3 mm). Their ducts empty into hair follicles. These glands, which often become active during puberty, produce a turbid and viscous secretion that is rich in lipids and carbohydrates and carries a characteristic body odor that has spawned an entire industry to conceal. Apocrine sweat glands have no role in temperature regulation in humans, although they may act as a source of pheromones.

A APOCRINE AND ECCRINE SWEAT GLANDS

B COMPONENTS OF AN ECCRINE SWEAT GLAND

FIGURE 60-9 Sweat glands. The sebaceous gland—the duct of which empties into the hair follicle independently of the duct of the apocrine sweat gland—secretes sebum, a mixture of fat and the remnants

Eccrine sweat glands are distributed over the majority of the body surface, are numerous (several million), and are small in diameter (50 to 100 μm). The palms of the hands and soles of the feet tend to have both larger and more densely distributed eccrine glands than elsewhere. The full complement of eccrine sweat glands is present at birth, they become functional within a few months, and their density decreases as the skin enlarges during normal growth. The essential role of eccrine sweating is temperature regulation (see [p. 1197](#)), although stimuli such as food, emotion, and pain can evoke secretory activity. Regionally, the trunk, head, and neck show more profuse sweating than the extremities. Sweat production is quantitatively lower in women than in men, which reflects less output per gland rather than fewer eccrine sweat glands.

Eccrine sweat glands are tubules comprising a secretory coiled gland and a reabsorptive duct

An eccrine sweat gland is a simple tubular epithelium composed of a coiled gland and a duct (see [Fig. 60-9B](#)). A rich microvascular network surrounds the entire sweat gland. The **coiled gland**, located deep in the dermis, begins at a single blind acinus innervated by postganglionic sympathetic fibers that are cholinergic. [N14-4](#) The release of acetylcholine stimulates muscarinic receptors on the acinar cells, causing them to secrete into the lumen a clear, odorless solution, similar in composition to protein-free plasma. This primary secretion flows through a long, wavy **duct** that passes outward through the dermis and epidermis. Along the way, duct cells reabsorb salt and water until the fluid reaches the skin surface through an opening, the **sweat pore**. Although these pores are too small to be seen with the naked eye, their location is readily identified as sweat droplets form on the skin surface. Both the secretory cells in the coil and reabsorptive cells in the duct are rich in mitochondria, which are essential for providing sustained energy for the high rates of ion transport that are necessary for prolonged periods of intense sweating—for example, during exercise in hot environments.

Surrounding the secretory cells in the coil is a layer of myoepithelial cells that resemble smooth muscle and may contract, thereby expressing sweat to the skin surface in a pulsatile fashion. However, this action is not essential because the hydrostatic pressures generated within the gland can exceed 500 mm Hg.

Secretion by Coil Cells

The release of acetylcholine onto the secretory coil cells activates muscarinic G protein–coupled receptors (see [p. 341](#)), which leads to the activation of phospholipase C; phospholipase C activation in turn stimulates protein kinase C and raises $[\text{Ca}^{2+}]_i$. These signals trigger the primary secretion, which follows the general mechanism for Cl^- secretion (see [p. 139](#)). An Na/K/Cl cotransporter (see [p. 122](#)) mediates the uptake of Cl^- across the basolateral membrane, and the Cl^- exits across the apical membrane via a Cl^- channel (see [Fig. 60-9B](#), lower inset). As Cl^- diffuses into the lumen, the resulting lumen-negative voltage drives Na^+ secretion through the paracellular pathway.

The secretion of NaCl, as well as of urea and lactate, into the lumen sets up an osmotic gradient that drives the secretion of water, so the secreted fluid is nearly isotonic with plasma. This secretion of fluid into the lumen increases hydrostatic pressure at the base of the gland and thereby provides the driving force for moving the fluid along the duct to reach the skin surface.

Reabsorption by Duct Cells

As the secreted solution flows along the sweat gland duct, the duct cells reabsorb Na^+ and Cl^- (see Fig. 60-9B, upper inset). Na^+ enters the duct cells across the apical membrane via epithelial Na^+ channels (ENaCs; see p. 126), and Cl^- enters through the cystic fibrosis transmembrane conductance regulator (CFTR; see p. 120). The Na-K pump is responsible for the extrusion of Na^+ across the basolateral membrane, and Cl^- exits via a Cl^- channel. Because the water permeability of the epithelium lining the sweat duct is low, water reabsorption is limited, so that the final secretory fluid is always hypotonic to plasma.

Because sweat is hypotonic, sweating leads to the loss of **solute-free water** (see pp. 806–807), that is, the loss of more water than salt. As a result, the ECF contracts and becomes hyperosmolar, which causes water to exit from cells. Thus, intracellular fluid volume decreases and *intracellular* osmolality increases (see pp. 132–133). This water movement out of cells helps to correct the fall in ECF volume. The solute-free water lost in perspiration therefore is ultimately derived from all body fluid compartments.

The NaCl content of sweat increases with the rate of secretion but decreases with acclimatization to heat

Flow Dependence

With mild stimulation of acinar cells, the small volume of primary secretion travels slowly along the duct, and the ducts reabsorb nearly all of the Na^+ and Cl^- , which can fall to final concentrations as low as ~10 to 20 mM (Fig. 60-10). In contrast, with strong cholinergic stimulation, large volume of primary secretion travels rapidly along the duct, so the load exceeds the capacity of the ductal epithelium to reabsorb Na^+ and Cl^- . Thus, a greater fraction of the secreted Na^+ and Cl^- remains within the lumen, which results in levels of 60 to 70 mM. In contrast, $[\text{K}^+]$ in the sweat remains nearly independent of flow at 5 to 10 mM.

FIGURE 60-10 Flow dependence of sweat composition. CF, cystic fibrosis.

Cystic Fibrosis

In patients with cystic fibrosis (see [Box 43-1](#)), abnormal sweat gland function is attributable to a defect in the CFTR, a cAMP-regulated Cl^- channel (see [p. 120](#)) that is normally present in the apical membrane of sweat gland duct cells. These individuals secrete normal volumes of sweat into the acinus but have a defect in absorption of Cl^- (and, therefore, Na^+) as the fluid travels along the duct. As a result, the sweat is relatively rich in NaCl (see [Fig. 60-10](#)).

Replenishment

During a thermoregulatory response in a healthy individual, the rate of sweat production can commonly reach 1 to 2 L/hr, which, after a sufficient time, can represent a substantial fraction of total-body water. Such a loss of water and salt requires adequate repletion to preserve fluid and electrolyte balance. Restoration of body fluid volume following dehydration is often delayed in humans despite the consumption of fluids. The reason for this delay is that dehydrated persons drink *free water*, which reduces the osmolality of the ECF and thus reduces the osmotic drive for drinking (see [pp. 845–846](#)). This consumed free water distributes into the cells as well as the extracellular space, diluting the solutes. In addition, the reduced plasma osmolality leads to decreased secretion of arginine vasopressin (i.e., antidiuretic hormone), so that free-water excretion by the kidney is increased (see [p. 844](#)).

A more effective means of restoring body fluid volume is to ingest NaCl with water. When Na^+ is taken with water (as in many exercise drinks), plasma $[\text{Na}^+]$ remains elevated throughout a longer duration of

the rehydration period and is significantly higher than with the ingestion of water alone. In such conditions, the salt-dependent thirst drive is maintained and the stimulation of urine production is delayed, which leads to more complete restoration of body water content.

Acclimatization

With ample, continuing hydration, a heat-acclimatized individual can sweat up to 4 L/hr during maximal sweating. Over several weeks, as the body acclimates to high rates of eccrine sweat production, the ability to reabsorb NaCl increases, which results in a more hypotonic sweat. This adaptation is mediated by aldosterone (see [p. 766](#)) in response to the net loss of Na^+ from the body during the early stages of acclimatization. For example, an individual who is not acclimatized and who sweats profusely can lose >30 g of salt per day for the first few days. In contrast, after several weeks of acclimatization, salt loss falls to several grams per day. Thus, an important benefit of physical training and heat acclimatization is the development of more dilute perspiration, which promotes evaporative cooling while conserving NaCl content and thus effective circulating volume (see [pp. 554–555](#)) during dehydration.

The hyperthermia of exercise stimulates eccrine sweat glands

As discussed [on p. 1193](#), the rate of perspiration increases with body T_{core} , which in turn increases during exercise (see [p. 1202](#)). The major drive for increased perspiration is the sensing by the hypothalamic centers of increased T_{core} . Physical training increases the sensitivity of the hypothalamic drive to higher T_{core} . Indeed, the hyperthermia of exercise causes sweating to begin at a lower skin temperature than does sweating elicited by external heating. The efferent limb of the sweating reflex is mediated by postganglionic sympathetic cholinergic fibers (see [p. 543](#)). **📌N14-4**

Sweating is especially important for thermoregulation under hot ambient conditions and with exercise-induced increases in body temperature. Indeed, as ambient temperature rises to >30°C, heat loss through radiation, convection, and conduction (see [pp. 1196–1197](#)) becomes progressively ineffective, and evaporative cooling becomes by far the most important mechanism of regulating body temperature. Compounding the problem in hot humid environments, evaporative cooling becomes progressively less effective as ambient humidity rises (see [Equation 59-5](#)).

Endurance (Aerobic) Training

Aerobic training requires regular periods of stress and recovery

The body improves its capacity to perform work by responding to physical exertion. However, one must meet four conditions to achieve a **training effect**, or *adaptation* to exercise. First, the intensity of the activity must be higher than a critical threshold. For aerobic training (e.g., running, cycling, and swimming), the level of stress increases with the intensity of the activity. **N60-3** Second, each period of activity must be of sufficient duration. Third, one must repeat the activity over time on a regular basis (e.g., several times per week). Finally, sufficient rest must occur between each training session, because it is during the recovery period that the adaptations to exercise actually occur.

A great deal of research has focused on optimizing the foregoing four factors, as well as task specificity, for individual athletes competing in specific events. Increasing levels of exertion progressively recruit (see pp. 1204–1205) and thereby adapt type I muscle fibers, followed by type IIa fibers, and then type IIx fibers. In strength training, repetitive powerful bursts of activity favor hypertrophy of type IIx fibers. Regardless of how long or intensely an individual trains, prolonged inactivity reverses these adaptations with an associated decrement in aerobic performance (type I and IIa fibers) or loss of muscle mass (primarily type IIx fibers). Aerobic conditioning increases $\dot{V}_{O_{2\max}}$ (see pp. 1213–1214) as well as the body's ability to eliminate excess heat that is produced during exercise (see Fig. 59-5).

Aerobic training increases maximal O₂ delivery by increasing plasma volume and maximal cardiac output

$\dot{V}_{O_{2\max}}$ could increase as the result of either optimizing O₂ delivery to active muscle or optimizing O₂ extraction by active muscle, as demonstrated in the following modification of Equation 60-7:

$$\begin{array}{ccccccc} \text{Maximal} & & \text{Optimal} & & \text{Optimal} & & \text{Maximal} \\ \text{rate of O}_2 & & \text{heart} & & \text{stroke} & & \text{a-v difference} \\ \text{uptake} & & \text{rate} & & \text{volume} & & \text{of O}_2 \text{ content} \\ \\ \underbrace{\dot{V}_{aO_{2\max}}}_{\frac{\text{mL O}_2}{\text{min}}} & = & \underbrace{\text{HR}_{\text{opt}}}_{\substack{\text{Maximal} \\ \text{cardiac output}}} & \cdot & \underbrace{\text{SV}_{\text{opt}}}_{\substack{\text{mL blood} \\ \text{min}}} & \cdot & \underbrace{(\text{CaO}_2 - \text{CvO}_2)_{\max}}_{\substack{\text{mL O}_2 \\ \text{mL blood}}} \\ & & & & & & \text{(60-9)} \end{array}$$

In fact, aerobic training improves both O₂ delivery and O₂ extraction; the problem for physiologists has been to determine to what extent each system contributes to the whole-body response. For example, an increase in the circulatory system's capacity to deliver O₂ could reflect an increase in either the maximal arterial O₂ content or the maximal cardiac output, or both.

Maximizing Arterial O_2 Content

Several factors could theoretically contribute to maximizing Ca_{O_2} :

1. Increasing the maximal alveolar ventilation enhances the driving force for O_2 uptake by the lungs (see Fig. 31-4).
2. Increasing the pulmonary diffusing capacity (see p. 668) could enhance O_2 uptake at very high cardiac output, particularly at high altitude (see Fig. 30-10).
3. Improving the matching of pulmonary ventilation to perfusion should increase arterial P_{O_2} and the saturation of hemoglobin (see pp. 689–690).
4. Increasing the concentration of hemoglobin enables a given volume of arterial blood to carry a greater amount of O_2 (see pp. 651–652).

Under nearly all conditions of exercise, the pulmonary system maintains alveolar P_{O_2} at levels that are sufficiently high to ensure nearly complete (i.e., ~97%) saturation of hemoglobin with O_2 , even at maximal power output. Thus, it is unlikely that an increase in the maximal alveolar ventilation or pulmonary diffusing capacity could explain the large increase in $\dot{V}_{O_{2max}}$ that occurs with training.

Ca_{O_2} would be increased by elevating the blood's hemoglobin concentration. However, no evidence exists to indicate that physical training induces such an increase. On the contrary, [hemoglobin] tends to be slightly lower in endurance athletes, a phenomenon called *sports anemia*, which reflects an expansion of the plasma compartment (discussed below). Whereas increasing [hemoglobin] provides a greater O_2 -carrying capacity in blood, maximal O_2 transport does not necessarily increase accordingly because blood viscosity, and therefore total vascular resistance, also increase. The heart would be required to develop a higher arterial pressure to generate an equivalent cardiac output. The resultant increased cardiac work would thus be counterproductive to the overall adaptive response. Blood doping—transfusion of blood before competition—is thus not only illegal but also hazardous to athletes, particularly when water loss through sweating leads to further hemoconcentration.

Maximizing Cardiac Output

Factors that contribute to increasing maximal cardiac output include optimizing the increases in heart rate and cardiac stroke volume so that their product (i.e., cardiac output) is maximal (see Equation 60-9 and pp. 580–583). Because aerobic training does not increase maximal heart rate and has a relatively small effect on O_2 extraction, nearly all the increase in $\dot{V}_{O_{2max}}$ that occurs with training must be the result of an increase in maximal cardiac output, the product of optimal heart rate and optimal stroke volume (see Equation 60-9). The athlete achieves this increased cardiac output by increasing maximal cardiac stroke volume. Maximal cardiac output can increase by ~40% during physical conditioning that also increases maximal aerobic power by 50%. The difference between 40% and 50% is accounted for by increased extraction: $(Ca_{O_2} - Cv_{O_2})_{max}$. Enhanced extraction in endurance training is a consequence of capillary proliferation and increased mitochondrial content of muscle fibers, which creates a greater O_2 sink under maximal aerobic conditions.

Maximal cardiac stroke volume increases during aerobic training because expansion of the plasma—and thus blood volume—increases the heart's preload (see [p. 526](#)), with a concomitant hypertrophy of the heart. An increase in preload increases ventricular filling and proportionally increases stroke volume (Starling's law of the heart; see [pp. 524–526](#)), thereby elevating maximal cardiac output accordingly. An additional benefit is that a trained athlete achieves a given cardiac output at a lower heart rate, both at rest and during moderate exercise. Because it is more efficient to increase stroke volume than heart rate, increasing stroke volume reduces the myocardial metabolic load for any particular level of activity.

The expansion of plasma volume probably reflects an increase in **albumin content** (1 g albumin is dissolved in 18 g of plasma H_2O). This increase appears to be caused both by translocation from the interstitial compartment and by increased synthesis by the liver. The result of more colloid in the capillaries is a shift of fluid from the interstitium to the blood. Although the total volume of red blood cells also increases with aerobic training, the plasma volume expansion is greater than the red blood cell expansion, so that the hemoglobin concentration falls. This **sports anemia** occurs in highly trained endurance athletes, particularly those acclimatized to hot environments.

The increased blood volume has another beneficial effect. It enhances the ability to maintain high skin blood flow in potentially compromising conditions (e.g., heavy exercise in the heat), thus providing greater heat transport from core to skin and relatively lower storage of heat (see [pp. 1195–1196](#)).

Aerobic training enhances O_2 diffusion into muscle

Whereas an increase in maximal cardiac output accounts for a major fraction of the increased O_2 delivery to muscle with training, a lesser fraction reflects increased O_2 extraction from blood. Fick's law describes the diffusion of O_2 between the alveolar air and pulmonary capillary blood (see [Equation 30-4](#)). A similar relationship describes the diffusion of O_2 from the systemic capillary blood to the mitochondria.

The factors that contribute to O_2 diffusing capacity (D_{O_2}) are analogous to those that affect the diffusing capacity in the lung (see [pp. 663–664](#)). Trained muscle can accommodate a greater maximal blood flow because of the growth of new microvessels, particularly capillaries. Indeed, well-conditioned individuals have a 60% greater number of capillaries per cross-sectional area of muscle than do sedentary people. This increased capillary density increases D_{O_2} because it provides a greater surface area for diffusion. Increase in capillary density also reduces the diffusion distance for O_2 between the capillary and muscle fibers (see [Fig. 20-4](#)). In addition, training increases total capillary length and volume, prolonging the transit time of red blood cells along capillaries and thereby promoting the extraction of O_2 and nutrients from the blood as well as the removal of metabolic byproducts. Finally, the increase in cardiac output enhances muscle blood flow, which helps to preserve a relatively high capillary P_{O_2} throughout the muscle and thereby maintain the driving force for O_2 diffusion from capillaries to mitochondria.

Aerobic training increases mitochondrial content

In untrained (but otherwise healthy) individuals, the maximum ability of mitochondria to consume O_2 is considerably greater than that of the cardiovascular system to supply O_2 . Thus, mitochondrial content does not limit $\dot{V}_{O_{2max}}$. We have already seen that endurance training markedly increases O_2 delivery. In parallel, endurance training can also increase the mitochondrial content of skeletal muscle fibers nearly 2-fold by

stimulating the synthesis of mitochondrial enzymes and other proteins (Fig. 60-11). The stimulus for mitochondrial biogenesis is the repeated activation of the muscle fiber during training, leading to increases in the time-averaged $[Ca^{2+}]_i$, which may act in two ways (Fig. 60-12). One is by directly modulating the transcription of *nuclear genes*. The other is by increasing cross-bridge cycling and raising $[AMP]_i$, thereby stimulating the fuel sensor **AMP kinase (AMPK)**, which, in turn, can modulate transcription. Some of the newly synthesized proteins are themselves transcription factors that modulate the transcription of nuclear genes. At least one protein—**transcription factor A, mitochondrial (TFAM)**—enters the mitochondrion and stimulates the transcription and translation of *mitochondrial genes* (see p. 22) for key elements of the electron-transport chain (see p. 118). Finally, some newly synthesized proteins encoded by genomic DNA, guided by cytoplasmic chaperones, target to the mitochondrial import machinery and become part of multisubunit complexes—together with proteins of mitochondrial origin.

FIGURE 60-11 Enzyme adaptation during aerobic training. Endurance training causes a slow increase in the level of several enzymes, as well as in the number of capillaries, maximal O_2 uptake, and size of muscle fibers. These changes reverse rapidly on the cessation of training. (Data from Saltin B, Henriksson J, Nygaard E, Andersen P: Fiber types and metabolic potentials of skeletal muscles in sedentary man and endurance runners. *Ann N Y Acad Sci* 301:3–29, 1977.)

FIGURE 60-12 Exercise-induced mitochondrial biogenesis. mRNA, messenger RNA; mtDNA, mitochondrial DNA. (Adapted from Chabi B, Adhihetty PJ, Ljubcic V, Hood DA: How is mitochondrial biogenesis affected in mitochondrial disease? *Med Sci Sports Exerc* 37:2102–2110, 2005.)

Because mitochondria create the sink for O_2 consumption during the oxidative phosphorylation of ADP to ATP, increased mitochondrial content promotes O_2 extraction from the blood. However, the primary benefit from mitochondrial adaptation in aerobic conditioning is the capacity to oxidize substrates, particularly fat, an ability that enhances endurance of muscle. Recall that mitochondria are responsible not only for the citric acid cycle (see p. 1185) and oxidative phosphorylation (see p. 1185) but also for β -oxidation of fatty acids (see p. 1185). As exemplified by marathon and ultramarathon athletes, the greater reliance on fat at a given level of \dot{V}_{O_2} is the metabolic basis of **glycogen sparing**, and thus reduced production of lactate and H^+ (see p. 1176).

Environmental Physiology

Arthur DuBois

The earth and its atmosphere provide environments that are compatible with an extraordinary number of diverse life forms, each adapted to its particular ecological niche. However, not all the earth's surface is equally friendly for *human* survival, let alone comfort and function. Mountain climbers and deep-sea divers know the profound effects of **barometric pressure (PB)** on human physiology, and astronauts quickly learn how the physically equivalent forces of **gravity** and **acceleration** affect the body. Humans can adapt to changes in PB and gravity up to a point, but survival under extreme conditions requires special equipment; otherwise, our physiological limitations would restrict our occupancy of this planet to its lowland surfaces.

Much can be learned from exposure to extreme environmental conditions. Although most people do not seek out these extreme environments, the same physiological responses that occur under extreme environmental conditions may also occur, to a lesser extent, in everyday life. In this chapter, we first discuss general principles of environmental physiology and then focus on extreme environments encountered in three activities: deep-sea diving, mountain climbing, and space flight.

The Environment

Voluntary feedback control mechanisms can modulate the many layers of our external environment

Claude Bernard introduced the concept of the *milieu intérieur* (basically the extracellular fluid in which cells of the organism live; see pp. 3–4) and the notion that *fixité du milieu intérieur* (the constancy of this extracellular fluid) is the condition of “free, independent life.” Most of this book focuses mainly on the interaction between cells and their extracellular fluid. In this chapter, we consider how the *milieu extérieur*, which physically surrounds the whole organism, affects our body functions and how we, in turn, modify our surroundings when it is necessary to improve our comfort or to extend the range of habitable environments.

The *milieu extérieur*, in fact, has several layers: the skin surface, the air that surrounds the skin, clothing that may surround that air, additional air that may surround the clothing, a structure (e.g., a house) that may surround that air, and finally a natural environment that surrounds that structure. As we interact with our multilayered environment, sensors monitor multiple aspects of the *milieu extérieur* and *involuntary* physiological feedback control mechanisms—operating at a *subconscious* level—make appropriate adjustments to systems that control a panoply of parameters, including blood pressure (see pp. 533–545), ventilation (see pp. 675–683), effective circulating volume (see pp. 554–555), gastric secretions (see pp. 865–872), blood glucose levels (see p. 1038), and temperature (see p. 1193).

The sensory input can also rise to a *conscious* level and, if perceived as discomfort, can motivate us to take *voluntary* actions that make the surroundings more comfortable. For example, if we sense that we are uncomfortably hot, we may move out of the sun or, if indoors, turn on the air conditioning. If we then sense that we are too cool, we may move into the sun or turn off the air conditioning. Such conscious actions are part of the effector limb in a complex negative-feedback system that includes sensors, afferent pathways, integration and conscious decision making in the brain, efferent pathways to our muscles, and perhaps inanimate objects such as air conditioners.

For a voluntary feedback system to operate properly, the person must be aware of a signal from the surroundings and must be able to determine the error by which this signal deviates from a desirable set-point condition. Moreover, the person must respond to this error signal by taking actions that reduce the error signal and thereby restore the *milieu intérieur* to within a normal range. Humans respond to discomfort with a wide variety of activities that may involve any layer of the environment. Thus, we may adjust our clothing, build housing, and eventually even make equipment that allows us to explore the ocean depths, mountain heights, and outer space.

Physiological control mechanisms—involuntary or voluntary—do not always work well. Physicians are acutely aware that factors such as medication, disease, or the extremes of age can interfere with involuntary feedback systems. These same factors can also interfere with voluntary feedback systems. For example, turning on the air conditioning is a difficult or even impossible task for an unconscious person, a bedridden patient, or a perfectly healthy baby. In these situations, a caregiver substitutes for the voluntary physiological control mechanisms. However, to perform this role effectively, the caregiver must understand how the environment would normally affect the care recipient and must anticipate how the involuntary and voluntary physiological control mechanisms would respond. 🟡N61-1

N61-1

Role of a Caregiver

Contributed by Arthur DuBois

In the text, we pointed out that a person's involuntary or voluntary physiological control mechanisms sometimes may not function properly. Under these conditions, a caregiver must take control. In a systematic approach, the caregiver would (1) assess the environmental stresses to which the care recipient may be subjected, including their range of intensity; (2) predict the body's ideal involuntary and voluntary reactions to the stresses; (3) consider how the limitations of the care recipient interfere with the natural reactions; (4) determine how to supplement or replace control mechanisms that are not functioning adequately; and (5) express the essential empathy between the caregiver and the patient (i.e., the important words, “I care”).

Environmental temperature provides conscious clues for triggering voluntary feedback mechanisms

Involuntary control mechanisms (see [pp. 1198–1201](#)) can only go so far in stabilizing body core temperature in the face of extreme environmental temperatures. Thus, voluntary control mechanisms can become extremely important.

The usual range of body core temperature is 36°C to 38°C (see [Table 59-1](#)). At an environmental temperature of 26°C to 27°C and a relative humidity of 50%, a naked person is in a **neutral thermal environment** (see [p. 1196](#))—feeling comfortable and being within the zone of vasomotor regulation of body temperature. At 28°C to 29°C, the person feels warm, and ~25% of the skin surface becomes wetted with perspiration. At 30°C to 32°C, the person becomes slightly uncomfortable. At 35°C to 37°C, the person becomes hot and uncomfortable, ~50% of the skin area is wet, and heat stroke (see [Box 59-1](#)) may become a hazard. The environmental temperature range of 39°C to 43°C is very hot and uncomfortable, and the body may fail to regulate core temperature. At 46°C, the heat is unbearable and heat stroke is imminent—the body heats rapidly, and the loss of extracellular fluid to sweat (see [pp. 1215–1219](#)) may lead to circulatory collapse and death (see [p. 1215](#)).

At the other extreme, we regard environmental temperatures of 24°C to 25°C as cool, and 21°C to 22°C as slightly uncomfortable. [N61-2](#) At temperatures of 19°C to 20°C, we feel cold, vasoconstriction occurs in the hands and feet, and muscles may be painful. [N61-3](#)

N61-2

Temperature Sensations and Computer Models

Contributed by Arthur DuBois

Thermal sensations reported by sedentary people wearing a summer shirt and trousers correspond closely to those predicted by computer models that simulate the changes in circulation between the core and surface of the body at either warm or cool environmental temperatures. Skin and clothing temperatures can be measured at a distance using an inexpensive infrared detector available at auto supply stores and used for measuring engine temperatures.

N61-3

Physical Work and the Conscious Control of Body Core Temperature

Contributed by Arthur DuBois

Performance of physically demanding labor in the heat or cold requires assessment of environmental temperature, wind speed, humidity, the clothing worn, and whether the work is light (standing at a bench), moderate (walking with a 3-kg load), or heavy (e.g., working with a pick and shovel). From these considerations one may predict the permissible duty cycle—for instance, 75% work and 25% recovery, where recovery is a rest period with warming up from a cold environment or cooling off from a hot environment. For a period of up to 3 weeks, acclimatization to heat improves tolerance for working in a hot environment.

Room ventilation should maintain P_{O_2} , P_{CO_2} , and levels of toxic substances within acceptable limits

Ventilation of a room (\dot{V}_{Room}) must be sufficient to supply enough O_2 and to remove enough CO_2 to keep the partial pressures of these gases within acceptable limits. In addition, it may be necessary to increase \dot{V}_{Room} even more to lower relative humidity and to reduce odors. Dry air in the natural environment at sea level (see Table 26-1) has a P_{O_2} of ~159 mm Hg (20.95%) and a P_{CO_2} of ~0.2 mm Hg (0.03%).

Acceptable Limits for P_{O_2} and P_{CO_2}

In the United States, the Occupational Safety and Health Administration (OSHA) has adopted an **acceptable lower limit** for O_2 of 19.5% of dry air at sea level (i.e., 148 mm Hg).

According to OSHA, the **acceptable upper limit for** P_{CO_2} in working environments at sea level is 3.8 mm Hg, or 0.5% of dry air. This P_{CO_2} would increase total ventilation (\dot{V}_T) by ~7% (see p. 716), a hardly noticeable rise. Exposures to 3% CO_2 in the ambient air—which initially would cause more substantial respiratory acidosis (see p. 633)—could be tolerated for at least 15 minutes, by the end of which time \dot{V}_T would be nearly double. With longer exposures to 3% CO_2 , the metabolic compensation to respiratory acidosis (see p. 641) would have already begun to increase plasma $[HCO_3^-]$ noticeably. 🍌

N61-4

N61-4

Effect of Disease on the Acute Response to Hypercapnia

Contributed by Arthur DuBois

How do subjects respond to increasing levels of CO_2 in the surrounding air? An example follows. A **normal person** who breathed 3% CO_2 for 5 or 6 minutes had a total ventilation (\dot{V}_T or minute volume of ventilation) of 8 L/min; then after a rest, the person breathed 5% CO_2 , which produced a \dot{V}_T of 27 L/min,

and after another rest breathed 7.5% CO₂, which produced a \dot{V}_T of 48 L/min.

We then repeated the experiment with a person with **chronic obstructive pulmonary disease (COPD)**. For the same three CO₂ levels, this COPD patient had \dot{V}_T values of 12, 19, and 27 L/min instead of 8, 27, and 48 L/min. The reason why—at 3% CO₂—the COPD patient had a higher \dot{V}_T (12 L/min) than the normal person (8 L/min) was that the COPD patient had a pathologically broad distribution of \dot{V}/\dot{Q} ratios and thus arterial hypoxemia. But the incremental values in response to 5% and 7.5% CO₂ were clearly depressed in the COPD patient, compared to the control, owing to a combination of mechanical obstruction and diminished responsiveness to CO₂ (due to metabolic compensation for respiratory acidosis).

Finally, we repeated the experiment with a person having a **depressed respiratory center**. For the same three CO₂ levels, this patient had \dot{V}_T values of 11, 11, and 12 L/min. In other words, this patient exhibited virtually no increase in \dot{V}_T in response to inhaling CO₂.

In some cases, particularly if the person is **anesthetized**, it becomes necessary to take over the mechanical work of breathing by using a ventilation pump that is set to provide sufficient ventilation in liters per minute to keep the arterial CO₂ level at ~40 mm Hg (equal to an end-tidal alveolar CO₂ level of ~5.6% of dry gas in healthy lungs). A spring-loaded safety valve is used to prevent the pump from delivering too much pressure, which could burst the lungs, and an alarm system alerts an attendant in case the pump fails to deliver the necessary amount of ventilation.

Measuring Room Ventilation

Two approaches are available for determining \dot{V}_{Room} . The first is a **steady-state method** that requires knowing (1) the rate of CO₂ production (\dot{V}_{CO_2}) by the occupants of the room and (2) the fraction of the room air that is CO₂. The equation is analogous to the one we introduced for determining *alveolar* ventilation, beginning with [Equation 31-9](#):

$$\dot{V}_{\text{Room}} = \frac{\dot{V}_{\text{CO}_2}}{\left(\text{Fraction of room air that is CO}_2 \right)}$$

(61-1)

We could use a similar equation based on the O₂ mole fraction and the rate of O₂ extraction (\dot{V}_{O_2}) by the occupants. 🍎[N61-5](#)

N61-5

Steady-State Method for Computing Room Ventilation

Contributed by Arthur DuBois

Suppose the occupant of a room has a resting metabolic rate that produces 200 mL/min (standard

temperature and pressure/dry [STPD]) of CO₂ and removes 250 mL/min (STPD) of O₂. STPD means mL at 760 mm Hg (or torr), 0°C, dry gas. However, if the ambient temperature is 24°C and the relative humidity is 50%, then the resting metabolic rate would have to increase by ~10%, so that the \dot{V}_{CO_2} would be ~220 mL/min (0.220 L/min) and the \dot{V}_{O_2} would be ~275 mL/min (0.275 L/min).

In addition, suppose that air (ambient temperature 24°C and relative humidity 50%) enters and leaves this room at a rate of 100 L/min—the **room ventilation** (\dot{V}_{Room}). Fresh air has almost zero CO₂ and 20.9% O₂. The pulmonary ventilation of the *occupant* would raise the CO₂ of the air inside and leaving the room by (0.220 L/min)/(100 L/min) = 0.22%, and would lower the O₂ by (0.275 L/min)/(100 L/min) = 0.275%. Thus, the inspired O₂ would be reduced from 20.9% to (20.9% – 0.27%) = 20.63%, and this concentration of O₂ (and also the correspondingly elevated concentration of CO₂) would be easily tolerated by the occupant. Suppose, however, that the person were exercising, with 10 times the metabolic rate, or that 10 people were in the room in a resting condition. The CO₂ level would increase to 10 persons × 0.22%/person = 2.2%, and the O₂ would fall to 20.9% – (10 persons × 0.275%/person) = 20.9 – 2.75 = 18.15%. Given a minimal standard for O₂ of 19.5%, we would clearly need to increase room ventilation.

In the **exponential decay method**, the second approach for determining \dot{V}_{Room} , the washout of a gas from the room is monitored. The approach is to add a test gas (e.g., CO₂) to the room and then measure the concentrations of the gas at time zero (C_{initial}) and—as \dot{V}_{Room} washes out the gas over some time interval (Δt)—at some later time (C_{final}). The equation for exponential decay is as follows: **N61-6**

$$\dot{V}_{\text{Room}} = \frac{V_{\text{Room}}}{\Delta t} \ln \left(\frac{C_{\text{initial}}}{C_{\text{final}}} \right)$$

(61-2)

N61-6

Exponential-Decay Method for Determining Room Ventilation

Contributed by Arthur DuBois

The Principle

The equation that describes the washout of a volume (V) by a flow (\dot{V}) is:

$$\dot{V} = \frac{V}{\tau}$$

(NE 61-1)

Here τ is the time constant. For example, imagine that we have stirred a 1-L beaker filled with water containing some dye. If we flow clear water into this beaker at a rate of 1 L/min and simultaneously remove 1 L/min of the newly mixed solution, the dye concentration will decrease exponentially with a time constant of $(\frac{V}{\dot{V}}) = (1 \text{ L})/(1 \text{ L/min}) = 1 \text{ min}$. One minute after the start of the flow (i.e., after 1 time constant), the dye concentration will have fallen to $1/e$ of its initial value. We could compute the time constant by comparing dye concentrations obtained at any two convenient times. For example, if C_{initial} is the initial dye concentration and C_{final} is the dye concentration after some time Δt , then

$$\tau = \frac{\Delta t}{\ln\left(\frac{C_{\text{initial}}}{C_{\text{final}}}\right)}$$

(NE 61-2)

Substituting Equation NE 61-2 into Equation NE 61-1, we have

$$\dot{V} = \frac{V}{\Delta t} \ln\left(\frac{C_{\text{initial}}}{C_{\text{final}}}\right)$$

(NE 61-3)

The above is analogous to Equation 61-2 in the text.

The Implications

In Equation 61-3, we saw that the ventilation of the hypothetical room (\dot{V}_{Room}) is 1871 L/min. This amount of ventilation would be adequate for a person exercising at 10 met (i.e., a metabolic rate that is 10-fold higher than resting metabolism) because the CO_2 production of 2.20 L/min **EN61-5** would be diluted by 1871 L/min of ventilation to raise the room CO_2 concentration to 0.12%. Similarly, the O_2 uptake of 2.75 L/min **EN61-5**—diluted by 1871 L/min—would lower the incoming level from 20.9% to $(20.9\% - 0.15\%) = 20.75\%$. Both the computed CO_2 level and the computed O_2 level are easily tolerated. Note that the room ventilation of 1871 L/min in this example is 18 times as much as the room ventilation in the example in **EN61-5**, where the occupant had to work with a room ventilation of only 100 L/min.

For example, imagine that we wish to measure the ventilation of a room that is $3 \times 3 \times 3 \text{ m}$ —a volume of 27 m^3 or 27,000 L. Into this room, we place a tank of 100% CO_2 and a fan to mix the air. We then open the valve on the tank until an infrared CO_2 meter reads 3% CO_2 ($C_{\text{initial}} = 3\%$), at which point we shut off the valve on the tank. Ten minutes later ($\Delta t = 10 \text{ minutes}$), the meter reads 1.5% ($C_{\text{final}} = 1.5\%$). Substituting these measured values into [Equation 61-2](#) yields **EN61-6**

$$\dot{V}_{\text{Room}} = \frac{27,000 \text{ L}}{10 \text{ min}} \ln\left(\frac{3.0\%}{1.5\%}\right) = 1871 \text{ L/min}$$

(61-3)

This approach requires that the incoming air contain virtually no CO₂ and that the room contain no CO₂ sources (e.g., people). Diffusion, thermal convection, and turbulence produce proper mixing of the gases.

Carbon Monoxide

More insidious than hypoxia, and less noticeable, is the symptomless encroachment of carbon monoxide (CO) gas on the oxyhemoglobin dissociation curve (see pp. 649–652). CO—which can come from incomplete combustion of fuel in furnaces, in charcoal burners, or during house fires—suffocates people without their being aware of its presence. Detectors for this gas are thus essential for providing an early warning. CO can be lethal when it occupies approximately half of the binding sites on hemoglobin (Hb), which occurs at a P_{CO} of ~0.13 mm Hg or 0.13/760 ≅ 170 parts per million (ppm). **N61-7** However, the half-time for washing CO into or out of the body is ~4 hours. Thus, if the ambient CO level were high enough to achieve a 50% saturation of Hb at equilibrium, then after a 2-hour exposure (i.e., one half of the half-time) the CO saturation would be $\frac{1}{2} \times \frac{1}{2} \times 50\% = 12.5\%$. The symptoms **N29-5** at this point would be mild and nonspecific and would include headache, nausea, vomiting, drowsiness, and interference with night vision. Victims with limited coronary blood flow could experience angina. **N61-8** After a 4-hour exposure (i.e., one half-time), the CO saturation would be $\frac{1}{2} \times 50\% = 25\%$. The symptoms would be more severe and would include impaired mental function and perhaps unconsciousness.

N61-7

Calculating the Lethal Partial Pressure of CO

Contributed by Arthur DuBois

To calculate the carboxyhemoglobin (HbCO) concentration, remember that when the Hb is exposed to CO the HbCO concentration will equal the HbO₂ concentration when the Hb is exposed to oxygen at 210 times the CO concentration. For example, at equilibrium, Hb is 50% saturated with O₂ when the P_{O₂} is 28 mm Hg. Similarly, the Hb is 50% saturated with CO at a P_{CO} of 28/210 mm Hg, which would be 0.13 mm Hg of CO. Because an atmosphere of pressure is 760 mm Hg, 0.13 mm Hg of CO is 0.13/760 of an atmosphere of CO, that is, 0.000,170 of an atmosphere or 170 ppm of CO.

N61-8

Effects of CO Poisoning in Patients with Reduced Coronary Blood Flow

Contributed by Arthur DuBois

The heart muscle extracts most of the oxygen from the blood supplied to it in the coronary circulation. With exercise, autoregulation of coronary blood flow normally supplies more oxygen to the myocardium

by increasing coronary blood flow. However, in stable angina, the fixed rate of coronary blood flow prevents autoregulation. Thus, when carboxyhemoglobin (HbCO) reduces the ability of arterial blood to release O₂ due to the leftward shift of the Hb-O₂ dissociation curve (see pp. 654–655), the heart muscle is deprived of oxygen and anginal pain develops even upon mild exercise.

Threshold Limit Values and Biological Exposure Indices

Threshold limit values (TLVs) are reasonable environmental levels of toxic substances or physical agents (e.g., heat or noise) to which industrial workers can be exposed—over a lifetime of working days—without causing predictable harm. Rather than depending on concentrations measured in air or food, we can use **biological exposure indices (BEIs)** to limit exposure to toxic substances by detecting changes in the body—*biomarkers of exposure* (e.g., carboxyhemoglobin levels in blood)—that correlate with the intensity and duration of exposure to toxic substances (e.g., CO). 🏠N61-9

N61-9

Threshold Limit Values and Biological Exposure Indices

Contributed by Arthur DuBois

A list of threshold limit values and biological exposure indices applicable to industrial exposure can be obtained from the American Conference of Governmental Industrial Hygienists (ACGIH) in Cincinnati, Ohio (<http://www.acgih.org/home>, accessed February 2015).

Tissues must resist the G force produced by gravity and other mechanisms of acceleration

Standing motionless on the earth's surface at sea level, we experience a gravitational force (\mathcal{F}) 🏠N61-10—our weight—that is the product of our mass (m) and the acceleration due to gravity ($g = 9.8 \text{ m} \cdot \text{s}^{-2}$):

$$\underset{\text{newtons}}{\mathcal{F}} = \underset{\text{kg}}{m} \times \underset{\text{m} \cdot \text{s}^{-2}}{g}$$

(61-4)

N61-10

The Laws of Motion

Contributed by Arthur DuBois

Newton's **first law of motion** establishes the concept of *inertia*: an object at rest remains at rest, and a body in motion remains in motion—at the same velocity—unless acted upon by an external force.

The **second law of motion** deals with changes in *momentum*, which is the product of mass and velocity. Because velocity has both magnitude and direction, so does momentum. When an external force (which also has magnitude and direction) acts on a body, the change in the body's momentum is in the

direction of the force. Furthermore, momentum changes at a rate that is proportional to the magnitude of the force. Thus, the change in the momentum (i.e., velocity) of a spacecraft depends on the magnitude, direction, and duration of the force (i.e., thrust) exerted by the engine.

The **third law of motion** states that application of an external force generates an equivalent, but opposing, inertial force (“for every action, there is an equal and opposite reaction”).

Under a particular condition, we may experience a different acceleration (a) from that due to gravity. The **G force** is a dimensionless number that describes force ($m \cdot a$) that we experience under a particular condition relative to the gravitational force ($m \cdot g$):

$$G = \frac{m \cdot a}{m \cdot g} = \frac{a}{g}$$

(61-5)

Thus, we normally experience a force of +1G that would cause us to fall with an acceleration of $9.8 \text{ m} \cdot \text{s}^{-2}$ if we were not supported in some way.

Accelerations besides that due to gravity also affect physiology. An accelerometer, placed on a belt, would show that we can jump upward with an acceleration of $\sim 3\text{G}$. It would also show that, on landing, we would strike the ground with a force of +3G—a force that our bones and other tissues can tolerate if we flex the joints. We discuss G forces from the perspective of air and space flight on pages 1232–1233.

At +1G, each square centimeter of the cross section of a vertebral body, for example, can withstand the compressive force generated by a mass of $\sim 20 \text{ kg}$ before the trabeculae begin to be crushed. 🧑🏻N61-11 Thus, at +1G a vertebral body with a surface area of 10 cm^2 could support the compressive force generated by a mass of $\sim 200 \text{ kg}$, far more than enough to support 35 kg , the mass of the upper half of the body of a 70-kg person. In fact, this strength would be adequate to withstand a G force of a $(200 \text{ kg})/(35 \text{ kg}) = +5.7\text{G}$ —provided the backbone is straight. However, if the backbone is not straight, the tolerance could be +3G, or approximately the acceleration achieved by jumping upward and landing on the feet with the back curved. When a pilot ejects from an aircraft, the thrust of the explosive cartridges accelerates the seat upward, and this can crush a vertebral body unless the pilot keeps the back straight.

N61-11

Forces Supported by a Vertebral Body

Contributed by Arthur DuBois

In the text, we analyzed the body mass that a vertebral body could withstand at +1G. Another way to approach the problem is to determine the maximal pressure that a vertebral body can withstand.

At +1G, each square centimeter of a vertebral body, for example, can withstand the compressive force generated by a mass of $\sim 20 \text{ kg}$ before the trabeculae begin to be crushed. In other words, a vertebral body can withstand a compressive pressure of

$$P_{\text{Max}} = \frac{\mathcal{F}_{\text{Max}}}{\text{Area}} = \frac{\text{Mass} \times \text{Acceleration}}{\text{Area}} = \frac{(20 \text{ kg}) \cdot (9.8 \text{ m} \cdot \text{cm}^{-2})}{\text{cm}^2} = \frac{196 \text{ N}}{\text{cm}^2}$$

(NE 61-4)

Thus, a vertebral body with a cross-sectional area of 10 cm^2 could support a maximal force (\mathcal{F}_{Max}) of

$$\mathcal{F}_{\text{Max}} = P_{\text{Max}} \times \text{Area} = \left(196 \frac{\text{N}}{\text{cm}^2}\right) \cdot (10 \text{ cm}^2) = 1960 \text{ N}$$

(NE 61-5)

This \mathcal{F}_{Max} is more than enough to support the upper half of the body of a 70-kg person (i.e., 35 kg). Because a vertebral body with a cross-sectional area of 10 cm^2 could support a mass of $20 \text{ kg/cm}^2 \times 10 \text{ cm}^2 = 200 \text{ kg}$ at $1 \times G$, it could withstand a headward acceleration of $(200 \text{ kg}/35 \text{ kg}) = +5.7G$ —provided the backbone were straight.

With increasing age, bones tend to demineralize (see [p. 1243](#)), which weakens them. Stepping off a curb, an elderly person with demineralized bones may fracture the neck of the femur or crush a vertebra. Demineralization of the vertebrae also reduces stature. Other causes of demineralization are immobilization and space flight. In one study a 6- to 7-week period of immobilization from bed rest led to losses of 14 g of calcium from bones, 1.7 kg of muscle, 21% in the strength of the gastrocnemius muscle, and 6% in average blood volume. The subjects became faint when suddenly tilted on a board, head above feet. After resuming ambulation, the subjects required 4 weeks for muscle strength to return to normal.

The partial pressures of gases—other than water—inside the body depend on PB

As discussed in the next two subchapters, extremely high or extremely low values of PB create special challenges for the physiology of the body, particularly the physiology of gases. **N26-8 Dalton's law** (see [Box 26-2](#)) states that PB is the sum of the **partial pressures** of the individual gases in the air mixture. Thus, in the case of ordinary *dry* air (see [Table 26-1](#)), most of the sea-level PB of 760 mm Hg is due to N_2 (~593 mm Hg) and O_2 (~159 mm Hg), with smaller contributions from trace gases such as argon (~7 mm Hg) and CO_2 (~0.2 mm Hg). As PB increases during diving beneath the water, or as PB decreases during ascent to high altitude, the partial pressure of each constituent gas in dry ambient air changes in proportion to the change in PB. At high values of PB, this relationship is especially important for ambient P_{N_2} and P_{O_2} , which can rise to toxic levels. At low values of PB, this relationship is important for ambient P_{O_2} , which can fall to levels low enough to compromise the O_2 saturation of Hb (see [pp. 649–652](#)) and thus the delivery of O_2 to the tissues.

The proportionality between PB and the partial pressure of constituent gases breaks down in the presence of liquid water. When a gas is in equilibrium with liquid water—as it is for inspired air by the time it reaches the trachea (see [p. 600](#))—the partial pressure of water vapor ($P_{\text{H}_2\text{O}}$) depends not on PB but on temperature. Thus, $P_{\text{H}_2\text{O}}$ becomes a negligible fraction of PB at the very high pressures associated with

deep-sea diving, whereas P_{H_2O} becomes an increasingly dominant factor as we ascend to altitude.

Diving Physiology

Immersion raises PB, thereby compressing gases in the lungs

The average PB at sea level is 760 mm Hg. In other words, if you stand at sea level, the column of air extending from your feet upward for several tens of kilometers through the atmosphere exerts a pressure of 1 atmosphere (atm). In a deep mine shaft, over which the column of air is even taller, PB is higher still. However, it is only when diving underwater that humans can experience extreme increases in PB. A column of fresh water extending from the earth's surface upward 10.3 m exerts an additional pressure of 760 mm Hg—as much as a column of air extending from sea level to tens of kilometers skyward. The same is true for a column of water extending from the surface of a lake to a depth of 10.3 m. For seawater, which has a density ~2.5% greater than that of fresh water, the column must be only 10 m to exert 1 atm of pressure. Because liquid water is virtually incompressible, PB increases linearly with the height (weight) of the column of water (Fig. 61-1). Ten meters below the surface of the sea, PB is 2 atm, 1 atm for the atmospheric pressure plus 1 atm for the column of water. As the depth increases to 20 m and then to 30 m, PB increases to 3 atm, then 4 atm, and so on.

FIGURE 61-1 Pressures at increasing depth of immersion. The pressure at the surface of the ocean is 1 atm and increases by 1 atm for each 10 m of immersion in seawater.

Increased external water pressure does not noticeably compress the body's *fluid and solid components* until a depth of ~1.5 km. However, external pressure compresses each of the body's *air* compartments to an extent that depends on the compliance of the compartment. In compliant cavities such as the intestines,

external pressure readily compresses internal gases. In relatively stiff cavities, or those that cannot equilibrate readily with external pressure, increases of external pressure can distort the cavity wall and result in pain or damage. For example, if the eustachian tube is blocked, the middle-ear pressure cannot equilibrate with external pressure, and blood fills the space in the middle ear or the tympanic membrane ruptures.

According to **Boyle's law**, [N26-8](#) pressure and volume vary inversely with each other. Thus, if the chest wall were perfectly compliant, a breath-holding dive to 10 m below the surface would double the pressure and compress the air in the lungs to half its original volume. Aquatic mammals can dive to extreme depths because rib flexibility allows the lungs to empty. Whales, for example, can extend a breath-hold dive for up to 2 hours, descending to depths as great as 900 m (91 atm) without suffering any ill effects. The human chest wall does not allow complete emptying of the lungs—except in a few trained individuals, and indeed the human record for a breath-hold dive is in excess of 200 m below the surface.

[N61-12](#)

N61-12

Decrease in Lung Volume with Depth of Immersion

Contributed by Arthur DuBois

Imagine that a person at sea level makes a maximal inspiration, achieving a **total lung capacity (TLC;** see p. 602) of 6 L. What happens if this individual then dives into seawater to a depth of 10 m? The P_B as well as the pressure of the air in the lungs doubles to 2 atm at this depth. If the chest wall is perfectly compliant, this increase in P_B would reduce the original lung volume to (6 L)/2, or 3 L. This new lung volume is only about twice the lung's normal **residual volume (RV)**, which is normally 1.5 to 1.9 L (see p. 602).

If the person descends an additional 10 m to a total depth of 20 m, P_B will now increase to 3 atm. Under these conditions, lung volume will fall to one third of its original value, or to 2 L.

A total descent to 30 m ($P_B = 4$ atm) will reduce lung volume to one quarter of its initial value, or to about the normal RV.

Competitive freediving is organized by two international bodies: the International Association for the Development of Apnea (AIDA) and the World Underwater Federation (CMAS). These organizations recognize different disciplines, based on the permissible methods of descent and ascent. In the No-Limits Apnea category, Herbert Nitsch reached a depth of 214 m in 2007.

If the person is using a SCUBA system (see p. 1226) to breathe compressed air, then the lungs will re-expand to normal volume. If the individual at depth were to make a maximal inspiration to TLC, remove the SCUBA mouthpiece, and then rapidly ascend toward the surface, the air in the lungs would expand to a greater-than-physiological volume. Therefore, the individual would have to exhale during the ascent to prevent the lungs from overexpanding.

In a **breath-hold dive** that is deep enough to double P_B , alveolar P_{CO_2} will also double to 80 mm Hg (see p. 1225). Because this value is substantially higher than the P_{CO_2} of mixed-venous blood at sea level (46 mm Hg), the direction of CO_2 diffusion across the blood-gas barrier reverses, alveolar CO_2 enters pulmonary-capillary blood, and thus arterial P_{CO_2} increases. In time, metabolically generated CO_2

accumulates in the blood and eventually raises mixed-venous P_{CO_2} to values higher than alveolar P_{CO_2} , so CO_2 diffusion again reverses direction and CO_2 diffuses into the alveoli. The increase in arterial P_{CO_2} can reduce the duration of the dive by increasing ventilatory drive (see p. 716). During a rapid ascent phase of a breath-hold dive, the fall in P_B leads to a fall in alveolar P_{CO_2} and P_{O_2} , which promotes the exit of both gases from the blood and thus a rapid fall in both arterial (a) P_{CO_2} and P_{O_2} . The fall in P_{aCO_2} reduces the drive to breathe. The fall in P_{aO_2} —and thus cerebral P_{O_2} —can lead to **deep-water blackout**. 🟡N61-13

N61-13

Shallow-Water Blackout

Contributed by Arthur DuBois

Imagine that a person excessively hyperventilates before taking a deep breath and attempting to swim a long distance underwater. During the underwater exercise, arterial P_{O_2} will fall, and the person may become hypoxic before the arterial P_{CO_2} rises sufficiently to increase the drive to ventilate and cause the swimmer to surface. The result can be shallow-water blackout and—if help is not close at hand—drowning.

Although it may be intuitive to overbreathe in preparation for a long underwater swim, beware of too much of a good thing: two deep breaths are acceptable, but prolonged hyperventilation can be fatal.

SCUBA divers breathe compressed air to maintain normal lung expansion

Technical advances have made it possible for divers to remain beneath the water surface for periods longer than permitted by a single breath-hold. One of the earliest devices was a **diving bell** that surrounded the diver on all sides except the bottom. Such a bell was reportedly used by Alexander the Great in 330 BC and then improved by Sir Edmund Halley in 1716 (Fig. 61-2). 🟡N61-14 By the early 19th century, pumping compressed air from above the water surface through a hose to the space underneath the bell kept water out of the bell. In all of these cases, the diver breathed air at the same pressure as the surrounding water. Although the pressures both surrounding the diver's chest and inside the airways were far higher than at sea level, the pressure *gradient* across the chest wall was normal. Thus, the lungs were normally expanded.

FIGURE 61-2 Diving bell. Between 1716 and 1721, Halley, the astronomer who gave his name to the comet, designed and built a wooden diving bell with an open bottom. Because the bell was at a relatively shallow depth (~12 m), the water rose only partly into the bell. In Halley's system, the air was replenished from a barrel that was open at the bottom and weighted with lead to sink beneath the diving bell. Thus, the air pressure in the barrel was higher than that in the bell. The diver used a valve to regulate airflow into the bell. This design was in use for a century, until a practical pump was available for pumping air directly from the surface. The lower part of the figure illustrates what would have happened if Halley's bell had been lowered to much larger depths. The greater the depth, the greater the water pressure. Because the air pressure inside the bell must be the same as the water pressure, the air volume progressively decreases at greater depths, and the water level rises inside the bell.  **N61-14**

N61-14

The Diving Bell

Contributed by Arthur DuBois, translated by Ulrich Hopfer

The following is a translation of a passage from a book (written in German) titled *Diseases of Air Pressure with Special Considerations of So-called Caisson Disease* by Dr. Richard Heller, Dr. Wilhelm Mager, and Hermann von Schroetter, PhD, MD.

“There are several reports that Aristotle had the idea to provide air to divers underwater by using an air tube. One also hears from Figuiet that a diver apparatus was used in Venice in the beginning of the 17th century. This apparatus was called ‘**Cornemuse**’ or ‘**Capuchon**’ and used a bellows to provide air.* Nevertheless, the first certain information we have is that Denys Papin had the idea to renew air in diver bells by way of bellows and valves to prolong the time to remain underwater.

“Therefore, a new period of diving begins with Papin and Halley, who actually put the idea into practice in 1716. The new period brings about the most important progress in this area.

“The invention of the Cornemuse, as well as the inventions of Papin and Halley, constitute the beginning of the diving apparatus in use today.

“Papin dealt already in 1672, in a theoretical publication with Huygens, with the influence of changes in air pressure and gave an explanation why animals die under a vacuum chamber venting valve.

“Edm. Halley, the famous Astronomer and Secretary of the English Society of Sciences, wrote up his experiences in 1716 in the ‘Transactions anglic’ under the title of ‘The art of living under water.’

“For low depths, the air delivery into the diving bell was achieved by two leather tubes, whereby one was used to pump in air with a bellows and the other allowed the air to escape. This arrangement with bellows did not work for greater depths of over 3 fathoms [i.e., 18 feet or ~5.5 m]. For these depths, barrels with air would be lowered into the water, while the used air was released into the water through a valve. Halley lowered himself together with 4 other persons to a depth of 9–10 fathoms, about 17 m, in 1721, whereby 7-8 barrels of air had to be used.

“His diving bell was made of wood, 8 feet high, in the form of a cut-off cone, with 3 feet diameter at the apex and 5 feet at the base [see Fig. 61-2]. The diving bell had a cap of lead. Additional lead weights were fastened at the lower edge so that the bell could sink to the bottom of the sea.... Glass in the ceiling served as window. There was a valve in the dome, through which the used-up, warm air could escape. A type of platform was attached to the free edge of the bell with ropes and fixed in place through weights. Divers would use this platform.

“The entire apparatus was fastened to the main spreader of a ship used to move the bell to its destination. To renew air when the bell was underwater, Halley used two small barrels of 160 L each and

lowered the barrels with the aid of weights. The barrels were connected to the bell via a leather tube that was puttied with wax and oil into the cover of the barrel. A hole in the bottom of the barrel allowed water to enter it thus generating pressure to move the air into the bell.

“The barrels were moved to the surface, refilled with air and re-lowered on a signal. The diver serviced the tubes, brought them into the bell, and regulated the airflow through valves at the end of the tubes.

“Nevertheless, the divers suffered, as described by Halley, from the significant increase in temperature within the bell due to compression of the air so that any stay in the bell was difficult. Moreover, he describes that the workers had pain in their ears, and nosebleeds once they were back at the surface.

“During this time, there was also remarkable progress in efforts to get air travel going. On August 8, 1709, the Portuguese Pater Bartholomeo Laurencio de Gussmann lifted himself up in the air with an airship constructed by him in the Indian House in Lisbon and in front of King John V and the entire court. Unfortunately, he got stuck at the roof of the palace and crashed. His device consisted of stiffened paper and the uplifting was caused by heated air. ... As often seen in the history, this great invention was snagged by an unfortunate, small obstruction so that the inventor got forgotten.”

*This apparatus was supposed to contain a pipe with an enlargement at the lower end that could go over the head of the diver. This pipe provided air driven by bellows, while another pipe returned exhaled air to the surface.

The conditions are essentially the same in a modern-day **caisson**, a massive, hollow, pressurized structure that functions like a large diving bell. Once again, the pressure inside the caisson (3 to 4 atm) has to be high enough to prevent water at the bottom of the caisson from entering. Several workers (“sand hogs”) at the bottom of the caisson may excavate material from the bottom of a river for constructing tunnels or foundations of bridges.

Technical advances also extended to individual divers, who first wore diving suits with spherical helmets over their heads (Fig. 61-3A). The air inside these helmets was pressurized to match exactly the pressure of the water in which they were diving. In 1943, Jacques Cousteau perfected the self-contained underwater breathing apparatus, or **SCUBA**, that replaced cumbersome gear and increased the mobility and convenience of an underwater dive (see Fig. 61-3B). 🟡N61-15

A DIVING HELMET

B SCUBA SYSTEM

FIGURE 61-3 Devices for breathing underwater. **A**, Compressed air, pumped from the surface to the diver, keeps the pressure inside the helmet slightly higher than that of the surrounding water. **B**, SCUBA is an acronym for *self-contained underwater breathing apparatus*.

N61-15

Diving Helmets and the SCUBA System

Contributed by Arthur DuBois

In the diving helmet shown in Figure 61-3A, a nonreturn valve was placed at the point where the air hose met the helmet. This device prevented air from escaping from the helmet in case the hose were to rupture.

The SCUBA system devised by Jacques Cousteau (see Fig. 61-3B) consists of five major elements:

1. A tank of gas compressed to a pressure that exceeds the highest pressures that the diver will encounter during the dive.
2. A reducing valve that delivers gas from the tank to the diver's hose at a pressure of 6 to 7 atm.
3. A “demand” breathing valve for inspiration, triggered to open by the slight decrease in pressure caused by the diver's inspiration. This valve delivers the air mixture to the diver at the ambient pressure.
4. An exhaust valve that allows expired air to be released at a pressure that is slightly higher than the ambient pressure.
5. A face mask or mouthpiece with a gas-delivery system that has a small ventilatory dead space (see p. 675).

Deep dives for extended periods of time require training and carry the risk of drowning secondary to muscle fatigue and hypothermia. Air flotation and thermal insulation of the diving suit lessen these

hazards. For reasons that will become apparent, use of any of these techniques while breathing *room air* carries additional hazards, including nitrogen narcosis, O_2 toxicity, and problems with decompression.

Increased alveolar P_{N_2} can cause narcosis

Descending beneath the water causes the inspired P_{N_2} —nearly 600 mm Hg at sea level (see [Table 26-1](#))—to increase as P_B increases. According to **Henry's law** (see [Box 26-2](#)), the increased P_{N_2} will cause more N_2 to dissolve in pulmonary-capillary blood and, eventually, the body's tissues. The dissolved $[N_2]$ in various compartments begins to increase immediately but may take many hours to reach the values predicted by Henry's law. Because of its high lipid solubility, N_2 dissolves readily in adipocytes and in membrane lipids. A high P_{N_2} reduces the ion conductance of membranes, and therefore neuronal excitability, by mechanisms that are similar to those of gas anesthetics. Diving to increased depths (e.g., 4 to 5 atm) while breathing compressed air causes **nitrogen narcosis**. Mild nitrogen narcosis resembles alcohol intoxication (e.g., loss of psychosocial inhibitions). According to “Martini's law,” each 15 m of depth has the effects of drinking an additional martini. Progressive narcosis occurs with increasing depth or time of the dive and is accompanied by lethargy and drowsiness, rapid onset of fatigue, and, eventually, a loss of consciousness. Because it develops insidiously, nitrogen narcosis poses a potentially fatal threat to divers who are not aware of the risks.

Increased alveolar P_{O_2} can lead to O_2 toxicity

At sea level, dry inspired air has a P_{O_2} of 159 mm Hg. However, the *alveolar* (A) P_{O_2} of a healthy person at sea-level air is ~101 mm Hg, reduced from 159 mm Hg by humidification in the airways and removal of O_2 by gas exchange with the blood (see [p. 681](#)). P_{aO_2} at sea level is very close to P_{AO_2} (within ~10 mm Hg) and nearly saturates Hb, to yield an arterial O_2 content of ~20 mL/dL blood ([Fig. 61-4](#), red curve). As P_B —and therefore arterial P_{O_2} —increases at greater depths, the O_2 bound to Hb increases very little. However, according to Henry's law (see [p. 593](#)), the O_2 that is physically dissolved in the water of blood increases linearly (see [Fig. 61-4](#), black line). Thus, the increment of total O_2 content at depth reflects dissolved O_2 (see [Fig. 61-4](#), blue curve).

FIGURE 61-4 O_2 content of blood at high pressures. The red curve is the same Hb- O_2 dissociation curve as that in Figure 29-3, except that the range is extended to very high values of P_{O_2} .

During a breath-hold dive to 5 atm, or in a hyperbaric chamber pressurized to 5 atm, arterial P_{O_2} increases to ~700 mm Hg, slightly higher than when breathing 100% O_2 at sea level. Exposure to such a high P_{O_2} has no ill effects for up to several hours. However, prolonged exposure damages the airway epithelium and smooth muscle, causing bronchiolar and alveolar membrane inflammation and, ultimately, pulmonary edema, atelectasis, fibrin formation, and lung consolidation. These effects are the result of inactivation of several structural repair enzymes and oxidation of certain cellular constituents.

A prolonged elevation of P_{O_2} also has detrimental effects on nonpulmonary tissues, including the central nervous system (CNS). Exposure to an ambient P_{O_2} of ~1500 mm Hg (e.g., breathing room air at ~10 atm) for as little as 30 to 45 minutes can cause seizures and coma. Preliminary symptoms of O_2 **toxicity** include muscle twitching, nausea, disorientation, and irritability. The toxic effects of O_2 occur because free radicals (e.g., superoxide anion and peroxide free radicals; see pp. 1238–1239) oxidize the polyunsaturated fatty-acid component of cell membranes as well as enzymes that are involved in energy

metabolism. At the more modest P_{O_2} levels that normally prevail at sea level, scavenger enzymes such as superoxide dismutase (see p. 1238) eliminate the relatively few radicals formed. 🕒N61-16

N61-16

Effect of SCUBA Diving on Alveolar P_{CO_2}

Contributed by Emile Boulpaep, Walter Boron

If a diver were instantaneously submerged to a depth of 10 m in seawater (i.e., with a doubling of P_B), in the absence of ventilation, alveolar P_{CO_2} would double (see p. 1225). If the diver is not ventilating, alveolar P_{CO_2} would exceed pulmonary-capillary P_{CO_2} . As a result, CO_2 would diffuse slowly into the blood and raise arterial $[CO_2]$. The result would be a gradually developing respiratory acidosis (see p. 633). However, in real life, SCUBA divers breathe as they descend to depth gradually. This ventilation prevents alveolar P_{CO_2} from rising beyond the value at sea level. In the new steady state—assuming that both the body's CO_2 production rate (\dot{V}_{CO_2}) and the alveolar ventilation (\dot{V}_A) remain constant—the alveolar CO_2 at depth will be the same as that at sea level (see Equation 31-9).

Using helium to replace inspired N_2 and O_2 avoids nitrogen narcosis and O_2 toxicity

Several occupations—including deep mining, caisson work, and deep diving 🕒N61-17—require people to spend extended periods at a P_B greater than that at sea level.

N61-17

High-Pressure Occupations

Contributed by Arthur DuBois

Deep Mining

In deep mining, workers descend down a shaft to depths as great as 2.4 km below the surface. Just as P_B falls with ascent to a high altitude, it rises with descent to a great depth in a mine, doubling approximately every 5.5 km of depth. Nevertheless, 2.4 km below the earth's surface, P_B is only ~ 1.4 atm, which presents little problem to the miner. The greatest health hazards for the deep miner are from exposure to high temperature (ambient temperature increases by $1^\circ C$ every ~ 300 m), from humidity (miners use a fine water spray to minimize dust), and from inspiration of particulates.

Caisson Work

Caisson workers rarely experience >3 or 4 atm, and only for relatively brief periods. Because nitrogen narcosis begins to appear only at ~ 5 atm of room air after more than an hour, and because oxygen toxicity only begins to appear at ~ 10 atm of room air after >30 min, caisson workers can avoid the adverse effects of increased P_B while they are *in* the caisson. However, caisson workers may have major difficulties caused by decompression when *exiting* the caisson.

Deep-Diving Work

Divers may spend hours, days, or even weeks at depths between 60 m and 300 m below the water surface. They wear diving suits when working and live in compression chambers when at “leisure.” Deep divers who spend days or weeks at high PB must breathe special gas mixtures to avoid nitrogen narcosis and oxygen toxicity.

During an extended dive or other exposure to high pressure (one exceeding several hours), the body's tissues gradually *equilibrate* with the high-pressure gases that one has been breathing. This equilibrated state is referred to by the misnomer **saturation**. At sea level, the human body normally contains ~1 L of dissolved N_2 , equally distributed between the body's water and fat compartments. As P_{N_2} rises, the N_2 equilibrates only slowly with the body's lipid stores because adipose tissue is relatively underperfused. Although a deep dive of several minutes does not provide sufficient time to equilibrate the fat with N_2 , one of several hours' duration does. At equilibrium—as required by Henry's law—the volume of N_2 dissolved in the tissues is proportional to alveolar P_{N_2} . Thus, if the body normally dissolves 1 L of N_2 at a PB of 1 atm, it will ultimately dissolve 4 L of N_2 at a PB of 4 atm. These same principles apply to O_2 , although with different solubilities and speeds of equilibration in various tissues.

The adverse effects of N_2 and O_2 depend on the amount of gas that is dissolved in tissues. The amount, in turn, increases with the dive's depth (i.e., partial pressure of the gas) and duration (i.e., how close the gas is to achieving equilibrium with various tissues). Thus, the length of time that a diver can spend safely underwater is inversely proportional to the depth of the dive.

To prevent **nitrogen narcosis** in saturation diving conditions, divers must partly or completely replace N_2 with another inert gas. Helium is the replacement gas of choice for four reasons: 🏠N61-18

N61-18

Properties of Helium

Contributed by Ethan Nadel

Helium is an odorless, tasteless, and colorless gas. Compared to N_2 , it has a lower solubility in water, which means that it dissolves in tissues to a lesser extent. In fact, helium has the lowest water solubility of all gases.

The density of helium is nearly an order of magnitude lower than that of nitrogen ($0.178 \times 10^{-3} \text{ g/cm}^3$ versus $1.25 \times 10^{-3} \text{ g/cm}^3$), so that the Reynolds number (Re ; see Equation 27-11) is reduced by a similar factor. Thus, at the same air velocity, helium is far less likely to exceed Re and thereby engage in turbulent flow. Because turbulent flow increases the effective airway resistance (see p. 617), helium will have a lower effective airway resistance than nitrogen.

The viscosity of helium (194 μP at 20°C) is not markedly different from that of nitrogen (178 μP at 27.4°C). Thus, according to Poiseuille's law (see Equation 27-8), the resistance under laminar flow conditions would be very similar for helium and nitrogen—assuming that the length and radius of the airway is unchanged.

Weast RC. *Handbook of Chemistry and Physics*. 59th ed. CRC Press: Boca Raton, FL; 1978–1979.

1. Helium has only a fraction of the narcotizing effect of N_2 .
2. Helium dissolves in the tissues to a lesser extent than N_2 .
3. Helium has a lower density than N_2 and this lowers effective airway resistance. However, the low density of helium facilitates convective “air” cooling around the body, so that heat loss is increased. Thus, ambient temperature must be higher in a high-helium compression chamber.
4. During the decompression phase of a dive, helium diffuses out of the tissues more rapidly than does N_2 , which alleviates most of the problems associated with decompression.

To prevent **O_2 toxicity** in saturation diving conditions, divers must reduce the fraction of inspired air that is O_2 (F_{IO_2}) in the compressed-gas mixture. Thus, at a PB of 10 atm, an F_{IO_2} of 2% O_2 in helium will provide the same inspired P_{O_2} as room air does at sea level (i.e., F_{IO_2} of ~20% O_2 at a PB of 1 atm). Of course, the diver must monitor the inspired P_{O_2} , which is the physiologically relevant parameter.

After an extended dive, one must decompress slowly to avoid decompression illness

Although the preceding three sections have focused on problems divers face *while* at great depths, serious difficulties also arise if—*after* a deep saturation dive—the diver *returns* to the surface too quickly. At the end of a saturation dive, P_{N_2} is at the same high value in the alveoli and most tissues. As PB falls during ascent, alveolar P_{N_2} will fall as well, which creates a P_{N_2} gradient from the mixed-venous blood to the alveolar air. Washout of N_2 from the blood creates a P_{N_2} gradient from tissues to blood. To allow enough time for the dissolved N_2 to move from tissues to blood to alveoli,  **N61-19** a diver must rise to the surface slowly (no faster than ~3 m/hr). Because N_2 exits from water much faster than it does from fat, the total elimination of N_2 has two components: some compartments empty quickly (e.g., blood), and some empty slowly (e.g., joints, fat, eyeballs).

N61-19

Nitrogen Washout

The Oxygen Window

The extra nitrogen can be eliminated without forming bubbles in the venous blood because of something called the **oxygen window**. This window occurs because the sum of gas pressures in the venous blood *leaving the tissues* is less than the sum of gas pressures in the arterial blood *entering the tissues*. The reason for this is that—for a resting person at sea level—the partial pressure of oxygen falls from an arterial level of 100 mm Hg to a venous tension of 40 mm Hg, whereas the carbon dioxide tension rises only from 40 to 46 mm Hg; this difference leaves a “window” of $100 - 40 - 6 = 54$ mm Hg, the so-called oxygen window, into which nitrogen can move from the tissues into the blood—in an amount that corresponds to a partial pressure of 54 mm Hg in the blood—without raising the sum of pressures of the gases above the water pressure surrounding the body. The nitrogen dissolved at 54 mm Hg is carried from the tissues to the alveolar air without forming bubbles in the bloodstream as the person ascends at a rate of 3 m/hr following a saturation dive because in 1 hour, the dissolved nitrogen carried to the lungs in the oxygen window is expired and leaves the body.

Too rapid an ascent causes the N_2 in the tissues—previously dissolved under high pressure—to leave solution and form bubbles as P_B falls. This process is identical to the formation of gas bubbles when one opens a bottle of a carbonated beverage that had been capped under high pressure. Similar problems can occur in pilots who bail out from a pressurized aircraft at high altitude and in divers who ascend to altitude or become aircraft passengers (i.e., are exposed to a lower-than-normal P_B) too soon after completing a dive that, by itself, would not cause difficulties.

During a too-rapid decompression, bubble formation can occur in any tissue in which N_2 has previously been dissolved. **Decompression illness (DCI)** 🟡**N61-20** is the general term for two major types of clinical disorder:

N61-20

Dysbarism

For a discussion of **dysbarism**—medical conditions resulting from changes in barometric (i.e., ambient) pressure—visit <http://emedicine.medscape.com/article/769902-overview> (accessed July 2015).

For a discussion of **decompression illness**, visit http://www.medscape.com/viewarticle/710379_6 (accessed July 2015).

For a discussion of **decompression sickness**, visit <http://emedicine.medscape.com/article/769717-overview> (accessed July 2015).

1. Decompression sickness (DCS) is caused by local bubble formation, either in tissues or in venous blood. In tissues, the distortion produced by these bubbles can affect function and cause itching or pain. In veins, the bubbles can cause obstruction, leading to capillary leaks. Mild or **type I DCS** can include short-lived mild pains (“niggles”), pruritus, a skin rash, and deep throbbing pain (bends), resulting from bubbles that form in muscles and joints. Serious or **type II DCS** can include symptoms in the CNS, lungs, and circulatory system. The CNS disorder—most commonly involving the spinal cord—reflects bubble formation in the myelin sheath of axons, which compromises nerve conduction. Symptoms may range from dizziness—the staggers—to paralysis. Pulmonary symptoms—the chokes—result from bubbles that originate in the systemic veins and travel as gas emboli to lodge in the pulmonary circulation, and include

burning pain on inspiration, cough, and respiratory distress. In the circulatory system, bubbles not only can obstruct blood flow but also can trigger the coagulation cascade (see pp. 440–444), leading to the release of vasoactive substances. Hypovolemic shock is also a part of this syndrome.

2. Arterial gas embolization (AGE) is caused by bubbles that enter the systemic arterial blood via either tears in the alveoli or right-to-left shunts (e.g., a patent foramen ovale) and then become wedged in the brain or other organs. Large arterial gas emboli can have catastrophic consequences unless the victim receives immediate recompression treatment.

Figure 61-5 shows how long a diver can spend at various depths—breathing room air—without having to undergo a decompression protocol during the ascent. For example, a dive to 8 m can last indefinitely without any ill effects during the ascent. A dive of 25 minutes' duration will not provide sufficient time to saturate the tissues unless the dive exceeds 40 m. However, a longer dive at 40 m will require a decompression program. For instance, a 20-minute dive to a depth of 90 m requires nearly 3 hours of decompression time. Thus, the rate at which a diver should ascend to avoid DCI depends on both the depth and the duration of the dive. Divers use detailed tables to plan their rate of ascent from a deep dive.

FIGURE 61-5 Need for decompression as a function of depth and duration of dive. If the dive is sufficiently brief or sufficiently shallow, no decompression is required (*teal area*). For greater depths or longer durations, a decompression protocol is required (*salmon area*). (Data from Duffner GJ: Medical problems involved in underwater compression and decompression. Ciba Clin Symp 10:99–117, 1958.)

The best treatment for DCI is to *recompress* the diver in a hyperbaric chamber. Recompression places the gases back under high pressure, forcing them to redissolve in the tissues, a process that instantly relieves many symptoms. Once the diver is placed under high pressure, decompression can be carried out at a deliberate and supervised pace. 📍**N61-21**

N61-21

Recompression Schedules

Contributed by Emile Boulpaep, Walter Boron

U.S. Navy Treatment Table 6—discussed in the review by Vann and colleagues listed below (see their Fig. 5)—is commonly used to treat type II DCS. Other Navy tables describe treatment protocols for other

situations.

High-Altitude Physiology

PB and ambient P_{O_2} on top of Mount Everest are approximately one third of their values at sea level

Unlike a column of water, which is relatively noncompressible and has a uniform density, the column of air in the atmosphere is compressible and has a density that decreases exponentially ascending from sea level. Half of the mass of the earth's atmosphere is contained in the lowest 5500 m. Another quarter is contained in the next 5500 m (i.e., 5500 to 11,000 m of altitude). In other words, at higher and higher altitudes, the number of gas molecules pressing down on a mountain climber also falls exponentially; PB falls by half for each ~5500 m of ascent (Fig. 61-6).

FIGURE 61-6 Altitude dependence of PB and P_{O_2} in dry air.

Everest Base Camp

At an altitude of 5500 m—which also happens to be the altitude of the first base camp used in most ascents of Mount Everest—PB is half the value at sea level ($P_B \cong 380$ mm Hg), as is the ambient P_{O_2} ($P_{O_2} \cong 80$ mm Hg). At this altitude, arterial O_2 delivery (arterial blood O_2 content \times cardiac output) can still meet O_2 demands in most healthy, active persons, even during mild physical activity. However, the body's compensatory responses to reduced ambient P_{O_2} at high altitude vary among individuals. Thus, exposure to an altitude of 5500 m is problematic for a significant portion of the population.

Peak of Mount Everest

The peak of Mount Everest—8848 m above sea level—is the highest point on earth. PB at the peak is ~255 mm Hg, approximately one third that at sea level, and the ambient P_{O_2} is only ~53 mm Hg. For a climber at the peak of Mount Everest, the P_{O_2} of the *humidified* inspired air entering the alveoli is even lower, because of the effects of water vapor ($P_{H_2O} = 47$ mm Hg at 37°C). Therefore, inspired $P_{O_2} = 21\% \times (255 - 47) = 44$ mm Hg, compared with 149 mm Hg at sea level (see [Table 26-1](#)). Hypoxia is thus a major problem at the summit of Mount Everest.

Air Travel

Pressurized cabins in passenger planes maintain an ambient pressure equivalent to ~1800 m of altitude (~79% of sea-level pressure) in cross-continental flights, or ~2400 m of altitude (~74% of sea-level pressure) in transoceanic flights. Considering that most people do not need supplemental O_2 in the inspired air at Denver (~1500 m) or at some ski resorts (~3000 m), most airline passengers are not bothered by the slight reduction in arterial O_2 saturation (89% saturation at 3000 m) associated with these airline cabin pressures. However, passengers with chronic obstructive pulmonary disease (see [Box 27-2](#)) may need to carry supplemental O_2 onto the plane even if they do not require it at sea level.

Up to modest altitudes, arterial O_2 content falls relatively less than PB due to the shape of the Hb- O_2 dissociation curve

Although PB and ambient P_{O_2} decrease by the same fraction with increasing altitude, the O_2 saturation of Hb in arterial blood decreases relatively little at altitudes up to ~3000 m. The reason is that at this altitude, arterial P_{O_2} is 60 to 70 mm Hg, which corresponds to the relatively flat portion of the O_2 -Hb dissociation curve (see [Fig. 29-3](#)), so that arterial O_2 content is little affected. Thus, the characteristics of Hb protect the arterial O_2 content, despite modest reductions of P_{O_2} . At higher altitudes, where arterial O_2 content falls more steeply, aviators are advised to breathe supplemental O_2 .

Although the amount of O_2 in the blood leaving the lung is important, even more important is the amount of O_2 that the systemic tissues extract. This uptake is the product of cardiac output and the arteriovenous (a-v) difference in O_2 content (see [Equation 29-7](#)). At sea level, arterial P_{O_2} is ~100 mm Hg, corresponding to an Hb saturation of ~97.5%, whereas the mixed-venous P_{O_2} is ~40 mm Hg, corresponding to an Hb saturation of ~75%. The difference between the arterial and the venous O_2 contents is ~22.5% of Hb's maximal carrying capacity for O_2 . However, at an altitude of 3000 m, arterial P_{O_2} is only ~60 mm Hg, which may correspond to an Hb saturation of only 88%. This reduction in blood O_2 content is called **hypoxemia**. Assuming that everything else remains the same (e.g., O_2 utilization by the tissues, hematocrit, 2,3-bisphosphoglycerate levels, pH, cardiac output), then the mixed a-v difference in Hb saturation must still be 22.5%. Thus, the mixed-venous blood at 3000 m must have an Hb saturation of $88\% - 22.5\% = 65.5\%$, which corresponds to a P_{O_2} of ~33 mm Hg. As a result, the a-v difference of O_2 partial pressure is much larger at sea level ($100 - 40 = 60$ mm Hg) than at 3000 m ($60 - 33 = 27$ mm Hg), even though the a-v difference in O_2 content is the same. The reason for the discrepancy is that the O_2 -Hb dissociation curve is steeper in the region covered by the P_{O_2} values at high altitude. 🍌N61-22

Capillary-Tissue P_{O_2} Gradients

Contributed by Arthur DuBois

The oxygen tension or (partial pressure, P_{O_2}) in mixed-venous blood—a measure of average end-capillary P_{O_2} —is normally 40 mm Hg, sufficient to allow O_2 to diffuse into the tissue cells. Although mitochondria can use O_2 down to very low levels, the *radial O_2 diffusion gradient* between capillary blood and cell surfaces becomes barely sufficient when the mixed-venous P_{O_2} is ≤ 20 mm Hg. A sign of tissue hypoxia would be **lactic acidosis**.

Oxygen electrodes measure P_{O_2} in arterial or venous blood samples. The difference between arterial and mixed-venous P_{O_2} is a measure of the average *axial O_2 gradient* along systemic capillaries. Note that finger pulse oximeters measure the oxyhemoglobin saturation in the *pulsating* (i.e., arterial) blood that rushes into the tissue of the finger (see Box 29-2).

At high altitude, the fall in arterial P_{O_2} causes a reflex hyperventilation that lowers arterial and thus tissue P_{CO_2} and thereby increases the affinity of Hb for oxygen. By itself, this Bohr effect (see p. 652) would further lower tissue P_{O_2} . Conversely, raising tissue P_{CO_2} raises tissue P_{O_2} by displacing O_2 from Hb.

At very high altitudes, still another factor comes into play. The uptake of O_2 by pulmonary-capillary blood slows at high altitudes, which reflects the smaller O_2 gradient from alveolus to blood (see Fig. 30-10D). As a result, at sufficiently high altitudes, particularly during exercise, O_2 may no longer reach diffusion equilibrium between alveolar air and pulmonary-capillary blood by the time the blood reaches the end of the capillary. Thus, at increasing altitude, not only does alveolar P_{O_2} —and hence the maximal attainable arterial P_{O_2} —fall in a predictable way, but also the actual arterial P_{O_2} may fall to an even greater extent because of a failure of pulmonary-capillary blood to equilibrate with alveolar air.

During the first few days at altitude, compensatory adjustments to hypoxemia include tachycardia and hyperventilation

A reduction in arterial P_{O_2} stimulates the peripheral chemoreceptors (see pp. 710–713) and causes an immediate increase in ventilation, which has two effects. First, it brings alveolar P_{O_2} (and thus arterial P_{O_2}) closer to the ambient P_{O_2} . Second, hyperventilation blows off CO_2 , producing a respiratory alkalosis (see p. 680) that inhibits the peripheral but especially the central chemoreceptors and thereby decreases ventilatory drive (see pp. 709–717). Thus, \dot{V}_T during an acute exposure to an altitude of 4500 m is only about twice that at sea level, whereas the hypoxia by itself would have produced a much larger stimulation. Accompanying the increased ventilatory drive during acute altitude exposure is an increase in heart rate, probably owing to the heightened sympathetic drive that accompanies acute hypoxemia (see p. 545). The resultant increase in cardiac output enhances O_2 delivery.

During the next few days to weeks at an elevation of 4500 m, **acclimatization** causes ventilation to

increase progressively by about the same amount as the acute response. As a result, P_{O_2} continues to rise, and P_{CO_2} , to fall. Two mechanisms appear to cause this slower phase of increased ventilation. First, the pH of the cerebrospinal fluid (CSF) decreases, which counteracts the respiratory alkalosis induced by the increase in ventilation and thus offsets the inhibition of central chemoreceptors. However, the time course of the pH decrease in CSF does not correlate tightly with the time course of the increase in ventilation. The pH at the actual site of the central chemoreceptors may fall with the appropriate time course. Long-term hypoxia appears to increase the sensitivity of the peripheral chemoreceptors to hypoxia, and this effect may better account for acclimatization.

In the second mechanism for acclimatization, the kidneys respond over a period of several days to the respiratory alkalosis by decreasing their rate of acid secretion (see pp. 832–833) so that blood pH decreases toward normal (i.e., metabolic compensation for respiratory alkalosis). Another result of this compensation is that the unreabsorbed HCO_3^- produces an osmotic diuresis and an alkaline urine. The consequence of reducing both CSF and plasma pH is to remove part of the inhibition caused by alkaline pH and thus allow hypoxia to drive ventilation to higher values.

An extreme case of adaptation to high altitude occurs in people climbing very high mountains. In 1981, a team of physiologists ascended to the peak of Mount Everest. Although on their way up to the summit the climbers breathed supplemental O_2 , at the summit they obtained alveolar gas samples while breathing ambient air—trapping exhaled air in an evacuated metal container. The alveolar P_{CO_2} at the summit was a minuscule 7 to 8 mm Hg, or ~20% of the value of 40 mm Hg at sea level. Thus, assuming a normal rate of CO_2 production, the climbers' alveolar ventilation would have been 5-fold higher than normal (see pp. 679–680). Because the work of heavy breathing and increased cardiac output at the summit (driven by hypoxia) would increase CO_2 production substantially, the increase in alveolar ventilation must have been much greater than 5-fold.

The climbers' alveolar P_{O_2} at the peak of Mount Everest was ~28 mm Hg, which is marginally adequate to provide a sufficient arterial O_2 content to sustain the resting metabolic requirement at the summit. However, the term *resting* is somewhat of a misnomer, because the work of breathing and the cardiac output are markedly elevated.

Long-term adaptations to altitude include increases in hematocrit, pulmonary diffusing capacity, capillarity, and oxidative enzymes

Although the increases in ventilation and cardiac output help to maintain O_2 delivery during acute hypoxia, they are costly from an energy standpoint and cannot be sustained for extended periods. During prolonged residence at a high altitude, the reduced arterial P_{O_2} triggers profound adaptations that enhance O_2 delivery to tissues at a cost that is lower than that exacted by short-term compensatory strategies. Many of these adaptations are mediated by an increase in **hypoxia-inducible factor 1 (HIF-1)**, a transcription factor that activates genes involved in erythropoiesis, angiogenesis, and other processes.

Hematocrit

Red blood cell (RBC) mass slowly increases with prolonged hypoxemia. The Hb concentration of blood increases from a sea-level value of 14 to 15 g/dL to >18 g/dL, and hematocrit increases from 40% to 45%

to >55%. Normally, the body regulates RBC mass within fairly tight limits. However, renal hypoxia and norepinephrine stimulate the production and release of **erythropoietin (EPO)** from fibroblast-like cells in the kidney (see [pp. 431–433](#)). EPO is a growth factor that stimulates production of proerythroblasts in bone marrow and also promotes accelerated development of RBCs from their progenitor cells. 🍷N18-2

Pulmonary Diffusing Capacity

Acclimatization to high altitude also causes a 2- to 3-fold increase in pulmonary diffusing capacity (see [p. 668](#)). Much of this increase appears to result from a rise in the blood volume of pulmonary capillaries (see [p. 664](#)) and from the associated increase in capillary surface area available for diffusion (see [p. 661](#)). This surface area expands even further because hypoxia stimulates an increase in the depth of inspiration. Finally, right ventricular hypertrophy raises pulmonary arterial pressure, thereby increasing perfusion to the upper regions of the lungs (see [Fig. 31-9](#)).

Capillary Density

Hypoxia causes a dramatic increase in tissue vascularity. Tissue **angiogenesis** (see [pp. 481–482](#)) occurs within days of exposure to hypoxia, triggered by growth factors released by hypoxic tissues. Among these angiogenic factors are vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF), and angiogenin.

Oxidative Enzymes

Hypoxia promotes expression of oxidative enzymes in the mitochondria, thereby enhancing the tissues' ability to extract O₂ from the blood (see [pp. 1220–1222](#)). Thus, acclimatization to high altitude increases not only O₂ delivery to the periphery but also O₂ uptake by the tissues.

High altitude causes mild symptoms in most people and acute or chronic mountain sickness in susceptible individuals

Symptoms of Hypoxia

The first documented evidence of the ill effects of high altitude was in 35 BC, when Chinese travelers called the Himalayas the “Headache Mountains.” Recreational mountain climbing became popular in the mid-19th century, and with modern transportation, many people can now travel rapidly to mountain resorts. In fact, it is possible to ascend passively from sea level to high altitude in a matter of minutes (e.g., in a balloon) to hours. A rapid ascent may precipitate a constellation of relatively *mild symptoms*: drowsiness, fatigue, headache, nausea, and a gradual decline in cognition. These uncomfortable effects of acute hypoxia are progressive with increasing altitude. They occur in some people at altitudes as low as 2100 m and occur in most people at altitudes higher than 3500 m. Initially, these symptoms reflect an inadequate response (i.e., compensatory hyperventilation) to hypoxemia, which results in insufficient O₂ delivery to the brain. In the longer term, symptoms may stem from mild *cerebral edema*, which probably results from dilation of the cerebral arterioles leading to increased capillary filtration pressure and enhanced transudation (see [p. 468](#)).

Acute Mountain Sickness

Some people who ascend rapidly to altitudes as seemingly moderate as 3000 to 3500 m develop acute

mountain sickness (AMS). The constellation of symptoms is more severe than those described in the previous paragraph and includes headache, fatigue, dizziness, dyspnea, sleep disturbance, peripheral edema, nausea, and vomiting. The symptoms usually develop within the first day and last for 3 to 5 days. The primary problem in AMS is hypoxia, and the symptoms probably have two causes. The first is thought to be a progressive, more severe case of **cerebral edema**. The second cause of the symptoms is **pulmonary edema**, which occurs as hypoxia leads to hypoxic pulmonary vasoconstriction (see p. 687), which in turn increases total pulmonary vascular resistance, pulmonary-capillary pressure, and transudation. Certain people have an exaggerated pulmonary vascular response to hypoxia, and they are especially susceptible to AMS. Cerebral or pulmonary edema can be fatal if the exposure to hypoxia is not rapidly reversed, first by providing supplemental O_2 to breathe and then by removing the individual from the high altitude.

Although being physically fit provides some protection against AMS, the most important factor is an undefined constitutional difference. Persons who are least likely to develop symptoms ventilate more in response to the hypoxia and therefore tend to have a higher P_{O_2} and a lower P_{CO_2} . The higher P_{O_2} and lower P_{CO_2} lead to less cerebral vasodilation, and the higher P_{O_2} minimizes pulmonary vasoconstriction.

Chronic Mountain Sickness

After prolonged residence at high altitude, chronic mountain sickness may develop. The cause of this disorder is an overproduction of RBCs—an exaggerated response to hypoxia. In such conditions, the hematocrit can exceed 60%—**polycythemia**—which dramatically increases blood viscosity and vascular resistance, and increases the risk of intravascular thrombosis. The combination of pulmonary hypoxic vasoconstriction and increased blood viscosity is especially onerous for the right heart, which experiences a greatly increased load. These conditions eventually lead to *congestive heart failure* of the

right ventricle. 🏠 **N61-23**

Flight and Space Physiology

Acceleration in one direction shifts the blood volume in the opposite direction

To accelerate a rocket from rest, we must apply enough force to overcome its inertial force (i.e., its weight, the product of its mass, and the acceleration caused by gravity), as well as the frictional forces of the environment. This requirement is merely a restatement of Newton's *second law* of motion. [N61-10](#) With the rocket accelerating vertically, astronauts inside experience an inertial *G force* (see [p. 1225](#)), as required by Newton's *third law*, a force that presses the astronauts into their seats in the direction opposite that of the rocket's acceleration.

Before liftoff, an astronaut experiences only the force of gravity, +1G. As a rocket blasts off from earth, the astronaut experiences higher G forces. In early rockets, astronauts sometimes experienced G forces as high as +10G. Maximal G forces in the space shuttle were only approximately +4G ([Fig. 61-7](#)). Similarly, pilots of high-performance aircraft experience *positive* G forces as they pull out of a dive, and we all experience *negative* G forces when an aircraft hits turbulence, suddenly loses altitude, and lifts us out of our seats. Although G forces can frequently have potentially large effects on aircraft pilots, they affect astronauts only during the liftoff and re-entry phases of space flight. To ensure that acceleration effects have a minimal influence on body function, astronauts sit with their backs perpendicular to the direction of the accelerating force, so the G force acts across the chest from front to back. [N61-24](#)

FIGURE 61-7 G forces during ascent into space on the space shuttle. Before liftoff, astronauts experience +1G, the acceleration that is due to earth's gravity. After liftoff, the solid rockets burn for ~2 minutes, during which time the G force ramps up to slightly more than +3G. After the solid-rocket burn, the G force falls back to +1G. Thereafter, the main engine gradually builds up the G force to about +4G before engine cutoff. These G-force data were generated in a human centrifuge to simulate the profile of a shuttle launch. (Data from Buckey JC, Goble RL, Blomqvist CG: A new device for continuous ambulatory central venous pressure measurement. *Med Instrum* 21:238–243, 1987.)

Effects of Acceleration on Astronauts

Contributed by Arthur DuBois

If we sit in a human centrifuge with acceleration directed from head to foot, and if the seat pushes headward by the same force, blood drains from our heads and we nearly pass out at +4G. Fighter pilots wear tight leggings with air bladders inside inflated to support the circulation, which extends tolerance an extra +2G. Some pilots in an aircraft undergoing a tight turn can withstand up to +8G or +9G by straining to provoke vasoconstriction. Astronauts in takeoff or landing mode lie transversely to the acceleration or deceleration to be able to tolerate up to 9G. But above 10G, they can hardly move the chest wall to breathe.

G forces propel the body's tissues in the direction opposite that of acceleration; these forces compress soft tissues against underlying structural elements (e.g., bone) or pull these tissues away from overlying structural elements. In addition, G forces tend to shift the blood volume away from the direction of acceleration, thereby adding to the other component forces that determine blood pressure (see [p. 414](#)).

In high-performance aircraft, the rapid motions associated with changes in flight direction or altitude produce G forces that can be considerable for several minutes, exceeding 8G. Even in relatively primitive aircraft, aerobatic maneuvers can shift blood volume away from the head, resulting in transient reductions in cerebral blood flow and O₂ delivery. If these reductions are sufficiently large, they can result in loss of consciousness. The early warnings of such an event are narrowing of the visual field (i.e., loss of peripheral vision) and loss of color perception as the retina is deprived of O₂, a phenomenon called **gray-out**. The term **blackout** describes a total loss of consciousness that occurs during acceleration that lasts for tens of seconds or minutes. Pilots experiencing gray-out or blackout are at extreme risk. As early as World War II, fighter pilots used G suits that provided counterpressure to the lower extremities during repeated tight maneuvers during dogfights. The counterpressure opposed the pooling of blood in the extremities and maintained sufficient cardiac filling, cardiac output, and blood flow to the brain, thereby eliminating the tendency toward gray-out.

“Weightlessness” causes a cephalad shift of the blood volume and an increase in urine output

An astronaut in an orbiting spacecraft experiences “weightlessness,” a state of near-zero G force, also called a **microgravity** environment. Although an astronaut at an altitude of 200 km still experiences ~94% of the force of the earth's gravity at sea level (i.e., the astronaut truly has weight), the centrifugal force of the spacecraft's orbital trajectory balances the earth's gravitational force, and the astronaut experiences no net acceleration forces and thus has the sensation of weightlessness. This weightlessness, however, differs from the true near-zero-gravity environment in “outer space.”

We are adapted to life at +1G, and arteriolar tone in the lower extremities prevents pooling of blood in the capacitance vessels, thereby ensuring adequate venous return to the right heart (see [p. 576](#)). The acute effects of microgravity on the circulatory system are exactly what one would expect for a system designed to oppose the effect of gravity in a standing person: blood volume redistributes toward the head. This cephalad shift of blood volume—away from the capacitance vessels of the legs—expands the **central blood volume**, increasing the cardiac preload and increasing the filtration of plasma water into the interstitium of the facial region. The resulting edema explains the dramatically bloated facial appearance

of astronauts in microgravity within 24 hours of the launch. From this discussion, one would think that the **central venous pressure (CVP)** is higher in space. However, such an increase in CVP has been difficult to confirm.

In laboratory studies involving prolonged head-down tilt (i.e., a model intended to simulate microgravity exposure), the cephalad shift of blood volume produces the expected increase in CVP and rapid reflex responses to the apparent volume overload. First, the increased stretch on the right atrium causes release of **atrial natriuretic peptide (ANP)**; see p. 547). Second, stimulation of the low-pressure baroreceptors inhibits secretion of **arginine vasopressin**, or antidiuretic hormone (see p. 547), from the posterior pituitary. These two events increase excretion of salt and water by the kidneys (see pp. 838–840), which tends to correct the perceived volume overload and explains the tendency for astronauts to remain relatively underhydrated during space flight.

In orbiting spacecraft, the cephalad shift of blood volume, even without an increase in CVP, causes a small increase in cerebral arterial pressure and thus in blood flow to the brain. Such regional alterations in blood volume and flow do not substantially impact *total* peripheral resistance in space. Thus, mean arterial pressure and cardiac output are not significantly different from their values on the earth's surface.

Space flight leads to motion sickness and to decreases in muscle and bone mass

Despite training (e.g., in three-dimensional motion simulators), more than half of all astronauts experience motion sickness during the initial days of microgravity. **Motion sickness** (i.e., nausea and vomiting) results from conflicting sensory input to the brain regarding the position of the body. In space flight, motion sickness is the consequence of altered inertial stimulation of the vestibular system in the absence of normal gravitational forces. Nearly all cases of motion sickness resolve within the first 96 hours of microgravity exposure as the vestibular system or the CNS accommodates to the novel input.

The increased cerebral blood flow and blood volume in microgravity, accompanied by increased capillary filtration of fluid from the intravascular space, contribute to the increased incidence of headache, nausea, and motion sickness, at least during the period of transition to microgravity. These symptoms reduce performance. Astronauts attempt to minimize these effects by restricting water intake before launch.

Numerous other changes occur during prolonged residence in microgravity, many of which are related to the markedly diminished aerobic power output in space, where the force of gravity does not oppose muscle contraction. The major physiological alterations include reductions in body water content, plasma and RBC volume, total-body nitrogen stores, muscle mass, and total-body calcium and phosphate (associated with a loss in bone mass). The bone loss appears to be continuous during time in a weightless environment, whereas the other changes occur only during the first weeks in space. The reductions in plasma and RBC volumes result in a marked decrease in *maximal* cardiac output (see pp. 1214–1215), a determinant of maximal aerobic power. The reduction of muscle mass decreases the maximal force developed by muscle. The reduction in bone mass similarly decreases bone strength. Although these changes are appropriate adaptations to a microgravity environment, in which great strength and high aerobic capacity have little inherent value, they are decidedly disadvantageous on return to the earth's surface. Prolonged bed rest simulates weightlessness by causing loss of calcium from the bones and protein from the muscles.

Exercise partially overcomes the deconditioning of muscles during space flight

The intermittent loading of muscles, bone, and the cardiovascular system prevents—to some extent—the *deconditioning* effects of space flight on muscle mass and performance. Astronauts have used bungee (i.e., elastic) cords and ergometric (i.e., work-measuring) stationary bicycles to provide resistance against which to exert force. The most effective exercise regimen appears to be walking on a motor-driven treadmill with the lower body encased in a **negative-pressure chamber**. Reducing the chamber pressure to 100 mm Hg lower than ambient pressure creates transmural pressure differences across the blood vessels in the feet that are similar to pressure differences when standing upright on the earth's surface. However, this arrangement greatly exaggerates transmural pressure differences near the waist. For this reason, the astronauts also wear positive-pressure pants that compress the tissues by 70 mm Hg at the level of the waist and decrease the compression decrementally to 0 mm Hg at the feet. The net effect of the negative-pressure chamber and the graded positive-pressure pants is to create a physiological toe-to-waist gradient of transmural pressures across the blood vessels of the lower body. The aerobic activity, the impact of the feet on the treadmill, and the generation of physiological transmural pressure gradients appear to be sufficient to simulate exercise at +1G. This regimen can reduce or even eliminate the deconditioning effects of space flight.

Return to earth requires special measures to maintain arterial blood pressure

The problems associated with re-entry reflect a return to full gravity on earth's surface. The most dramatic effects result from reduced blood volume and decreased tone of the leg vessels. Both factors contribute to reductions in cardiac preload, orthostatic tolerance, and exercise capacity. It has been common practice to shield astronauts from public view immediately after return to the earth's surface, until they have regained a good orthostatic response.

In recent years, astronauts have employed various strategies just before re-entry to counter the adaptations to microgravity. The countermeasure to orthostatic intolerance is restoration of blood volume before re-entry. One means of attenuating the reduction of blood volume in space flight is an exercise program. Even a brief period (e.g., 30 minutes) of intense exercise expands plasma albumin content (see [p. 1220](#)), increasing plasma oncotic pressure and plasma volume by 10% within 24 hours. The problems with exercise programs are difficulties in logistics and the astronauts' lack of motivation. A second means of minimizing the reduced blood volume is increasing salt and fluid intake. However, this practice has proven difficult to implement because of the consequent increase in urine flow. Currently, astronauts are educated about the effects of prolonged space flight and then are maintained under continuous observation after re-entry until they have regained a normal orthostatic response. This usually occurs within hours, and certainly within 1 day, of re-entry.

The Physiology of Aging

Edward J. Masoro

Biomedical science paid surprisingly little attention to a remarkable change in human biology during the 20th century—the marked increase of human **life expectancy** [N62-1](#) in developed nations. Life expectancy is the projected mean length of life of those born in a given calendar year (e.g., 1984)—or those of a particular age (e.g., 30 years)—computed from the mortality characteristics of the entire population in a particular year (e.g., 2016). In the United States, life expectancy for men progressively increased from 47.9 years in 1900 to 76.4 years in 2012, and for women, from 50.7 years in 1900 to 81.2 years in 2012. [N62-2](#)

N62-1

Life Expectancy

Contributed by Emile Boulpaep, Walter Boron

Human life-expectancy data—such as those cited in the first paragraphs of this chapter—are computed from mortality data for a particular year (e.g., 2002)—that is, the ages of all people who happen to have died in a particular year. Note that some of these individuals who died in 2002 were born in 2002, and some were born in 1900. The first step in computing life expectancy is to use the mortality data of 2002, for example, to compute age-specific death rates, from which we can derive a variety of other statistics. For example, we can compute the life expectancy at a particular age. The **life expectancy at birth** in the United States in 2002 was 74.5 years for men and 79.9 years for women. However, based on 2012 data, the life expectancy at birth in the United States had already risen to 76.4 for men and 81.2 for women. Clearly, these life expectancies are not predictions about how long someone alive today will live. Rather, they are death rates that are frozen in time.

Another way of approaching the question is to analyze an **extinct cohort**, such as all those born in the year 1800. Based on the age at death of each member of this cohort, we could compute the true life expectancy of those born in the year 1800. Note that it is impossible—today—to predict the true life expectancy of those born in the year 2000 because that cohort is not extinct.

National Institute on Aging

Contributed by Edward Masoro

Responding to the increase in life expectancy, the United States in 1974 established the National Institute on Aging (NIA) in the National Institutes of Health. The NIA has had a major impact in the United States and throughout the world in the promotion of research on aging and in the development of geriatric medicine.

Concepts in Aging

During the 20th century, the age structure of populations in developed nations shifted toward older individuals

The fraction of the U.S. population ≥ 65 years of age was only 4% in 1900 but 12.4% in 2000. This trend in age structure is projected to continue ([Fig. 62-1](#)). Moreover, because women have a greater life expectancy, they comprised 70.5% of the population >80 years of age in 1990 in developed nations.

FIGURE 62-1 Age structure of the 1955 U.S. population and the projected age structure of the 2010 U.S. population. (From Tauber C: Sixty-five Plus in America. Washington, DC, US Bureau of the Census, 1992; revised 1993.)

The shift in the age structure of the U.S. population during the 20th century depended only modestly on an increase in life expectancy from birth. More important was the progressive decrease in birth rates. As a result, the elderly have become an ever-increasing fraction of the population, particularly in developed nations. Indeed, the effect of the post-World War II “baby boom” generation on population age structure is

clearly apparent in [Figure 62-1](#). If birth rates do not fall much further, future changes in the age structure of the U.S. population will depend mainly on further increases in life expectancy.  **N62-3**

N62-3

Socioeconomic Impact of a Graying Population

Contributed by Edward Masoro

There is concern that the increasing fraction of the population ≥ 65 years will have a negative socioeconomic impact. Part of the potential problem is cultural in that individuals expect to exit the work force at or around 65 years of age. Also, with advancing age, there is progressive deterioration of physiological capacity and an increasing prevalence of age-associated diseases. Thus, with advancing age, individuals need greater assistance in living and more medical care. In the United States, hospital admissions in 1993 for those >65 years of age were more than twice the admissions for those 45 to 64 years of age.

The definition, occurrence, and measurement of aging are fundamental but controversial issues

The **age** of an organism usually refers to the length of time the individual has existed. Biogerontologists and members of the general public alike usually use aging to mean the process of **senescence**. For example, we may say that a person is young for her age, an expression meaning that the processes of senescence appear to be occurring slowly in that person. **Aging**—the synonym for senescence that we use throughout this chapter—is *the progressive deteriorative changes during the adult period of life that underlie an increasing vulnerability to challenges and thereby decrease the ability of the organism to survive*.

Biogerontologists distinguish **biological age** from **chronological age**. Although we easily recognize the biological aging of family members, friends, and pets, it would be helpful to have a quantitative measure of the rate of aging of an *individual*. **Biomarkers of aging**—morphological and functional changes that occur with time in the adult organism—could in principle serve as a measure of senescent deterioration. Alas, a generally agreed-on panel of biomarkers of aging has yet to emerge, so it is currently impossible to quantitate the aging of individuals.

Although measuring the aging of *individuals* is difficult, it has long been possible to measure the rate of aging of *populations*. In 1825, Benjamin Gompertz, a British actuary, published a report on the human **age-specific death rate**—the fraction of the population entering an age interval (e.g., 60 to 61 years of age) that dies during the age interval. For the British population, Gompertz found that, after early adulthood, the age-specific death rate increases exponentially with increasing adult age. The same is true for other human populations ([Fig. 62-2](#)) and for many animal populations. Based on the assumption that the death rate reflects the vulnerability caused by senescence, it has generally been accepted that the slope of the curve in [Figure 62-2](#) reflects the rate of population aging. Although gompertzian and related analyses had long been viewed as the “gold standard” for measuring population aging, some biogerontologists have challenged this approach.

FIGURE 62-2 Age-specific mortality for the U.S. population (men and women) for the year 2002. Data are projections from the 2000 U.S. census.

Aging is an evolved trait

Most evolutionary biologists no longer accept the once popular belief that aging is an evolutionary adaptation with a genetic program similar to that for development. The current view is that aging evolved

by default as the result of the absence of **forces of natural selection** that might otherwise eliminate mutations that promote senescence. For example, consider a cohort of a species that reaches reproductive maturity at age X. At that age, all members of the cohort will be involved in generating progeny. Furthermore, assume that this species is evolving in a hostile environment—the case for most species. As the age of this cohort increases past X, fewer and fewer members survive so that all members of the cohort die before exhibiting senescence. In this cohort, genes with detrimental actions expressed only at advanced ages would not be subjected to natural selection. If we now move the progeny of our cohort to a highly protective environment, many may well live to ages at which the deleterious genes can express their effects, thereby giving rise to the **aging phenotype**. This general concept led biologists to put forward three genetic mechanisms that we discuss in the following three paragraphs. These are not mutually exclusive, and each has experimental support.

In 1952, Peter Medawar  [N62-4](#) proposed a variant of the foregoing model, now referred to as the **mutation-accumulation mechanism**. He proposed that most deleterious mutations in gametes will result in progeny that are defective during most of life, and natural selection removes such genes from the population. However, a very few of mutated genes will not have deleterious effects until advanced ages, and natural selection would fail to eliminate such genes.

N62-4

Peter Medawar

For more information about Peter Medawar and his work on acquired immunological tolerance, for which he shared a Nobel Prize, visit http://nobelprize.org/nobel_prizes/medicine/laureates/1960/index.html (accessed February 2015).

George Williams proposed another variant in 1957. He postulated that the genes that have deleterious actions in late life actually increase evolutionary fitness in early adulthood. Natural selection will strongly favor such alleles because they promote the ability of the young adult to generate progeny and because they have a negative impact only after reproduction—**antagonistic pleiotropy**. In this scenario, aging is a byproduct of natural selection.

In 1977, Tom Kirkwood proposed the **disposable soma theory**, according to which the fundamental life role of organisms is to generate progeny. Natural selection would apportion the use of available energy between reproduction and body (i.e., somatic) maintenance to maximize the individual's lifetime yield of progeny. As a consequence, less energy is available for somatic maintenance than needed for indefinite survival. This theory further proposes that a hostile environment increases the fraction of energy expended in reproduction, so that a smaller fraction is left for somatic maintenance.

Human aging studies can be cross-sectional or longitudinal

Measuring the effects of aging on the human physiology presents investigators with a difficulty—the subjects' life span is longer than the investigator's scientific life span.

Cross-Sectional Design

The usual approach to the foregoing difficulty is a cross-sectional design in which investigators study cohorts with several different age ranges (e.g., 20- to 29-year-olds, 30- to 39-year-olds) over a brief

period (e.g., a calendar year). However, this design suffers from two serious potential confounders. One is the **cohort effect**; that is, different cohorts have had different environmental experiences. For example, in studies of the effects of aging on cognition, a confounding factor could be that younger cohorts have had the benefit of a relatively higher level of education. If aware of a potential confounder, the investigator may be able to modify the study's design to avoid the confounder.

The second potential confounder is **selective mortality**—individuals with risk factors for diseases that cause death at a relatively young age are underrepresented in older age groups. For example, in a study on the effect of age on plasma lipoproteins, mortality at a young age from cardiovascular disease would preferentially eliminate individuals with the highest low-density lipoprotein levels.

Longitudinal Design

To circumvent the confounders encountered in cross-sectional designs, investigators can repeatedly study a subject over a significant portion of his or her lifetime. However, this longitudinal design has other problems. Long-term longitudinal studies require a special organizational structure that can outlive an individual investigator and ensure completion of the study. Even shorter longitudinal studies are very costly. Some problems are inherent in the time course of longitudinal studies, including the effect of repeated measurements on the function being assessed, changes in subjects' lifestyle (e.g., diet), dropout of subjects from the study, and changes in professional personnel and technology.

Whether age-associated diseases are an integral part of aging remains controversial

Age-associated diseases are those that do not cause morbidity or mortality until advanced ages. Examples are coronary artery disease, stroke, many cancers, type 2 diabetes, osteoarthritis, osteoporosis, cataracts, Alzheimer disease, and Parkinson disease. These are either chronic diseases or acute diseases that result from long-term processes (e.g., atherogenesis).

Most gerontologists have held the view that age-associated diseases are *not* an integral part of aging. These gerontologists developed the concept of primary and secondary aging to explain why age-associated diseases occur in almost all elderly people. **Primary aging** refers to *intrinsic* changes occurring with age, unrelated to disease or environmental influences. **Secondary aging** refers to changes caused by the interaction of primary aging with environmental influences or disease processes.

In contrast, some gerontologists adhere to a view expressed by Robin Holliday: “The distinction between age-related changes that are not pathological and those that are pathological is not at all fundamental.” Moreover, the genetic mechanisms proposed for the evolution of aging (see p. 1235) may apply equally to the processes underlying both primary and secondary aging.

Cellular and Molecular Mechanisms of Aging

In this subchapter, we consider three major classes of cellular and molecular processes that may be proximate causes of organismic aging: (1) damage caused by oxidative stress and other factors, (2) inadequate repair of damage, and (3) dysregulation of cell number. No one of these is *the* underlying mechanism of aging. The basic mechanism of aging is likely to be the long-term imbalance between damage and repair. During growth and development, the genetic program not only creates a complex structure, but also repairs damaged molecules that arise in the process. Following development is a brief adult period when damage and repair are in balance, and then begins a long-term imbalance in favor of damage.

The factors underlying the imbalance vary among species and among individuals within species, as a result of both genetic and environmental variability. For example, oxidative stress is one of many damaging processes that underlie aging, but an individual's genome and environment determine the extent to which it is an important causal factor.

Oxidative stress and related processes that damage macromolecules may have a causal role in aging

Raymond Pearl in 1928 proposed that organisms have a finite amount of a “vital principle,” which they deplete at a rate proportional to the rate of energy expenditure. Although this once-dominant “rate of living” theory of aging has now been discarded, some of its concepts helped to spawn the **oxidative stress theory of aging**. 🟡N62-5

N62-5

Free-Radical Theory of Aging

Contributed by Edward Masoro

Also contributing to the development of the oxidative stress theory of aging was the free-radical theory of aging. In 1954, Denham Harman published an article setting forth the **free-radical theory of aging**. Free radicals are highly reactive chemical entities containing unpaired outer orbital electrons. Harman proposed that free radicals are generated in living organisms from both endogenous and exogenous sources. He theorized that these highly reactive entities damage biologically important molecules, resulting in aging.

Reactive Oxygen Species

As illustrated in Figure 62-3A, **reactive oxygen species (ROS)** include molecules such as **hydrogen peroxide (H_2O_2)**, neutral free radicals such as the **hydroxyl radical ($\cdot\text{OH}$)**, and anionic radicals such as the **superoxide anion radical ($\text{O}_2^{\cdot-}$)**. **Free radicals** have an unpaired electron in the outer orbital, shown in red in Figure 62-3A. These free radicals are extremely unstable because they react with a target molecule to capture an electron, so that they become a stable molecule with only paired electrons in the outer shell. However, the target molecule left behind becomes a free radical, which initiates a chain

reaction that continues until two free radicals meet to create a product with a covalent bond. ROS—particularly $\cdot\text{OH}$, which is the most reactive of them all—have the potential to damage important biological molecules, such as proteins, lipids, and DNA. However, ROS also play important physiological roles in the oxidation of iodide anions by thyroid peroxidase in the formation of thyroid hormone (see pp. 1006–1010), as well as in the destruction of certain bacteria by reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and myeloperoxidase in phagocytic cells. **N62-6** Finally, the highly reactive signaling molecule nitric oxide (see p. 66) is a free radical (see Fig. 62-3A). **N62-7**

N62-6

Physiological Roles of ROS

For more information about ROS and their physiological roles, see the following Web page, particularly the discussion under the heading “ROS Are Essential”:

<http://users.rcn.com/jkimball.ma.ultranet/BiologyPages/R/ROS.html> (accessed February 2015).

N62-7

Nitric Oxide

For more information on the chemistry and physiology of nitric oxide (NO), visit the following websites:

1. <http://users.rcn.com/jkimball.ma.ultranet/BiologyPages/N/NO.html> (accessed February 2015)

2. <http://herkules.oulu.fi/isbn9514268512/html/i231674.html> (accessed February 2015)

Quantitatively, the most important source of ROS is the mitochondrial electron transport chain (see p. 118). Complex I and complex III of the electron transport chain generate $\text{O}_2^{\bullet -}$ as byproducts (see Fig. 62-3B). The enzyme **superoxide dismutase (SOD)** converts $\text{O}_2^{\bullet -}$ to hydrogen peroxide, which in turn can yield the highly reactive $\cdot\text{OH}$.

Only a small fraction of the oxygen used in aerobic metabolism (<1%) generates ROS. However, even that amount would be lethal in the absence of protective mechanisms. Fortunately, organisms have two potent antioxidant defenses. The major defense is enzymatic, specifically SODs, catalase, and glutathione peroxidase (Fig. 62-4). In addition, low-molecular-weight antioxidants, such as vitamins C and E, play a minor role in the defense against the metabolically produced radicals.

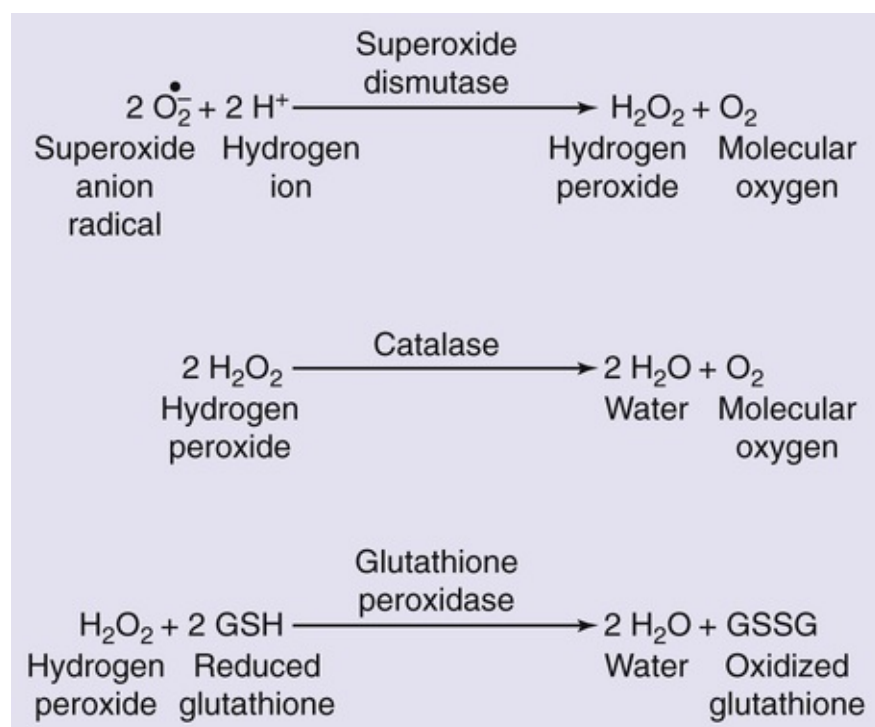

FIGURE 62-4 Enzymatic defenses against ROS. SODs eliminate the superoxide radical but generate hydrogen peroxide, which, as shown in Figure 62-3B, can yield the highly reactive hydroxyl radical via the Fenton reaction. The hydrogen peroxide is eliminated by catalase or glutathione peroxidase, which yield relatively nonreactive products: water, molecular oxygen, and oxidized glutathione.

Because these antioxidant defense mechanisms are not fully protective, the dominant concept of the oxidative stress theory is that an imbalance between the production and removal of ROS by antioxidant defenses is the major cause of aging. Nevertheless, recent studies using genetically engineered mice—with either deficient or overexpressed antioxidant enzymes—do not support this theory.

Glycation and Glycoxidation

Glycation refers to nonenzymatic reactions between the carbonyl groups of reducing sugars (e.g., glucose) and the amino groups of macromolecules (e.g., proteins, DNA) to form **advanced glycation end products (AGEs)**. Figure 62-5 shows an interaction of open-chain D-glucose with a lysine residue on a

protein, yielding a Schiff base and water. The Schiff base undergoes an intramolecular rearrangement to form an open-chain Amadori compound that undergoes the Amadori rearrangement to form a ring structure called an **Amadori product**. In cooking, Amadori products undergo a series of further reactions to produce polymers and copolymers called melanoidins, which give a brown color to cooked food. **N62-8** In humans, the Amadori product can undergo a series of intramolecular and intermolecular rearrangements that include oxidation—**glycoxidation**—to form AGE molecules. For example, the Amadori product in Figure 62-5 can either form **carboxymethyllysine** or react with an arginine residue on the same or a different protein to form a cross-link called **pentosidine**.

FIGURE 62-5 Examples of glycation, glycoxidation, and the formation of AGEs. R_1 and R_2 refer to two different proteins or two different domains of the same protein.

N62-8

Maillard Reaction

Contributed by Emile Boulpaep, Walter Boron

In the Maillard reaction, the amino group of an amino acid reacts with the carbonyl group of a sugar. As shown in the left side of Figure 62-5, the products are water plus an N-substituted glycosylamine (i.e., an open-chained Amadori compound). This reaction, discovered by the physiologist Louis Camille Maillard (see http://en.wikipedia.org/wiki/Louis_Camille_Maillard) in the 1910s is responsible for the brown color of toast and the color of seared meat. For more information about the reaction, visit the following websites:

2. http://brewery.org/library/Maillard_CS0497.html

The formation of AGEs is especially important for long-lived proteins and appears to play a role in the long-term complications of diabetes. The similarity between the aging phenotype and that of the diabetic patient led Anthony Cerami to propose the **glycation hypothesis of aging**. Although glucose is not the only reducing sugar involved in glycation, it is an important one. Thus, the level of **glycemia** is a major factor in glycation, and periods of hyperglycemia are probably the reason glycation—including the glycation of hemoglobin (see [Box 29-1](#))—is enhanced in patients with diabetes. Proteins containing AGEs exhibit altered structural and functional properties. For example, AGE formation in lens proteins of the eye probably contributes to age-associated opacification. Moreover, with advancing age, the increased stiffness of collagen in connective tissues (e.g., blood vessels; see pp. [458–459](#)) may also, in part, be due to AGE-mediated collagen cross-links. AGE-induced DNA damage may lead to alterations in genomic function.

Mitochondrial Damage

Because mitochondria are the major *source* of ROS, they are also likely to be a major *target* of oxidative damage. Damage to mitochondrial DNA (mtDNA) increases greatly with age because, unlike genomic DNA, mtDNA is not protected by histones (see pp. [75–76](#)). According to the **mitochondrial theory of aging**, the damage to mtDNA reduces the ability of the mitochondria to generate ATP, and this decreased production of ATP results in the loss of cell function and hence aging.

Somatic Mutations

Damage to genomic and mitochondrial DNA can occur as the result of radiation and other environmental agents, such as toxic chemicals. In recent years, oxidative stress has been recognized as a major source of DNA damage. Cells can repair much of the damage to DNA, and the level of damage is in a steady state between damaging and repair processes. According to the **DNA damage theory of aging**, accumulated DNA damage interferes with DNA replication and transcription, thereby impairing the ability of cells to function and causing aging. Moreover, this loss of function increases as the steady-state level of DNA damage increases with advancing age. However, it is not clear that DNA damage and mutations in somatic cells are sufficient to cause the organismic functional deterioration that characterizes the aging phenotype.

Inadequacy of repair processes may contribute to the aging phenotype

Many biogerontologists believe that even more important than damage per se is the progressive age-associated loss in the ability to repair such damage. 🍷[N62-9](#)

N62-9

Age-Associated Inadequacy of Repair Processes

Contributed by Edward Masoro

Those who believe in the concept of primary and secondary aging would feel that, because repair processes are an intrinsic component of an organism, their inadequate functioning is a component of **primary aging**. Some distinguished biogerontologists do not regard the concept of primary and secondary aging as useful. On the other hand, other distinguished biogerontologists, including some in the medical area, still subscribe to the concept.

DNA Repair

As noted above, the steady-state level of damaged DNA depends on the balance between damage and repair processes. The **DNA repair theory of aging** proposes that DNA repair declines with advancing age, which causes a rise in the steady-state level of damaged DNA and thereby compromises the integrity of the genome. Because DNA repair is a complex process, it is difficult to measure in vivo. Moreover, not only the rate but also the accuracy of the repair processes could contribute to aging. Particularly in stem cells, unrepaired or inappropriately repaired DNA may play a major role in aging.

Protein Homeostasis

In addition to oxidative stress and nonenzymatic glycation, a host of other processes—including deamidation, racemization, and isomerization—may lead to deterioration of proteins, resulting in changes in the secondary and tertiary structures as well as aggregation and fragmentation. Protecting the organism from an excessive accumulation of altered proteins are proteolytic degradation and replacement—**protein turnover**.

As noted beginning on page [33](#), cells have mechanisms for monitoring and maintaining the quality of their proteome. A major role of these mechanisms is the maintenance of the appropriate conformation of the proteins in the face of factors tending to unfold and misfold them, thereby abolishing function and often converting the protein into a toxic agent. An age-associated decrease in chaperone proteins—involved in protein folding and refolding—may be a factor in the accumulation of protein oligomers and aggregates. Small oligomers, not mature amyloid fibers, are believed to be the most toxic species in some age-associated diseases, such as Alzheimer disease. The ubiquitin/proteasome system (see pp. [33–34](#)) degrades many of the proteins not refolded by the chaperones. The catalytic activity of the proteasome may decrease with age.

The rate of total-body protein turnover in humans decreases with age. Thus, the average lifetime of most but not all protein species increases with age. Long-lived proteins in the extracellular matrix, particularly collagen and elastin, undergo age-associated changes such as oxidation, glycation, and cross-linking. These changes, for cells embedded in the matrix, probably alter proliferation, migration, and the response to extracellular signals.

Autophagy

Damaged proteins that are not either refolded or degraded by the ubiquitin/proteasome system may be broken down by lysosomal proteases. In addition to proteases, lysosomes contain enzymes that can break down lipids, carbohydrates, and nucleic acids. Degradation of cellular components by the lysosomes is referred to as autophagy, of which there are three types.

Macroautophagy involves the sequestering of proteins and other cytosolic components inside double-membrane vesicles called autophagosomes, the outer membrane of which fuses with a lysosome. The lysosomal enzymes degrade the cytosolic cargo.

In **microautophagy**, the lysosome membrane engulfs single damaged cytosolic molecules, exposing

them to the lysosomal enzymes.

In **chaperone-mediated autophagy**, a complex of a damaged cytosolic protein and a chaperone traffics and then binds to a receptor on the lysosomal membrane. Lysosomal machinery then unfolds the protein and translocates it into the lysosome.

With increasing age, lysosomes in most tissues undergo marked changes, including an expansion of the lysosomal compartment, changes in lysosomal enzyme activities, and the accumulation of undegraded lysosomal products in the form of lipofuscin. A loss of lysosomal function adversely affects all three types of autophagy. In addition, other age-associated defects may be specific to macroautophagy and to chaperone-mediated autophagy.

Dysfunction of the homeostasis of cell number may be a major factor in aging

For most cell types, the total number of cells remains nearly constant over much of adult life. An imbalance in favor of *cell division* results in hyperplasia (see p. 990), such as occurs in the prostates of elderly men, or in neoplasia (i.e., formation of new, abnormal cells), a disease process that also increases in frequency with age. An imbalance in favor of *cell removal* results in a reduction of cell number, such as occurs with age in some skeletal muscles. Of course, in cell types that are truly postmitotic in adult life, any age-associated loss of cells results in a decrease in number.

Limitations in Cell Division

In 1961, Leonard Hayflick and Paul Moorhead reported that human fibroblasts in culture could divide only a limited number of times, a phenomenon known as the **Hayflick limit** that also applies to many other somatic cell types in culture. Although Hayflick hypothesized that this limited cell proliferation in culture is a “test tube” model of aging, more recent findings indicate that the in vitro cell-culture system falls short as a valid model of organismic aging. Nevertheless, intensive study of the Hayflick limit led to consideration of the role of **telomeres** in aging.

Telomeres are elements at the ends of linear chromosomes and are composed of repeated specific DNA sequences and associated proteins. In the late 1980s, Calvin Harley found that the telomeres of human cells in culture shorten with each mitotic division. When the telomeres shorten to a critical length, the cell can no longer divide—a probable basis of the Hayflick limit. Such cells also exhibit other functional changes.

Are the telomere findings in culture systems relevant to organismic senescence? A reduction in telomere length could play a role in cell types that exhibit an age-associated decrease in cell number. Clearly, a reduction in telomere length cannot be a factor in the aging of cells that are truly postmitotic during adult life. Telomeres do not shorten in the germline, which, unlike somatic cells, contains significant levels of **telomerase**, an enzyme that catalyzes the extension of telomere length. Cancer cells are also rich in telomerase. For their work on telomeres and telomerase, Elizabeth Blackburn, Carol Greider, and Jack Szostak shared the 2009 Nobel Prize in Physiology or Medicine.  **N62-10**

N62-10

For more information about Elizabeth H. Blackburn, Carol W. Greider, and Jack W. Szostak and the work that led to their Nobel Prize, visit http://www.nobelprize.org/nobel_prizes/medicine/laureates/2009/ (accessed July 2015).

Although not associated with a major dysregulation of cell number, aging may impair the burst in proliferation necessary to meet certain challenges. For example, with increasing age, the immune system is less effective in protecting the organism from infection. An important factor may be that an antigenic challenge may be less effective in triggering a proliferation of T lymphocytes, perhaps because of an age-associated decrease in the length of T-lymphocyte telomeres.

Cell Removal

Necrosis, apoptosis, and necroptosis are major processes by which the body loses cells. **Necrosis**, a cellular response to severe trauma, is manifested by uncontrolled breakdown of cellular structure, cell lysis, and an inflammatory response. The morphological characteristics of necrosis are cell swelling and loss of membrane integrity.

Apoptosis is a form of programmed cell death (see p. 22).  **N62-11** It plays a key role in organogenesis and tissue renewal, and it also occurs in response to relatively mild damage. Apoptosis requires ATP, is gene driven, and is characterized by preservation of organelles, maintenance of membrane integrity, absence of inflammation, cell shrinkage, and fragmentation of the cell into multiple membrane-enclosed apoptotic bodies. Macrophages or neighboring cells remove the apoptotic bodies by phagocytosis.

N62-11

Apoptosis

For a summary of apoptosis, consult <http://herkules.oulu.fi/isbn9514266676/html/i267388.html> (accessed February 2015).

Three interacting pathways  **N62-12** lead to apoptosis (Fig. 62-6). First, in the **extrinsic pathway**, extracellular signals bind to cell-surface receptors—**death receptors (DRs)**—of the tumor necrosis factor receptor (TNFR) family, which are examples of receptors that act at least in part via regulated proteolysis (see p. 48). The DRs include Fas, TNFR1, DR3, DR4, and DR5, all of which have a **cytosolic death domain**. In the case of the receptor **Fas**, the homotrimeric ligand called **FasL** binds to three Fas molecules, which results in the formation of a trimer of ligand-receptor complexes. This clustering allows the death domains on Fas to bind to death domains of an intracellular adapter protein called FADD (Fas-associated death domain). Death-effector domains of FADD recruit several copies of **procaspase-8**, the aggregation of which leads to the autoproteolytic cleavage of procaspase-8 and thereby releases active **caspase-8**. This **initiator caspase** is a member of the **caspase** family of proteolytic enzymes.  **N62-13** Relatively small numbers of caspase-8 molecules, by proteolytic cleavage, activate much larger numbers of **executioner caspases**, including caspases 3 and 7, as well as another initiator caspase called caspase-9. This amplified cascade results in the proteolysis of numerous cytosolic and nuclear proteins, leading to apoptosis. One caspase target is a **gelsolin**, which, when cleaved, severs actin filaments and leads to a loss of normal cell shape. Another caspase target is **inhibitor of caspase-activated deoxyribonuclease (ICAD)**, which normally binds to and thereby inactivates **caspase-**

activated deoxyribonuclease (CAD). Cleavage of ICAD releases active CAD, which translocates to the nucleus and severs chromosomal DNA. **N62-14**

Interacting Pathways

Contributed by Emile Boulpaep, Walter Boron

For an example of interacting pathways in a connected diagram, see Figure 25-1C.

N62-13

Caspases

Contributed by Edward Masoro

Caspases are proteases with a cysteine (Cys) residue at their active site. They cleave a protein substrate at an aspartate (Asp) residue. The Cys and Asp give rise to the name **caspase**. They exist as inactive precursors called **procaspases** or **zymogen caspases**. Only after cleavage of the procaspase does the

enzyme become active.

N62-14

ICAD and CAD

Contributed by Emile Boulpaep, Walter Boron

CAD (caspase-activated DNase) is also known as DNA fragmentation factor 40 (DFF40) because it has a mass of 40 kDa. It is encoded by the *DFFB* gene.

ICAD (inhibitor of caspase-activated DNase) is also known as DNA fragmentation factor 45 (DFF45) because it has a mass of 45 kDa. It is encoded by the *DFFA* gene.

The second pathway involves damage to the mitochondria (see Fig. 62-6), triggered by such agents as ROS, increases in $[Ca^{2+}]$ in the mitochondrial matrix, and caspases. The result is the opening of a large pore in the mitochondrial inner membrane—the **mitochondrial permeability transition pore (MPTP)**—followed by mitochondrial swelling, rupture of the outer mitochondrial membrane, and release of cytochrome c into the cytosol. There, **apoptotic protease-activating factor (Apaf-1)** complexes with the cytochrome c and ATP, forming a wheel-like structure that contains seven of each molecule—an **apoptosome**. This structure recruits seven procaspase-9 molecules, which results in the formation of active caspase-9 and thus commits the cell to apoptosis.

The third pathway is triggered by damage to nuclear DNA (see Fig. 62-6). The tumor-suppressor p53, a nuclear protein, recognizes certain base-pair mismatches. In cases of modest DNA damage, p53 increases the transcription of p21, which in turn halts the cell cycle. In cases of more severe DNA damage, p53 upregulates its own transcription. In addition, p53 increases the transcription of the proapoptotic protein **Bax** and decreases the transcription of the antiapoptotic protein **Bcl-2**. The increase in the Bax/Bcl-2 ratio appears to activate MPTP, thereby precipitating the events leading to apoptosis described in the second pathway. Finally, p53 also upregulates Fas, which reinforces the first pathway.

Dysregulation of apoptosis promotes aging. Failure of apoptosis to remove damaged cells could result in abnormal function or increase the risk of cancer. Excess apoptosis would unnecessarily decrease cell number.

Necroptosis is a second important mode of regulated cell death. Like apoptosis, necroptosis involves a highly orchestrated sequence of intracellular signaling reactions. Notably, necroptosis is activated in response to many of the same microbial or environmental stresses that trigger apoptosis. In cells in which the stress or infectious stimuli suppress initiator caspases (e.g., caspase-8; see pp. 1241–1242) or executioner caspases (e.g., caspase-3; see pp. 1241–1242), the cells activate the necroptotic cascade as an alternative to apoptosis. Indeed, some microbial pathogens express potent inhibitors of host cell caspases, which allows the pathogens to establish protected replicative niches within infected host cells.

Engagement of the necroptosis pathway facilitates death of the infected host cells with consequent release of the internalized pathogens into extracellular compartments, where multiple innate immune mechanisms more readily destroy the pathogens. These mechanisms include complement-mediated cytolysis and neutrophil-mediated production of reactive oxygen and nitrogen species (see pp. [1238–1239](#)). Recently identified pronecrototic gene products include the RIP1 and RIP3 protein kinases and the mixed-lineage kinase-like (MLKL) protein, which appears to function as an endogenous porin (see p. [109](#)) when recruited to the plasma membrane. Ischemia-reperfusion injury of organs such as the brain, kidney, and liver may trigger necroptosis and thus cell death.

Aging of the Human Physiological Systems

The age-related changes just described at the cellular and molecular levels can also manifest themselves as deterioration of physiological systems. Although here we discuss *typical* age-related changes in physiological systems, the extent of change among individuals may range from barely perceptible to very marked. Indeed, a subset of individuals shows minimal physiological deterioration—these people have undergone “successful” aging. Many individuals show marked deterioration with age in all physiological systems (Box 62-1), whereas other individuals exhibit little or no deterioration in one or more systems. Although the nature of the aging process is similar in the two sexes—except, of course, for the reproductive system—important quantitative differences exist. Because of the great reserve capacity or redundancy of some physiological systems, the effect of aging on a physiological process is often not apparent until either the individual faces an unusual challenge or function has fallen below some critical level.

Box 62-1

Frailty

Frailty is a geriatric syndrome prevalent at advanced ages. It has been estimated that 7% of people over age 65 years and 20% of those over age 80 years are frail. According to the Fried frailty criteria, frailty exists when at least three of the following characteristics are present*:

- Unintentional weight loss (4 kg in the past year)
- Self-reported exhaustion
- Weakness (reduced grip strength)
- Slow walking speed
- Low physical activity

Individuals defined as frail using these criteria are at increased risk of falls, worsening disability, hospitalization, and death. Frailty is distinct from age-associated diseases and is not a synonym for **disability**—the inability to perform one or more of the so-called activities of daily living. In a cohort identified as frail, ~27% of the individuals had neither comorbidity nor disability. However, comorbidity and disability are risk factors for becoming frail, and disability is an adverse outcome of frailty.

Although it had long been believed that long-term involuntary weight loss is due to reduced food intake, newer insights indicate that this is not the case. For example, attempting to increase the patient's food intake is usually not effective. Moreover, rats of advanced ages undergo a prolonged terminal weight loss, even though many of the rats exhibited an *increase* and not a decrease in food intake during the weight loss (a phenomenon not related to a particular pathological process). The likelihood and extent of frailty rises with increasing steepness as the number of abnormal physiological processes increases.

Aging people lose height and lean body mass but gain and redistribute fat

Women reach peak height by age 16 to 17 years and men by 18 to 19 years. After reaching these peaks, height starts to decline, primarily due to compression of the cartilaginous disks between the vertebrae and loss of vertebral bone. This decline begins at ~20 years of age in women and at 25 years in men. By the age of 70 years, height has fallen 2.5% to 5% from the peak level.

In most Americans, **body mass** increases until middle age in both sexes and begins to decrease after age 70. **Fat-free mass** is defined as body mass minus **adipose-tissue fat mass**, and **lean body mass** is defined as fat-free mass minus both bone mass and non-adipose-tissue fat mass. Both fat-free mass and lean body mass progressively decrease over most of adult life in both sexes. Although a sedentary lifestyle may contribute to this loss, lifelong athletes also show a progressive age-associated loss in fat-free mass and lean body mass.

Adipose-tissue fat mass increases with adult age, with the extent differing markedly among individuals. Although a sedentary lifestyle may be a factor, even physically fit individuals who do not exhibit an age-associated increase in body mass show a small but progressive increase in adipose-tissue fat mass (in parallel with the aforementioned decrease in fat-free body mass). In addition, the distribution of body fat changes with increasing age, with an accumulation of fat around abdominal viscera and in abdominal subcutaneous tissue. At the same time, a decrease in fat occurs in the extremities and the face; facial fat loss can give rise to a gaunt look. Visceral adipose tissue is an important source of cytokines (often referred to as adipokines) that promote inflammation, which in turn may play a role in the occurrence and progression of senescence.

Aging thins the skin and causes the musculoskeletal system to become weak, brittle, and stiff

Skin

As is clearly evident from cosmetic advertisements, most of us use the skin as an indicator of aging. Intrinsic aging (see p. 1237) is manifest in skin areas protected from the sun, such as the buttocks. The additional damage caused by long-term exposure to the sun's ultraviolet radiation is called *photoaging*.

In intrinsic aging, the thickness of the **epidermis** (see pp. 383–384) decreases slightly, with no change in the outermost epidermal layer, the stratum corneum. The rate of generation of keratinocytes, which end their lives as the stratum corneum, slows with age, which increases the dwell time of stratum-corneum components. The decreasing number of melanocytes reduces photoprotection, and the decreasing number of Langerhans cells reduces immune surveillance.

Intrinsic aging of the **dermis** affects mainly the extracellular matrix. The amount of elastin and collagen decreases, and their structures change. Glycosaminoglycan composition also changes. 🍌N62-15 As a result, the dermis thins by ~20% and becomes stiffer, less malleable, and thus more vulnerable to injury.

Effect of Aging on Glycosaminoglycan Composition

Contributed by Edward Masoro

As indicated in the text, glycosaminoglycan composition changes with aging. However, the story is complex. The levels of **hyaluronic acid** and the proteoglycan **versican**—which contains **chondroitin sulfate (CS)** and **dermatan sulfate (DS)**—are decreased. On the other hand, the level of the proteoglycan **decorin**—which also contains CS and DS—is increased.

Photoaging increases the extent of most intrinsic age changes in both the epidermis and dermis, and it has additional effects. For example, photoaging causes coarse wrinkles, which occur minimally or not at all because of intrinsic aging.

Aging also reduces the number and function of sweat glands as well as the production of sebum by sebaceous glands. The number of active melanocytes in hair follicles decreases, resulting in graying of hair. Nail growth also slows with increasing age.

Skeletal Muscle

A steady loss in skeletal muscle mass—**sarcopenia**—occurs with aging, particularly beyond 50 years, and it primarily reflects a loss of number and, to a lesser extent, size of muscle fibers. The sarcopenia is due in part to inactivity, but also to a progressive loss of the motor neurons innervating type II motor units (see pp. [228–229](#) and [1205–1206](#)), which are recruited less frequently. With loss of their motor nerve, affected muscle fibers either atrophy and die or become innervated by a sprout that emerges from a healthy axon nearby. This process of reinnervation ultimately results in larger motor units and thus a decrement in fine motor control. The reduction in muscle strength and power is often a major cause of disability in the elderly. However, strength training in elderly persons can increase the *size* of the fibers and can thereby increase muscle mass.

Bone

Remodeling of bone (see pp. [1057–1058](#)) occurs throughout adult life; it involves the coordinated activity of **osteoclasts**, which resorb bone, and **osteoblasts**, which form bone. During early adulthood, bone resorption and formation are in balance. However, starting late in the third decade of life, resorption exceeds formation, which leads to a slow progressive loss in bone mass. This loss is likely due to the action on osteoblasts of ROS, decreased insulin-like growth factor 1 (IGF-1), and increased parathyroid hormone. In women, bone loss accelerates for 5 to 10 years following menopause because of decreased levels of estrogen and increased levels of follicle-stimulating hormone (FSH). After this postmenopausal period, the rate of bone loss with increasing age in women returns to that of men. In addition to the factors noted for bone loss in 20- and 30-year-olds, low levels of estrogen and testosterone are also involved at advanced ages. Bone loss can progress to **osteoporosis** (see [Box 52-3](#)), defined by the World Health Organization as a bone mineral density ≥ 2.5 SD below the mean values for young adults. Osteoporosis, a major problem in geriatric medicine, carries a heightened risk of bone fractures.

Synovial Joints

The synovial joint permits free movement of the bones linked by the joint. With increasing adult age, joint flexibility falls, due mainly to the aging of **articular cartilage**. This cartilage thins and exhibits altered mechanical features, including decreased tensile stiffness, fatigue resistance, and strength. These changes

are partly due to decreases in water content. Aging impairs the function of **chondrocytes**, increases the cross-linking of collagen, and causes a loss of proteoglycans. The age-related changes in joint cartilage undoubtedly play a major role in the development of **osteoarthritis**.

The healthy elderly experience deficits in sensory transduction and speed of central processing

It is a common misconception that advancing age causes marked deterioration in the nervous system. However, in the absence of neurodegenerative disorders such as Alzheimer disease and Parkinson disease, impairment of the nervous system with age is much less severe than often believed.

Sensory Functions

Most sensory systems exhibit some deterioration with age. Sensitivity to **touch** decreases, as do the abilities to sense vibration and to distinguish two spatially distinct points of contact. Proprioception, including the vestibular system of the inner ear, also deteriorates somewhat. As discussed on page 1194, the loss of thermoregulatory ability, a serious problem for many elderly, occurs in part because of an impaired ability to sense heat and cold.

Hearing loss, particularly of high-frequency sound, is an almost invariable consequence of advancing age. This impairment is usually caused by loss of hair cells of the organ of Corti (see pp. 377–378), but it can also stem from loss of nerve cells of the auditory nerve or from a reduced blood supply to the cochlea. A deficit in central processing can make it difficult for some elderly to distinguish spoken words from background noise.

Vision also deteriorates with increasing age. A progressive loss in the power of accommodation—**presbyopia**—occurs during adult life (see p. 362). Almost all elderly have a reduced number of retinal cones, lessened ability to alter pupil size in response to light intensity, and decreased ability of retinal rods to adapt to low intensity light (see pp. 368–369). In addition, age-associated diseases—cataracts, glaucoma, and macular degeneration—can markedly decrease vision in many of the elderly.

The ability to detect and discriminate among sweet, sour, salty, and bitter **taste** qualities (see p. 356) deteriorates somewhat at advanced ages, along with a marked reduction in **olfaction** (see pp. 354–356). Because “taste” involves both gustation and olfaction, many elderly live in a world of “pastel” food flavors.

Motor Functions

A major effect of aging is the slowing of **reaction time**: the time elapsed between the occurrence of a stimulus and the motor response to it. This delay is observable in simple responses and becomes more pronounced as the complexity of the response increases (e.g., the need to make a choice among responses). Thus, a hallmark of nervous system aging is the slowing of **central processing**. One result is that the elderly tend to execute movements more slowly than the young.

The ability to maintain posture and balance deteriorates with increasing age. Slowing of central processing is a factor, but decreased muscle strength and deterioration of vision and proprioception also play important roles. Not surprisingly, the elderly have a high incidence of falls. Even when *capable* of walking at normal speeds, the healthy elderly *tend* to walk more slowly than the young and take shorter and more frequent steps. This walking pattern is less taxing for a person with knee and ankle joints that are less flexible, aids in maintaining balance, and enables a deteriorating sensory system to monitor

hazards more effectively.

Cognitive Functions

Although lay people generally believe that cognitive functions (e.g., intelligence, memory, learning) decline with advancing age, the cognitive decline is not marked in the absence of dementia. The decline that does occur in the healthy elderly may reflect the slowing of central processing. The capacity to use knowledge is not decreased in the healthy aged, but the ability to solve novel problems does decline. Certain types of memory deteriorate with advancing age, such as remembering where the car keys were left, but other types are not lost, such as retrieving conceptual information. Older people are capable of learning, but they do so less quickly than younger people.

Aging causes decreased arterial compliance and increased ventilation-perfusion mismatching

Atherosclerosis can cause marked deterioration of cardiovascular function in the elderly, and chronic obstructive pulmonary disease (see p. 619) can do the same for pulmonary function. However, in the absence of such diseases, age-associated changes in these physiological systems are modest.

Cardiovascular Function

As discussed on pages 458–459, aging decreases the distensibility of arteries. The decreased compliance elevates systolic pressure, slightly decreases diastolic pressure, and thus widens pulse pressure. Afterload (see p. 526), the resistance to ejection of blood from the left ventricle, increases with advancing age, primarily because of reduced arterial compliance. The increased afterload causes thickening of the left ventricular wall, which involves an increase in size but not number of myocytes.

Preload, the end-diastolic volume of blood in the left ventricle (see p. 526), does not change with age in subjects at rest. Although early diastolic filling falls, a compensatory increase in left atrial contraction enhances late-diastolic filling.

Many elderly experience postural hypotension (see p. 576) because of age-associated blunting of the arterial baroreceptor reflex.

Pulmonary Function

The strength and endurance of the respiratory muscles decrease with age, primarily because of atrophy of type IIa muscle fibers. Lung volumes—both static volumes and forced expiratory volumes (e.g., FEV₁; see p. 602) gradually decrease with age. In addition, small airways have an increased tendency to collapse (atelectasis) because of degeneration of the collagen and elastin support structure. The result is impaired ventilation of dependent lung regions, ventilation-perfusion mismatch, and reduced resting arterial P_{O₂}. In spite of these functional deteriorations, healthy elderly people do not experience a failure of either ventilation or gas exchange. However, when challenged by homeostatic disturbances—such as those occurring during ill health—old people may have compromised pulmonary function.

Exercise

Maximal O₂ uptake ($\dot{V}_{O_{2max}}$; see pp. 1213–1214) declines progressively with aging in physically trained individuals and even more so in untrained individuals of the same chronological age. Decreasing muscle

mass as well as reduced cardiovascular and pulmonary function probably all contribute to the decline in $\dot{V}_{O_{2\max}}$, and the relative importance of each factor varies among individuals.

The cardiovascular system responds to exercise differently in the elderly than in the young. For a given increase in cardiac output, heart rate rises less and stroke volume rises more in the elderly. Because the aging heart is less responsive to adrenergic stimulation, the increase in stroke volume is due primarily to the Frank-Starling mechanism (see pp. 524–526). Thus, during exercise, the left ventricular end-diastolic and end-systolic volumes increase, and maximal left ventricular ejection fraction falls.

The elderly exhibit a decrease in the pulmonary diffusing capacity (D_L)—due in part to decreased alveolar capillary volume—and an increase in the ventilation-perfusion mismatch. These alterations in pulmonary function have been implicated in the decrease in $\dot{V}_{O_{2\max}}$.

The ability of the body to respond to physical conditioning decreases with aging. Nevertheless, skeletal muscle and the cardiovascular system remain responsive to exercise into the 10th decade of life.

Glomerular filtration rate falls with age in many but not all people

On average, renal blood flow decreases progressively with increasing age. Basal levels of renin and angiotensin II are lower in older adults. Cross-sectional studies show that glomerular filtration rate (GFR) starts to decline at 30 years of age and thereafter falls linearly with age. However, analysis of longitudinal data from the Baltimore Longitudinal Study of Aging reveals that one third of the participants exhibited the GFR decline predicted from cross-sectional analysis, one third had a steeper decline, and one third had no decline at all. Thus, an age-associated decline in GFR is not inevitable.

Cross-sectional studies indicate that renal-tubule transport functions decrease with age. The kidneys do not respond as effectively to changes in sodium load, do not dilute or concentrate urine as effectively, and also have a somewhat impaired ability to excrete potassium, phosphate, and acid.

Many elderly men and women experience bladder symptoms such as urgency, nocturia, and frequency. The capacity and compliance of the urinary bladder decrease with advancing age, and the number of uninhibited or inappropriate detrusor contractions increases. These changes make it more difficult to postpone voiding, a symptom known as **urgency**. A decrease in detrusor activity can contribute to a decreased rate of bladder emptying as well as an increase in residual bladder volume after voiding—poor emptying performance, which contributes to **urinary frequency**. 🧠**N62-16** Sensory dysfunction also can underlie the above pathologic conditions.

N62-16

Effect of Aging on Bladder Function

Contributed by Edward Masoro

A decrease in the rate of urine flow with age occurs in both sexes. In men, **benign prostatic hypertrophy (BPH)** is the major factor causing an increase in residual bladder volume after voiding. However, a small increase with age often occurs in women as well.

Aging has only minor effects on gastrointestinal function

Although gastrointestinal (GI) problems are the second most common reason for hospital admission of elderly patients, the GI system functions in the healthy elderly about as well as in the young. Although a loss of ability to secrete gastric acid was previously thought to be a part of aging, it is now clear that this loss is limited to those infected with *Helicobacter pylori* (see [Box 42-3](#)). The loss of skeletal muscle at both ends of the GI tract can lead to minor age-related decreases in function (i.e., chewing, swallowing, fecal continence). [N62-17](#) Minor decreases occur in secretion by exocrine glands. Liver mass and hepatic blood flow, as well as the clearance of certain drugs, decrease significantly. Moreover, the elderly experience a delay in hepatic regeneration following damage.

N62-17

Effect of Aging on the GI Tract

Contributed by Edward Masoro

Aging is associated with a loss in the mass of the skeletal muscles at both ends of the GI tract. At the oral end, muscles involved in mastication and the oropharyngeal phase of swallowing tend to decrease in mass. However, the loss usually is not sufficient to cause morbidity.

The frequency of fecal incontinence increases with age. The problem is underreported because it is often hidden, even from physicians. Weakness of the external anal sphincter is often an important contributory factor.

Aging causes modest declines in most endocrine functions

Total energy expenditure decreases with age, primarily due to decreases in physical activity. An age-associated decrease in the **resting metabolic rate (RMR)**; see p. [1170](#)) reflects a decrease in fat-free mass (see p. [1243](#)); that is, the RMR per kilogram of fat-free mass does not decrease.

Insulin

The impaired **glucose tolerance** (see [Fig. 51-3](#)) that usually occurs with aging is due primarily to increased **insulin resistance**, which in turn results mainly from increased adiposity and decreased physical activity. However, aging per se does play a small role. In addition, the elderly exhibit an age-associated decrease in insulin secretion that does not appear to be due to the lifestyle factors underlying insulin resistance.

Growth Hormone and IGF-1

Aging diminishes the concentrations of growth hormone (GH) generated by the pulsatile action of somatotrophs. A consequence is greatly reduced plasma IGF-1 concentrations (see p. [997](#)). However, it is not clear what roles, if any, these alterations play in age-associated physiological deterioration.

Adrenal Steroids

The basal, circadian, and stimulated secretion of **cortisol** exhibits little age-related change. **Aldosterone** secretion is also well preserved. In contrast, the plasma concentration of the adrenal cortical hormone **dehydroepiandrosterone** (see p. [1097](#)) decreases markedly with increasing age.

Thyroid Hormones

Thyroid function appears to be unaffected by age into the ninth decade of life. However, in centenarians plasma levels of thyroid-stimulating hormone (TSH) may decrease due to decreased secretion, and free triiodothyronine levels may fall due to impaired 5'/3'-deiodinase (see p. [1010](#)).

Parathyroid Hormone

Plasma **parathyroid** hormone levels increase with advancing age due to an increase in the rate of secretion by the parathyroid glands.

Gonadal Hormones

Reproductive ability in women abruptly ceases at ~50 years of age with the occurrence of the **menopause** (see pp. [1127–1128](#)). Men do not undergo an abrupt change in reproductive function during middle age. However, a progressive decrease in male reproductive and related functions does occur, often referred to as the **andropause** (see [Box 54-1](#)).

Aging Slowly

Slowing the aging process, and thereby extending life, has been a human goal throughout recorded history and probably in preliterate times as well. The marked increase in human life expectancy in the 20th century could be viewed as achieving this goal. However, much of that increase results from prevention of premature deaths related to infections and other environmental hazards. It remains to be established how much, if any, of the increase relates to slowing the aging process. Indeed, over the centuries, the life span of the oldest of the old in human populations has changed little, although the fraction of the population reaching these advanced ages has increased significantly. In contrast, both environmental and genetic manipulations can markedly extend the maximal life span of a population in several other species.

Caloric restriction slows aging and extends life in several species, including some mammals

Restricting the food intake of rats, starting soon after weaning, increases both mean and maximum life span of both genders of several strains of rats—as first reported by Clive McCay in 1935. [N62-18](#) The marked increase in rat longevity is graphically illustrated by the survival curves in [Figure 62-7](#). Manipulation of the components (protein, fat, carbohydrate, minerals, and vitamins) of a purified rat diet revealed that the life-extending action of food restriction in rats results from caloric restriction rather than from a specific dietary component.

FIGURE 62-7 Survival curves for a population of 115 male F344 rats fed ad libitum and 115 male F344 rats with restricted food intake (i.e., 60% of the ad libitum intake) starting at 6 weeks of age. Note that both the median length of life and the maximum length of life are markedly greater in the restricted population. (Data from Yu BP, Masoro EJ, Murata I, et al: Life span of SPF Fischer 344 male rats fed ad libitum or restricted diets: Longevity, growth, lean body mass, and disease. *J Gerontol* 37:130–141, 1982. Copyright The Gerontological Society of America. Reproduced by permission of the publisher.)

Clive McCay

For information on the scientific papers of Clive McCay (1920–1967), visit <http://rmc.library.cornell.edu/EAD/htmldocs/RMA01087.html> (accessed February 2015).

Reducing food intake also extends the life of mice,  **N62-19** hamsters, dogs, fish, several invertebrate animal species, and yeast. Studies of rhesus monkeys, still in progress, indicate that food restriction may also extend the life of nonhuman primates.

Effects of Caloric Restriction in Mice

Contributed by Edward Masoro

A recent study by James Nelson and colleagues, in which 41 inbred mouse strains were used, indicates that caloric restriction–induced life extension in different mouse genotypes is less common than heretofore believed. Determining how common it is among species for caloric restriction to extend life will require much more research.

Does food restriction extend life by slowing aging processes? This is a difficult question to answer because of the lack of consensus on how to measure the aging of individuals or populations. However, for two reasons, most biogerontologists believe that food restriction does retard aging processes. First, compared to rodents of the same age fed ad libitum, those on life-extending food-restriction regimens maintain physiological processes more like those of young animals. Second, life-extending food restriction delays the onset or progression of most age-associated diseases, including neoplastic, degenerative, and immune diseases.

During the past 70 years, many hypotheses have been proposed regarding the biological mechanisms underlying the life-prolonging action of food restriction, but none is firmly established. McCay proposed that caloric restriction extends life by retarding growth. However, later observations showed that food restriction, even when initiated in young adult rats or middle-age mice, significantly extends life. Another early hypothesis was that food restriction extends life by markedly reducing adipose fat mass. However, it is possible to dissociate the effects of food restriction on longevity from the effects on fat mass in rats and mice.

Currently, the most popular view is that food restriction extends life by decreasing oxidative stress (see pp. [1238–1239](#)). Indeed, life-extending food restriction does decrease the accumulation of age-associated oxidative damage. It also causes a sustained reduction in plasma glucose levels, which could reduce glycation and glycoxidation (see p. [1239](#)), as well as a marked and sustained reduction in plasma levels of insulin and IGF-1. Genetic studies strongly indicate that decreasing insulin-like signaling (see pp. [996](#)

and 1041–1042) extends life. Thus, the decrease in the levels of insulin and IGF-1 may well play an important role in food restriction–induced life extension.

Inhibiting the mTOR pathway (see Fig. 51-6) by administering rapamycin extends the life of 600-day-old mice. **N62-20** This mTOR pathway senses nutrient status and is involved in regulating eukaryotic growth and cell division. Thus, it is possible that inhibiting the TOR pathway has a role in caloric restriction–induced life extension.

N62-20

TOR Kinases and the Aging Process

Contributed by Edward Masoro

To survive, organisms must be able to respond to variable nutrient availability by transitioning between anabolic and catabolic status. The **mTOR** (mechanistic target of rapamycin) protein kinase systems play a major role in enabling organisms to do so. Rapamycin—which is produced by a soil bacterium and has antifungal, anticancer, and immunosuppressive actions—inhibits mTOR protein kinases.

In mammals, mTOR is found in two multiprotein complexes: mTORC1 and mTORC2. The protein components of **mTORC1** are mTOR, Raptor (scaffold protein), Pras 40 (mTORC1 inhibitor), Deptor (mTOR inhibitor), mLST8 (function unknown), and tti1 and tel2 (stability and assembly proteins). The components of **mTORC2** are mTOR, Rictor (scaffold protein), mSn1 (scaffold protein), Protor 1/2 (assists in activation of SGK1), Deptor, mLST8, tti1, and tel2.

The activity of mTORC1 is promoted by amino acids, energy level, growth factors, and oxygen and is inhibited by stress. In turn, mTORC1 promotes growth, cell-cycle progression, macromolecular biosynthesis, and metabolism, and inhibits autophagy.

The activity of mTORC2 is promoted by growth factors. In turn, mTORC2 promotes metabolism, cytoskeletal organization, and cell survival.

These actions of the TOR complexes involve a spectrum of signaling pathways and are the subject of continuing research.

It was long held that rapamycin inhibits only the activity of TORC1. However, it is now clear that the sustained use of rapamycin also inhibits TORC2, which complicates the interpretation of studies based on the actions of this inhibitor.

That TOR may play a role in aging was first suggested in 2003 when Vellai and colleagues reported that a deficiency of TOR kinases more than doubles the life span of *C. elegans*. A year later, Kapahi and coworkers reported that inhibiting TOR kinases extends the life span of *Drosophila*. And in 2005, Kaeberlein and colleagues reported that deletion of TORC1 increases the replicative life span of yeast. In 2009, Harrison and colleagues reported that rapamycin fed to genetically heterogeneous mice starting late in life (600 days of age) extended the life span by 14% in females and 9% in males.

In a recently published study, Lamming and coworkers hypothesized that rapamycin extends the life span of females more than that of males because it inhibits both TORC1 and TORC2. Indeed, when they decreased or eliminated the Rictor component of TORC2 in mice by any of three different procedures, they found that the life span was significantly decreased in male mice but was not affected in female mice.

Although much more remains to be learned about the role of TOR kinases in aging, it is clear that, via their signaling networks, they play important roles in the aging process. Studies aimed at defining these networks in relation to aging almost certainly will be a major focus of future biogerontological research.

Another theory of the antiaging action of caloric restriction is **hormesis**, defined as the beneficial effects resulting from cellular responses to mild repeated stress, which would stimulate maintenance and repair processes and thereby retard aging. Food restriction at the level that extends life is a mild stress repeated daily. Moreover, food-restricted rodents have an increased ability to cope with acute, intense damaging agents, such as surgery, toxic chemicals, and high environmental temperatures.

Genetic alterations can extend life in several species

Caloric restriction is an example of environmental factors that determine longevity. It is also clear that genetics has a major role. For example, the large differences in life span among species (from <100 days in *Drosophila melanogaster* to <5 years in mice to >100 years in humans) are primarily, if not exclusively, due to genetic differences. Moreover, selective breeding within a species can produce populations that differ significantly in longevity.

Longevity probably depends on multiple genes. Thus, it was a surprise when Friedman and Johnson reported in 1988 that mutation of the *age-1* gene of the nematode worm, *Caenorhabditis elegans*, results in a marked increase in longevity. The *age-1* gene encodes a phosphatidylinositol 3-kinase (see p. 1042), which is a component of the insulin-like signaling pathway. Note that *C. elegans*, like other invertebrates, does not have separate signaling pathways for insulin (see pp. 1041–1042) and IGF-1 (see p. 996), as do mammals. The mutation of *age-1* studied by Friedman and Johnson causes some loss of function—that is, it is a weak mutation. Among other single-gene manipulations found to extend the life of *C. elegans*, *D. melanogaster*, *Saccharomyces cerevisiae*, and mice, many but not all involve a partial loss of function of the insulin-like signaling pathway.

Ames dwarf mice have a recessive point mutation in the *Prop-1* gene, which results in the inability of the pituitary to produce GH, TSH, and prolactin. These mice have low levels of thyroid hormone, IGF-1, and insulin. Significantly, these dwarf mice have an increased life span compared with littermates not homozygous for this mutation.

Further support for a role of reduced insulin-like signaling in life extension comes from studies of mice with a knockout of the *GHR/BP* gene, which encodes the GH receptor and its proteolytic cleavage

product, GH-binding protein. This knockout mouse exhibits growth retardation, high plasma GH levels, low plasma IGF-1 levels, and significant life extension. Reducing the expression of the insulin receptor by 85% to 90% in the adipose tissue of mice resulted in significant life extension. Finally, overexpression of the ***KLOTHO*** gene  **N36-12** in mice increases the plasma level of Klotho protein, which suppresses insulin and IGF-1 signaling and extends the life of mice.

In yeast, overexpression of the *sir2* gene increases the level of a sirtuin protein called Sir2 and extends the replicative life of *S. cerevisiae*. Sir2 is a deacetylase that stabilizes ribosomal DNA. Sir2 may play a role in other species. Indeed, stimulating Sir2 orthologs extends the life span of *C. elegans*, *D. melanogaster*, and human cell lines. However, it is not yet clear whether sirtuin proteins play an important role in the life-prolonging action of caloric restriction.

Proposed interventions to slow aging and extend human life are controversial

We have already seen that life-extending dietary manipulations, pharmacological interventions, and genetic alterations may have in common that they modify signaling pathways. Because these signaling pathways probably interact extensively, it is attractive to speculate that they are components of a longevity-signaling network.

The practice of **antiaging medicine** is becoming popular and plays an important role in preventing the occurrence and progression of certain age-associated diseases. For example, exercise and diet can reduce the incidence of coronary heart disease, stroke, and type 2 diabetes. However, some practitioners of antiaging medicine, as well as suppliers of pharmaceuticals and nutraceuticals, claim to have “magic bullets” that slow or even reverse aging. These purported magic bullets include antioxidants (e.g., vitamins E and C), amino acids (e.g., methionine), drugs (e.g., deprenyl), and hormones (e.g., melatonin, dehydroepiandrosterone, GH, estrogen, and testosterone). No credible evidence indicates that any of these agents will reverse or even slow human aging. Aside from the question of efficacy is the possibility of long-term adverse effects of these supposed magic bullets. Combined estrogen and progestin therapy is a case in point. Although hailed for relieving the symptoms of menopause, this hormone replacement therapy was long in use before a well-designed study uncovered its harmful effects on the cardiovascular system. In light of the animal studies strongly indicating that insulin-like signaling promotes aging, the current use of recombinant GH is of concern. Although GH increases lean body mass in the elderly, well-designed studies are needed before GH is used as an antiaging agent.

Voice, [1088.e1b](#)

Voiding phase, [738](#)

Voltage, [107.e1b](#)

Voltage clamping, [152](#)

Voltage dependence, [157](#), [178–180](#)

Voltage dependent, [324](#)

Voltage difference across the membrane (V_m), [106](#)

Voltage-gated channels, [182–199](#), [162.e1b](#)

calcium (Ca^{2+}), [182–185](#), [190t](#), [191f](#)

crystal structures of, [186f](#), [185.e1t–185.e2t](#), [185.e3b–185.e4b](#)

evidence for, [182.e1b](#)

genetic defects of, [188b–189b](#)

potassium (K^+), [182–185](#)

selectivity filters, [184](#), [184f](#), [184.e1b](#)

sodium (Na^+), [182–185](#)

voltage sensors, [184](#), [184f](#)

Voltage-gated Ca^{2+} channels (Cavs), [190](#)

Voltage-gated Na^+ channels (Navs), [187](#)

Voltage-gated–like (VGL) ion channel superfamily, [182](#)

Voltage-sensing domain, [184](#), [184f](#)

Voltage sensor, [184](#), [184f](#), [229](#)

Volume

distribution, [602–604](#)

gas, [594.e1b–594.e3b](#)

lung, [601–605](#), [601f](#), [603f](#)

Volume of blood plasma, [740.e1b](#)

Volume distensibility, [454](#)

Volume of distribution, [602](#)

Volume of exhaled air (V_E), [676.e1b](#)

Volume of inhaled air (V_I), [676.e1b](#)

Volume of protein-free plasma solution, [740.e1b](#)

Volume overload, [530b](#)

Volumes, [602](#)

Vomiting, [877b](#), [635.e1b](#)

V-type H pumps, [127](#)

W

Wall tension, [457.e2b](#)

Wallerian degeneration, [268b](#)

Warming, [600](#)

Warming functions, [600](#)

Warmth receptors, [386](#), [1198–1199](#)

Warren J. Robin, [876.e1b](#)

Washout, [831](#)

Waste products, [959](#)

Waster material excretion, [855](#)

Water, [476](#), [376.e1b](#)

- carbon dioxide (CO₂) interactions, [630f](#)
- fraction of filtered water reabsorbed, [733](#)
- transport, [102–140](#). *See also* [Transport](#)
- water-pump controversy, [906b](#)
- water-salt balance integration, [836–849](#)

Water channel AQP1, [435](#)

Water channels, [762](#)

Water diuresis, [762b](#), [808](#)

Water loading, [809](#)

Water permeability coefficient, [468.e1b](#)

Water-soluble nutrients, [567](#)

Waves, [493](#)

Waves, peristaltic, [735–736](#)

WBCs, [429](#)

Weak acid, [628](#)

Weak base, [628–629](#). *See also* [Bases](#)

Weak cross-bridge formation, [235](#)

Wedge pressure, [519](#)

Wet gases, [592b](#), [592f](#)

Wheal, [571](#)

When net flow falls to nearly zero (i.e., J_v is ~ 0), [474](#)

Whether the system is open or closed, [630](#)

White reaction, [571](#)

Whole brain or large portions of the brain can be isolated in vitro, [702.e1b](#)

Whole-cell currents, [154](#)

Whole-cell voltage clamping, [154](#)

Whooping cough, [1167](#)

Wiggers diagram, [508.e1b](#)

Willebrand factor (vWF), [439](#)

Wilson disease, [971b](#)

Wind chill factor, [1197](#)

Wolff-Parkinson-White (WPW) syndrome, [504](#)

Wolffian ducts, [1079–1080](#)

Work, [520](#), [521.e1b](#)

Work (W), [240](#)

Working memory, [328](#)

X

x minimum, [516](#)

¹³³Xe scanning, [683.e1b](#)

X-chromosome, partial deletion of, [1075b](#)

X-chromosome ring, [1075b](#)

X-inactivation, [94](#)

X-linked congenital stationary night blindness, [192b](#)

Xenobiotics, [71](#)

Y

Y chromosomes, [1075–1076](#)

y minimum, [516](#)

Yalow, Rosalyn, [976](#), [976.e1b](#)

Yawn, [616.e1b](#)

Yawns, [704b](#), [718b–719b](#)

YY peptide, [857](#), [857t](#), [857.e1b](#)

Z

Z disk

Zinc fingers, [82](#)

Zipper

 basic (bZIP), [83](#)

 Leucine family, [83](#)

Zollinger-Ellison syndrome, [866](#)

Zona basalis, [1126](#)

Zona compacta, [1125–1126](#)

Zona pellucida, [1122](#)

Zona spongiosa, [1126](#)

Zonal fibers, [362](#)

Zone I, [946](#)

Zone II, [947–948](#)

Zone III, [947](#)

Zones, active, [210](#)

Zygote, [1074](#), [1132](#)

Zymogen caspases, [1241.e1b](#)

Zymogen granules, [880](#)

Zymogens, [887–888](#), [887t](#)
