Vibration transfer is not as simple as it might seem because sound starts as a set of pressure waves in the air (within the ear canal) and ends up as pressure waves in a watery cochlear fluid within the inner ear. Air and water have very different **acoustic impedances**, which is the tendency of each medium to oppose movement brought about by a pressure wave. **N15-10** This impedance mismatch means that sound traveling directly from air to water has insufficient pressure to move the dense water molecules. Instead, without some system of compensation, >97% of a sound's energy would be reflected when it met a surface of water. The middle ear serves as an *impedance-matching device* that saves most of the aforementioned energy by two primary methods. First, the tympanic membrane has an area that is ~20-fold larger than that of the oval window, so a given pressure at the air side (the tympanic membrane) is amplified as it is transferred to the water side (the footplate of the stapes). Second, the malleus and incus act as a lever system, which again amplifies the pressure of the wave. Rather than being reflected, most of the energy is successfully transferred to the liquids of the inner ear.

Acoustic Impedance

Contributed by Barry Connors

Acoustic impedance is defined as the ratio of sound pressure to volume velocity. **Air** has a low acoustic impedance. Consider what happens when the membrane of a loudspeaker is displaced in air. Because the air is very compressible, the displacement of the loudspeaker membrane does not increase air pressure very much, but it does impart a high volume velocity to the air. On the other hand, the acoustic impedance of **water** is about 10,000 times higher than that of air because water is highly incompressible and dense. Consider what happens when we submerge a watertight loudspeaker in water. If we were able to displace the loudspeaker membrane to the same extent just as fast as we did when the loudspeaker was in air, we would find that the resulting pressure wave would be far greater. (The way we set up this thought experiment, the volume velocities would be identical in the two cases.)

In the case of the ear—which takes advantage of (1) the area difference between the tympanic membrane and the oval window, and (2) the lever action of the ossicles—the pressure amplification occurs at the expense of volume velocity, thereby conserving energy.

Two tiny muscles of the middle ear, the **tensor tympani** and the **stapedius**, insert onto the malleus and the stapes, respectively. These muscles exert some control over the stiffness of the ossicular chain, and their contraction serves to dampen the transfer of sound to the inner ear. They are reflexively activated when ambient sound levels become high. These reflexes are probably protective and may be particularly important for suppression of self-produced sounds, such as the roar you produce in your head when you speak or chew.

The cochlea is a spiral of three parallel, fluid-filled tubes

The auditory portion of the inner ear is mainly the **cochlea**, a tubular structure that is ~35 mm long and is coiled 2.5 times into a snail shape about the size of a large pea ([Fig. 15-20](#)). Counting its stereovilli, the cochlea has a million moving parts, which makes it the most complex mechanical apparatus in the body.

FIGURE 15-20 The cochlea. Reissner's membrane and the basilar membrane divide the cochlea into three spiraling fluid-filled compartments: the scala vestibuli, the scala media, and the scala tympani. (Data from Philine Wangemann, Kansas State University.)

The cut through the cochlea in the lower left drawing in [Figure 15-20](#) reveals five cross sections of the spiral. We see that in each cross section, two membranes divide the cochlea into three fluid-filled compartments. On one side is the compartment called the **scala vestibuli** (see [Fig. 15-20](#), right side), which begins at its large end near the oval window—where vibrations enter the inner ear. **Reissner's membrane** separates the scala vestibuli from the middle compartment, the **scala media**. The other boundary of the scala media is the **basilar membrane**, on which rides the **organ of Corti** and its hair cells. Below the basilar membrane is the **scala tympani**, which terminates at its basal or large end at the round window. Both the oval and round windows look into the middle ear (see [Fig. 15-19B](#)).

Both the scala vestibuli and scala tympani are lined by a network of **fibrocytes** and filled with **perilymph** (see [pp. 372–373](#)). Like its counterpart in the vestibular system, this perilymph is akin to CSF (i.e., low $[K^+]$, high $[Na^+]$). Along the lengths of scala vestibuli and scala tympani, the two perilymphs communicate through the leaky interstitial fluid spaces between the fibrocytes. At the apex of the cochlea,

the two perilymphs communicate through a small opening called the **helicotrema**. Cochlear perilymph communicates with vestibular perilymph through a wide passage at the base of the scala vestibuli (see Fig. 15-17B), and it communicates with the CSF through the cochlear aqueduct.

The scala media is filled with **endolymph**. Like its vestibular counterpart—with which it communicates through the ductus reuniens (see Fig. 15-17B)—auditory endolymph is extremely rich in K^+ . Unlike vestibular endolymph, which has the same voltage as the perilymph, auditory endolymph has a voltage of +80 mV relative to the perilymph (see Fig. 15-20, right side). This **endocochlear potential**, which is the highest transepithelial voltage in the body, is the main driving force for sensory transduction in both inner and outer hair cells. Moreover, loss of the endocochlear potential is a frequent cause of hearing loss. A highly vascularized tissue called the stria vascularis secretes the K^+ into the scala media, and the resulting K^+ gradient between endolymph and perilymph generates the strong endocochlear potential.

The **stria vascularis** is functionally a two-layered epithelium (Fig. 15-21). Marginal cells separate endolymph from a very small intrastrial compartment inside the stria vascularis, and basal cells separate the intrastrial compartment from the interstitial fluid of the spiral ligament, which is contiguous with perilymph. Gap junctions connect one side of the basal cells to intermediate cells and the other side of the basal cells to fibrocytes of the spiral ligament. This architecture is essential for generation of the endocochlear potential.

FIGURE 15-21 K^+ secretion into the endolymph by the stria vascularis. (Data from Philine Wangemann, Kansas State University.)

The fibrocytes are endowed with K^+ uptake mechanisms that maintain a high $[K^+]_i$ in the intermediate cells. The KCNJ10 K^+ channel of the intermediate cells generates the endocochlear potential. The K^+ equilibrium potential of these cells is extremely negative because of the combination of their very high $[K^+]_i$ and the very low $[K^+]$ of the intrastrial fluid. Finally, the marginal cells support the endocochlear potential by mopping up the K^+ from the intrastrial fluid—keeping the intrastrial $[K^+]$ very low—and

depositing the K^+ in the endolymph through a KCNQ1 K^+ channel.

Inner hair cells transduce sound, whereas the active movements of outer hair cells amplify the signal

The business end of the cochlea is the **organ of Corti**, [N15-11](#) the portion of the basilar membrane that contains the hair cells. The organ of Corti stretches the length of the basilar membrane and has four rows of hair cells: one row of ~3500 **inner hair cells** and three rows with a total of ~16,000 **outer hair cells** (Fig. 15-22). In the *auditory* system, the arrangement of stereovilli is also quite orderly. The hair cells lie within a matrix of supporting cells, with their apical ends facing the endolymph of the scala media (Fig. 15-23A). The stereovilli of *inner* hair cells (see Fig. 15-23B) are unique in that they float freely in the endolymph. The stereovilli of the *outer* hair cells (see Fig. 15-23C) project into the gelatinous, collagen-containing **tectorial membrane**. The tectorial membrane is firmly attached only along one edge, with a sort of hinge, so that it is free to tilt up and down.

FIGURE 15-22 Hair cells of the cochlea. This scanning electron microscopic image shows the outer and inner hair cells of the organ of Corti of a chinchilla after removal of the tectorial membrane. The three rows of outer hair cells are on the bottom, and the single row of inner hair cells is along the top. (Courtesy of I. Hunter-Duvar, MD, and R. Harrison, PhD, the Hospital for Sick Children, Toronto, Canada.)

N15-11

Alfonso Giacomo Gaspare Corti

Contributed by Emile Boulpaep, Walter Boron

While working in the laboratory of Albert von Kölliker in Würzburg (Germany), Corti (1822–1876) developed novel histological staining techniques that allowed him to distinguish individual—and previously unidentified—elements within the cochlea. It was he who first identified the sensory organ that now bears his name, the **organ of Corti**.

How do air pressure waves actually stimulate the auditory hair cells? Movements of the stapes against the oval window create traveling pressure waves within the cochlear fluids. Consider, for example, what happens as sound pressure falls in the outer ear.

Step 1: Stapes moves outward. As a result, the oval window moves *outward*, causing pressure in the scala vestibuli to decrease. Because the perilymph that fills the scala vestibuli and scala tympani is incompressible and the cochlea is encased in rigid bone, the round window moves *inward* (see [Fig. 15-19B](#)).

Step 2: Scala vestibuli pressure falls below scala tympani pressure.

Step 3: Basilar membrane bows upward. Because Reissner's membrane is very thin and flexible, the low scala vestibuli pressure pulls up the incompressible scala media, which in turn causes the **basilar membrane** (and the organ of Corti) to bow upward.

Step 4: Organ of Corti shears toward hinge of tectorial membrane. The upward bowing of the basilar membrane creates a shear force between the hair bundle of the outer hair cells and the attached tectorial membrane.

Step 5: Hair bundles of outer hair cells tilt toward their longer stereovilli.

Step 6: Transduction channels open in outer hair cells. Because K^+ is the major ion, the result is *depolarization* of the outer hair cells (see [Fig. 15-16A](#))—**mechanical to electrical transduction**. The transduction-induced changes in membrane potential are called **receptor potentials**. The molecular mechanisms of these V_m changes (see [p. 373](#)) are basically the same as in vestibular hair cells.

Step 7: Depolarization contracts the motor protein prestin. Outer hair cells of mammals express very high levels of **prestin** (named for the musical notation *presto*, or fast). The contraction of myriad prestin molecules—each attached to its neighbors—causes the outer hair cell to contract; this phenomenon is unique to outer hair cells and is called **electrical to mechanical transduction** or

electromotility. Conversely, hyperpolarization (during *downward* movements of the basilar membrane) causes outer hair cells to elongate. Indeed, imposing changes in V_m causes cell length to change by as much as ~5%. The change in shape is fast, beginning within 100 μ s. The mechanical response of the outer hair cell does not depend on ATP, microtubule or actin systems, extracellular Ca^{2+} , or changes in cell volume. Prestin is a member of the SLC26 family of anion transporters (see [p. 125](#)), although it is not clear whether prestin also functions as an anion transporter.

Step 8: Contraction of outer hair cells accentuates *upward* movement of the basilar membrane.

Conversely, outer hair cell *elongation* (during *downward* movements of the basilar membrane) accentuates the *downward* movement of the basilar membrane. Thus, outer hair cells act as a **cochlear amplifier**—sensing and then rapidly accentuating movements of the basilar membrane. The electromotility of outer hair cells is a prerequisite for sensitive hearing and, as we will see (see [pp. 380–383](#)), the ability to discriminate frequencies sharply. In the absence of prestin, the cochlear amplifier ceases to function and animals become deaf.

Step 9: Endolymph moves beneath the tectorial membrane. The upward movement of the basilar membrane—accentuated by the cochlear amplifier—forces endolymph to flow out from beneath the tectorial membrane, toward its tip.

Step 10: Inner hair cell hair bundles bend toward longer stereovilli. The flow of endolymph now causes the free-floating hair bundles of the inner hair cells to bend.

Step 11: Transduction channels open in inner hair cells. As in the outer hair cells, the result is a *depolarization*.

Step 12: Depolarization opens voltage-gated Ca^{2+} channels. $[\text{Ca}^{2+}]_i$ rises in the inner hair cells.

Step 13: Synaptic vesicles fuse, releasing glutamate. The neurotransmitter triggers action potentials in afferent neurons, relaying auditory signals to the brainstem. Note that the main response to depolarization is very different in the two types of hair cells. The outer hair cell contracts and thereby amplifies the movement of the basilar membrane. The inner hair cell releases neurotransmitter.

When the stapes reverses direction and moves inward, all of these processes reverse as well. The basilar membrane bows downward. In the outer hair cells, transduction channels close, causing *hyperpolarization* and cell elongation. The accentuated downward movement of the basilar membrane causes endolymph to move back under the tectorial membrane. In inner hair cells, transduction channels close, causing hyperpolarization and reduced neurotransmitter release.

A fascinating clue to the existence of the cochlear amplifier was the early observation that the ear not only detects sounds, but also generates them! Short click sounds trigger an “echo,” a brief vibration of the tympanic membrane that far outlasts the click. A microphone in the auditory canal can detect the echo, which is called an evoked **otoacoustic emission**. On occasion, damaged ears may produce spontaneous otoacoustic emissions that can even be loud enough to be heard by a nearby listener.  **N15-12** The source of evoked otoacoustic emissions is the prestin-mediated cochlear amplifier: sounds outside the ear lead to vibrations of the basilar membrane, which trigger active length changes of the outer hair cells, and these in turn accentuate the vibrations of the basilar membrane (step 8). In otoacoustic emission, the system then works in reverse as the basilar membrane causes pressure waves in the cochlear fluids,

which vibrate the oval window, ossicles, and tympanic membrane, and finally generates new pressure waves in the air of the auditory canal.

N15-12

Otoacoustic Emissions

Contributed by Philine Wangemann

Amplification by the outer hair cells evokes vibrations of the basilar membrane that travel through the middle ear, set the tympanic membrane in motion, and produce a sound that comes out of the ear canal. Clinically most relevant are **transient otoacoustic emissions** and **distortion-product otoacoustic emissions**. Transient otoacoustic emissions are sounds that are detected in the ear canal milliseconds after a very brief stimulus. Amplification by the outer hair cells is nonlinear, which means that the cochlea produces and emits **distortion products**. Distortion products in response to two pure tones at nearby frequencies (f_1 and f_2) relate to these stimuli by simple math, for example, $2f_1 - f_2$ or $2f_2 - f_1$. Transient otoacoustic emissions and distortion-product otoacoustic emissions provide useful clues for the evaluation of outer hair cell function.

The cochlea receives sensory and motor innervation from the **auditory or cochlear nerve**, a branch of CN VIII. We discuss the motor innervation below (see [p. 382](#)). The cell bodies of the sensory or *afferent* neurons of the cochlear nerve lie within the spiral ganglion, which corkscrews up around the axis of the cochlea (see [Fig. 15-20](#), lower left). The dendrites of these neurons contact nearby hair cells, whereas the axons project to the cochlear nucleus in the brainstem (see [Fig. 16-15](#)). About 95% of the roughly 30,000 sensory neurons (i.e., type I cells) of each cochlear nerve innervate the relatively few inner hair cells—the true auditory sensory cells. The remaining 5% of spiral ganglion neurons (i.e., type II cells) innervate the abundant outer hair cells, which are so poorly innervated that they must contribute very little *direct* information about sound to the brain.

The frequency sensitivity of auditory hair cells depends on their position along the basilar membrane of the cochlea

The subjective experience of tonal discrimination is called **pitch**. Young humans can hear sounds with frequencies from ~20 to 20,000 Hz. 🟡N15-13 This range is modest by the standards of most mammals because many hear up to 50,000 Hz, and some, notably whales and bats, can hear sounds with frequencies >100,000 Hz.

N15-13

Auditory Range

Contributed by Philine Wangemann

The auditory frequency range of the human ear is well adapted to the perception of speech, which encompasses frequencies between 60 and 12,000 Hz. We can comfortably hear sounds with amplitudes from 0 to 120 dB SPL. Higher sound pressure levels cause pain and destruction of the ear 🟡N15-9.

Typical sound pressure levels are 20 dB SPL for whispering, 60 dB SPL for normal conversation, 80 dB SPL for loud traffic, and 120 dB SPL for a nearby train horn.

A continuous pure tone (see [p. 376](#)) produces a wave that travels along the basilar membrane and has different amplitudes at different points along the base-apex axis ([Fig. 15-24A](#)). Increases in sound *amplitude* cause an increase in the *rate* of action potentials in auditory nerve axons—**rate coding**. 🗣️

N15-14 The *frequency* of the sound determines *where* along the cochlea the cochlear membranes vibrate most—high frequencies at one end and low at the other—and thus which hair cells are stimulated. This selectivity is the basis for **place coding** in the auditory system; that is, the frequency selectivity of a hair cell depends mainly on its longitudinal position along the cochlear membranes. The cochlea is essentially a spectral analyzer that evaluates a complex sound according to its pure tonal components, with each pure tone stimulating a specific region of the cochlea.

A ENVELOPE OF MAXIMUM WAVE AMPLITUDES

B EFFECT OF FREQUENCY ON ENVELOPE POSITION

C UNCOILED COCHLEA

FIGURE 15-24 Waves along the basilar membrane of the cochlea. **A**, As a wave generated by a sound of a single frequency travels along the basilar membrane, its amplitude changes. The green and yellow curves represent a sample wave at two different times. The upper and lower broken lines (i.e., the envelope) encompass all maximum amplitudes of all waves, at all points in time. Thus, a wave can never escape the envelope. The figure exaggerates the amplitudes of the traveling waves ~1 million-fold. **B**, For a pure tone of 10,000 Hz, the envelope is confined to a short region of the basilar membrane near the stapes. For pure tones of 4000 Hz and 200 Hz, the widest part of the envelope moves closer to the helicotrema. **C**, The cochlea narrows in diameter from base to apex, whereas the basilar membrane tapers in the opposite direction.

N15-14

Rate Coding

Contributed by Philine Wangemann

Amplitude information is transmitted by **rate coding**. Rate coding refers to the principle that increases in sound *amplitude* result in an increase the *rate* of action potentials. Cooperation between neurons is required to code the full range of sound pressure levels from 0 to 120 dB SPL.

Using optical methods to study cadaver ears, Georg von Békésy found that sounds of a particular frequency generate relatively localized waves in the basilar membrane and that the envelope of these waves changes position according to the frequency of the sound (see Fig. 15-24B). Low frequencies generate their maximal amplitudes near the apex. As sound frequency increases, the envelope shifts progressively toward the basal end (i.e., near the oval and round windows). For his work, von Békésy  **N15-15** received the 1961 Nobel Prize in Physiology or Medicine.

N15-15

Georg von Békésy

For more information about Georg von Békésy and the work that led to his Nobel Prize, visit <http://www.nobel.se/medicine/laureates/1961/index.html> (accessed December 2014).

Two properties of the basilar membrane underlie the low-apical to high-basal gradient of resonance: taper and stiffness (see Fig. 15-24C). If we could unwind the *cochlea* and stretch it straight, we would see that it tapers from base to apex. The *basilar membrane* tapers in the opposite direction—wider at the apex, narrower at the base. More important, the narrow basal end is ~100-fold stiffer than its wide and floppy apical end. Thus, the basilar membrane resembles a harp. At one end—the base, near the oval and round windows—it has short, taut strings that vibrate at high frequencies. At the other end—the apex—it has longer, looser strings that vibrate at low frequencies.

Although von Békésy's experiments were illuminating, they were also paradoxical. A variety of experimental data suggested that the tuning of living hair cells is considerably sharper than the broad envelopes of von Békésy's traveling waves on the basilar membrane could possibly produce.  **N15-16** Recordings from primary auditory nerve cells are also very sharp, implying that this tuning must occur within the cochlea, not in the CNS. Some enhancement of tuning comes from the structure of the inner hair cells themselves. Those near the base have shorter, stiffer stereovilli, which makes them resonate to higher frequencies than possible with the longer, floppier stereovilli on cells near the apex.

N15-16

Sharpening of Cochlear Tuning

Contributed by Philine Wangemann

Outer hair cells express the motor protein prestin along the lateral cell wall, which is responsible for electromotility. Transduction-mediated depolarization of outer hair cells during upward movements of the basilar membrane causes prestin to contract; this shortens the hair cell body and increases the upward movement of the basilar membrane (see Fig. 15-23). Conversely, hyperpolarization during downward movements of the basilar membrane expands prestin, elongates the outer hair cells, and enlarges the downward movement of the basilar membrane. This electromotility, which amplifies and sharpens the peak of the sound-induced traveling wave, is a prerequisite for the sensitivity of hearing and the ability to sharply discriminate frequencies (see Fig. 15-25).

FIGURE 15-25 Peak movement of the basilar membrane. The graph illustrates the displacement of the basilar membrane in response to a pure tone as a function of distance along the base-to-apex axis. The dashed line indicates the displacement threshold for triggering of an electrical response. (Data from Ashmore JF: Mammalian hearing and the cellular mechanisms of the cochlear amplifier. In Corey DP, Roper SD [eds]: Sensory Transduction. New York, Rockefeller University Press, 1992, pp 396–412.)

The blue curve in Figure 15-25 approximates von Békésy's envelope of traveling waves for a passive basilar membrane from cadavers. It is important to note that von Békésy used unnaturally loud sounds. With reasonable sound levels, the maximum *passive* displacement of the basilar membrane would be slightly more than 0.1 nm. This distance is less than the pore diameter of an ion channel and also less than the threshold (0.3 to 0.4 nm) for an electrical response from a hair cell. However, measurements from the basilar membrane in *living* animals (the orange curve in Fig. 15-25) by very sensitive methods show that movements of the basilar membrane are much more localized and much larger than predicted by von Békésy. The maximal physiological displacement is ~20-fold greater than threshold and ~40-fold greater than that predicted by the passive von Békésy model. Moreover, the physiological displacement decays sharply on either side of the peak, >100-fold within ~0.5 mm (recall that the human basilar membrane has a total length of >30 mm).

Both the extremely large physiological excursions of the basilar membrane and the exquisitely sharp tuning of the cochlea depend on the **cochlear amplifier** (see p. 380). Indeed, selectively damaging outer hair cells—with large doses of certain antibiotics, for example—considerably dulls the sharpness of cochlear tuning and dramatically reduces the amplification.

The brain can control the tuning of hair cells. Axons that arise in the superior olivary complex in the brainstem synapse mainly on the outer hair cells and, sparsely, on the afferent axons that innervate the inner hair cells. **N15-17** Stimulation of these olivocochlear efferent fibers suppresses the responsiveness of the cochlea to sound and is thought to provide **auditory focus** by suppressing

responsiveness to unwanted sounds—allowing us to hear better in noisy environments ([Box 15-2](#)). The main efferent neurotransmitter is acetylcholine (ACh), which activates ionotropic ACh receptors (see [pp. 206–207](#))—nonselective cation channels—and triggers an entry of Ca^{2+} . The influx of Ca^{2+} activates Ca^{2+} -activated K^{+} channels, causing a hyperpolarization—effectively an inhibitory postsynaptic potential—that suppresses the electromotility of outer hair cells and action potentials in afferent dendrites. Thus, the efferent axons allow the brain to control the gain of the inner ear.

Box 15-2

Cochlear Implants

The most common cause of human deafness is damage to the hair cells of the cochlea. **N15-18** This damage can be caused by genetic factors, a variety of drugs (e.g., some antibiotics, including quinine), chronic exposure to excessively loud sounds, and other types of disease. Even when all hair cells have been destroyed, if the auditory nerve is intact, it is often possible to restore substantial hearing with a cochlear implant.

N15-18

Conductive Hearing Loss

Contributed by Philine Wangemann

Conductive hearing losses are disorders that compromise the conduction of sound through the external ear, tympanic membrane, or middle ear. Pressure differences across the tympanic membrane (eardrum) can rupture it. Accumulations of fluid in the middle ear can lead to conductive hearing losses that are seen particularly often in children with **middle ear infections (otitis media)**. With proper treatment, the hearing loss due to otitis media is usually self-limited. **Otosclerosis**, which stiffens the ossicular chain, is another common cause of conductive hearing loss.

Treatments for conductive hearing loss encompass a palette of devices including hearing aids and middle ear implants. **Hearing aids** amplify the sound in the external ear canal. Prosthetic devices can replace the tympanic membrane and the ossicular chain. **Middle ear implants** are clamped onto the incus and enhance the vibrations of the ossicular chain.

A cochlear implant **N15-19** is essentially an electronic cochlea. Most of the system resides outside the body. The user wears a headpiece with a microphone, which is connected to a small, battery-powered digital speech processor. This processor sends signals to a miniature radio transmitter next to the scalp, which transmits digitally encoded signals—no wires penetrate the skin—to a receiver/decoder that is surgically implanted in the mastoid bone behind the ear. A very thin and flexible set of wires carries the signals through a tiny hole into the basal end of the cochlea, where an array of 8 to 22 electrodes lies adjacent to the auditory nerve endings (where healthy hair cells would normally be) along the cochlea. Each electrode activates a small portion of the auditory nerve axons.

N15-19

Cochlear Implants

Contributed by Emile Boulpaep, Walter Boron

See the following websites for more information on cochlear implants:

<http://www.nidcd.nih.gov/health/hearing/pages/coch.aspx>

<http://ecs.utdallas.edu/loizou/cimplants/tutorial/>

The cochlear implant exploits the tonotopic arrangement of auditory nerve fibers. By stimulating near the base of the cochlea, it is possible to trigger a perception of high-frequency sounds; stimulation toward the apex evokes low-frequency sounds. The efficacy of the implant can be extraordinary. Users require training of a few months or longer, and in many cases, they achieve very good comprehension of spoken speech, even as it comes across on a telephone.

As the technology and safety of cochlear implants have improved, so has their popularity. By 2010, >200,000 people were using cochlear implants worldwide, ~80,000 of them infants and children. The best candidates for cochlear implants are young children (optimally as young as 1 year) and older children or adults whose deafness was acquired after they learned some speech. Children older than ~7 years and adults whose deafness preceded any experience with speech generally do not fare as well with cochlear implants. The systems of sensory neurons in the brain, including the auditory system, need to experience normal inputs at a young age to develop properly. When the auditory system is deprived of sounds early in life, it can never develop completely normal function even if sensory inputs are restored during adulthood.

N15-17

Central Processing of Auditory Patterns

Contributed by Philine Wangemann

Auditory patterns are analyzed in the medial geniculate and the auditory cortex. Neurons in these areas are often highly specialized and respond only to a specific frequency and intensity pattern. Interpretation of sound elements requires cortical input beyond the auditory cortex.

Central processing is clinically evaluated by **auditory brainstem recordings**. The coordinated firing of groups of neurons in responses to brief stimuli (clicks or tone pips) produces transient voltage fluctuations that can be detected with surface electrodes. Distinctive voltage fluctuations occur 2 to 12 ms after the stimulus and can be associated with neuronal activity in the auditory pathway including the cochlear nerve, cochlear nucleus, and superior olivary complex.

Somatic Sensory Receptors, Proprioception, and Pain

Somatic sensation is the most widespread and diverse of the body's sensory systems (*soma* means “body” in Greek). Its receptors are distributed throughout the body instead of being condensed into small and specialized sensory surfaces, as most other sensory systems are arranged. Somatosensory receptors cover the skin, subcutaneous tissue, skeletal muscles, bones and joints, major internal organs, epithelia, and cardiovascular system. These receptors also vary widely in their specificity. The body has mechanoreceptors to transduce pressure, stretch, vibration, and tissue damage; thermoreceptors to gauge temperature; and chemoreceptors to sense a variety of substances. Somatic sensation (or **somesthesia**) is usually considered to be a combination of at least four sensory modalities: the senses of touch, temperature, body position (proprioception), and pain (nociception).

A variety of sensory endings in the skin transduce mechanical, thermal, and chemical stimuli

To meet a wide array of sensory demands, many kinds of specialized receptors are required. Somatic sensory receptors range from simple bare nerve endings to complex combinations of nerve, muscle, connective tissue, and supporting cells. As we have seen, the other major sensory systems have only one type of sensory receptor or a set of very similar subtypes.

Mechanoreceptors, which are sensitive to physical distortion such as bending or stretching, account for many of the somatic sensory receptors. They exist throughout our bodies and monitor the following: physical contact with the skin, blood pressure in the heart and vessels, stretching of the gut and bladder, and pressure on the teeth. The transduction site of these mechanoreceptors is one or more unmyelinated axon branches. Our progress in understanding the molecular nature of mechanosensory transduction has been relatively slow. Similar to the transduction process in hair cells, that in cutaneous mechanoreceptive nerve endings probably involves the gating of ion channels. Some of these channels belong to the TRP superfamily (see [Table 6-2](#), family No. 5).

Thermoreceptors respond best to changes in temperature, whereas **chemoreceptors** are sensitive to various kinds of chemical alterations. In the next three sections, we discuss mechanoreceptors, thermoreceptors, and chemoreceptors that are located in the skin.

Mechanoreceptors in the skin provide sensitivity to specific stimuli such as vibration and steady pressure

Skin protects us from our environment by preventing evaporation of body fluids, invasion by microbes, abrasion, and damage from sunlight. However, skin also provides our most direct contact with the world. The two major types of mammalian skin are *hairy* and *glabrous*. **Glabrous skin** (or hairless skin) is found on the palms of our hands and fingertips and on the soles of our feet and pads of our toes ([Fig. 15-26A](#)). **Hairy skin** makes up most of the rest and differs widely in its hairiness. Both types of skin have an outer layer, the **epidermis**, and an inner layer, the **dermis**, and sensory receptors innervate both. The receptors in the skin are sensitive to many types of stimuli and respond when the skin is vibrated, pressed, pricked,

or stroked, or when its hairs are bent or pulled. These are quite different kinds of mechanical energy, yet we can feel them all and easily tell them apart. Skin also has exquisite sensitivity; for example, we can reliably feel a dot only 0.006 mm high and 0.04 mm across when it is stroked across a fingertip. The standard Braille dot is 167 times higher!

FIGURE 15-26 Sensors in the skin. (Data from Mendelson M, Loewenstein WR: Mechanisms of receptor adaptation. *Science* 144:554–555, 1964.)

The sensory endings in the skin take many shapes, and most of them are named after the 19th-century European histologists who observed them and made them popular. The largest and best-studied mechanoreceptor is **Pacini's corpuscle**, which is up to 2 mm long and almost 1 mm in diameter (see [Fig. 15-26B](#)). Pacini's corpuscle is located in the subcutaneous tissue of both glabrous and hairy skin. It has an ovoid capsule with 20 to 70 onion-like, concentric layers of connective tissue and a nerve terminal in the middle. The capsule is responsible for the rapidly adapting response of the Pacini's corpuscle. When the capsule is compressed, energy is transferred to the nerve terminal, its membrane is deformed, and mechanosensitive channels open. Current flowing through the channels generates a depolarizing receptor potential that, if large enough, causes the axon to fire an action potential (see [Fig. 15-26B](#), left panel). However, the capsule layers are slick, with viscous fluid between them. If the stimulus pressure is maintained, the layers slip past one another and transfer the stimulus energy away so that the underlying axon terminal is no longer deformed and the receptor potential dissipates (see [Fig. 15-26B](#), right panel). When pressure is released, the events reverse themselves and the terminal is depolarized again. In this way, the non-neural covering of Pacini's corpuscle specializes the corpuscle for sensing of vibrations and makes it almost unresponsive to steady pressure. Pacini's corpuscle is most sensitive to vibrations of 200 to 300 Hz, and its threshold increases dramatically below 50 Hz and above ~500 Hz. The sensation evoked by stimulation of Pacini's corpuscle is a poorly localized humming feeling.

Werner Loewenstein and colleagues in the 1960s showed the importance of the Pacini corpuscle's capsule to its frequency sensitivity. With fine microdissection, they were able to strip away the capsule from single corpuscles. They found that the resultant naked nerve terminal is much less sensitive to vibrating stimuli and much more sensitive to steady pressure. Clearly, the capsule modifies the sensitivity of the bare mechanoreceptive axon. The encapsulated Pacini corpuscle is an example of a **rapidly adapting** sensor, whereas the decapsulated nerve ending behaves like a **slowly adapting** sensor.

Several other types of encapsulated mechanoreceptors are located in the dermis, but none has been studied as well as Pacini's corpuscle. **Meissner's corpuscles** (see [Fig. 15-26A](#)) are located in the ridges of glabrous skin and are about one tenth the size of Pacini's corpuscles. They are rapidly adapting, although less so than Pacini's corpuscles. **Ruffini's corpuscles** resemble diminutive Pacini's corpuscles and, like Pacini's corpuscles, occur in the subcutaneous tissue of both hairy and glabrous skin. Their preferred stimuli might be called “fluttering” vibrations. As relatively *slowly* adapting receptors, they respond best to low frequencies. **Merkel's disks** are also slowly adapting receptors made from a flattened, non-neural epithelial cell that synapses on a nerve terminal. They lie at the border of the dermis and epidermis of glabrous skin. It is not clear whether it is the nerve terminal or epithelial cell that is mechanosensitive. The nerve terminals of **Krause's end bulbs** appear knotted. They innervate the border areas of dry skin and mucous membranes (e.g., around the lips and external genitalia) and are probably rapidly adapting mechanoreceptors.

The **receptive fields** of different types of skin receptors vary greatly in size. Pacini's corpuscles have extremely broad receptive fields ([Fig. 15-27A](#)), whereas those of Meissner's corpuscles (see [Fig. 15-27B](#)) and Merkel's disks are very small. The last two seem to be responsible for the ability of the fingertips to make very fine tactile discriminations. Small receptive fields are an important factor in achieving high spatial resolution. Resolution varies widely, a fact easily demonstrated by measuring the skin's two-point discrimination. Bend a paper clip into a U shape. Vary the distance between the tips and test how easily you can distinguish the touch of one tip versus two on your palm, your fingertips, your lips, your back, and your foot. To avoid bias, a colleague—rather than you—should apply the stimulus. Compare the results with standardized data (see [Fig. 15-27C](#)).

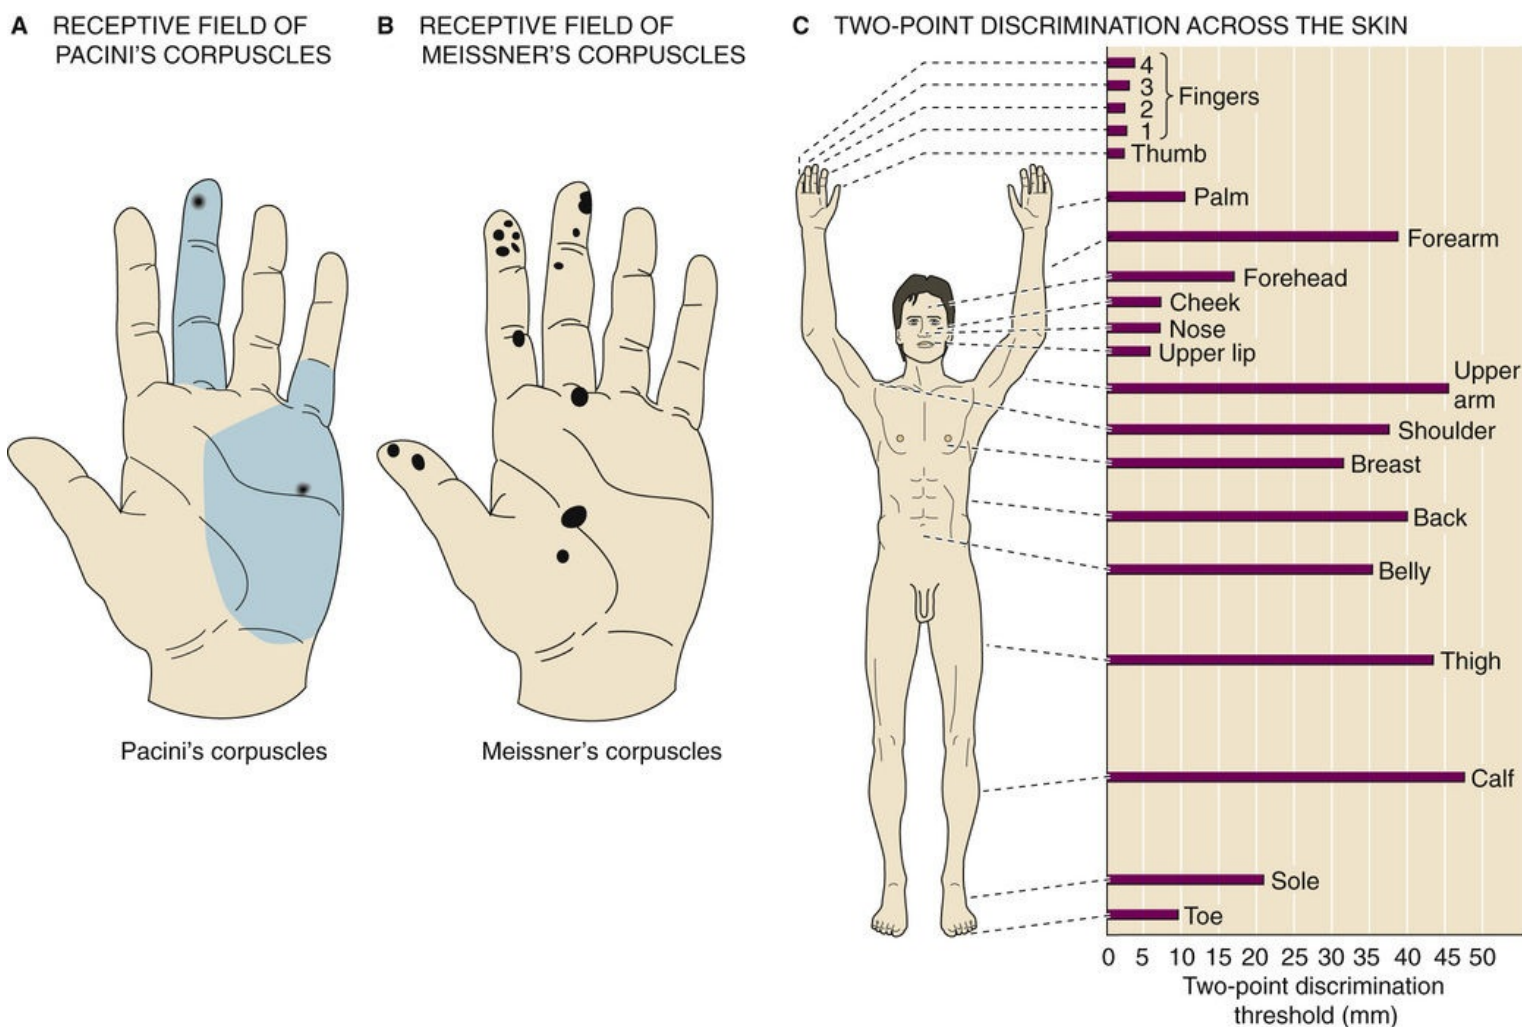

FIGURE 15-27 Receptive fields and spatial discrimination of skin mechanoreceptors. **A**, Each of the two black dots indicates an area of *maximal sensitivity* of a single Pacini corpuscle. Each blue-green area is the receptive field of a corpuscle (i.e., the corpuscle responds when stimulus strength increases sufficiently anywhere within the area). **B**, Each dot represents the entire receptive field of a single Meissner corpuscle. Note that the fields are much smaller than in **A**. **C**, The horizontal bars represent the minimum distance at which two points can be perceived as distinct at various locations over the body. Spatial discrimination depends on both receptor density and receptive-field size. (**A** and **B**, Data from Vallbo AB, Johansson RS: Properties of cutaneous mechanoreceptors in the human hand related to touch sensation. *Hum Neurobiol* 3:3–14, 1984; **C**, data from Weinstein S: Intensive and extensive aspects of tactile sensitivity as a function of body part, sex and laterality. In Kenshalo DR [ed]: *The Skin Senses*. Springfield, IL, Charles C Thomas, 1968.)

The identities of somatosensory transduction molecules remain elusive. A variety of TRP channel subtypes transduce mechanical stimuli in invertebrate species (e.g., *Drosophila*, *Caenorhabditis elegans*). In mammals, rapidly adapting ion channels are associated with receptors for light touch, and several of the TRPC channels appear to be involved in sensitivity to light touch in mice. A non-TRP protein named Piezo2 is associated with rapidly adapting mechanosensory currents in mouse sensory neurons, and knocking down the expression of Piezo2 expression causes deficits in touch. Other mechanosensory channels are expressed in some sensory neurons, including TRPA1 and TRPV4, two-pore potassium channels (KCNKs), and degenerin/epithelial sodium channels (especially ASIC1 to ASIC3 and their accessory proteins), but their roles in mammalian mechanosensation are still controversial.

One reason it is difficult to identify mechanosensory channels is that they often need to be associated with other cellular components in order to be sensitive to mechanical stimuli. The mechanisms by which mechanical force is transferred from cells and their membranes to mechanosensitive channels are unclear. Ion channels may be physically coupled to either extracellular structures (e.g., collagen fibers) or cytoskeletal components (e.g., actin, microtubules) that transfer energy from deformation of the cell to the

gating mechanism of the channel. Mechanically gated ion channels of sensory neurons, including those requiring Piezo2, depend on the actin cytoskeleton. Some channels may be sensitive to stress, shear, or curvature of the lipid bilayer itself and require no other types of anchoring proteins. Other channels may respond to mechanically triggered second messengers such as DAG (acting directly on the channel) or IP_3 (acting indirectly via an IP_3 receptor).

Two things determine the sensitivity of spatial discrimination in an area of skin. The first is the size of the receptors' receptive fields—if they are small, the two tips of your paper clip are more likely to stimulate different sets of receptors. The second parameter that determines spatial discrimination is the density of the receptors in the skin. Indeed, two-point discrimination of the fingertips is better than that of the palm, even though their receptive fields are the same size. The key to finer discrimination in the fingertips is their higher *density* of receptors. Crowding more receptors into each square millimeter of fingertip has a second advantage: because the CNS receives more information per stimulus, it has a better chance of detecting very small stimuli.

Although we rarely think about it, **hair** is a sensitive part of our somatic sensory system. For some animals, hairs are a major sensory system. Rodents whisk long facial vibrissae (hairs) and feel the texture, distance, and shape of their local environment. Hairs grow from **follicles** embedded in the skin, and each follicle is richly innervated by free mechanoreceptive nerve endings that either wrap around it or run parallel to it. Bending of the hair causes deformation of the follicle and surrounding tissue, which stretches, bends, or flattens the nerve endings and increases or decreases their firing frequency. Various mechanoreceptors innervate hair follicles, and they may be either slowly or rapidly adapting.

Separate thermoreceptors detect warmth and cold

Neurons are sensitive to changes in temperature, as are all of life's chemical reactions. Neuronal temperature sensitivity has two consequences: first, neurons can measure temperature; but second, to work properly, most neural circuits need to be kept at a relatively stable temperature. Neurons of the mammalian CNS are especially vulnerable to temperature changes. Whereas skin tissue temperatures can range from 20°C to 40°C without harm or discomfort, brain temperature must be near 37°C to avoid serious dysfunction. The body has complex systems to control brain (i.e., body core) temperature tightly (see pp. 1198–1201). Even though all neurons are sensitive to temperature, not all neurons are thermoreceptors. Because of specific membrane mechanisms, some neurons are extremely sensitive to temperature and seem to be adapted to the job of sensing it. Although many temperature-sensitive neurons are present in the skin, they are also clustered in the hypothalamus and the spinal cord (see pp. 1198–1199). The hypothalamic temperature sensors, like their cutaneous counterparts, are important for regulation of the physiological responses that maintain stable body temperature.

Perceptions of temperature apparently reflect warmth and cold receptors located in the skin. Thermoreceptors, like mechanoreceptors, are not spread uniformly across the skin. When you map the skin's sensitivity to temperature with a small cold or warm probe, you find spots ~1 mm across that are especially sensitive to *either* warmth or cold, but not to both. In addition, some areas of skin in between are relatively insensitive. The spatial dissociation of the hot and cold maps shows that they are separate submodalities, with separate receptors to encode each. Recordings from single sensory fibers have confirmed this conclusion. The responses of both warmth and cold thermoreceptors adapt during long stimuli, as many sensory receptors commonly do. Most cutaneous thermoreceptors are probably free nerve endings, without obvious specialization. Their axons are small, either unmyelinated *C fibers* or the smallest-diameter myelinated *Aδ fibers* (see Table 12-1).

We can perceive changes in our average skin temperature of as little as 0.01°C . Within the skin are separate types of thermoreceptors that are sensitive to a range of relatively hot or cold temperatures. [Figure 15-28A](#) shows how the steady discharge rate of both types of receptors varies with temperature. **Warmth receptors** begin firing above $\sim 30^{\circ}\text{C}$ and increase their firing rate until 44°C to 46°C , beyond which the rate falls off steeply and a sensation of pain begins, presumably mediated by nociceptive endings (see the next section). **Cold receptors** have a much broader temperature response. They are relatively quiet at skin temperatures of $\sim 40^{\circ}\text{C}$, but their steady discharge rate increases as the temperature falls to 24°C to 28°C . Further decreases in temperature cause the steady discharge rate of the cold receptors to decrease until the temperature falls to $\sim 10^{\circ}\text{C}$. Below that temperature, firing ceases and cold becomes an effective local anesthetic.

A STEADY (TONIC) RESPONSES

B TRANSIENT (PHASIC) RESPONSES OF "COLD" FIBERS

FIGURE 15-28 Temperature sensitivity of cutaneous thermoreceptors. **A**, The curves represent the mean steady firing rates of neurons from warmth receptors and cold receptors. **B**, These data from two experiments on cold receptors show the effects of cooling steps of similar magnitude but starting from different temperatures (20.5°C and 35°C). In both instances, the transient (phasic) responses are the same: an increase in the firing rate. When the starting temperature is 20.5°C, the final firing rate is less than the initial one. However, when the initial temperature is 35°C, the final rate is greater than the initial one. (Data from Somjen GG: *Sensory Coding in the Mammalian Nervous System*. New York, Appleton-Century-Crofts, 1972.)

In addition to the *tonic* response just described (i.e., the steady discharge rate), cold receptors also have a *phasic* response that enables them to report *changes* in temperature. As shown in [Figure 15-28B](#), when the temperature suddenly shifts from 20.5°C to 15.2°C (both points are to the left of the peak in [Fig. 15-28A](#)), the firing rate transiently increases (i.e., the phasic response). However, the new steady-state level is lower, as suggested by the left pair of points in [Figure 15-28A](#). When the temperature suddenly shifts from 35°C to 31.5°C (both points are to the right of the peak in [Fig. 15-28A](#)), the firing rate transiently increases, and the new steady-state level is higher, as suggested by the right pair of points in [Figure 15-28A](#).

The transduction of relatively warm temperatures is carried out by several types of TRPV channels

(specifically TRPV1 to TRPV4—see [Table 6-2](#), family No. 5) expressed in thermoreceptors. TRPV1 is a vanilloid receptor—it is activated by the vanilloid class of compounds that includes capsaicin, the pungent ingredient that gives spicy foods their burning quality. Aptly enough, chili peppers taste “hot” because they activate some of the same ion channels that heat itself activates! TRPV1 and TRPV2 channels have painfully high temperature thresholds ($\sim 43^{\circ}\text{C}$ and $\sim 50^{\circ}\text{C}$, respectively) and thus help mediate the noxious aspects of thermoreception (see [p. 387](#)). Other TRPV channels (TRPV3 and TRPV4) are activated at more moderate temperatures and presumably provide our sensations of warmth.

Yet another TRP channel, TRPM8, mediates sensations of moderate cold. TRPM8 channels begin to open at temperatures below $\sim 27^{\circ}\text{C}$ and are maximally activated at 8°C . In a remarkable analogy to the hot-sensitive TRPV1 channel (the capsaicin receptor), the cool-sensitive TRPM8 channel is a menthol receptor. Menthol evokes sensations of cold because it activates the same ion channel that is opened by cold temperatures.

Nociceptors are specialized sensory endings that transduce painful stimuli

Physical energy that is informative at low and moderate levels can be destructive at higher intensity. Sensations of pain motivate us to avoid such situations. **Nociceptors** are the receptors mediating acutely painful feelings to warn us that body tissue is being damaged or is at risk of being damaged (as the Latin roots imply: *nocere* [to hurt] + *recipere* [to receive]). The pain-sensing system is entirely separate from the other modalities we have discussed; it has its own peripheral receptors and a complex, dispersed, chemically unique set of central circuits. Nociceptors are free nerve endings, widely distributed throughout the body. They innervate the skin, bone, muscle, most internal organs, blood vessels, and heart. Ironically, nociceptors are generally absent from the brain substance itself, although they are in the meninges.

Nociceptors vary in their selectivity. **Mechanical nociceptors**, some of which are quite selective, respond to strong pressure—in particular, pressure from sharp objects. A subset of nociceptors expresses **Mas-related G protein–coupled receptor D (MrgprD)**; genetic ablation of just these neurons makes mice insensitive to noxious mechanical stimuli without affecting their responses to painful heat or cold. TRPA1 channels are involved in some forms of pain-related mechanosensation, and they may transduce stimuli that trigger pain originating from viscera such as the colon and bladder.

Thermal nociceptors signal either burning heat (above $\sim 45^{\circ}\text{C}$, when tissues begin to be destroyed) or unhealthy cold; the heat-sensitive nociceptive neurons express the TRPV1 and TRPV2 channels, whereas the cold-sensitive nociceptors express TRPA1 and TRPM8 channels. A uniquely cold-resistant Na^{+} channel, Nav1.8, allows cold-sensitive nociceptors to continue firing action potentials even at temperatures low enough to silence other neurons.

Chemical nociceptors, which are mechanically insensitive, respond to a variety of agents, including K^{+} , extremes of pH, neuroactive substances such as histamine and bradykinin from the body itself, and various irritants from the environment. Some chemosensitive nociceptors may express TRP channels that respond to, among other things, plant-derived irritants such as capsaicin (TRPV1), menthol (TRPM8), and the pungent derivatives of mustard and garlic (TRPA1).

Finally, **polymodal nociceptors** are single nerve endings that are sensitive to combinations of mechanical, thermal, and chemical stimuli. Nociceptive axons include both fast $\text{A}\delta$ fibers and slow, unmyelinated C fibers. $\text{A}\delta$ axons mediate sensations of sharp, intense pain; C fibers elicit more persistent feelings of dull, burning pain. The Na^{+} channel Nav1.7 has a particularly interesting relationship to pain.

Patients with loss-of-function mutations of Nav1.7 are insensitive to noxious stimuli and experience repeated injuries because they lack protective reflexes. Several gain-of-function Nav1.7 mutations cause channel hyperexcitability and syndromes of intense chronic pain.

Sensations of pain can be modulated in a variety of ways. Skin, joints, or muscles that have been damaged or inflamed are unusually sensitive to further stimuli. This phenomenon is called **hyperalgesia**, and it can be manifested as a reduced threshold for pain, an increase in perceived intensity of painful stimuli, or spontaneous pain. **Primary hyperalgesia** occurs within the area of damaged tissue, but within ~20 minutes after an injury, tissues surrounding a damaged area may become supersensitive by a process called **secondary hyperalgesia**. Hyperalgesia seems to involve processes near peripheral receptors (Fig. 15-29) as well as mechanisms in the CNS.

FIGURE 15-29 Hyperalgesia of inflammation.

Damaged skin releases a variety of chemical substances from its many cell types, blood cells, and nerve endings. These substances—sometimes called the *inflammatory soup*—include neurotransmitters

(e.g., glutamate, serotonin, adenosine, ATP), peptides (e.g., substance P, bradykinin), various lipids (e.g., prostaglandins, endocannabinoids), proteases, neurotrophins, cytokines, and chemokines, K^+ , H^+ , and others; they trigger the set of local responses that we know as **inflammation**. As a result, blood vessels become more leaky and cause tissue swelling (or edema) and redness (see [Box 20-1](#)). Nearby mast cells release the chemical histamine, which directly excites nociceptors.

By a mechanism called the **axon reflex**, action potentials can propagate along nociceptive axons from the site of an injury into side branches of the same axon that innervate neighboring regions of skin. The spreading axon branches of the nociceptors themselves may release substances that sensitize nociceptive terminals and make them responsive to previously nonpainful stimuli. Such “silent” nociceptors among our small $A\delta$ and C fibers are normally unresponsive to stimuli—even destructive ones. Only after sensitization do they become responsive to mechanical or chemical stimuli and contribute greatly to hyperalgesia. For example, the neurotrophin nerve growth factor (NGF)—part of the inflammatory soup—triggers strong hypersensitivity to heat and mechanical stimuli by modulating TRPV1 channels. Activation of TRPA1 and ASICs are also important in hyperalgesia. The cytokine tumor necrosis factor- α (TNF- α) potentiates the inflammatory response directly and enhances release of substances that sensitize nociceptors. Drugs that interfere with neurotrophin and cytokine actions can be effective treatments for the pain of inflammatory diseases.

The cognitive sensations of pain are under remarkably potent control by the brain, more so than other sensory system. In some cases, nociceptors may fire wildly, although perceptions of pain are absent; on the other hand, pain may be crippling although nociceptors are silent. Chronic activation of nociceptors can lead to central sensitization, a chronic enhancement of central pain-processing circuits. Prolonged activity in nociceptive axons and their spinal cord synapses causes increased glutamate release, strong activation of AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid)—and NMDA (*N*-methyl-D-aspartate)—type glutamate receptors, and eventually a form of long-term potentiation (see [pp. 329–337](#)).

Nonpainful sensory input and neural activity from various nuclei within the brain can modify pain. For example, pain evoked by activity in nociceptors ($A\delta$ and C fibers) can be reduced by simultaneous activity in low-threshold mechanoreceptors ($A\alpha$ and $A\beta$ fibers). This phenomenon is a familiar experience—some of the discomfort of a burn, cut, or bruise can be relieved by gentle massage or rubbing (stimulating mechanoreceptors) around the injured area. In 1965, Melzack and Wall proposed that this phenomenon involves a circuit in the spinal cord that can “gate” the transmission of nociceptive information to the brain; control of the gate could be provided by other sensory information (e.g., tactile stimulation) or by descending control from the brain itself. Gate-like regulation of pain may arise from the modulation of gamma-aminobutyric acid (GABA)—mediated and glycine-mediated inhibitory circuits in the spinal cord.

A second mechanism for modifying the sensation of pain involves the relatively small peptides called endorphins. In the 1970s, it was discovered that a class of drugs called opioids (including morphine, heroin, and codeine) act by binding tightly and specifically to **opioid receptors** in the brain and, furthermore, that the brain itself manufactures “endogenous morphine-like substances,” collectively called endorphins (see [p. 315](#)).

Muscle spindles sense changes in the length of skeletal muscle fibers, whereas Golgi tendon organs gauge the muscle's force

The somatic sensory receptors described thus far provide information about the *external* environment. However, the body also needs detailed information about itself to know where each of its parts is in space, whether it is moving, and if so, in which direction and how fast. **Proprioception** provides this sense of self and serves two main purposes. First, knowledge of the positions of our limbs as they move helps us judge the identity of external objects. It is much easier to recognize an object if you can actively palpate it than if it is placed passively into your hand so that your skin is stimulated but you are not allowed to personally guide your fingers around it. Second, proprioceptive information is essential for accurately guiding many movements, especially while they are being learned.

Skeletal muscles, which mediate voluntary movement, have two mechanosensitive proprioceptors: the muscle spindles (or stretch receptors) and Golgi tendon organs ([Fig. 15-30](#)). Muscle spindles measure the length and rate of stretch of the muscles, whereas the Golgi tendon organs gauge the force generated by a muscle by measuring the tension in its tendon. Together, they provide a full description of the dynamic state of each muscle. The different sensitivities of the spindle and the tendon organ are due partly to their structures but also to their placement: spindles are located in modified muscle fibers called *intrafusal* muscle fibers, which are aligned in *parallel* with the “ordinary” force-generating or *extrafusal* skeletal muscle fibers. On the other hand, Golgi tendon organs are aligned in *series* with the extrafusal fibers.

FIGURE 15-30 Golgi tendon organ and muscle spindle fibers. A muscle contains two kinds of muscle fibers, extrafusal fibers (ordinary muscle fibers that cause contraction) and intrafusal fibers (aligned in parallel with the extrafusal fibers). Some of the extrafusal fibers have Golgi tendon organs located in series between the end of the muscle fiber and the macroscopic tendon. The intrafusal fibers contain muscle spindles, which receive both afferent (sensory) and efferent (motor) innervation. The spindle (*inset*) contains both bag fibers, with nuclei bunched together, and chain fibers, with nuclei in a row.

The **Golgi tendon organ** consists of bare nerve endings of group Ib axons (see [Table 12-1](#)). These endings intimately invest an encapsulated collagen matrix and usually sit at the junction between skeletal muscle fibers and the tendon. When tension develops in the muscle as a result of either passive stretch or active contraction, the collagen fibers tend to squeeze and distort the mechanosensitive nerve endings, triggering them to fire action potentials.

The mammalian **muscle spindle** is a complex of modified skeletal muscle fibers (**intrafusal fibers**) combined with both afferent and efferent innervation. The spindle does not contribute significant force generation to the muscle but serves a purely sensory function. A simplified summary of the muscle spindle is that it contains two kinds of intrafusal muscle fibers (bag and chain), with two kinds of sensory endings entwined about them (the primary and secondary endings). The different viscoelastic properties of the muscle fibers make them differentially sensitive to the consequences of muscle stretch. Because the primary sensory endings of group Ia axons coil around and strongly innervate individual bag muscle fibers (in addition to chain fibers), they are very sensitive to the dynamics of muscle length (i.e., *changes*

in its length). The secondary sensory endings of group II axons mainly innervate the chain fibers and most accurately transduce the static length of the muscle; in other words, they are slowly adapting receptors. The discharge rate of afferent neurons increases when the whole muscle—and therefore the spindle—is stretched. ENaC and ASIC2 channels may contribute to the stretch sensitivity of the sensory nerve terminals in muscle spindles.

What is the function of the motor innervation of the muscle spindle? Consider what happens when the α motor neurons stimulate the force-generating extrafusal fibers and the muscle contracts. The spindle, connected in parallel to the extrafusal fibers, quickly tends to go slack, which makes it insensitive to further changes in length. To avoid this situation and to continue to maintain control over the sensitivity of the spindle, γ motor neurons cause the intrafusal muscle fibers to contract in parallel with the extrafusal fibers. This ability of the spindle's intrafusal fibers to change their length as necessary greatly increases the range of lengths over which the spindle can work. It also means that the sensory responses of the spindle depend not only on the *length* of the whole muscle in which the spindle sits but also on the *contractile state* of its own intrafusal muscle fibers. Presumably, the ambiguity in this code is sorted out centrally by circuits that simultaneously keep track of the spindle's sensory output and the activity of its motor nerve supply.

In addition to the muscle receptors, various mechanoreceptors are found in the connective tissues of **joints**, especially within the capsules and ligaments. Many resemble Ruffini, Golgi, and Pacini end organs; others are free nerve endings. They respond to changes in the angle, direction, and velocity of movement in a joint. Most are rapidly adapting, which means that sensory information about a *moving* joint is rich. Nerves encoding the resting *position* of a joint are few. We are nevertheless quite good at judging the position of a joint, even with our eyes closed. It seems that information from joint receptors is combined with that from muscle spindles and Golgi tendon organs, and probably from cutaneous receptors as well, to estimate joint angle. Removal of one source of information can be compensated by use of the other sources. When an arthritic hip is replaced with a steel and plastic one, patients are still able to tell the angle between their thigh and their pelvis, even though all hip joint mechanoreceptors are long gone.

CHAPTER 16

Circuits of the Central Nervous System

Barry W. Connors

Elements of Neural Circuits

Neural circuits process sensory information, generate motor output, and create spontaneous activity

A neuron never works alone. Even in the most primitive nervous systems, all neurons participate in synaptically interconnected networks called **circuits**. In some hydrozoans (small jellyfish), the major neurons lack specialization and are multifunctional. They serve simultaneously as photodetectors, pattern generators for swimming rhythms, and motor neurons. Groups of these cells are repetitively interconnected by two-way electrical synapses into simple ring-like arrangements, and these networks coordinate the rhythmic contraction of the animal's muscles during swimming. This simple neural network also has the flexibility to command defensive changes in swimming patterns when a shadow passes over the animal. Thus, neuronal circuits have profound advantages over unconnected neurons.

In more complex animals, each neuron within a circuit may have very specialized properties. By the interconnection of various specialized neurons, even a simple neuronal circuit may accomplish astonishingly intricate functions. Some neural circuits may be primarily sensory (e.g., the retina) or motor (e.g., the ventral horns of the spinal cord). Many circuits combine features of both, with some neurons dedicated to providing and processing **sensory input**, others to commanding **motor output**, and many neurons (perhaps most) doing both. Neural circuits may also generate their own intrinsic signals, with no need for any sensory or central input to activate them. The brain does more than just respond reflexively to sensory input, as a moment's introspection will amply demonstrate. Some neural functions—such as walking, running, breathing, chewing, talking, and piano playing—require precise timing, with coordination of rhythmic temporal patterns across hundreds of outputs. These basic rhythms may be generated by neurons and neural circuits called **pacemakers** because of their clock-like capabilities. The patterns and rhythms generated by a pacemaking circuit can always be modulated—stopped, started, or altered—by input from sensory or central pathways. Neuronal circuits that produce rhythmic motor output are sometimes called **central pattern generators**; we discuss these in a section below.

This chapter introduces the basic principles of neural circuits in the mammalian central nervous system (CNS). We describe a few examples of specific systems in detail to illuminate general principles as well as the diversity of neural solutions to life's complex problems. However, this topic is enormous, and we have necessarily been selective and somewhat arbitrary in our presentation.

Nervous systems have several levels of organization

The function of a nervous system is to generate adaptive behaviors. Because different species face unique problems, we expect brains to differ in their organization and mechanisms. Nevertheless, certain principles apply to most nervous systems. It is useful to define various levels of organization. 🍷 **N16-1** We can analyze a complex **behavior**—reading the words on this page—in a simple way, with progressively finer detail, down to the level of ion channels, receptors, messengers, and the genes that control them. At the highest level, we recognize neural **subsystems and pathways** (see [Chapter 10](#)), which in this case include the sensory input from the retina (see [Chapter 15](#)) leading to the visual cortex, the central processing regions that make sense of the visual information and the motor systems that coordinate movement of the eyes and head. Many of these systems can be recognized in the gross anatomy of the brain. Each specific brain region is extensively interconnected with other regions that serve

different primary functions. These regions tend to have profuse connections that send information *in both directions* along most sensory/central motor pathways. The advantages of this complexity are obvious; while you are interpreting visual information, for example, it can be very useful simultaneously to analyze sound and to know where your eyes are pointing and how your body is oriented.

N16-1

Levels of Organization of the Nervous System

Contributed by Barry Connors

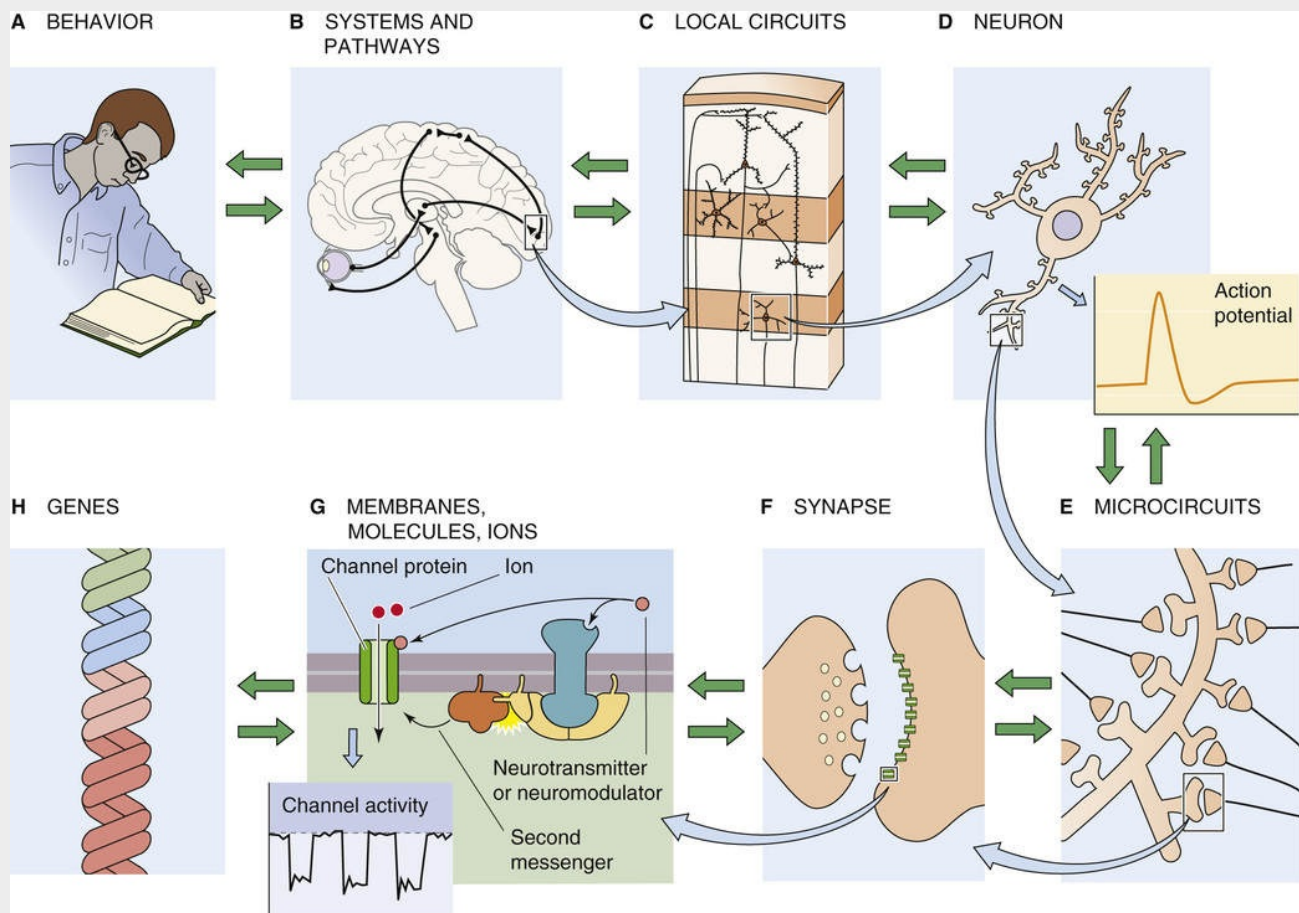

FIGURE 16-1 (Data from Shepherd GM: Neurobiology, 3rd ed. New York, Oxford University Press, 1994.)

The systems of the brain can be more deeply understood by studying their organization at the cellular level. Within a local brain region, the arrangement of neurons and their synaptic connections is called a **local circuit**. A local circuit typically includes the set of inputs, outputs, and all the interconnected neurons that are essential to functions of the local brain region. Many regions of the brain are composed of a large number of stereotyped local circuits, almost modular in their interchangeability, that are themselves interconnected. Within the local circuits are finer arrangements of neurons and synapses sometimes called **microcircuits**. Microcircuits may be repeated numerous times within a local circuit, and they determine the transformations of information that occur within small areas of dendrites and the collection of synapses impinging on them. At even finer resolution, neural systems can be understood by the properties of their individual neurons (see [Chapter 12](#)), **synapses**, **membranes**, **molecules** (e.g.,

neurotransmitters and neuromodulators), and ions as well as the **genes** that encode and control the system's molecular biology.

Most local circuits have three elements: input axons, interneurons, and projection (output) neurons

One of the most fascinating things about the nervous system is the wide array of different local circuits that have evolved for different behavioral functions. Despite this diversity, we can define a few general components of local circuits, which we illustrate with two examples from very different parts of the CNS: the ventral horn of the spinal cord and the cerebral neocortex. Some of the functions of these circuits are described in subsequent sections; here, we examine their cellular anatomy.

All local circuits have some form of **input**, which is usually a set of axons that originate elsewhere and terminate in synapses within the local circuit. A major input to the spinal cord ([Fig. 16-1](#)) is the afferent sensory axons in the dorsal roots. These axons carry information from somatic sensory receptors in the skin, connective tissue, and muscles (see [pp. 383–389](#)). However, local circuits in the spinal cord also have many other sources of input, including descending input from the brain and input from the spinal cord itself, both from the contralateral side and from spinal segments above and below. Input to the local circuits of the neocortex ([Fig. 16-2](#)) is also easily identified; relay neurons of the thalamus send axons into particular layers of the cortex to bring a range of information about sensation, motor systems, and the body's internal state. By far, the most numerous type of input to the local circuits of the neocortex comes from the neocortex itself—from adjacent local circuits, distant areas of cortex, and the contralateral hemisphere. These two systems illustrate a basic principle: local circuits receive multiple types of input.

FIGURE 16-1 Local circuits in the spinal cord. A basic local circuit in the spinal cord consists of inputs (e.g., sensory axons of the dorsal roots), interneurons (both excitatory and inhibitory), and output neurons (e.g., α motor neurons that send their axons through the ventral roots).

FIGURE 16-2 Local circuits in the neocortex. A basic local circuit in the neocortex consists of inputs (e.g., afferent axons from the thalamus), excitatory and inhibitory interneurons, and output neurons (e.g., pyramidal cells).

Output is usually achieved with a subset of cells known as *projection neurons*, or *principal neurons*, which send axons to one or more targets. The most obvious spinal output comes from the α motor neurons, which send their axons out through the ventral roots to innervate skeletal muscle fibers. Output axons from the neocortex come mainly from large pyramidal neurons in layer V, which innervate many targets in the brainstem, spinal cord, and other structures, as well as from neurons in layer VI, which make their synapses back onto the cells of the thalamus. However, as was true with inputs, most local circuits have multiple types of outputs. Thus, spinal neurons innervate other regions of the spinal cord and the brain, whereas neocortical circuits make most of their connections to other neocortical circuits.

Rare, indeed, is the neural circuit that has only input and output cells. **Local processing** is achieved by additional neurons whose axonal connections remain within the local circuit. These neurons are usually called *interneurons* or *intrinsic neurons*. Interneurons vary widely in structure and function, and a single local circuit may have many different types. Both the spinal cord and neocortex have excitatory and inhibitory interneurons, interneurons that make very specific or widely divergent connections, and interneurons that either receive direct contact from input axons or process only information from other

interneurons. In many parts of the brain, interneurons vastly outnumber output neurons. To take an extreme example, the cerebellum has $\sim 10^{11}$ granule cells—a type of excitatory interneuron—which is more than the total number of all other types of neurons in the entire brain!

The “principles” of local circuits outlined here have many variations. For example, a projection cell may have some of the characteristics of an interneuron, as when a branch of its output axon stays within the local circuit and makes synaptic connections. This branching is the case for the projection cells of both the neocortex (pyramidal cells) and the spinal cord (α motor neurons). On the other hand, some interneurons may entirely lack an axon and instead make their local synaptic connections through very short neurites or even dendrites. In some rare cases, the source of the input to a local circuit may not be purely synaptic but chemical (as with CO_2 -sensitive neurons in the medulla; see [p. 714](#)) or physical (as with temperature-sensitive neurons in the hypothalamus; see [p. 1199](#)). Although the main neurons within a generic local circuit are wired in *series* (see [Figs. 16-1](#) and [16-2](#)), local circuits, often in massive numbers, operate in *parallel* with one another. Furthermore, these circuits usually demonstrate a tremendous amount of *crosstalk*; information from each circuit is shared mutually, and each circuit continually influences neighboring circuits. Indeed, one of the things that makes analysis of local neural circuits so exceptionally difficult is that they operate in highly interactive, simultaneously interdependent, and expansive networks.

Simple, Stereotyped Responses: Spinal Reflex Circuits

Passive stretching of a skeletal muscle causes a reflexive contraction of that same muscle and relaxation of the antagonist muscles

Reflexes are among the most basic of neural functions and involve some of the simplest neuronal circuits. A motor *reflex* is a rapid, stereotyped motor response to a particular sensory stimulus. Although the existence of reflexes had been long appreciated, it was Sir Charles Sherrington  [N10-2](#) who, beginning in the 1890s, first defined the anatomical and physiological bases for some simple spinal reflexes. So meticulous were Sherrington's observations of reflexes and their timing that they offered him compelling evidence for the existence of synapses, a term he originated.

Reflexes are essential, if rudimentary, elements of behavior. Because of their relative simplicity, more than a century of research has taught us a lot about their biological basis. However, reflexes are also important for understanding more complex behaviors. Intricate behaviors may sometimes be built up from sequences of simple reflexive responses. In addition, neural circuits that generate reflexes almost always mediate or participate in much more complex behaviors. Here we examine a relatively well understood example of reflex-mediating circuitry.

The CNS commands the body to move about by activating motor neurons, which excite skeletal muscles (Sherrington called motor neurons the final common path). Motor neurons receive synaptic input from many sources within the brain and spinal cord, and the output of large numbers of motor neurons must be closely coordinated to achieve even uncomplicated actions such as walking. However, in some circumstances, motor neurons can be commanded directly by a simple sensory stimulus—muscle stretch—with only the minimum of neural machinery intervening between the sensory cell and motor neuron: one synapse. Understanding of this simplest of reflexes, the **stretch reflex** or **myotatic reflex**, first requires knowledge of some anatomy.

Each motor neuron, with its soma in the spinal cord or brainstem, commands a group of skeletal muscle cells; a single motor neuron and the muscle cells that it synapses on are collectively called a **motor unit** (see [pp. 241–242](#)). Each muscle cell belongs to only one motor unit. The size of motor units varies dramatically and depends on muscle function. In small muscles that generate finely controlled movements, such as the extraocular muscles of the eye, motor units tend to be small and may contain just a few muscle fibers. Large muscles that generate strong forces, such as the gastrocnemius muscle of the leg, tend to have large motor units with as many as several thousand muscle fibers. There are two types of motor neurons (see [Table 12-1](#)): **α motor neurons** innervate the main force-generating muscle fibers (the extrafusal fibers), whereas **γ motor neurons** innervate only the fibers of the muscle spindles. The group of all motor neurons innervating a single muscle is called a **motor neuron pool** (see [pp. 241–242](#)).

When a skeletal muscle is abruptly stretched, a rapid, reflexive contraction of the same muscle often occurs. The contraction increases muscle tension and opposes the stretch. This stretch reflex is particularly strong in physiological extensor muscles—those that resist gravity—and it is sometimes called the myotatic reflex because it is specific for the same muscle that is stretched. The most familiar version is the knee jerk, which is elicited by a light tap on the patellar tendon. The tap deflects the tendon,

which then pulls on and briefly stretches the quadriceps femoris muscle. A reflexive contraction of the quadriceps quickly follows ([Fig. 16-3](#)). Stretch reflexes are also easily demonstrated in the biceps of the arm and the muscles that close the jaw. Sherrington showed that the stretch reflex depends on the nervous system and requires sensory feedback from the muscle. For example, cutting the dorsal (sensory) roots to the lumbar spinal cord abolishes the stretch reflex in the quadriceps muscle. The basic circuit for the stretch reflex begins with the primary sensory axons from the **muscle spindles** (see [p. 388](#)) in the muscle itself. Increasing the length of the muscle stimulates the spindle afferents, particularly the large group Ia axons from the primary sensory endings. In the spinal cord, these group Ia sensory axons terminate monosynaptically onto the α motor neurons that innervate the same (i.e., the homonymous) muscle from which the group Ia axons originated. Thus, stretching a muscle causes rapid feedback excitation of the same muscle through the minimum possible circuit: one sensory neuron, one central synapse, and one motor neuron ([Box 16-1](#)).

FIGURE 16-3 Knee-jerk (myotatic) reflex. Tapping the patellar tendon with a percussion hammer elicits a reflexive knee jerk caused by contraction of the quadriceps muscle: the *stretch reflex*. Stretching the tendon pulls on the muscle spindle, exciting the primary sensory afferents, which convey their information via group Ia axons. These axons make monosynaptic connections to the α motor neurons that innervate the quadriceps, resulting in the contraction of this muscle. The Ia axons also excite inhibitory interneurons that reciprocally innervate the motor neurons of the antagonist muscle of the quadriceps (the flexor), resulting in relaxation of the semitendinosus muscle. Thus, the reflex relaxation of the antagonistic muscle is polysynaptic.

Box 16-1

Motor System Injury

The motor control systems, because of their extended anatomy, are especially susceptible to damage from

trauma or disease. The nature of a patient's motor deficits often allows the neurologist to diagnose the site of neural damage with great accuracy. When injury occurs to lower parts of the motor system, such as motor neurons or their axons, deficits may be very localized. If the motor nerve to a muscle is damaged, that muscle may develop **paresis** (weakness) or complete **paralysis** (loss of motor function). When motor axons cannot trigger contractions, there can be no reflexes (**areflexia**). Normal muscles are slightly contracted even at rest—they have some *tone*. If their motor nerves are transected, muscles become flaccid (**atonia**) and eventually develop profound **atrophy** (loss of muscle mass) because of the absence of trophic influences from the nerves.

Motor neurons normally receive strong excitatory influences from the upper parts of the motor system, including regions of the spinal cord, the brainstem, and the cerebral cortex. When upper regions of the motor system are injured by stroke, trauma, or demyelinating disease, for example, the signs and symptoms are distinctly different from those caused by lower damage. Complete transection of the spinal cord leads to profound paralysis below the level of the lesion. This is called **paraplegia** when only both legs are selectively affected, **hemiplegia** when one side of the body is affected, and **quadriplegia** when the legs, trunk, and arms are involved. For a few days after an acute injury, there is also areflexia and reduced muscle tone (**hypotonia**), a condition called **spinal shock**. The muscles are limp and cannot be controlled by the brain or by the remaining circuits of the spinal cord. Spinal shock is temporary; after days to months, it is replaced by both an exaggerated muscle tone (**hypertonia**) and heightened stretch reflexes (**hyperreflexia**) with related signs—this combination is called **spasticity**. The biological mechanisms of spasticity are poorly understood, although the hypertonia is the consequence of tonically overactive stretch reflex circuitry, driven by spinal neurons that have become chronically hyperexcitable.

Monosynaptic connections account for much of the rapid component of the stretch reflex, but they are only the beginning of the story. At the same time the stretched muscle is being stimulated to contract, parallel circuits are inhibiting the α motor neurons of its *antagonist* muscles (i.e., those muscles that move a joint in the opposite direction). Thus, as the knee-jerk reflex causes contraction of the quadriceps muscle, it simultaneously causes relaxation of its antagonists, including the semitendinosus muscle (see Fig. 16-3). To achieve inhibition, branches of the group Ia sensory axons excite specific interneurons that *inhibit* the α motor neurons of the antagonists. This **reciprocal innervation** increases the effectiveness of the stretch reflex by minimizing the antagonistic forces of the antagonist muscles.

Force applied to the Golgi tendon organ regulates muscle contractile strength

Skeletal muscle contains another mechanosensory transducer in addition to the stretch receptor: the **Golgi tendon organ** (see p. 388). Tendon organs are aligned in series with the muscle; they are exquisitely sensitive to the *tension* within a tendon and thus respond to the force generated by the muscle rather than to muscle length. Tendon organs may respond during passive muscle stretch, but they are stimulated particularly well during active contractions of a muscle. The group Ib sensory axons of the tendon organs excite both excitatory and inhibitory interneurons within the spinal cord (Fig. 16-4). In some cases, this interneuron circuitry *inhibits* the muscle in which tension has increased and *excites* the antagonistic muscle; therefore, activity in the tendon organs can yield effects that are almost the opposite of the stretch reflex. Under other circumstances, particularly during rapid movements such as locomotion, sensory input from Golgi tendon organs actually excites the motor neurons activating the same muscle. The reflex effects

of Golgi tendon organ activity vary because the interneurons receiving input from Ib axons also receive input from other sensory endings in the muscle and skin, and from axons descending from the brain. In general, reflexes mediated by the Golgi tendon organs serve to control the force within muscles and the stability of particular joints.

FIGURE 16-4 Golgi tendon organ reflex. Contraction of the quadriceps muscle can elicit a reflexive relaxation of this muscle and contraction of the antagonistic semitendinosus muscle. Contraction of the muscle pulls on the tendon; this squeezes and excites the sensory endings of the Golgi tendon organ, which convey their information via group Ib axons. These axons synapse on both inhibitory and excitatory interneurons in the spinal cord. The inhibitory interneurons innervate α motor neurons to the quadriceps, relaxing this muscle. The excitatory interneurons innervate α motor neurons to the antagonistic semitendinosus muscle, contracting it. Thus, both limbs of the reflex are polysynaptic.

Noxious stimuli can evoke complex reflexive movements

Sensations from the skin and connective tissue can also evoke strong spinal reflexes. Imagine walking on a beach and stepping on a sharp piece of shell. Your response is swift and coordinated and does not require thoughtful reflection: you rapidly withdraw the wounded foot by activating the leg flexors and

inhibiting the extensors. To keep from falling, you also extend your opposite leg by activating its extensors and inhibiting its flexors ([Fig. 16-5](#)). This response is an example of a **flexion-withdrawal reflex**. The original stimulus for the reflex came from fast pain afferent neurons in the skin, primarily the group A δ axons.

FIGURE 16-5 Flexion-withdrawal reflex. A painful stimulus to the right foot elicits a reflexive flexion of the right knee and an extension of the left knee. The noxious stimulus activates nociceptor afferents, which convey their information via group A δ axons. These axons synapse on both inhibitory and excitatory interneurons. The inhibitory interneurons that project to the *right* side of the spinal cord innervate α motor neurons to the quadriceps and relax this muscle. The excitatory interneurons that project to the *right* side of the spinal cord innervate α motor neurons to the antagonistic semitendinosus muscle and contract it. The net effect is a coordinated *flexion* of the right knee. Similarly, the inhibitory interneurons that project to the *left* side of the spinal cord innervate α motor neurons to the left semitendinosus muscle and relax this muscle. The excitatory interneurons that project to the *left* side of the spinal cord innervate α motor neurons to the left quadriceps and contract it. The net effect is a coordinated *extension* of the left knee.

This bilateral flexor reflex response is coordinated by sets of inhibitory and excitatory interneurons within the spinal gray matter. Note that this coordination requires circuitry not only on the side of the cord ipsilateral to the wounded side but also on the contralateral side. That is, while you withdraw the foot that

hurts, you must also extend the opposite leg to support your body weight. Flexor reflexes can be activated by most of the various sensory afferents that detect noxious stimuli. Motor output spreads widely up and down the spinal cord, as it must to orchestrate so much of the body's musculature into an effective response. A remarkable feature of flexor reflexes is their specificity. Touching a hot surface, for example, elicits reflexive withdrawal of the hand in the direction opposite the side of the stimulus, and the strength of the reflex is related to the intensity of the stimulus. Unlike simple stretch reflexes, flexor reflexes coordinate the movement of entire limbs and even pairs of limbs. Such coordination requires precise and widespread wiring of the spinal interneurons.

Spinal reflexes are strongly influenced by control centers within the brain

Axons descend from numerous centers within the brainstem and the cerebral cortex and synapse primarily on the spinal interneurons, with some direct input to the motor neurons. This descending control is essential for all conscious (and much unconscious) command of movement, a topic beyond the scope of this chapter. Less obvious is that the descending pathways can alter the strength of reflexes. For example, to heighten an anxious patient's stretch reflexes, a neurologist will sometimes ask the patient to perform the **Jendrassik maneuver**. The patient clasps his or her hands together and pulls; while the patient is distracted with that task, the examiner tests the stretch reflexes of the leg. Another example of the brain's modulation of a stretch reflex occurs when you catch a falling ball. If a ball were to fall unexpectedly from the sky and hit your outstretched hand, the force applied to your arm would cause a rapid *stretch reflex*—contraction in the *stretched* muscles and reciprocal inhibition in the *antagonist* muscles. The result would be that your hand would slap the ball back up into the air. However, if you *anticipate* catching the falling ball, for a short period around the time of impact (about ± 60 ms), both your stretched muscles *and* the antagonist muscles contract! This maneuver stiffens your arm just when you need to squeeze that ball to avoid dropping it. Stretch reflexes of the leg also vary dramatically during each step as we walk, thereby facilitating movement of the legs.

Like stretch reflexes, flexor reflexes can also be strongly affected by descending pathways. With mental effort, painful stimuli can be tolerated and withdrawal reflexes suppressed. On the other hand, anticipation of a painful stimulus may heighten the vigor of a withdrawal reflex when the stimulus actually arrives. Most of the brain's influence on spinal circuitry is achieved by control of the many spinal interneurons.

Spinal reflexes are frequently studied in isolation from one another, and textbooks often describe them this way. However, under realistic conditions, many reflex systems operate simultaneously, and motor output from the spinal cord depends on interactions among them as well as on the state of controlling influences descending from the brain. It is now well accepted that reflexes do not simply correct for external perturbations of the body; in addition, they play a key role in the control of all movements.

The neurons involved in reflexes are the same neurons that generate other behaviors. Think again of the flexor response to the sharp shell—the pricked foot is withdrawn while the opposite leg extends. Now imagine that a crab pinches that opposite foot—you respond with the opposite pattern of withdrawal and extension. Repeat this a few times, crabs pinching you left and right, and you have achieved the basic pattern necessary for walking! Indeed, rhythmic locomotor patterns use components of these same spinal reflex circuits, as discussed next.

Rhythmic Activity: Central Pattern Generators

Central pattern generators in the spinal cord can create a complex motor program even without sensory feedback

A common feature of motor control is the **motor program**, a set of structured muscle commands that are determined by the nervous system before a movement begins and that can be sent to the muscles with the appropriate timing so that a sequence of movements occurs without any need for sensory feedback. The best evidence for the existence of motor programs is that the brain or spinal cord can command a variety of voluntary and automatic movements, such as walking and breathing (see [pp. 706–709](#)), even in the complete absence of sensory feedback from the periphery. The existence of motor programs certainly does not mean that sensory information is unimportant; on the contrary, motor behavior without sensory feedback is always different from that with normal feedback. The neural circuits responsible for various motor programs have been defined in a wide range of species. Although the details vary endlessly, certain broad principles emerge, even when vertebrates and invertebrates are compared. Here we focus on **central pattern generators**, well-studied circuits that underlie many of the rhythmic motor activities that are central to animal behavior.

Rhythmic behavior includes walking, running, swimming, breathing, chewing, certain eye movements, shivering, and even scratching. The central pattern generators driving each of these activities share certain basic properties. At their core is a set of cyclic, coordinated timing signals that are generated by a cluster of interconnected neurons. These basic signals are used to command as many as several hundred muscles, each precisely contracting or relaxing during a particular phase of the cycle; for example, with each walking step, the knee must first be flexed and then extended. [Figure 16-6A](#) shows how the extensor and flexor muscles of the left hind limb of a cat contract rhythmically—and out of phase with one another—while the animal walks. Rhythms must also be coordinated with other rhythms; for humans to walk, one leg must move forward while the other thrusts backward, then vice versa, and the arms must swing in time with the legs, but with the opposite phase. For four-footed animals, the rhythms are even more complicated and must be able to accommodate changes in gait (see [Fig. 16-6B](#)). For coordination to be achieved among the various limbs, sets of central pattern generators must be interconnected. The motor patterns must also have great flexibility so that they can be altered on a moment's notice—consider the adjustments necessary when one foot strikes an obstacle while walking or the changing motor patterns necessary to go from walking, to trotting, to running, to jumping. Finally, reliable methods must be available for regulating the speed of the patterns and for turning them on and off.

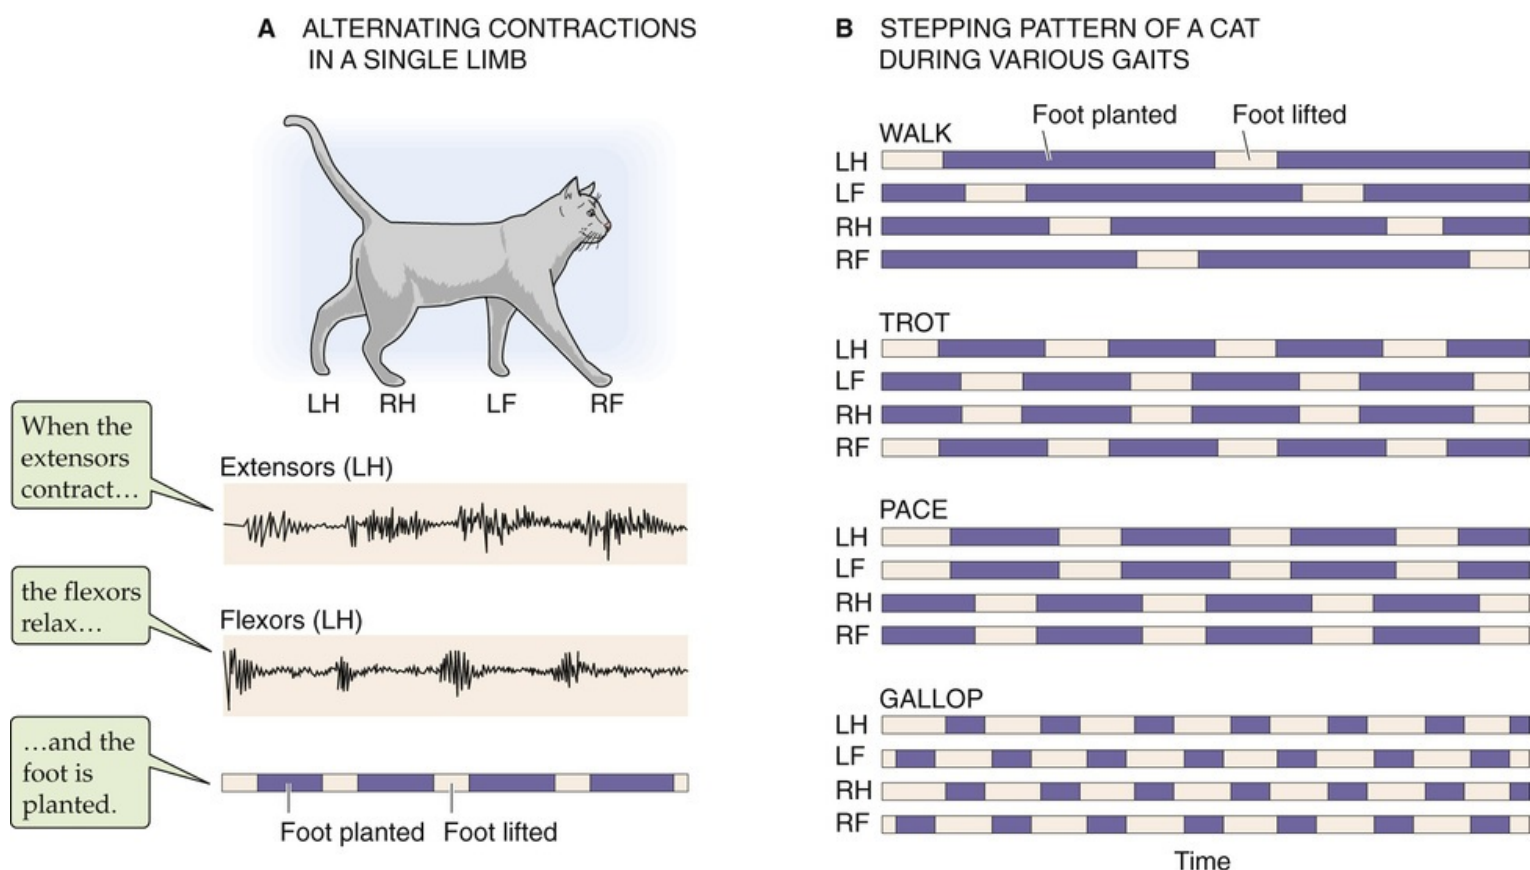

FIGURE 16-6 Rhythmic patterns during locomotion. **A**, The experimental tracings are electromyograms (EMGs)—extracellular recordings of the electrical activity of muscles—from the extensor and flexor muscles of the left hind limb of a walking cat. The pink bars indicate that the foot is lifted; the purple bars indicate that the foot is planted. **B**, The *walk*, *trot*, *pace*, and *gallop* not only represent different patterns and frequencies of planting and lifting for a single leg but also different patterns of coordination among the legs. LF, left front; LH, left hind; RF, right front; RH, right hind. (Data from Pearson K: The control of walking. *Sci Am* 2:72–86, 1976.)

The central pattern generators for some rhythmic functions, such as breathing, are in the brainstem (see p. 706). Surprisingly, those responsible for locomotion reside in the spinal cord itself. Even with the spinal cord transected so that the lumbar segments are isolated from all higher centers, cats on a treadmill can generate well-coordinated stepping movements. Furthermore, stimulation of sensory afferents or descending tracts can induce the spinal pattern generators in four-footed animals to switch rapidly from walking, to trotting, to galloping patterns by altering not only the frequency of motor commands but also their pattern and coordination. During walking and trotting and pacing, the hind legs *alternate* their movements, but during galloping, they both flex and extend *simultaneously* (compare the different leg patterns in Fig. 16-6B). Grillner and colleagues showed that each limb has at least one central pattern generator. If one leg is prevented from stepping, the other continues stepping normally. Under most circumstances, the various spinal pattern generators are coupled to one another, although the nature of the coupling must change to explain, for example, the switch from trotting to galloping patterns.

Pacemaker cells and synaptic interconnections both contribute to central pattern generation

How do neural circuits generate rhythmic patterns of activity? There is no single answer, and different circuits use different mechanisms. The simplest pattern generators are single neurons whose membrane characteristics endow them with pacemaker properties that are analogous to those of cardiac muscle cells (see p. 489) and smooth muscle cells (see p. 244). Even when experimentally isolated from other

neurons, pacemaker neurons may be able to generate rhythmic activity by relying only on their intrinsic membrane conductances (see Fig. 12-4). It is easy to imagine how intrinsic pacemaker neurons might act as the primary rhythmic driving force for sets of motor neurons that in turn command cyclic behavior. Among vertebrates, however, pacemaker neurons may contribute to some central pattern generators, but they do not appear to be solely responsible for generating rhythms. Instead, pacemakers are embedded within interconnected circuits, and it is the combination of intrinsic pacemaker properties and synaptic interconnections that generates rhythms.

Neural circuits without pacemaker neurons can also generate rhythmic output. In 1911, T. Graham Brown proposed a pattern-generating circuit for locomotion. The essence of Brown's **half-center model** is a set of excitatory and inhibitory interneurons arranged to inhibit one another reciprocally (Fig. 16-7). The half-centers are the two halves of the circuit, each commanding one of a pair of antagonist muscles. For the circuit to work, a tonic (i.e., nonrhythmic) drive must be applied to the excitatory interneurons; this drive could come from axons originating outside the circuit (e.g., from neurons in the brain) or from the intrinsic excitability of the neurons themselves. Furthermore, some built-in mechanism must limit the duration of the inhibitory activity so that excitability can cyclically switch from one half-center to the other. Note that feedback from the muscles is not needed for the rhythms to proceed indefinitely. In fact, studies of >50 vertebrate and invertebrate motor circuits have confirmed that rhythm generation can continue in the absence of sensory information.

FIGURE 16-7 Half-center model for alternating rhythm generation in flexor and extensor motor neurons. Stimulating the upper excitatory interneuron has two effects. First, the stimulated excitatory interneuron excites the motor neuron to the flexor muscle. Second, the stimulated excitatory interneuron excites an inhibitory interneuron, which inhibits the lower pathway. Stimulating the lower excitatory interneuron has the opposite effects. Thus, when one motor neuron is active, the opposite one is inhibited.

Central pattern generators in the spinal cord take advantage of sensory feedback, interconnections among spinal segments, and interactions with brainstem control centers

The half-center model can produce rhythmic, alternating neural activity, but it is clearly too simplistic to

account for most features of locomotor pattern generation. Analysis of vertebrate pattern generators is a daunting task, made difficult by the complexity of the circuits and the behaviors they control. In one of the most detailed investigations, Grillner and colleagues studied a simple model of vertebrate locomotion circuits: the spinal cord of the sea lamprey. Lampreys are among the simplest fish, and they swim with undulating motions of their body by using precisely coordinated waves of contractions of body muscles. At each spinal segment, muscle activity alternates—one side contracts as the other relaxes. As in mammals, the rhythmic pattern is generated within the spinal cord, and neurons in the brainstem control the initiation and speed of the patterns. The basic pattern-generating circuit for the lamprey spinal cord is repeated in each of the animal's 100 or so spinal segments.

The lamprey pattern-generating circuit improves on the half-center model in three ways. The first is **sensory feedback**. The lamprey has two kinds of stretch receptor neurons in the lateral margin of the spinal cord itself. These neurons sense stretching of the cord and body, which occurs as the animal bends during swimming. One type of stretch receptor excites the pattern generator interneurons on that same side and facilitates contraction, whereas the other type inhibits the pattern generator on the contralateral side and suppresses contraction. Because stretching occurs on the side of the cord that is currently relaxed, the effect of both stretch receptors is to terminate activity on the contracted side of the body and to initiate contraction on the relaxed side.

The second improvement of the lamprey circuit over the half-center model is the **interconnection of spinal segments**, which ensures the smooth progression of contractions down the length of the body, so that swimming can be efficient. Specifically, each segment must command its muscles to contract slightly later than the one anterior to it, with a lag of ~1% of a full activity cycle for normal forward swimming. Under some circumstances, the animal can also reverse the sequence of intersegment coordination to allow it to swim backward!

A third improvement over the half-center model is the **reciprocal communication** between the lamprey spinal pattern generators and control centers in the brainstem. Not only does the brainstem use numerous pathways and transmitters to modulate the generators, but the spinal generators also inform the brainstem of their activity.

The features outlined for swimming lampreys are relevant to walking cats and humans. All use spinal pattern generators to produce rhythms. All use sensory feedback to modulate locomotor rhythms (in mammals, feedback from muscle, joint, and cutaneous receptors is all-important). All coordinate the spinal pattern generators across segments, and all maintain reciprocal communication between spinal generators and brainstem control centers.

Spatial Representations: Sensory and Motor Maps in the Brain

We have already seen that the spinal cord can receive sensory input, integrate it, and produce motor output that is totally independent of the brain. The brain also receives this sensory information and uses it to control the motor activity of the spinal reflexes and central pattern generators. How does the brain organize this sensory input and motor output? In many cases, it organizes these functions spatially with neural maps.

In everyday life, we use maps to represent spatial locations. You may use endless ways to construct a map, depending on which features of an area you want to highlight and what sort of transformation you make as you take measurements from the source (the thing being mapped) and place them on the target (the map). Maps of the earth may emphasize topography, the road system, political boundaries, distributions of air temperature and wind direction, population density, or vegetation. A map is a model of a part of the world—and a very limited model at that. The brain also builds maps, most of which represent very selected aspects of our sensory information about the environment or the motor systems controlling our body. These maps can represent spatial qualities of various sensory modalities (e.g., a place in the visual field) or nonspatial qualities (e.g., smell).

The nervous system contains maps of sensory and motor information

Almost all sensory receptors are laid out in planar sheets. In some cases, these receptor sheets are straightforward **spatial maps** of the sensory environment that they encode. For example, the somatic sensory receptors of the skin literally form a map of the body surface. Similarly, a tiny version of the visual scene is projected onto the mosaic of retinal photoreceptors. The topographies of other sensory receptor sheets represent qualities other than spatial features of the sensory stimuli. For example, the position of a hair cell along the basilar membrane in the cochlea determines the range of sound frequencies to which it will respond. Thus, the sheet of hair cells is a **frequency map** of sound rather than a map of the location of sounds in space. Olfactory and taste receptors also do not encode stimulus position; instead, because the receptor specificity varies topographically, the receptor sheets may be **chemical maps** of the types of stimuli. The most interesting thing about sensory receptor maps is that they often project onto many different regions of the CNS. In fact, each sensory surface may be mapped and remapped many times within the brain, the characteristics of each map being unique. In some cases, the brain constructs maps of stimulus features even when these features are not mapped at the level of the receptors themselves. Sound localization is a good example of this property (see the next section). Some neural maps may also combine the features of other neural maps, for example, overlaying visual information with auditory information.

The cerebral cortex has multiple visuotopic maps

Some of the best examples of brain maps are those of the visual fields. [Figure 16-8A](#) shows the basic anatomical pathway extending from the retina to the lateral geniculate nucleus of the thalamus and on to the **primary visual cortex** (area V1). Note that area V1 actually maps the visual thalamus, which in turn

maps the retina, the first visuotopic map in the brain. Thus, the V1 map is sometimes referred to as a *retinotopic map*. **Figure 16-8B** shows how the visual fields are mapped onto cortical area V1. The first thing to notice is that the *left* half of the visual field is represented on the *right* cortex and the *upper* half of the visual field is represented on the *lower* portions of the cortex. This orientation is strictly determined by the system's anatomy. For example, all the retinal axons from the *left*-most halves of both eyes (which are stimulated by light from the *right* visual hemifield) project to the *left* half of the brain. Compare the red and blue pathways in **Figure 16-8A**. During development, each axon must therefore make an unerring decision about which side of the brain to innervate when it reaches the optic chiasm!

FIGURE 16-8 Visual fields and visual maps. **A**, The right sides of both retinas (which sense the left visual hemifield) project to the left lateral geniculate nucleus (LGN), which in turn projects to the left primary visual cortex (area V1). **B**, The upper parts of the visual fields project to lower parts of the contralateral visual cortex, and vice versa. Although the fovea represents only a small part of the visual field, its representation is greatly magnified in the primary visual cortex, which reflects the large number of retinal ganglion cells that are devoted to the fovea.

The second thing to notice is that scaling of the visual fields onto the visual cortex—often called the **magnification factor**—is not constant. In particular, the central region of the visual fields—the fovea—is greatly magnified on the cortical surface. Behavioral importance ultimately determines mapping in the brain. Primates require vision of particularly high resolution in the center of their gaze; photoreceptors and ganglion cells are thus packed as densely as possible into the central retinal region (see [p. 363](#)). About half of the primary visual cortex is devoted to input from the relatively small fovea and the retinal

area just surrounding it.

Understanding a visual scene requires us to analyze many of its features simultaneously. An object may have shape, color, motion, location, and context, and the brain can usually organize these features to present a seamless interpretation, or image. The details of this process are only now being worked out, but it appears that the task is accomplished with the help of *numerous* visual areas within the cerebral cortex. Studies of monkey cortex by a variety of electrophysiological and anatomical methods have identified >25 areas that are mainly visual in function, most of which are in the vicinity of area V1. According to recent estimates, humans devote almost half of their neocortex primarily to the processing of visual information. Several features of a visual scene, such as motion, form, and color, are processed in parallel and, to some extent, in separate stages of processing. The neural mechanisms by which these separate features are somehow melded into one image or concept of an object remain unknown, but they depend on strong and reciprocal interconnections between the visual maps in various areas of the brain.

The apparently simple topography of a sensory map looks much more complex and discontinuous when it is examined in detail. Many cortical areas can be described as maps on maps. Such an arrangement is especially striking in the visual system. For example, within area V1 of Old World monkeys and humans, the visuotopic maps of the two eyes remain segregated. In layer IV of the primary visual cortex, this segregation is accomplished by having visual input derived from the left eye alternate every 0.25 to 0.5 mm with visual input from the right. Thus, two sets of information, one from the left eye and one from the right eye, remain separated but adjacent. Viewed edge on, these left-right alternations look like columns (Fig. 16-9A); hence their name: **ocular dominance columns**, which were identified by David Hubel and Torsten Wiesel, who shared half of the 1981 Nobel Prize in Physiology or Medicine.  **N16-2** Viewed from the surface of the brain, this alternating left-right array of inputs looks like bands or zebra stripes (see Fig. 16-9B).

A LAYERS OF AREA V1

B SPLIT-OPEN VIEW

FIGURE 16-9 Ocular dominance columns and blobs in the primary visual cortex (area V1). **A**, Ocular dominance columns are shown as alternating black (right eye) and gray (left eye) structures in layer IV. The alternating light and dark bands are visible in an autoradiograph taken 2 weeks after injecting one eye with ^3H -labeled proline and fucose. The ^3H label moved from the optic nerve to neurons in the lateral geniculate nucleus and then to the axon terminals in the V1 cortex that are represented in this figure. The blobs are shown as teal-colored pegs in layers II and III. They represent the regular distribution of cytochrome oxidase-rich neurons and are organized in pillar-shaped clusters. **B**, Cutting the brain parallel to its surface, but between layers III and IV, reveals a polka-dot pattern of blobs in layer II/III and zebra-like stripes in layer IV. (Data from Hubel D: *Eye, Brain and Vision*. New York, WH Freeman, 1988.)

N16-2

David Hubel and Torsten Wiesel

David H. Hubel and Torsten N. Wiesel shared the 1981 Nobel Prize in Physiology or Medicine with Roger W. Sperry. Hubel and Wiesel were cited “for their discoveries concerning information processing in the visual system.” For more information visit, http://nobelprize.org/nobel_prizes/medicine/laureates/1981/.

Superimposed on the zebra-stripe ocular dominance pattern in layer IV of the primary visual cortex, but quite distinct from these zebra stripes, layers II and III have structures called **blobs**. These blobs are visible when the cortex is stained for the mitochondrial enzyme cytochrome oxidase. Viewed edge on, these blobs look like round pegs (see Fig. 16-9). Viewed from the surface of the brain (see Fig. 16-9), the blobs appear as a polka-dot pattern of small dots that are ~0.2 mm in diameter.

Adjacent to the primary visual cortex (V1) is the secondary visual cortex (V2), which has, instead of blobs, a series of thick and thin **stripes** that are separated by pale interstripes. Some other higher-order visual areas also have striped patterns. Whereas ocular dominance columns demarcate the left and right eyes, blobs and stripes seem to demarcate clusters of neurons that process and channel different types of visual information between areas V1 and V2 and pass them on to other visual regions of the cortex. For example, neurons within the blobs of area V1 seem to be especially attuned to information about color and project to neurons in the thin stripes of V2. Other neurons throughout area V1 are very sensitive to

motion but are insensitive to color. They channel their information mainly to neurons of the thick stripes in V2.

Maps of somatic sensory information magnify some parts of the body more than others

One of the most famous depictions of a neural map came from studies of the human somatosensory cortex by Penfield and colleagues. Penfield stimulated small sites on the cortical surface in locally anesthetized but conscious patients during neurosurgical procedures; from their verbal descriptions of the position of their sensations, he drew a homunculus, a little person representing the **somatotopy**—mapping of the body surface—of the primary somatic sensory cortex ([Fig. 16-10A](#)). The basic features of Penfield's map have been confirmed with other methods, including recording from neurons while the body surface is stimulated and modern brain-imaging methods, such as positron emission tomography and functional magnetic resonance imaging. The human somatotopic map resembles a trapeze artist hanging upside down—the legs are hooked over the top of the postcentral gyrus and dangle into the medial cortex between the hemispheres, and the trunk, upper limbs, and head are draped over the lateral aspect of the postcentral gyrus.

A SOMATOSENSORY

B MOTOR

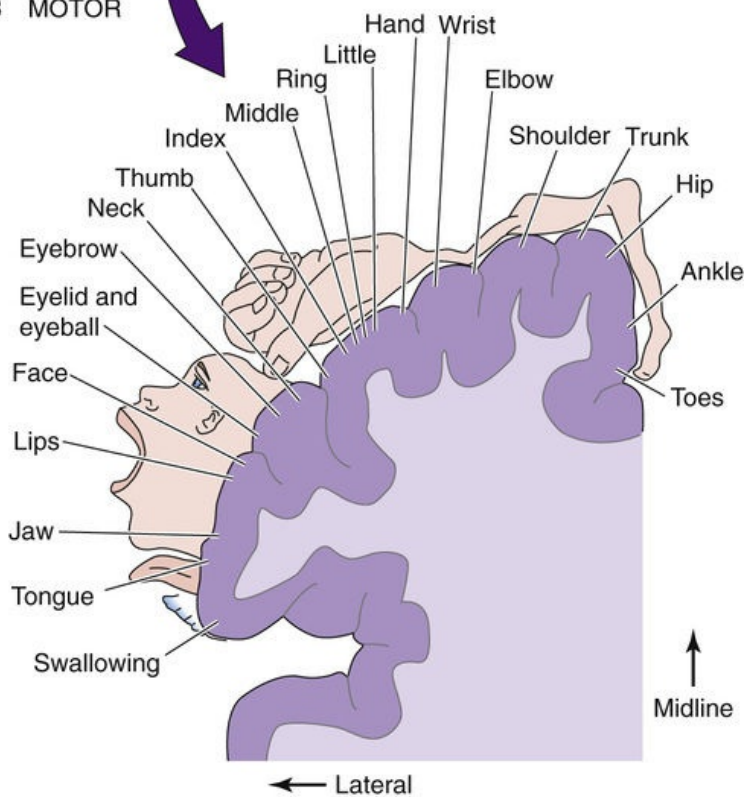

FIGURE 16-10 Somatosensory and motor maps. **A**, The plane of section runs through the postcentral gyrus of the cerebral cortex, shown as a blue band on the image of the brain. **B**, The plane of section runs through the precentral gyrus of the cerebral cortex, shown as a violet band on the image of the brain. (Data from Penfield W, Rasmussen T: *The Cerebral Cortex of Man*. New York, Macmillan, 1952.)

Two interesting features should be noticed about the somatotopic map in [Figure 16-10A](#). First, mapping of the body surface is not always continuous. For example, the representation of the hand separates those of the head and face. Second, the map is not scaled like the human body. Instead, it looks like a cartoon character: the mouth, tongue, and fingers are very large, whereas the trunk, arms, and legs are tiny. As was the case for mapping of the visual fields onto the visual cortex, it is clear in Penfield's map that the magnification factor for the body surface is not a constant but varies for different parts of the body. Fingertips are magnified on the cortex much more than the tips of the toes. The relative size of cortex that is devoted to each body part is correlated with the *density* of sensory input received from that part, and 1 mm² of fingertip skin has many more sensory endings than a similar patch on the buttocks. Size on the map is also related to the *importance* of the sensory input from that part of the body; information from the tip of the tongue is more useful than that from the elbow. The mouth representation is probably large because tactile sensations are important in the production of speech, and the lips and tongue are one of the last lines of defense in deciding whether a morsel is a potential piece of food or poison.

The importance of each body part differs among species, and indeed, some species have body parts that others do not. For example, the sensory nerves from the facial whisker follicles of rodents have a huge representation on the cortex, whereas the digits of the paws receive relatively little. Rodent behavior explains this paradox. Most are nocturnal, and to navigate they actively sweep their whiskers about as they move. By touching their local environment, they can sense shapes, textures, and movement with remarkable acuity. For a rat or mouse, seeing things with its eyes is often less important than “seeing” things with its whiskers.

As we have already seen for the visual system, other sensory systems usually map their information numerous times. Maps may be carried through many anatomical levels. The somatotopic maps in the cortex begin with the primary somatic sensory axons (see [Table 12-1](#)) that enter the spinal cord or the brainstem, each at the spinal segment appropriate to the site of the information that it carries. The sensory axons synapse on second-order neurons, and these cells project their axons into various nuclei of the thalamus and form synapses. Thalamic relay neurons in turn send their axons into the neocortex. The topographical order of the body surface (i.e., *somatotopy*) is maintained at each anatomical stage, and somatotopic maps are located within the spinal cord, the brainstem, and the thalamus as well as in the somatosensory cortex. Within the cortex, the somatic sensory system has several maps of the body, each unique and each concerned with different types of somatotopic information. Multiple maps are the rule in the brain.

The cerebral cortex has a motor map that is adjacent to and well aligned with the somatosensory map

Neural maps are not limited to sensory systems; they also appear regularly in brain structures that are considered to have primarily motor functions. Studies done in the 1860s by Fritsch and Hitzig showed that stimulation of particular parts of the cerebral cortex evokes specific muscle contractions in dogs. Penfield and colleagues generated maps of the primary motor cortex in humans (see [Fig. 16-10B](#)) by microstimulating and observing the evoked movements. They noted an orderly relationship between the site of cortical stimulation and the body part that moved. Penfield's motor maps look remarkably like his

somatosensory maps, which lie in the adjacent cortical gyrus (see [Fig. 16-10A](#)). Note that the *sensory and motor maps are adjacent and similar* in basic layout (legs represented medially and head laterally), and both have a striking magnification of the head and hand regions. Not surprisingly, there are myriad axonal interconnections between the primary motor and primary somatosensory areas. However, functional magnetic resonance imaging of the human motor cortex shows that the motor map for hand movements is not nearly as simple and somatotopic as Penfield's drawings might imply. Movements of individual fingers or the wrist that are initiated by the individual activate specific and widely distributed regions of motor cortex, but these regions also overlap one another. Rather than following an obvious somatotopic progression, it instead appears that neurons in the arm area of the motor cortex form distributed and cooperative networks that control collections of arm muscles. Other regions of the motor cortex also have a distributed organization when they are examined on a fine scale, although Penfield's somatotopic maps still suffice to describe the gross organization of the motor cortex.

In other parts of the brain, *motor and sensory functions may even occupy the same tissue*, and precise alignment of the motor and sensory maps is usually the case. For example, a paired midbrain structure called the *superior colliculus* receives direct retinotopic connections from the retina as well as input from the visual cortex. Accordingly, a spot of light in the visual field activates a particular patch of neurons in the colliculus. The same patch of collicular neurons can also command, through other brainstem connections, eye and head movements that bring the image of the light spot into the center of the *visual* field so that it is imaged onto the fovea. The *motor map* for orientation of the eyes is in precise register with the visual response map. In addition, the superior colliculus has maps of both *auditory* and *somatosensory* information superimposed on its visual and motor maps; the four aligned maps work in concert to represent points in polysensory space and help control an animal's orienting responses to prominent stimuli ([Fig. 16-11](#)).

A VISUAL MAP

Superior
colliculus of a cat

B AUDITORY MAP

C SOMATOSENSORY MAP

Here we show all three
maps superimposed.

D SUPERIMPOSITION

FIGURE 16-11 Polysensory space in the superior colliculus. **A**, The representation of visual space projected onto the right superior colliculus of a cat. Note that visual space is divided into nasal versus temporal space and superior versus inferior space. **B** and **C**, Comparable auditory and somatosensory

maps, respectively. **D**, Superimposition of the preceding three maps. Note the approximate correspondence among the visual (*red*), auditory (*green*), and somatosensory (*blue*) maps. The motor map for orienting the eyes (not shown) is in almost perfect register with the visual map in **A**. (Data from Stein BE, Wallace MT, Meredith MA: Neural mechanisms mediating attention and orientation to multisensory cues. In Gazzaniga M [ed]: The Cognitive Neurosciences. Cambridge, MA, MIT Press, 1995.)

Sensory and motor maps are fuzzy and plastic

We have described a sample of the sensory and motor maps in the brain, but we are left to wonder just why neural maps are so ubiquitous, elaborate, and varied. What is the advantage of mapping neural functions in an orderly way? You could imagine other arrangements: spatial information might be widely scattered about on a neural structure, much as the bytes of one large digital file may be scattered across the array of memory elements in a computer. Various explanations may be proposed for the phenomenon of orderly mapping in the nervous system, although most remain speculations. Maps may be the most efficient way of generating **nearest-neighbor relationships** between neurons that must be interconnected for proper function. For example, the collicular neurons that participate in sensing stimuli 10 degrees up and 20 degrees to the left and other collicular neurons that command eye movements toward that point undoubtedly need to be strongly interconnected. Orderly collicular mapping enforces togetherness for those cells and minimizes the length of axons necessary to interconnect them. In addition, if brain structures are arranged topographically, neighboring neurons will be most likely to become activated synchronously. Neighboring neurons are very likely to be interconnected in structures such as the cortex, and their synchronous activity serves to reinforce the strength of their interconnections because of the inherent rules governing synaptic plasticity (see [pp. 328–333](#)).

An additional advantage of mapping is that it may simplify establishment of the proper connections between neurons during **development**. For example, it is easier for an axon from neuron A to find neuron B if distances are short. Maps may thus make it easier to establish interconnections precisely among the neurons that represent the three sensory maps and one motor map in the superior colliculus. Another advantage of maps may be to facilitate the effectiveness of **inhibitory connections**. Perception of the edge of a stimulus (edge detection) is heightened by lateral connections that suppress the activity of neurons representing the space slightly away from the edge. If sensory areas are mapped, it is a simple matter to arrange the inhibitory connections onto nearby neurons and thereby construct an edge-detector circuit.

It is worth clarifying several general points about neural maps. “The map is not the territory,” as the philosopher Alfred Korzybski pointed out. In other words, all maps, including neural maps, are abstract representations. They are also distorted by the shortcomings of particular experimental measurements. A problem with neural maps is that different experimenters, using different methods, may sometimes generate quite different maps of the same part of the brain. As more and better-refined methods become available, our understanding of these maps is evolving. Moreover, the brain itself muddies its maps. Maps of sensory space onto a brain area are not point-to-point representations. On the contrary, a point in sensory space (e.g., a spot of light) activates a relatively large group of neurons in a sensory region of the brain. However, such activation of many neurons is not due to errors of connectivity; the spatial dissemination of activity is part of the mechanism used to encode and to process information. The *strength* of activation is most intense within the center of the activated neuronal group, but the population of more weakly activated neurons may encompass a large portion of an entire brain. This diversity in strength of activation means that a point in sensory space is unlikely to be encoded by the activity of a single neuron; instead it is represented by the distributed activity in a large population of neurons. Such a distributed code has computational advantages, and some redundancy also guards against errors, damage,

and loss of information.

Finally, maps may change with time. All sensory and motor maps are clearly dynamic and can be reorganized rapidly and substantially as a function of development, behavioral state, training, or damage to the brain or periphery. Such changes are referred to as **plasticity**. [Figure 16-12](#) illustrates two examples of dramatic changes in neocortical mapping, one sensory and one motor, after damage to peripheral nerves. In both cases, severing a peripheral nerve causes the part of the map that normally relates to the body part served by this severed nerve to become remapped to another body part. Although the mechanisms of these reorganizations are only partially known, they probably reflect the same types of processes that underlie our ability to learn sensorimotor skills with practice and to adjust and improve after neural damage from trauma or stroke.

A SOMATOSENSORY REORGANIZATION

B MOTOR-SYSTEM REORGANIZATION

FIGURE 16-12 Plasticity of maps. **A**, The first panel on the right, labeled “Normal organization,” shows the somatotopic organization of the right hand in the left somatosensory cortex of the monkey brain. The colors correspond to different regions of the hand (viewed from the palm side, except for portions labeled “Dorsum”). The second panel shows (*in gray*) the territory that is deprived of input by sectioning the median nerve. The third panel shows that the cortical map is greatly changed several months after nerve section. The nerve was not allowed to regrow, but the previously deprived cortical region now responds to the dorsal skin of D3, D2, and D1. Notice that responses to regions P1, P2, and T have disappeared; region I has encroached; and regions H and P3 have suddenly appeared at a second location. **B**, The first panel on the right, labeled “Normal organization,” shows the somatotopic organization of the left motor cortex (M1) of the rat brain. The colors correspond to the muscles that control different regions of the body. The second panel shows (*in gray*) the territory that normally provides motor output to the facial nerve, which has been severed. The third panel shows that, after several weeks, the deprived cortical territory is now remapped. Notice that the deprived territory that once evoked whisker movements now evokes eye, eyelid, and forelimb movements. FL, additional representation of forelimb; N, neck area. (A, Data from Kaas JH: The reorganization of sensory and motor maps in adult mammals. In Gazzaniga M [ed]: The Cognitive Neurosciences. Cambridge, MA, MIT Press, 1995; B, data from Sanes J, Suner S, Donoghue JP: Dynamic organization of primary motor cortex output to target muscles in adult rats: Long-term patterns of reorganization following motor or mixed peripheral nerve lesions. *Exp Brain Res* 79:479–491, 1990.)

Temporal Representations: Time-Measuring Circuits

To localize sound, the brain compares the timing and intensity of input to the ears

Neural circuits are very good at resolving time intervals, in some cases down to microseconds or less. One of the most demanding tasks of timing is performed by the auditory system as it localizes the source of certain sounds. Sound localization is an important skill, whether you are prey, predator, or pedestrian. Vertebrates use several different strategies for localization of sound, depending on the species, the frequency of the sound, and whether the task is to localize the source in the horizontal (left-right) or vertical (up-down) plane. In this subchapter, we briefly review general strategies of sound localization and then explain the mechanism by which a brainstem circuit measures the relative timing of low-frequency sounds so that the source of the sounds can be localized with precision.

Sound localization along the **vertical plane** (the degree of elevation) depends, in humans at least, on the distinctive shape of the external ear, the *pinna*. Much of the sound that we hear enters the auditory canal directly, and its energy is transferred to the cochlea. However, some sound reflects off the curves and folds of the pinna and tragus before it enters the canal and thus takes slightly longer to reach the cochlea. Notice what happens when the vertical direction of the sound changes. Because of the arcing shape of the pinna, the reflected path of sounds coming from above is shorter than that of sounds from below ([Fig. 16-13](#)). The two sets of sounds (the *direct* and, slightly delayed, the *reflected*) combine to create sounds that are slightly different on entering the auditory canal. Because of the interference patterns created by the direct and reflected sounds, the combined sound has spectral properties that are characteristic of the elevation of the sound source. This mechanism of vertical sound localization works well even with one ear at a time, although its precise neural mechanisms are not clear.

FIGURE 16-13 Detection of sound in the vertical plane. The detection of sound in the vertical plane requires only one ear. Regardless of the source of a sound, the sound reaches the auditory canal by both direct and reflected pathways. The brain localizes the source of the sound in the vertical plane by detecting differences in the combined sounds from the direct and reflected pathways.

For humans, accurate determination of the direction of a sound along the **horizontal plane** (the azimuth) requires two working ears. Sounds must first be processed by the cochlea in each ear and then compared by neurons within the CNS to estimate horizontal direction. But what exactly is compared? For sounds that are relatively high in frequency (~ 2 to 20 kHz), the important measure is the *interaural* (i.e., ear-to-ear) *intensity difference*. Stated simply, the ear facing the sound hears it as louder than the ear facing away because the head casts a “sound shadow” (Fig. 16-14A). If the sound is directly to the right or left of the listener, this difference is maximal; if the sound is straight ahead, no difference is heard; and if the sound comes from an oblique direction, intensity differences are intermediate. Note that this system can be fooled. A sound source straight ahead gives the same intensity difference (i.e., none) as a sound source directly behind.

FIGURE 16-14 Sound detection in a horizontal plane. **A**, Two ears are necessary for the detection of sound in a horizontal plane. For frequencies between 2 kHz and 20 kHz, the CNS detects the ear-to-ear *intensity* difference. In this example, the sound comes from the right. The left ear hears a weaker sound because it is in the shadow of the head. **B**, For frequencies <2 kHz, the CNS detects the ear-to-ear *delay*. In this example, the width of the head is 20 cm, and sound with a frequency of 200 Hz (wavelength of 172 cm) comes from the right. The peak of each sound wave reaches the left ear ~0.6 ms after it reaches the right.

The interaural intensity difference is not helpful at lower frequencies. Sounds below ~2 kHz have a wavelength that is longer than the width of the head itself. Longer sound waves are diffracted around the head, and differences in *interaural intensity* no longer occur. At low frequencies, the nervous system uses another strategy—it measures *interaural delay* (see Fig. 16-14B). Consider a 200-Hz sound coming directly from the right. Its peak-to-peak distance (i.e., the wavelength) is ~172 cm, which is considerably more than the 20-cm width of the head. Each sound wave peak will reach the right ear ~0.6 ms before it reaches the left ear. If the sound comes from a 45-degree angle ahead, the interaural delay is ~0.3 ms; if it comes from straight ahead (or directly behind), the delay is 0 ms. Delays of small fractions of a millisecond are well within the capabilities of certain brainstem auditory neurons to detect. Sounds need not be continuous for the interaural delay to be detected. Sound onset or offset, clicks, or any abrupt changes in the sound give opportunities for interaural time comparisons. Obviously, measurement of interaural delay is subject to the same front-back ambiguity as interaural intensity, and indeed, it is

sometimes difficult to distinguish whether a sound is in front of or behind your head.

The brain measures interaural timing by a combination of neural delay lines and coincidence detectors

How does the auditory system measure interaural timing? Surprisingly, to detect very small *time* differences, the nervous system uses a precise arrangement of neurons in *space*. [Figure 16-15A](#) summarizes the neuroanatomy of the first stages of central auditory processing within the brainstem. Notice that neurons in each of the cochlear nuclei receive information from only the ear on that one side, whereas neurons from the **medial superior olivary (MSO) nucleus**—and higher CNS centers—receive abundant input from both ears. Because horizontal sound localization requires input from both ears, we may guess that “direction-sensitive neurons” will probably be found somewhere central to the cochlear nuclei. When cochlear nucleus neurons are activated by auditory stimuli, their action potentials tend to fire with a particular phase relationship to the sound stimulus. For example, such a neuron might fire at the peak of every sound wave or at the peak of every fifth sound wave. That is, its firing is *phase locked* to the sound waves, at least for relatively low frequencies. Hence, cochlear neurons preserve the timing information of sound stimuli. Neurons in the MSO nucleus receive synaptic input from axons originating in both cochlear nuclei, so they are well placed to compare the timing (the phase) of sounds arriving at the two ears. Recordings from MSO neurons demonstrate that they are exquisitely sensitive to interaural time delay, and the optimal delay for superior olivary neurons varies systematically across the nucleus. In other words, the MSO nucleus has a spatial map of *interaural delay*. The MSO also has a systematic map of sound *frequency*, so it simultaneously maps two qualities of sound stimuli.

A SOME MAJOR AUDITORY PATHWAYS

B CALCULATION OF INTERAURAL DELAY BY COINCIDENCE DETECTION

FIGURE 16-15 CNS processing of sounds. **A**, A cross section of the mammalian medulla is shown.

After a sound stimulus to the cochlea, the cochlear nerve carries an action potential to the cochlear nucleus, which receives information only from the ear on the same side. However, higher auditory centers receive input from both ears. **B**, Neurons in the MSO nucleus are each tuned to a different interaural delay that provides information about the horizontal direction of sound sources. Only when action potentials from the right and left sides arrive at the MSO neuron simultaneously does the neuron fire an action potential (coincidence detection). In this example, the two action potentials are coincident at MSO neuron D because the brief acoustic delay to the left ear is followed by a long neuronal-conduction delay, whereas the long acoustic delay to the right ear is followed by a brief neuronal-conduction delay. Additional neural mechanisms, such as inhibitory circuits, probably contribute to the determination of interaural delays in the mammalian brain.

In the brains of birds, and perhaps also in mammals, the tuning of MSO neurons to interaural delay

seems to depend on neural circuitry that combines “delay lines” with “coincidence detection,” an idea first proposed by Jeffress in 1948. **Delay lines** are the axons from each cochlear nucleus; their length and conduction velocity determine how long it takes sound-activated action potentials to go from a cochlear nucleus to the axon's presynaptic terminals onto MSO neurons (see [Fig. 16-15B](#)). Axons from both the right and left cochlear nuclei converge and synapse onto a series of neurons in the MSO nucleus. However, each axon (each delay line) may take a different time to conduct its action potential to the same MSO neuron. The difference in conduction delay between the axon from the right side and that from the left side determines the optimal interaural delay for that particular olivary neuron. It is the olivary neuron that acts as the **coincidence detector**: only when action potentials from *both* the left- and right-ear axons reach the postsynaptic MSO neuron simultaneously (meaning that sound has reached the two ears at a particular interaural delay) is that neuron likely to receive enough excitatory synaptic transmitter to trigger an action potential. If input from the two ears arrives at the neuron out of phase, without coincidence in time, the neuron will not fire. All these postsynaptic MSO neurons are fundamentally the same: they fire when there is coincidence between input from the left and right. However, because neurons arrayed across the olive are mapped so that the axons connecting them have different delays, they display coincidence for different interaural delays. Thus, each is **tuned** to a different interaural delay and a different sound locale along the horizontal axis. The orderly arrangement of delay lines across the olive determines each of the neurons' preferred delays (and thus sound location preferences) and leads to the orderly spatial mapping of sound direction.

The neural circuit we just described, which combines axonal delay lines and coincidence detection neurons, may not be the main mechanism by which interaural timing is measured in mammalian brains. In the auditory system of gerbils, it appears that synaptic inhibition contributes to the sensitivity of MSO neurons to interaural delay. It is possible that delay lines, synaptic inhibition, and perhaps other neuronal properties combine to optimize the measurement of timing in mammals.

Neural maps of sound localization are an interesting example of a sensory map that the brain must *compute*. This computed map contrasts with many other sensory maps that are derived more simply, such as by an orderly set of connections between the sensory receptor sheet (e.g., the retinal photoreceptors) and a central brain structure (e.g., the superior colliculus), as described in the preceding subchapter (see [Fig. 16-8](#)). The cochlea does not have any map for sound location. Instead, the CNS localizes low-frequency sounds by calculating an interaural *time-delay* map, using information from both ears together. Other circuits can build a computed map of interaural *intensity differences*, which can be used for localization of high-frequency sounds (see [Fig. 16-14A](#)). Once these two orderly sensory maps have been computed, they can be remapped onto another part of the brain by a simple system of orderly connections. For instance, the inferior colliculus receives parallel information on both timing delay and intensity difference; it transforms these two sets of information, combines them, and produces a complete map of sound direction. This combination of hierarchic (lower to higher centers) and parallel information processing is ubiquitous in the CNS and is a general strategy for the analysis of much more complex sensory problems than those described here.

Elements of the Cardiovascular System

The circulation is an evolutionary consequence of body size

Isolated single cells and small organisms do not have a circulatory system. They can meet their metabolic needs by the simple processes of diffusion and convection of solutes from the *external* to the *internal milieu* (Fig. 17-1A). The requirement for a circulatory system is an evolutionary consequence of the increasing size and complexity of multicellular organisms. Simple diffusion (see p. 108) is not adequate to supply nutrients to centrally located cells or to eliminate waste products; in large organisms, the distances separating the central cells from the *external milieu* are too long. A simple closed-end tube (see Fig. 17-1B), penetrating from the extracellular compartment and feeding a central cell deep in the core of the organism, would not be sufficient. The concentration of nutrients inside the tube would become very low at its closed end because of both the uptake of these nutrients by the cell and the long path for resupply leading to the cell. Conversely, the concentration of waste products inside the tube would become very high at the closed end. Such a tube represents a long **unstirred layer**; as a result, the concentration gradients for both nutrients and wastes across the membrane of the central cell are very small.

A UNICELLULAR ORGANISM

B MULTICELLULAR ORGANISM

C CIRCULATION WITH ONE PUMP

D CIRCULATION WITH TWO PUMPS / TWO CIRCUITS

FIGURE 17-1 Role of the circulatory system in promoting diffusion. In **C**, nutrients and wastes exchange across two barriers: a surface for equilibration between the external milieu and blood, and another surface

between blood and the central cell. *Inset*, Blood is the conduit that connects the external milieu (e.g., lumina of lung, gut, and kidney) to the internal milieu (i.e., extracellular fluid bathing central cells). In **D**, the system is far more efficient, using one circuit for exchange of gases with the external milieu and another circuit for exchange of nutrients and nongaseous wastes.

In complex organisms, a circulatory system provides a steep concentration gradient from the blood to the central cells for nutrients and in the opposite direction for waste products. Maintenance of such steep intracellular-to-extracellular concentration gradients requires a fast convection system that rapidly circulates fluid between surfaces that equilibrate with the *external milieu* (e.g., the lung, gut, and kidney epithelia) and individual central cells deep inside the organism (see Fig. 17-1C). In mammals and birds, the exchange of gases with the external milieu is so important that they have evolved a two-pump, dual circulatory system (see Fig. 17-1D) that delivers the full output of the “heart” to the lungs (see pp. 683–684).

The primary role of the **circulatory system** is the distribution of dissolved gases and other molecules for nutrition, growth, and repair. Secondary roles have also evolved: (1) fast chemical signaling to cells by means of circulating hormones or neurotransmitters, (2) dissipation of heat by delivery of heat from the core to the surface of the body, and (3) mediation of inflammatory and host defense responses against invading microorganisms.

The circulatory system of humans integrates three basic functional parts, or organs: a pump (the **heart**) that circulates a liquid (the **blood**) through a set of containers (the **vessels**). This integrated system is able to adapt to the changing circumstances of normal life. Demand on the circulation fluctuates widely between sleep and wakefulness, between rest and exercise, with acceleration/deceleration, during changes in body position or intrathoracic pressure, during digestion, and under emotional or thermal stress. To meet these variable demands, the entire system requires sophisticated and integrated regulation.

The heart is a dual pump that drives the blood in two serial circuits: the systemic and the pulmonary circulations

A remarkable pump, weighing ~300 g, drives the human circulation. The heart really consists of two pumps, the **left heart**, or main pump, and the **right heart**, or boost pump (see Fig. 17-1D). These operate in series and require a delicate equalization of their outputs. The output of each pump is ~5 L/min, but this can easily increase 5-fold during exercise.

During a 75-year lifetime, the two ventricles combined pump 400 million L of blood (enough to fill a lake 1 km long, 40 m wide, and 10 m deep). The circulating fluid itself is an organ, kept in a liquid state by mechanisms that actively prevent cell-cell adhesion and coagulation. With each heartbeat, the ventricles impart the energy necessary to circulate the blood by generating the pressure head that drives the flow of blood through the **vascular system**. On the basis of its anatomy, we can divide this system of tubes into two main circuits: the **systemic** and the **pulmonary** circulations (see Fig. 17-1D). We could also divide the vascular system into a **high-pressure** part (extending from the contracting left ventricle to the systemic capillaries) and a **low-pressure** part (extending from the systemic capillaries, through the right heart, across the pulmonary circulation and left atrium, and into the left ventricle in its relaxed state). The vessels also respond to the changing metabolic demands of the tissues they supply by directing blood flow to (or away from) tissues as demands change. The circulatory system is also self-repairing/self-expanding. Endothelial cells lining vessels mend the surfaces of existing blood vessels and generate new vessels (**angiogenesis**).

Some of the most important life-threatening human diseases are caused by failure of the heart as a pump

(e.g., congestive heart failure), failure of the blood as an effective liquid organ (e.g., thrombosis and embolism), or failure of the vasculature either as a competent container (e.g., hemorrhage) or as an efficient distribution system (e.g., atherosclerosis). Moreover, failure of the normal interactions among these three organs can by itself elicit or aggravate many human pathological processes.

Hemodynamics

Blood flow is driven by a constant pressure head across variable resistances

To keep concepts simple, first think of the left heart as a constant pressure generator that maintains a steady mean arterial pressure at its exit (i.e., the aorta). In other words, assume that blood flow throughout the circulation is steady or nonpulsatile (below in the chapter, see the discussion of the consequences of normal cyclic variations in flow and pressure that occur as a result of the heartbeat). As a further simplification, assume that the entire systemic circulation is a single, straight tube.

To understand the *steady flow* of blood, driven by a *constant pressure* head, we can apply classical hydrodynamic laws. The most important law is analogous to Ohm's law of electricity:

$$\begin{aligned}\Delta V &= I \cdot R && \text{for electricity} \\ \Delta P &= F \cdot R && \text{for liquids}\end{aligned}\tag{17-1}$$

That is, the pressure difference (ΔP) between an upstream point (pressure P_1) and a downstream site (pressure P_2) is equal to the product of the flow (F) and the resistance (R) between those two points (Fig. 17-2). Ohm's law of hydrodynamics holds at any instant in time, regardless of how simple or how complicated the circuit. This equation also does not require any assumptions about whether the vessels are rigid or compliant, as long as R is constant.

FIGURE 17-2 Flow through a straight tube. The flow (F) between a high-pressure point (P_1) and a low-pressure point (P_2) is proportional to the pressure difference (ΔP). A_1 and A_2 are cross-sectional areas at these two points. A cylindrical bolus of fluid—between the disks at P_1 and P_2 —moves down the tube with a linear velocity v .

In reality, the **pressure difference** (ΔP) between the beginning and end points of the human systemic circulation—that is, between the high-pressure side (aorta) and the low-pressure side (vena cava)—turns out to be fairly constant over time. Thus, the heart behaves more like a generator of a constant pressure

head than like a generator of constant flow, at least within physiological limits. Indeed, **flow (F)**, the output of the left heart, is quite variable in time and depends greatly on the physiological circumstances (e.g., whether one is active or at rest). Like flow, **resistance (R)** varies with time; in addition, it varies with location within the body. The overall resistance of the circulation reflects the contributions of a complex network of vessels in both the systemic and pulmonary circuits.

Blood can take many different pathways *from the left heart to the right heart* (Fig. 17-3): (1) a single capillary bed (e.g., coronary capillaries), (2) two capillary beds in series (e.g., glomerular and peritubular capillaries in the kidney), or (3) two capillary beds in parallel that subsequently merge and feed into a single capillary bed in series (e.g., the parallel splenic and mesenteric circulations, which merge on entering the portal hepatic circulation). In contrast, blood flow *from the right heart to the left heart* can take only a single pathway, across a single capillary bed in the pulmonary circulation. Finally, some blood also courses *from the left heart directly back to the left heart* across shunt pathways, the most important of which is the bronchial circulation.

FIGURE 17-3 Circulatory beds.

The overall resistance (R_{total}) across a circulatory bed results from parallel and serial arrangements of branches and is governed by laws similar to those for the electrical resistance of DC circuits. For multiple resistance elements (R_1, R_2, R_3, \dots) arranged in series,

$$R_{\text{total}} = R_1 + R_2 + R_3 + \dots \quad (17-2)$$

For multiple elements arranged in parallel,

$$\frac{1}{R_{\text{total}}} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \dots \quad (17-3)$$

Blood pressure is always measured as a pressure difference between two points

Physicists measure pressure in the units of grams per square centimeter or dynes per square centimeter. However, physiologists most often gauge blood pressure by the height it can drive a column of liquid. This pressure is

$$P = \rho gh \quad (17-4)$$

where ρ is the density of the liquid in the column, g is the gravitational constant, and h is the height of the column. Therefore, if we neglect variations in g and know ρ for the fluid in the column (usually water or mercury), we can take the height of the liquid column as a measure of blood pressure. Physiologists usually express this pressure in millimeters of mercury or centimeters of water. Clinicians use the classical blood pressure gauge (sphygmomanometer) to report arterial blood pressure in millimeters of mercury.

Pressure is never expressed in absolute terms but as a **pressure difference** ΔP relative to some “reference” pressure. We can make this concept intuitively clear by considering pressure as a force \mathcal{F} applied to a surface area A .

$$P = \mathcal{F}/A \quad (17-5)$$

If we apply a force to one side of a free-swinging door, we cannot predict the direction the door will move unless we know what force a colleague may be applying on the opposite side. In other words, we can define a movement or distortion of a mechanical system only by the *difference* between two forces. In electricity, we compare the difference between two voltages. In hemodynamics, we compare the difference between two pressures. When it is not explicitly stated, the reference pressure in human physiology is the atmospheric or barometric pressure (P_B). Because P_B on earth is never zero, a pressure reading obtained at some site within the circulation, and referred to P_B , actually does not express the absolute pressure in that blood vessel but rather the difference between the pressure inside the vessel and P_B .

Because a pressure difference is always between two points—and these two points are separated by some distance (Δx) and have a spatial orientation to one another—we can define a pressure gradient ($\Delta P/$

Δx) with a spatial orientation. Considering orientation, we can define three different kinds of pressure differences in the circulation:

1. Driving pressure. In Figure 17-4, the ΔP between points x_1 and x_2 inside the vessel—along the axis of the vessel—is the axial pressure difference. Because this ΔP causes blood to flow from x_1 to x_2 , it is also known as the driving pressure. In the circulation, the driving pressure is the ΔP between the arterial and venous ends of the systemic (or pulmonary) circulation, and it governs blood flow. Indeed, this is the only ΔP we need to consider to understand flow in horizontal rigid tubes (see Fig. 17-2).

FIGURE 17-4 Three kinds of pressure differences, and their axes, in a blood vessel.

2. Transmural pressure. The ΔP in Figure 17-4 between point r_1 (inside the vessel) and r_2 (just outside the vessel)—along the radial axis—is an example of a radial pressure difference. Although there is normally no pressure difference through the blood along the radial axis, the pressure drops steeply across the vessel wall itself. The ΔP between r_1 and r_2 is the transmural pressure; that is, the difference between the intravascular pressure and the tissue pressure. Because blood vessels are distensible, transmural pressure governs vessel diameter, which is in turn the major determinant of resistance.

3. Hydrostatic pressure. Because of the density of blood and gravitational forces, a third pressure difference arises if the vessel does not lie in a horizontal plane, as was the case in Figure 17-2. The ΔP in Figure 17-4 between point h_1 (bottom of a liquid column) and h_2 (top of the column)—along the height axis—is the hydrostatic pressure difference $P_1 - P_2$. This ΔP is similar to the P in Equation 17-4 (here, ρ is the density of blood), and it exists even in the absence of any blood flow. If we express increasing altitude in positive units of h , then hydrostatic $\Delta P = -\rho g(h_1 - h_2)$.

Total blood flow, or cardiac output, is the product (heart rate) × (stroke volume)

The flow of blood delivered by the heart, or the total mean flow in the circulation, is the **cardiac output (CO)**. The output during a single heartbeat, from either the left or the right ventricle, is the stroke volume (SV). For a given **heart rate (HR)**,

$$CO = F = HR \cdot SV \quad (17-6)$$

The cardiac output is usually expressed in liters per minute; at rest, it is 5 L/min in a 70-kg human. Cardiac output depends on body size and is best normalized to body surface area. The cardiac index (*units*: liters per minute per square meter) is the cardiac output per square meter of body surface area. The normal adult cardiac index at rest is about 3.0 L/(min m²).

The principle of continuity of flow is the principle of conservation of mass applied to flowing fluids. It requires that the volume entering the systemic or pulmonary circuit per unit time be equal to the volume leaving the circuit per unit time, assuming that no fluid has been added or subtracted in either circuit. Therefore, the flow of the right and left hearts (i.e., right and left cardiac outputs) must be equal in the steady state.  **N17-1**

N17-1

Cardiac Output of the Left and Right Hearts

Contributed by Emile Boulpaep

As shown on the right side of Figure 17-3 the bronchial circulation—which carries ~2% of the cardiac output or ~100 mL/min at rest—originates from the aorta (i.e., the output of the left heart). After passing through bronchial capillaries, about half of this bronchial blood empties into the azygos vein (see p. 693) and returns to the right atrium, and about half enters pulmonary venules (i.e., the input to the left heart). In other words, ~1% or ~50 mL/min of the blood leaving the left ventricle reenters the left atrium, thus bypassing the right heart (i.e., a right-to-left shunt). Thus, although we generally say that the outputs of the left and right hearts are identical in the steady state, in fact the cardiac output of the left heart exceeds the cardiac output of the right heart by about 1% or 50 mL/min at rest.

Flow in an idealized vessel increases with the fourth power of radius (Poiseuille equation)

Flow (F) is the displacement of volume (ΔV) per unit time (Δt):

$$F = \frac{\Delta V}{\Delta t} \quad (17-7)$$

In [Figure 17-2](#), we could be watching a bolus (the blue cylinder)—with an area A and a length L —move along the tube with a mean velocity \bar{v} . During a time interval Δt , the cylinder advances by Δx , so that the volume passing some checkpoint (e.g., at P_2) is ($A \cdot \Delta x$). Thus,

$$F = \frac{\overbrace{A \cdot \Delta x}^{\Delta V}}{\Delta t} = A \cdot \frac{\overbrace{\Delta x}^{\bar{v}}}{\Delta t} = A \cdot \bar{v} \quad (17-8)$$

This equation holds at any point along the circulation, regardless of how complicated the circulation is or how irregular the cross-sectional area.

In a physically well defined system, it is also possible to *predict* the flow from the geometry of the vessel and the properties of the fluid. In 1840 and 1841, Jean Poiseuille observed the flow of liquids in tubes of small diameter and derived the law associated with his name. In a straight, rigid, cylindrical tube,

$$F = \Delta P \cdot \frac{\pi r^4}{\underbrace{8\eta l}_{1/R}} \quad (17-9)$$

This is the Hagen-Poiseuille equation, **N17-2** where F is the flow, ΔP is the driving pressure, r is the inner radius of the tube, l is its length, and η is the viscosity. The Poiseuille equation requires that both driving pressure and the resulting flow be constant.

N17-2

Hagen-Poiseuille Law

Jean Léonard Marie Poiseuille (1797–1869) was a French physician and experimentalist whose studies in hemodynamics in 1838, later published in 1840, are now known as the Hagen-Poiseuille law. (For more information, see

<http://www.cartage.org.lb/en/themes/Biographies/MainBiographies/P/Poiseuille/1.html>.)

What is widely known as Poiseuille's equation was in fact derived by Gotthilf Heinrich Ludwig Hagen (1797–1884), a German physicist, who in 1839 independently confirmed the findings of Poiseuille's experiments. (For more information, see

http://www.wikipedia.org/wiki/Gotthilf_Heinrich_Ludwig_Hagen.)

The Hagen-Poiseuille law describes the laminar flow of a viscous liquid through a cylindrical tube (see Fig. 17-5B). The viscous resistance reflects the frictional interaction between adjacent layers of fluid, each of which moves at a different velocity. This resistance does not reflect the friction between the outermost layer of fluid—which is stationary—and the wall of the tube.

In the Hagen-Poiseuille law (Equation 17-9, shown here as Equation NE 17-1),

$$F = \Delta P \cdot \frac{\pi r^4}{\underbrace{8\eta l}_{1/R}} \quad (\text{NE } 17-1)$$

F is the flow (in milliliters \cdot second⁻¹), ΔP is the pressure difference (in dynes \cdot centimeter⁻²), r is the

inner radius of the tube (in centimeters), l is the length of the tube (in centimeters), and η is the dynamic viscosity (in dynes \cdot second \cdot centimeter⁻² = poise). The unit of dynamic viscosity, the poise, is named after Poiseuille.

The discoveries of Hagen and Poiseuille are often described as the Hagen-Poiseuille equation, Poiseuille's law, or the Poiseuille equation. These terms are synonymous in meaning and are used interchangeably.

Three implications of Poiseuille's law are as follows:

1. Flow is directly proportional to the axial pressure difference, ΔP . The proportionality constant— $(\pi r^4)/(8\eta l)$ —is the reciprocal of resistance (R), as is presented below.
2. Flow is directly proportional to the fourth power of vessel radius.
3. Flow is inversely proportional to both the length of the vessel and the viscosity of the fluid.

Unlike Ohm's law of hydrodynamics ($F = \Delta P/R$), which applies to *all* vessels, no matter how complicated, the Poiseuille equation applies only to rigid, cylindrical tubes. Moreover, discussion below in this chapter reveals that the fluid flowing through the tube must satisfy certain conditions.

Viscous resistance to flow is proportional to the viscosity of blood but does not depend on properties of the blood vessel walls

The simplest approach for expressing vascular resistance is to rearrange Ohm's law of hydrodynamics (see [Equation 17-1](#)):

$$R = \frac{\Delta P}{F} \quad (17-10)$$

This approach is independent of geometry and is even applicable to very complex circuits, such as the entire peripheral circulation. Moreover, we can conveniently express resistance in units used by physicians for pressure (millimeters of mercury) and flow (milliliters per second). Thus, the units of total peripheral resistance are millimeters of mercury/(milliliters per second)—also known as **peripheral**

resistance units (PRUs).

Alternatively, if the flow through the tube fulfills Poiseuille's requirements, we can express “viscous” resistance in terms of the dimensions of the vessel and the *viscous* properties of the circulating fluid. 🔥

N17-3 Combining Equation 17-9 and Equation 17-10, we get

$$R = \frac{8}{\pi} \cdot \frac{\eta l}{r^4} \quad (17-11)$$

N17-3

Viscous Resistance

Contributed by Emile Boulpaep

The Hagen-Poiseuille equation describes the laminar flow of a viscous liquid through a cylindrical tube (see Fig. 17-5B). The **viscous resistance** reflects the frictional interaction between adjacent layers of fluid, each of which moves at a different velocity. This resistance does not reflect the friction between the outermost layer of fluid—which is stationary—and the wall of the tube. (In other words, Hagen and Poiseuille assumed that the outer edge of fluid does not move. It sticks to the wall!) Rather, viscous resistance depends on the fluid's viscosity and shape.

In Equation 17-11 (shown here as Equation NE 17-2), we define the viscous resistance as

$$R = \frac{8}{\pi} \cdot \frac{\eta l}{r^4} \quad (\text{NE } 17-2)$$

Here, the resistance term R has the fundamental dimensions $(\text{mass}) \cdot (\text{length})^{-4} \cdot (\text{time})^{-4}$. If the length (l) and the radius (r) are given in centimeters, and if the dynamic viscosity (η) is given in poise (or dynes \cdot second \cdot centimeter $^{-2}$), then resistance is in the units dynes \cdot centimeter $^{-5} \cdot$ second $^{-1}$.

If one instead expresses the dynamic viscosity (η) not in poise but in the units grams centimeter $^{-1}$ second $^{-1}$ (remembering that, because force = mass \times acceleration, the dyne has the units gram \cdot centimeter second $^{-2}$), then the units of resistance become gram centimeter $^{-4}$ second $^{-1}$.

Note that if the vessel is *not* straight, rigid, cylindrical (which implies a smooth internal surface), and unbranched, other nonviscous parameters will sum with the viscous resistance to make up the total resistance of the system (R) that appears in Ohm's law of hydrodynamics (see Equation 17-1). Such nonviscous resistances can arise from contributions from rough vessel walls and obstructions in the path of fluid flow—qualities of the container.

Thus, *viscous* resistance is proportional to the *viscosity* of the fluid and the length of the tube but inversely proportional to the fourth power of the radius of the blood vessel. Note that this equation makes no statement regarding the properties of the vessel wall per se. The resistance to flow results from the geometry of the fluid—as described by l and r —and the internal friction of the fluid, the **viscosity** (η). Viscosity is a property of the content (i.e., the fluid), 🔥**N17-3** unrelated to any property of the container (i.e., the vessel).

The viscosity of blood is a measure of the internal slipperiness between layers of fluid

Viscosity expresses the degree of lack of slipperiness between two layers of fluid. Isaac Newton described the interaction as illustrated in Figure 17-5A. Imagine that two parallel planes of fluid, each with an area A , are moving past one another. The velocity of the first is v , and the velocity of the slightly faster moving second plane is $\bar{v} + \Delta v$. The difference in velocity between the moving planes is Δv and the separation between the two planes is Δx . Thus, the *velocity gradient* in a direction perpendicular to the plane of shear, $\Delta v / \Delta x$ (units: [centimeters/second]/centimeter = second⁻¹), is the **shear rate**. The additional *force* that we must apply to the second sheet to make it move faster than the first is the **shear stress**. The greater the area of the sheets, the greater the force needed to overcome the friction between them. Thus, shear stress is expressed as force per unit area (\mathcal{F}/A). The *shear stress* required to produce a particular *shear rate* Newton defined as the viscosity:

$$\eta = \frac{\text{shear stress}}{\text{shear rate}} = \frac{\mathcal{F}/A}{\Delta v / \Delta x} \quad (17-12)$$

FIGURE 17-5 Viscosity.

Viscosity measures the resistance to sliding when layers of fluid are shearing against each other. The unit of viscosity is the **poise** (P). Whole blood has a viscosity of ~ 3 centipoise (cP).

If we apply Newton's definition of viscosity to a cylindrical blood vessel, the shearing laminae of the blood are not planar but concentric cylinders (see Fig. 17-5B). If we apply a pressure head to the blood in the vessel, each lamina will move parallel to the long axis of the tube. Because of cohesive forces between the inner surface of the vessel wall and the blood, we can assume that an infinitesimally thin layer of blood close to the wall of the tube (see Fig. 17-5B, layer #0) cannot move. However, the next concentric cylindrical layer, layer #1, moves in relation to the stationary outer layer #0, but slower than

the next inner concentric cylinder, layer #2, and so on. Thus, the velocities increase from the wall to the center of the cylinder. The resulting velocity profile is a parabola with a maximum velocity, v_{\max} , at the central axis. The lower the viscosity, the sharper the point of the bullet-shaped velocity profile.

How Blood Flows

As discussed, the Poiseuille equation (see [Equation 17-9](#)) is based on solid empirical and theoretical grounds. However, the equation requires the following assumptions:

1. The fluid must be incompressible.
2. The tube must be straight, rigid, cylindrical, and unbranched, and have a constant radius.
3. The velocity of the thin fluid layer at the wall must be zero (i.e., no “slippage”). This assumption holds for aqueous solutions, but not for some “plastic” fluids.
4. The flow must be laminar. That is, the fluid must move in concentric undisturbed laminae, without the gross exchange of fluid from one concentric shell to another.
5. The flow must be steady (i.e., not pulsatile).
6. The viscosity of the fluid must be constant. First, it must be constant throughout the cross section of the cylinder. Second, it must be constant in the “newtonian” sense; that is, the viscosity must be independent of the magnitude of the shear stress (i.e., force applied) and the shear rate (i.e., velocity gradient produced). In other words, the shear stress at each point is linearly proportional to its shear rate at that point.

To what extent does the circulatory system fulfill the conditions of the Poiseuille equation? The first condition (i.e., incompressible fluid) is well satisfied by blood. If we consider only flow in a vessel segment that is of fairly fixed size (e.g., thoracic aorta), the second assumption (i.e., simple geometry) is also reasonably well satisfied. The third requirement (i.e., no slippage) is true for blood in blood vessels. Indeed, if one forms a reservoir out of a piece of vessel (e.g., aorta) and fills it with blood, a meniscus forms with the concave surface facing upward, indicating adherence of blood to the vessel wall.

The fourth and fifth assumptions, which are more complex, are the subject of the next two sections. With regard to the sixth assumption, [Chapter 18](#) addresses the anomalous viscosity of blood.

Blood flow is laminar

From Ohm's law of hydrodynamics ($\Delta P = F \cdot R$), flow should increase linearly with driving pressure if resistance is constant. In cylindrical vessels, flow does indeed increase linearly with ΔP *up to a certain point* ([Fig. 17-6A](#)). However, at high flow rates—beyond a critical velocity—flow rises less steeply and is no longer proportional to ΔP but to roughly the square root of ΔP , because R apparently increases. Here, blood flow is no longer laminar but **turbulent**. Because turbulence causes substantial kinetic energy losses, it is energetically wasteful.

A PRESSURE-FLOW RELATIONSHIP

B VELOCITY PROFILES

FIGURE 17-6 Laminar versus turbulent flow.

The critical parameter that determines when flow becomes turbulent is a dimensionless quantity called the **Reynolds number (Re)**, named after Osborne Reynolds: [N17-4](#)

$$Re = \frac{2r\bar{v}\rho}{\eta} \quad (17-13)$$

N17-4

Reynolds Number

Contributed by Chevalier Emile Boulpaep

In Equation 17-13 (shown here as Equation NE 17-3),

$$Re = \frac{2r\bar{v}\rho}{\eta} \quad (\text{NE 17-3})$$

the mean linear velocity (\bar{v}) is expressed in $\text{centimeters} \cdot \text{second}^{-1}$, the radius (r) in centimeters, the density (ρ) in $\text{grams} \cdot \text{centimeter}^{-3}$, and the viscosity (η) in poise. When the equation is written as above—with the term $2r$ or *diameter* in the numerator—blood flow is laminar when Re is below ~ 2000 .

You may also encounter a similar equation with r , rather than $2r$, in the numerator:

$$Re = \frac{r\bar{v}\rho}{\eta} \quad (\text{NE 17-4})$$

When the equation is written in terms of radius rather than diameter, blood flow is laminar when Re is below ~ 1000 . In the first and second printings of the first edition of this text, the value 1160 was used assuming the “radius” convention in Equation NE 17-4.

Regardless of which version of the equation we use, the terms in the numerator reflect disruptive forces produced by the *inertial momentum* in the liquid, because of both the velocity term and the product $r \cdot \rho$, which is related to the mass of the moving fluid. In other words, a high inertial momentum predisposes to turbulence. The term in the denominator reflects the cohesive forces in the liquid; that is, the viscosity that tends to keep the layers of fluid together.

One way of looking at the above equations is that at low Re , flow is laminar and a tiny volume of fluid in one layer in Figure 17-5B tends to stay in that layer. When Re is sufficiently high, flow is turbulent, and that tiny volume may leave its original layer and become part of a neighboring layer—that is, it participates in eddy formation.

Another way of looking at the above equations is that a tiny volume of fluid has a certain probability of deviating course and leaving its original layer. This tendency to stray from its original layer is enhanced when velocity (\bar{v}) or density (ρ) is high (which raises inertial momentum) but is counteracted by the viscosity (which tends to hold it in the layer). The tendency to stray is also counteracted by a small radius, which reduces the number of layers and brings the average layer closer to a constraining wall—channeling the fluid.

Blood flow is laminar when Re is below ~ 2000 and is mostly turbulent when Re exceeds ~ 3000 . The terms in the numerator reflect disruptive forces produced by the *inertial momentum* in the fluid. Thus, turbulent blood flow occurs when r is large (e.g., aorta) or when \bar{v} is large (e.g., high cardiac output). Turbulent flow can also occur when a local decrease in vessel diameter (e.g., arterial stenosis) causes a local increase in \bar{v} . The term in the denominator of Equation 17-13, viscosity, reflects the cohesive forces that tend to keep the layers well organized. Therefore, a low viscosity (e.g., in anemia—a low red blood cell count) predisposes to turbulence. When turbulence arises, the parabolic profile of the linear velocity across the radius of a cylinder becomes blunted (see Fig. 17-6B).

The distinction between laminar and turbulent flow is clinically very significant. Laminar flow is silent, whereas vortex formation during turbulence sets up **murmurs**. These Korotkoff sounds are useful in assessing arterial blood flow in the traditional auscultatory method for determination of blood pressure. These murmurs are also important for diagnosis of vessel stenosis, vessel shunts, and cardiac valvular lesions (Box 17-1). Intense forms of turbulence may be detected not only as loud acoustic murmurs but also as mechanical vibrations or **thrills** that can be felt by touch.

Box 17-1

Heart Murmurs and Arterial Bruits

Stage 1: Turbulence as blood flows across diseased heart valves creates murmurs that can be readily detected by auscultation with a stethoscope. The factors causing turbulence are the ones that increase the Reynolds number: increases in vessel diameter or blood velocity and decreases in viscosity. Before the advent of sophisticated technology, such as cardiac ultrasonography, clinicians made a fine art of detecting these murmurs in an attempt to diagnose cardiac valvular disease. In general, it was appreciated that normal blood flow across normal heart valves is silent, although murmurs can occur with increased blood flow (e.g., exercise) and are not infrequently heard in young, thin individuals with dynamic circulations. The grading of heart murmurs helps standardize the cardiac examination from observer to observer. Thus, a grade 1 heart murmur is barely audible, grade 2 is one that is slightly more easily heard, and grades 3 and 4 are progressively louder. A grade 5 murmur is the loudest murmur that still requires a stethoscope to be heard. A grade 6 murmur is so loud that it can be heard with the stethoscope off the chest and is often accompanied by a thrill. The location, duration, pitch, and quality of a murmur aid in identifying the underlying valvular disorder.

Stage 2: Blood flowing through diseased arteries can also create a murmur or a thrill. By far the most common cause is atherosclerosis, which narrows the vessel lumen and thus increases velocity. In patients with advanced disease, these murmurs can be heard in virtually every major artery, most easily in the carotid and femoral arteries. Arterial murmurs are usually referred to as bruits.

Pressure and flow oscillate with each heartbeat between maximum systolic and minimum diastolic values

Thus far we have considered blood flow to be steady and driven by a constant pressure generator. That is, we have been working with a *mean* blood flow and a *mean* driving pressure (the difference between the mean arterial and venous pressures). However, we are all aware that the heart is a pump of the “two-stroke” variety, with a filling and an emptying phase. Because both the left and right hearts perform their work in a cyclic fashion, flow is pulsatile in both the systemic and pulmonary circulations.

The mean blood pressure in the large systemic arteries is ~95 mm Hg. This is a single, time-averaged value. In reality, the blood pressure cycles between a maximal **systolic** arterial pressure (~120 mm Hg) that corresponds to the contraction of the ventricle and a minimal **diastolic** arterial pressure (~80 mm Hg) that corresponds to the relaxation of the ventricle (Fig. 17-7). The difference between the systolic pressure and the diastolic pressure is the **pulse pressure**. Note that the mean arterial pressure is not the arithmetic mean of systolic and diastolic values, which would be $(120 + 80)/2 = 100$ mm Hg in our example; rather, it is the area beneath the curve, which describes the pressure in a single cardiac cycle (see Fig. 17-7, blue area) divided by the duration of the cycle. A reasonable value for the mean arterial pressure is 95 mm Hg.

FIGURE 17-7 Time course of arterial pressure during one cardiac cycle. The area beneath the blue pressure curve, divided by the time of one cardiac cycle, is mean arterial pressure (*horizontal yellow line*). The yellow cross-hatched area is the same as the blue area.

Like arterial pressure, flow through arteries also oscillates with each heartbeat. Because both pressure and flow are pulsatile, and because the pressure and flow waves are not perfectly matched in time, we cannot describe the relationship between these two parameters by a simple Ohm's law–like relationship ($\Delta P = F \cdot R$), which is analogous to a simple DC circuit in electricity. Rather, if we were to model pressure and flow in the circulatory system, we would have to use a more complicated approach, analogous to that used to understand AC electrical circuits. [N17-5](#)

N17-5

Mechanical Impedance of Blood Flow

Contributed by Ridder Emile Boulpaep

We began this chapter by drawing an analogy between the flow of blood and electrical current, as described by a Ohm's law of hydrodynamics: $\Delta P = F \cdot R$. We now know that there are other factors that influence pressure. In addition to the flow resistance R (electrical analogy = ohmic resistor), we must also consider the compliance C (electrical analogy = capacitance) as well as the inertance L (electrical analogy = inductance). A similar problem is faced in electricity when dealing with alternating (as opposed to direct) currents. In Ohm's law for alternating currents, $E = I \cdot Z$, where Z is a complex quantity called the impedance. Z depends on the electrical resistance R , the electrical capacitance C , and the electrical inductance L . Similarly, for blood flow, we can write $\Delta P = F \cdot Z$, where Z is also a complex quantity, called **mechanical impedance**, that includes the following:

1. **Compliant impedance** that opposes volume change (compliance of the vessel).

2. **Viscous (or resistive) impedance** that opposes flow (shearing forces in the liquid). This term is the R of Ohm's law of hydrodynamics: $\Delta P = F \cdot R$ (Equation 17-1).
3. **Inertial impedance** that opposes a change of flow (kinetic energy of fluid and vessels).

Considering all these sources of pressure, we can state that the total pressure difference at any point in time, instead of being given by Ohm's law, is

$$P_{\text{total}} = P_{\text{gravity}} + P_{\text{compliance}} + P_{\text{viscous resistance}} + P_{\text{inertance}} \quad (\text{NE 17-5})$$

The P_{gravity} term in the above equation is discussed on pages 418–419 in the section titled “Gravity causes a hydrostatic pressure difference when there is a difference in height.”

Origins of Pressure in the Circulation

Four factors help generate pressure in the circulation: gravity, compliance of the vessels, viscous resistance, and inertia.

Gravity causes a hydrostatic pressure difference when there is a difference in height

Because gravity produces a hydrostatic pressure difference between two points whenever there is a *difference in height* (Δh ; see [Equation 17-4](#)), one must always express pressures relative to some reference h level. In cardiovascular physiology, this reference—zero height—is the level of the heart.

Whether the body is recumbent (i.e., horizontal) or upright (i.e., erect) has a tremendous effect on the intravascular pressure. In the horizontal position ([Fig. 17-8A](#)), where we assume that the entire body is at the level of the heart, we do not need to add a hydrostatic pressure component to the various intravascular pressures. Thus, the mean pressure in the aorta is 95 mm Hg, and—because it takes a driving pressure of ~ 5 mm Hg to pump blood into the end of the large arteries—the mean pressure at the end of the large arteries in the foot and head is 90 mm Hg. Similarly, the mean pressure in the large veins draining the foot and head is 5 mm Hg, and—because it takes a driving pressure of ~ 3 mm Hg to pump blood to the right atrium—the mean pressure in the right atrium is 2 mm Hg.

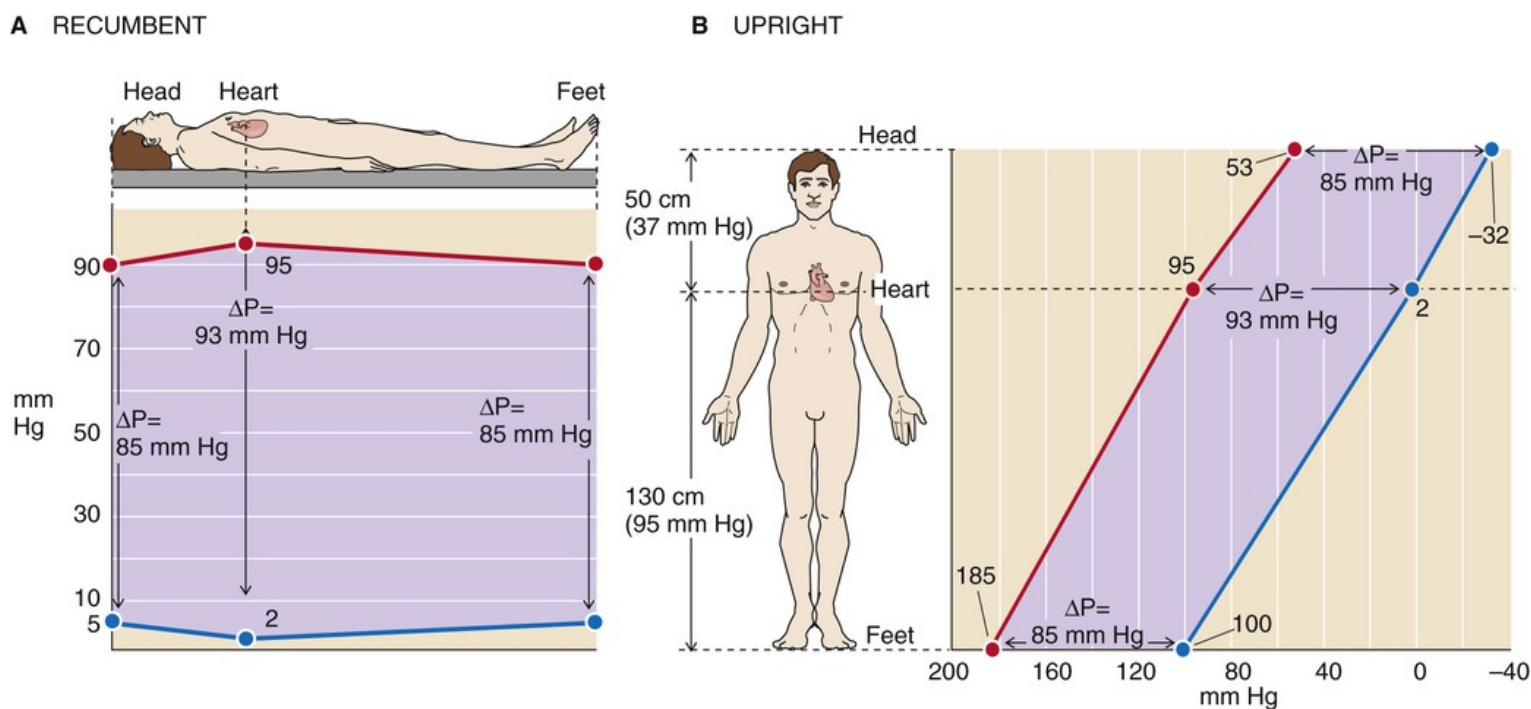

FIGURE 17-8 Arterial and venous pressures in the horizontal and upright positions. The pressures are different in **A** and **B**, but the driving pressures (ΔP) between arteries and veins (*separation between red and blue lines, violet shading*) are the same.

When a 180-cm tall person is standing (see [Fig. 17-8B](#)), we must *add* a 130-cm column of blood (the Δh between the heart and large vessels in the foot) to the pressure prevailing in the large arteries and veins of the foot. Because a water column of 130 cm is equivalent to 95 mm Hg, the mean pressure for a

large artery in the foot will be $90 + 95 = 185$ mm Hg, and the mean pressure for a large vein in the foot will be $5 + 95 = 100$ mm Hg. On the other hand, we must *subtract* a 50-cm column of blood from the pressure prevailing in the head. Because a water column of 50 cm is equivalent to 37 mm Hg, the mean pressure for a large artery in the head will be $90 - 37 = 53$ mm Hg, and the mean pressure for a large vein in the head will be $5 - 37 = -32$ mm Hg. Of course, this “negative” value really means that the pressure in a large vein in the head is 32 mm Hg lower than the reference pressure at the level of the heart.

In this example, we have simplified things somewhat by ignoring the valves that interrupt the blood column. In reality, the veins of the limbs have a series of one-way valves that allow blood to flow only toward the heart. These valves act like a series of relay stations, so that the contraction of skeletal muscle around the veins pushes blood from one valve to another (see [p. 516](#)). Thus, veins in the foot do not “see” the full hydrostatic column of 95 mm Hg when the leg muscles pump blood away from the foot veins.

Although the absolute arterial and venous pressures are much higher in the foot than in the head, the ΔP that *drives* blood flow is the same in the vascular beds of the foot and head. Thus, in the horizontal position, the ΔP across the vascular beds in the foot or head is $90 - 5 = 85$ mm Hg. In the upright position, the ΔP for the foot is $185 - 100 = 85$ mm Hg, and for the head, $53 - (-32) = 85$ mm Hg. Thus, gravity does not affect the driving pressure that governs flow. On the other hand, in “dependent” areas of the body (i.e., vessels “below” the heart in a gravitational sense), the hydrostatic pressure does tend to increase the *transmural* pressure (intravascular versus extravascular “tissue” pressure) and thus the diameter of distensible vessels. Because various anatomical barriers separate different tissue compartments, it is assumed that gravity does not appreciably affect this tissue pressure.

Low compliance of a vessel causes the transmural pressure to increase when the vessel blood volume is increased

Until now, we have considered blood vessels to be rigid tubes, which, by definition, have fixed volumes. If we were to try to inject a volume of fluid into a truly rigid tube with closed ends, we could in principle increase the pressure to infinity without increasing the volume of the tube ([Fig. 17-9A](#)). At the other extreme, if the wall of the tube were to offer no resistance to deformation (i.e., infinite compliance), we could inject an infinite volume of fluid without increasing the pressure at all (see [Fig. 17-9B](#)). Blood vessels lie between these two extremes; they are distensible but have a finite compliance (see [p. 454](#)). Thus, if we were to inject a volume of blood into the vessel, the volume of the vessel would increase by the same amount (ΔV), and the intravascular pressure would also increase (see [Fig. 17-9C](#)). The ΔP accompanying a given ΔV is greater if the compliance of the vessel is lower. The relationship between ΔP and ΔV is a *static* property of the vessel wall and holds whether or not there is flow in the vessel. Thus, if we were to infuse blood into a patient's blood vessels, the intravascular pressure would rise throughout the circulation, even if the heart were stopped.

FIGURE 17-9 Compliance: changes in pressure with vessels of different compliances.

The viscous resistance of blood causes an axial pressure difference when there is flow

As we saw in Ohm's law of hydrodynamics (see [Equation 17-1](#)), during steady flow down the axis of a tube (see [Fig. 17-2](#)), the driving pressure (ΔP) is proportional to both flow and resistance. Viewed differently, if we want to achieve a constant flow, then the greater the resistance, the greater the ΔP that we must apply along the axis of flow. Of the four sources of pressure in the circulatory system, this ΔP due to viscous resistance is the only one that appears in Poiseuille's law (see [Equation 17-9](#)).

The inertia of the blood and vessels causes pressure to decrease when the velocity of blood flow increases

For the most part, we have been assuming that the flow of blood as well as its mean linear velocity is steady. However, as we have already noted, blood flow in the circulation is not steady; the heart imparts its energy in a *pulsatile* manner, with each heartbeat. Therefore, \bar{v} in the aorta increases and reaches a maximum during systole and falls off during diastole. As we shall shortly see, these *changes in velocity* lead to compensatory changes in intravascular *pressure*.

The tradeoff between velocity and pressure reflects the conversion between two forms of energy. Although we generally state that fluids flow from a higher to a lower *pressure*, it is more accurate to say that fluids flow from a higher to a lower *total energy*. This energy is made up of both the pressure or **potential energy** and the **kinetic energy** ($KE = \frac{1}{2}mv^2$). The impact of the interconversion between these two forms of energy is manifested by the familiar **Bernoulli effect**. As fluid flows along a horizontal tube with a narrow central region, which has half the diameter of the two ends, the pressure in the central region is actually lower than the pressure at the distal end of the tube ([Fig. 17-10](#)). How can the fluid paradoxically flow against the *pressure gradient* from the lower-pressure central to the higher-pressure distal region of the tube? We saw above that flow is the product of cross-sectional area and velocity (see [Equation 17-8](#)). Because the flow is the same in both portions of the tube, but the cross-sectional area in the center is lower by a factor of 4, the *velocity* in the central region must be 4-fold higher (see table at bottom of [Fig. 17-10](#)). Although the blood in the central region has a lower potential energy (pressure = 60) than the blood at the distal end of the tube (pressure = 80), it has a 16-fold higher kinetic energy. Thus, the total energy of the fluid in the center exceeds that in the distal region, so that the fluid does

indeed flow down the *energy gradient*.

FIGURE 17-10 Bernoulli effect. For the top tube, which has a uniform radius, velocity (v) is uniform and transmural pressure (P) falls linearly with the length, which we artificially compress to fit in the available space. The bottom tube has the same upstream and downstream pressures but a constriction in the middle that is short enough so as not to increase overall resistance or overall fall in P . The constriction has cross-sectional area that is only one fourth that of the two ends. Thus, velocity in the narrow portion must be 4-fold higher than it is at the ends. Although the *total energy* of fluid falls linearly along the tube, *pressure* is lower in the middle than at the distal end.

This example illustrates an interconversion between potential energy (pressure) and kinetic energy (velocity) in *space* because velocity changes along the length of a tube even though flow is constant. We will see on [pages 511–513](#) that during ejection of blood from the left ventricle into the aorta, the flow and velocity of blood change with *time* at any point within the aorta. These changes in velocity contribute to the changes in pressure inside the aorta.

The Bernoulli effect has important practical implications for measurement of blood pressure with an open-tipped catheter. The pressure recorded with the open tip facing the flow is higher than the actual pressure by an amount corresponding to the kinetic energy of the oncoming fluid ([Fig. 17-11](#)). Conversely, the pressure recorded with the open tip facing away from the flow is lower than the actual pressure by an equal amount. The measured pressure is correct only when the opening is on the side of the catheter, perpendicular to the flow of blood.

FIGURE 17-11 Effects of kinetic energy on the measurement of blood pressure with catheters.

How to Measure Blood Pressure, Blood Flow, and Cardiac Volumes

Blood pressure can be measured directly by puncturing the vessel

One can record blood pressure anywhere along the circulation—inside a heart chamber, inside an artery, within a capillary, or within a vein. Clinicians are generally concerned with the intravascular pressure at a particular site (e.g., in a systemic artery) in reference to the barometric pressure outside the body and not with pressure *differences* between two sites.

The most direct approach for measurement of pressure is to introduce a needle or a catheter into a vessel and position the open tip at a particular site. In the first measurements of blood pressure ever performed, Stephen Hales in 1733 found that a column of blood from a presumably agitated horse rose to fill a brass pipe to a height of 3 m. It was Poiseuille who measured blood pressure for the first time by connecting a mercury-filled U-tube to arteries through a tube containing a solution of saturated NaHCO_3 . In modern times, a saline-filled transmission or conduit system connects the blood vessel to a pressure transducer. In the most primitive form of this system, a catheter was connected to a closed chamber, one wall of which was a deformable diaphragm. Nowadays, the pressure transducer is a stiff diaphragm bonded to a strain gauge that converts mechanical strain into a change in electrical resistance, capacitance, or inductance (Fig. 17-12). The opposite face of the diaphragm is open to the atmosphere, so that the blood pressure is referenced to barometric pressure. The overall performance of the system depends largely on the properties of the catheter and the strain gauge. The presence of air bubbles and a long or narrow catheter can decrease the displacement, velocity, and acceleration of the fluid in the catheter. Together, these properties determine overall performance characteristics such as sensitivity, linearity, damping of the pressure wave, and frequency response. To avoid problems with fluid transmission in the catheter, some high-fidelity devices employ a solid-state pressure transducer at the catheter tip.

FIGURE 17-12 Direct method for determining blood pressure.

In catheterizations of the **right heart**, the clinician begins by sliding a fluid-filled catheter into an antecubital vein and, while continuously recording pressure, advances the catheter tip into the superior vena cava, through the right atrium and the right ventricle, and past the pulmonary valve into the pulmonary artery. Eventually, the tip reaches and snugly fits into a smaller branch of the pulmonary artery, recording the **pulmonary wedge pressure** (see p. 519). The wedge pressure effectively measures the pressure downstream from the catheter tip, that is, the left atrial pressure.

In catheterizations of the **left heart**, the clinician slides a catheter into the brachial artery or femoral artery, obtaining the **systemic arterial blood pressure**. From there, the catheter is advanced into the aorta, the left ventricle, and finally the left atrium.

Clinical measurements of **venous pressure** are typically made by inserting a catheter into the jugular vein. Because of the low pressures, these venous measurements require very sensitive pressure transducers or water manometers.

In the research laboratory, one can measure **capillary pressure** in exposed capillary beds by inserting a micropipette that is pressurized just enough (with a known pressure) to keep fluid from entering or leaving the pipette.

Blood pressure can be measured indirectly by use of a sphygmomanometer

In clinical practice, one may measure arterial pressure indirectly by use of a manual sphygmomanometer (Fig. 17-13). An inextensible cuff containing an inflatable bag is wrapped around the arm (or occasionally, the thigh). Inflation of the bag by means of a rubber squeeze bulb to a pressure level above the expected systolic pressure occludes the underlying brachial artery and halts blood flow downstream. The pressure in the cuff, measured by means of a mercury or aneroid manometer, is then allowed to slowly decline (see Fig. 17-13, diagonal red line). The physician can use either of two methods to

monitor the blood flow downstream of the slowly deflating cuff. In the **palpatory method**, the physician detects the pulse as an indicator of flow by feeling the radial artery at the wrist. In the **auscultatory method**, the physician detects flow by using a stethoscope to detect the changing character of Korotkoff sounds over the brachial artery in the antecubital space.

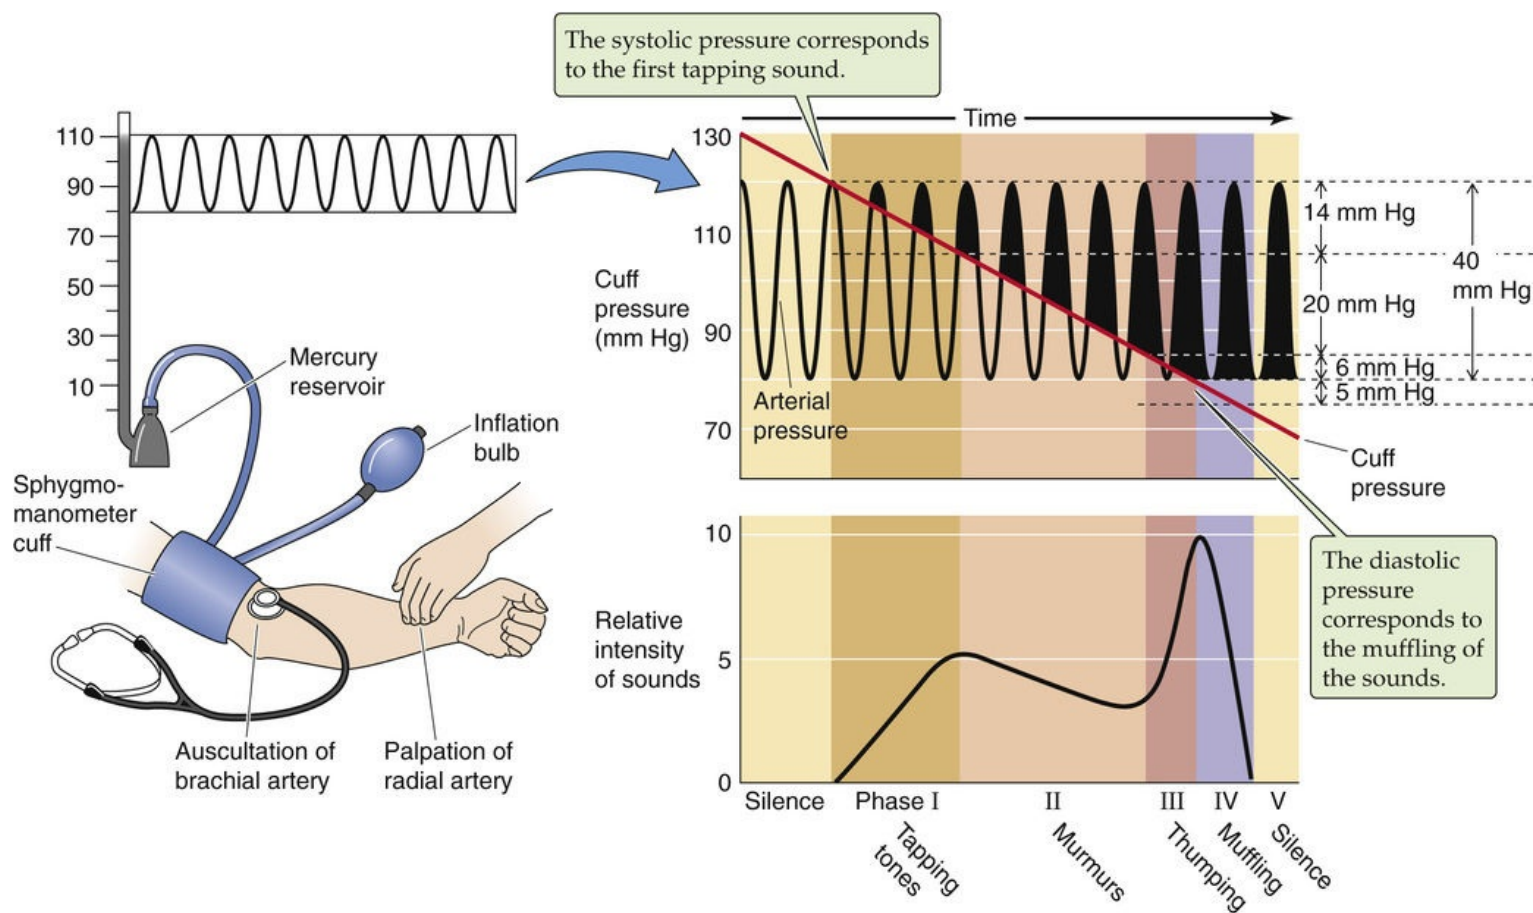

FIGURE 17-13 Sphygmomanometry. The clinician inflates the cuff to a pressure that is higher than the anticipated systolic pressure and then slowly releases the pressure in the cuff.

The palpatory method permits determination of the systolic pressure; that is, the pressure in the cuff below which it is just possible to detect a radial pulse. Because of limited sensitivity of the finger, palpation probably slightly underestimates systolic pressure. The auscultatory method permits the detection of both systolic and diastolic pressure. The sounds heard during the slow deflation of the cuff can be divided into five phases (see Fig. 17-13). During phase I, there is a sharp tapping sound, indicating that a spurt of blood is escaping under the cuff when cuff pressure is just below systolic pressure. The pressure at which these taps are first heard closely represents systolic pressure. In phase II, the sound becomes a blowing or swishing murmur. During phase III, the sound becomes a louder thumping. In phase IV, as the cuff pressure falls toward the diastolic level, the sound becomes muffled and softer. Finally, in phase V, the sound disappears. Although some debate persists about whether the point of muffling or the point of silence is the correct diastolic pressure, most favor the point of muffling as being more consistent. Actual diastolic pressure may be somewhat overestimated by the point of muffling but underestimated by the point of silence.

Practical problems arise when a sphygmomanometer is used with children or obese adults or when it is used to obtain a measurement on a thigh. Ideally, one would like to use a pressure cuff wide enough to ensure that the pressure inside the cuff is the same as that in the tissue surrounding the artery. In 1967, the

American Heart Association recommended that the pneumatic bag within the cuff be 20% wider than the diameter of the limb, extend at least halfway around the limb, and be centered over the artery. More recent studies indicate that accuracy and reliability improve when the pneumatic bag completely encircles the limb, as long as the width of the pneumatic bag is at least the limb diameter.

Blood flow can be measured directly by electromagnetic and ultrasound flowmeters

The spectrum of blood flow measurements in the circulation ranges from determinations of total blood flow (cardiac output) to assessment of flow within an organ or a particular tissue within an organ. Moreover, one can average blood flow measurements over time or record continuously. Examples of continuous recording include recordings of the phasic blood flow that occurs during the cardiac cycle or any other periodic event (e.g., breathing). We discuss both invasive and noninvasive approaches.

Invasive Methods

Invasive approaches require direct access to the vessel under study and are thus useful only in research laboratories. The earliest measurements of blood flow involved collecting venous outflow into a graduated cylinder and timing the collection with a stopwatch. This direct approach was limited to short time intervals to minimize blood loss and the resulting changes in hemodynamics. Blood loss could be avoided by ingenious but now antiquated devices that returned the blood to the circulation, in either a manual or a semiautomated fashion.

The most frequently used modern instruments for measurement of blood flow in the research laboratory are **electromagnetic flowmeters** based on the electromagnetic induction principle (Fig. 17-14). The vessel is placed in a magnetic field. According to Faraday's induction law, moving any conductor (including an electrolyte solution, such as blood) at right angles to lines of the magnetic field generates a voltage difference between two points along an axis perpendicular to both the axis of the movement and the axis of the magnetic field. The induced voltage is

$$E = B\bar{v}D \quad (17-14)$$

where B is the density of magnetic flux, \bar{v} is the average linear velocity, and D is the diameter of the moving column of blood.

The movement of an electrical conductor (i.e., blood in a vessel) through a magnetic field induces a voltage between two points (e_1 and e_2) along an axis that is mutually perpendicular to both the axis of the magnetic field and the axis of blood flow.

FIGURE 17-14 Electromagnetic flowmeter.

Ultrasound flowmeters employ a pair of probes placed at two sites along a vessel. One probe emits an ultrasound signal, and the other records it. The linear velocity of blood in the vessel either induces a change in the frequency of the ultrasound signal (Doppler effect) or alters the transit time of the ultrasound signal. Both the electromagnetic and ultrasound methods measure linear velocity, not flow per se.

Noninvasive Methods

The electromagnetic or ultrasonic flowmeters require the surgical isolation of a vessel. However, ultrasonic methods are also widely used transcutaneously on surface vessels in humans. This method is based on recording of the backscattering of the ultrasound signal from moving red blood cells. To the extent that the red blood cells move, the reflected sound has a frequency different from that of the emitted sound (Doppler effect). This frequency difference may thus be calibrated to measure flow. Plethysmographic methods are noninvasive approaches for measurement of changes in the volume of a limb or even of a whole person (see [p. 617](#)). Inflation of a pressure cuff enough to occlude veins but not arteries allows blood to continue to flow into (but not out of) a limb or an organ, so that the volume increases with time. The record of this rise in volume, as recorded by the plethysmograph, is a measure of blood flow.

With the exception of transcutaneous ultrasonography, the direct methods discussed for measurement of blood flow are largely confined to research laboratories. The next two sections include discussions of two indirect methods that clinicians use to measure mean blood flow.

Cardiac output can be measured indirectly by the Fick method, which is based on the conservation of mass

The Fick method requires that a substance be removed from or added to the blood during its flow through an organ. The rate at which X passes a checkpoint in the circulation (\dot{Q}) is simply the product of the rate at which blood volume passes the checkpoint (F) and the concentration of X in that blood:

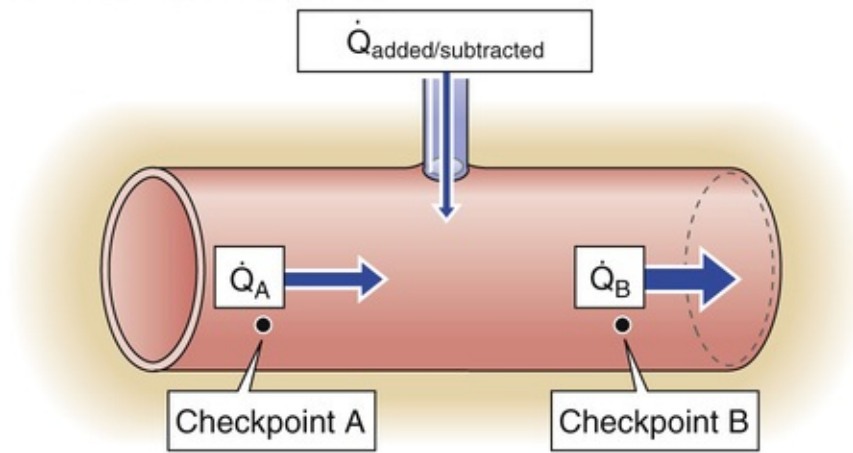

$$\dot{Q} = F \cdot [X] \quad (17-15)$$

Units: $\frac{\text{moles}}{\text{s}} = \frac{\text{liters}}{\text{s}} \cdot \frac{\text{moles}}{\text{liter}}$

The **Fick principle** is a restatement of the law of conservation of mass. The amount of X per unit time that passes a downstream checkpoint (\dot{Q}_B) minus the amount of X that passes an upstream checkpoint (\dot{Q}_A) must equal the amount of X added or subtracted per unit time ($\dot{Q}_{\text{added/subtracted}}$) between these two checkpoints (Fig. 17-15A):

$$\dot{Q}_{\text{added/subtracted}} = \dot{Q}_B - \dot{Q}_A \quad (17-16)$$

A THE FICK PRINCIPLE

B MEASUREMENT OF CARDIAC OUTPUT

FIGURE 17-15 Fick method for determining cardiac output.

$\dot{Q}_{\text{added/subtracted}}$ is positive for the addition of X. If the volume flow is identical at both checkpoints, combining [Equation 17-15](#) and [Equation 17-16](#) yields the Fick equation:

$$\dot{Q}_{\text{added/subtracted}} = F([X]_B - [X]_A) \quad (17-17)$$

We can calculate flow from the amount of X added or subtracted and the concentrations of X at the two checkpoints:

$$F = \frac{\dot{Q}_{\text{added/subtracted}}}{[X]_B - [X]_A} = \frac{\text{moles/min}}{\text{moles/liter}} = \frac{\text{liters}}{\text{min}} \quad (17-18)$$

It is easiest to apply the Fick principle to the blood flow through the lungs, which is the cardiac output (see Fig. 17-15B). The quantity added to the bloodstream is the O₂ uptake (\dot{Q}_{O_2}) by the lungs, which we obtain by measuring the subject's O₂ consumption. This value is typically 250 mL of O₂ gas per minute. The upstream checkpoint is the pulmonary artery (*point A*), where the O₂ content ([O₂]_A) is typically 15 mL of O₂ per deciliter of blood. The sample for this checkpoint must reflect the O₂ content of mixed venous blood, obtained by means of a catheter within the right atrium or the right ventricle or pulmonary artery. The downstream checkpoint is a pulmonary vein (*point B*), where the O₂ content ([O₂]_B) is typically 20 mL O₂ per deciliter of blood. We can obtain the sample for this checkpoint from any systemic artery. Using these particular values, we calculate a cardiac output of 5 L/min:

$$\begin{aligned} F &= \frac{\dot{Q}_{O_2}}{[O_2]_B - [O_2]_A} = \frac{250 \text{ mL O}_2/\text{min}}{(20 - 15) \text{ mL O}_2/\text{dL blood}} \\ &= 5 \text{ L blood/min} \end{aligned} \quad (17-19)$$

Cardiac output can be measured indirectly by dilution methods

The dye dilution method, inaugurated by G.N. Stewart in 1897 and extended by W.F. Hamilton in 1932, is a variation of the Fick procedure. One injects a known quantity of a substance (X) into a systemic vein (e.g., antecubital vein) at site A while simultaneously monitoring the concentration downstream at site B (Fig. 17-16A). It is important that the substance not leave the vascular circuit and that it be easy to follow the concentration, by either successive sampling or continuous monitoring. If we inject a single known amount (Q_X) of the indicator, an observer downstream at checkpoint B will see a rising concentration of X, which, after reaching its peak, falls off exponentially. Concentration measurements provide the interval (Δt) between the time the dye makes its first appearance at site B and the time the dye finally disappears there.

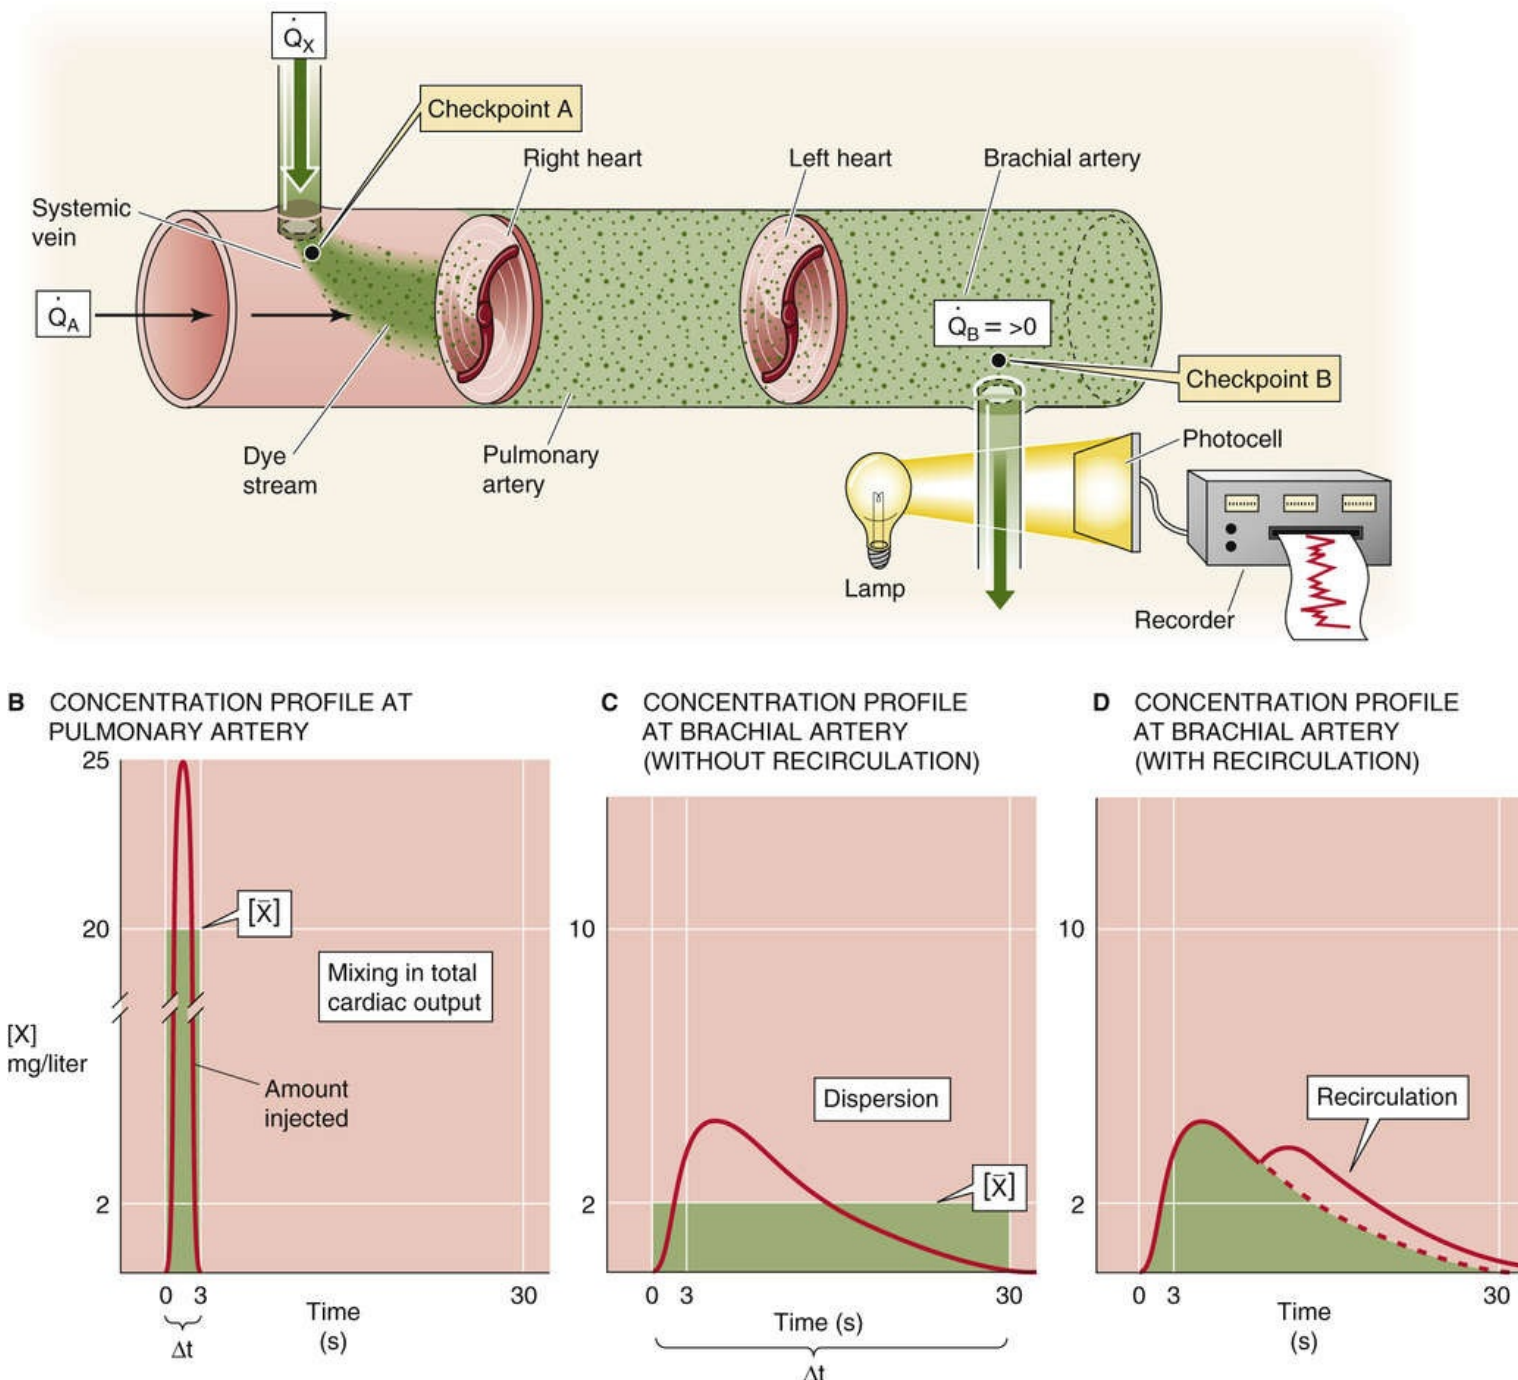

FIGURE 17-16 Dye dilution method for determining blood flow. In **B**, **C**, and **D**, the areas underneath the three red curves—as well as the three green areas—are all the same.

If site B is in the pulmonary artery, then the entire *amount* Q_X that we injected into the peripheral vein must pass site B during the interval Δt , carried by the entire cardiac output. We can deduce the average concentration $[\bar{X}]$ during the interval Δt from the concentration-versus-time curve in [Figure 17-16B](#). From the conservation of mass, we know that

$$Q_X = V \cdot [\bar{X}] \quad (17-20)$$

$$\text{Units: moles} = \text{liters} \cdot \frac{\text{moles}}{\text{liter}}$$

Because the volume of blood (V) that flowed through the pulmonary artery during the interval Δt is, by definition, the product of cardiac output and the time interval ($CO \cdot \Delta t$),

$$Q_x = CO \cdot \Delta t \cdot [\bar{X}] \quad (17-21)$$

$$\text{Units: moles} = \frac{\text{liters}}{\text{s}} \cdot \text{s} \cdot \frac{\text{moles}}{\text{liter}}$$

Note that the product $\Delta t \cdot [\bar{X}]$ is the area under the concentration-versus-time curve in [Figure 17-16B](#). Solving for CO, we have

$$CO = \frac{Q_x}{[\bar{X}] \cdot \Delta t} = \frac{Q_x}{\text{Area}} \quad (17-22)$$

In practice, cardiologists monitor $[X]$ in the brachial artery. Obviously, only a fraction of the cardiac output passes through a brachial artery; however, this fraction is the same as the fraction of Q_x that passes through the brachial artery. If we were to re-derive [Equation 17-22](#) for the brachial artery, we would end up multiplying both the CO and Q_x terms by this same fraction. Therefore, even though only a small portion of both cardiac output and injected dye passes through any single systemic artery, we can still use [Equation 17-22](#) to compute cardiac output with data from that artery.

Compared with the $[X]$ profile in the pulmonary artery, the $[X]$ profile in the brachial artery is not as tall and is more spread out, so that $[\bar{X}]$ is smaller and Δt is longer. However, the product $[\bar{X}] \cdot \Delta t$ in the brachial artery—or any other systemic artery—is the same as that in the pulmonary artery. Indocyanine green dye (Cardiogreen) is the most common dye employed. Because the liver removes this dye from the circulation, it is possible to repeat the injections, after a sufficient wait, without progressive accumulation of dye in the plasma. Imagine that after we inject 5 mg of the dye, $[\bar{X}]$ under the curve is 2 mg/L and Δt is 0.5 min. Thus,

$$CO = \frac{5 \text{ mg}}{2 \text{ mg/L} \times 0.5 \text{ min}} = 5 \text{ L/min} \quad (17-23)$$

A practical problem is that after we inject a marker into a systemic vein, blood moves more quickly through some pulmonary beds than others, so that the marker arrives at checkpoint B at different times. This process, known as dispersion, is the main cause of the flattening of the $[X]$ profile in the brachial artery (see [Fig. 17-16C](#)) versus the pulmonary artery (see [Fig. 17-16B](#)). If we injected the dye into the *left atrium* and monitored it in the *systemic veins*, the dispersion would be far worse because of longer and more varied path lengths in the systemic circulation compared with the pulmonary circulation. In fact, the concentration curve would be so flattened that it would be difficult to resolve the area underneath the $[X]$ profile.

A second practical problem with a closed circulatory system is that before the initial $[X]$ wave has

waned, recirculation causes the injected indicator to appear for a second time in front of the sensor at checkpoint B (see Fig. 17-16D). Extrapolation of the exponential decay of the first wave can correct for this problem.

The thermodilution technique is a convenient alternative approach to the dye technique. In this method, one injects a bolus of cold saline and an indwelling thermistor is used to follow the dilution of these “negative calories” as a change of temperature at the downstream site. In the thermodilution technique, a temperature-versus-time profile replaces the concentration-versus-time profile. During cardiac catheterization, the cardiologist injects a bolus of cold saline into the right atrium and records the temperature change in the pulmonary artery. The distance between upstream injection and downstream recording site is kept short to avoid heat exchange in the pulmonary capillary bed. The advantages of this method are that (1) the injection of cold saline can be repeated without harm, (2) a single venous (versus venous and arterial) puncture allows access to both the upstream and the downstream sites, (3) less dispersion occurs because no capillary beds are involved, and (4) less recirculation occurs because of adequate temperature equilibration in the pulmonary and systemic capillary beds. A potential drawback is incomplete mixing, which may result from the proximity between injection and detection sites.

Regional blood flow can be measured indirectly by “clearance” methods

The methods used to measure regional blood flow are often called clearance methods, although the term here has a meaning somewhat different from its meaning in kidney physiology. Clearance methods are another application of the Fick principle, using the rate of uptake or elimination of a substance by an organ together with a determination of the difference in concentration of the indicator between the arterial inflow and venous outflow (i.e., the **a-v difference**). By analogy with Equation 17-18, we can compute the blood flow through an organ (F) from the rate at which the organ removes the test substance X from the blood (\dot{Q}_x) and the concentrations of the substance in arterial blood ($[X]_a$) and venous blood ($[X]_v$):

$$F = \frac{\dot{Q}_x}{[X]_a - [X]_v} = \frac{\text{moles/min}}{\text{moles/liter}} = \text{liters/min} \quad (17-24)$$

One can determine **hepatic blood flow** with the use of BSP (bromsulphthalein), a dye that the liver almost completely clears and excretes into the bile (see p. 951). Here, \dot{Q}_x is the rate of removal of BSP from the blood, estimated as the rate at which BSP appears in the bile. $[X]_a$ is the concentration of BSP in a systemic artery, and $[X]_v$ is the concentration of BSP in the hepatic vein.

In a similar manner, one can determine **renal blood flow** with the use of PAH (para-aminohippurate). The kidneys almost completely remove this compound from the blood and secrete it into the urine (see pp. 749–750).

It is possible to determine **coronary blood flow** or **regional blood flow** through skeletal muscle from the tissue clearance of rapidly diffusing inert gases, such as the radioisotopes ^{133}Xe and ^{85}Kr .

Finally, one can use the rate of disappearance of nitrous oxide (N_2O), a gas that is historically important as the first anesthetic, to compute cerebral blood flow.

A similar although qualitative approach is thallium scanning to assess coronary blood flow. Here one

measures the uptake of an isotope by the heart muscle, rather than its clearance (Box 17-2).

Box 17-2

Thallium Scanning for Assessment of Coronary Blood Flow

Thallium is an ion that acts as a potassium analog and enters cells through the same channels or transporters as K^+ does. Active cardiac muscle takes up injected ^{201}Tl , provided there is adequate blood flow. Therefore, the rate of uptake of the ^{201}Tl isotope by the heart is a useful qualitative measure of coronary blood flow. Complete ^{201}Tl myocardial imaging is possible by two-dimensional scanning of the emitted gamma rays or by computed tomography for a three-dimensional image. Thus, in those portions of myocardial tissue supplied by stenotic coronary vessels, the uptake is slower, and these areas appear as defects on a thallium scan. Thallium scans are used to detect coronary artery disease during exercise stress tests.

Ventricular dimensions, ventricular volumes, and volume changes can be measured by angiography and echocardiography

Clinicians can use a variety of approaches to examine the cardiac chambers. **Gated radionuclide imaging** employs compounds of the gamma-emitting isotope $^{99\text{m}}\text{Tc}$,  **N17-6** which has a half-life of 6 hours. After $^{99\text{m}}\text{Tc}$ is injected, a gamma camera provides imaging of the cardiac chambers. Electrocardiogram (ECG) gating (i.e., synchronization to a particular spot on the ECG) allows the apparatus to snap a picture at a specific part of the cardiac cycle and to sum these pictures over many cycles. Because this method does not provide a high-resolution image, it yields only a *relative* ventricular volume. From the difference between the count at the maximally filled state (end-diastolic volume) and at its minimally filled state (end-systolic volume), the cardiologist can estimate the fraction of ventricular blood that is ejected during systole—the **ejection fraction**—which is an important measure of cardiac function.

N17-6

$^{99\text{m}}\text{Tc}$ Scanning

Contributed by Emile Boulpaep

Several compounds labeled with $^{99\text{m}}\text{Tc}$ —for instance, technetium Tc 99m sestamibi and technetium Tc 99m tetrofosmin—have been introduced for imaging myocardial perfusion. The $^{99\text{m}}\text{Tc}$ label emits gamma radiation at 140 keV by an isomeric transition (indicated by the *m* in 99m); it has a half-life of 6 hours. Following injection, the initial distribution of these agents in the myocardium is proportional to the *relative distribution* of myocardial blood flow. The radiochemical enters cardiac myocytes passively in such a way that about 30% to 40% of the chemical is extracted by the myocardium. Extraction may be enhanced by administering nitrates prior to injection. Because the radiochemical leaves the myocyte rather slowly (over several hours), one can perform the imaging with the gamma camera over a time period of hours. Note that *absolute measurements* of myocardial blood flow would require positron-emission tomography (PET), which can quantitate counts per unit volume of tissue.

It is possible to use $^{99\text{m}}\text{Tc}$ -labeled compounds not only for assessing myocardial perfusion but also for

assessing myocardial function. In single-photon emission computed tomography (SPECT), the computer acquires imaging data synchronized with the R wave of the ECG (see Fig. 21-7). This gated imaging allows one to display end-diastolic and end-systolic images along various axes of the heart. These end-diastolic and end-systolic dimensions can then be compared to assess ejection fraction, stroke volume, regional wall motion, and regional wall thickening.

Angiography can accurately provide the linear dimensions of the ventricle, allowing the cardiologist to calculate *absolute* ventricular volumes. A catheter is threaded into either the left or the right ventricle, and saline containing a contrast substance (i.e., a chemical opaque to x-rays) is injected into the ventricle. This approach provides a two-dimensional projection of the ventricular volume as a function of time. In magnetic resonance imaging, the physician obtains a nuclear magnetic resonance (NMR) image of the protons in the water of the heart muscle and blood. However, because standard NMR requires long data-acquisition times, it does not provide good time resolution.

Echocardiography, which exploits ultrasonic waves to visualize the heart and great vessels, can be used in two modes. In *M-mode echocardiography* (M is for motion), the technician places a single transducer in a fixed position on the chest wall and obtains a one-dimensional view of heart components. As shown in the upper portion of [Figure 17-17A](#), the ultrasonic beam transects the anterior wall of the right ventricle, the right ventricle, the septum, the left ventricle, the leaflets of the mitral valve, and the posterior wall of the left ventricle. The lower portion of [Figure 17-17A](#) shows the positions of the borders between these structures (x-axis) during a single cardiac cycle (y-axis) and thus how the size of the left ventricle—along the axis of the beam—changes with time. Of course, the technician can obtain other views by changing the orientation of the beam.

A PRINCIPLE OF ECHOCARDIOGRAPHY

B ASSUMED VENTRICULAR GEOMETRY

FIGURE 17-17 M-mode and two-dimensional echocardiography. In **A**, the tracing on the bottom shows the result of an M-mode echocardiogram (i.e., transducer in a single position) during one cardiac cycle. The waves represent motion (M) of heart boundaries transected by a stationary ultrasonic beam. In two-

dimensional echocardiography (*upper panel*), the probe rapidly rotates between the two extremes (*broken lines*), producing an image of a slice through the heart at one instant in time.

In *two-dimensional echocardiography*, the probe automatically and rapidly pivots, scanning the heart in a single anatomical slice or plane (see Fig. 17-17A, area between the two broken lines) and providing a true cross section. This approach is therefore superior to angiography, which provides only a two-dimensional projection. Because cardiac output is the product of heart rate and stroke volume, one can calculate cardiac output from echocardiographic measurements of ventricular end-diastolic and end-systolic volume.

A problem common to angiography and M-mode echocardiography is that it is impossible to compute ventricular volume from a single dimension because the ventricle is not a simple sphere. As is shown in Figure 17-17B, the left ventricle is often assumed to be a *prolate ellipse*, with a long axis L and two short axes D_1 and D_2 . To simplify the calculation and to allow ventricular volume to be computed from a single measurement, it is sometimes assumed that D_1 and D_2 are identical and that D_1 is half of L . Unfortunately, use of this algorithm and just a single dimension, as provided by M-mode echocardiography, often yields grossly erroneous volumes. Use of two-dimensional echocardiography to sum information from several parallel slices through the ventricle, or from planes that are at a known angle to one another, can yield more accurate volumes.

N17-7

Ventricular Volume from M-Mode Echocardiography

Contributed by Emile Boulpaep

As shown in Figure 17-17B, the left ventricle is often assumed to be a *prolate ellipse*, with a long axis L and two short axes D_1 and D_2 . To simplify the calculation, and to allow ventricular volume to be computed from a single measurement, it is sometimes assumed that D_1 and D_2 are identical, and that D_1 is half of L . Unfortunately, use of this algorithm and just a single dimension, as provided by M-mode echocardiography, often yields grossly erroneous volumes.

One can obtain a more accurate estimate of ventricular volume by including an independent measurement of a second dimension, as is done in two-dimensional echocardiography. For example, one could obtain the long axis (L) in addition to the short axes (D_1 and D_2 , which are assumed to be the same in the simple calculation). However, the ventricle often does not resemble a prolate ellipse, certainly not in pathological states. Thus, cardiologists have used more complex geometric models (e.g., bullet shape).

In addition to ultrasound methods and angiography, the technique of *magnetic resonance angiography*, an application of magnetic resonance tomography, is used to obtain two-dimensional images of slices of ventricular volumes or of blood vessels.

In contrast to standard echocardiography, **Doppler echocardiography** provides information on the velocity, direction, and character of blood flow, just as police radar monitors traffic. In Doppler echocardiography (as with police radar), most information is obtained with the beam parallel to the flow of blood. In the simplest application of Doppler flow measurements, one can continuously monitor the velocity of flowing blood in a blood vessel or part of the heart. On such a record, the x-axis represents time, and the y-axis represents the spectrum of *velocities* of the moving red blood cells (i.e., different cells can be moving at different velocities). Flow toward the transducer appears above baseline, whereas

flow away from the transducer appears below baseline. The intensity of the record at a single point on the y-axis (encoded by a gray scale or false color) represents the strength of the returning signal, which depends on the *number* of red blood cells moving at that velocity. Thus, Doppler echocardiography is able to distinguish the character of flow: laminar versus turbulent. Alternatively, at one instant in time, the Doppler technician can scan a region of a vessel or the heart, obtaining a two-dimensional, color-encoded map of blood velocities. If we overlay such two-dimensional Doppler data on a two-dimensional echocardiogram, which shows the position of the vessel or cardiac structures, the result is a color flow Doppler echocardiogram (Fig. 17-18).

FIGURE 17-18 The colors, which encode the velocity of blood flow, are superimposed on a two-dimensional echocardiogram, which is shown in a gray scale. **A**, Blood moves through the mitral valve and into the left ventricle during diastole. Because blood is flowing toward the transducer, its velocity is encoded as red. **B**, Blood moves out of the ventricle and toward the aortic valve during systole. Because blood is flowing away from the transducer, its velocity is encoded as blue. (From Feigenbaum H: Echocardiography. In Braunwald E [ed]: Heart Disease: A Textbook of Cardiovascular Medicine, 5th ed. Philadelphia, WB Saunders, 1997.)

Finally, a magnetic resonance scanner can also be used in two-dimensional phase-contrast mapping to yield quantitative measurements of blood flow velocity.

CHAPTER 18

Blood

Emile L. Boulpaep

Blood is a complex fluid consisting of plasma—extracellular fluid rich in proteins—and of formed elements—red blood cells (RBCs), white blood cells (WBCs), and platelets. Total blood volume is ~70 mL/kg body weight in the adult woman and ~80 mL/kg body weight in the adult man (see [Table 5-1](#)).

Blood Composition

Whole blood is a suspension of cellular elements in plasma

If you spin down a sample of blood containing an anticoagulant for ~5 minutes at 10,000 *g*, the bottom fraction contains **formed elements**—**RBCs** (or erythrocytes), **WBCs** (leukocytes, which include granulocytes, lymphocytes, and monocytes), and **platelets** (thrombocytes); the top fraction is blood plasma (Fig. 18-1). The RBCs having the highest density are at the bottom of the tube, whereas most of the WBCs and platelets form a whitish gray layer—the **buffy coat**—between the RBCs and plasma. Only a small amount of WBCs, platelets, and plasma is trapped in the bottom column of RBCs.

FIGURE 18-1 Determination of the hematocrit.

The **hematocrit** (see p. 102) is the fraction of the total column occupied by RBCs. The normal hematocrit is ~40% for adult women and ~45% for adult men. The hematocrit in the newborn is ~55% and falls to ~35% at 2 months of age, from which time it rises during development to reach adult values at puberty. The hematocrit is a measure of concentration of RBCs, not of total body red cell mass. Expansion of plasma volume in a pregnant woman reduces the hematocrit, whereas her total red cell volume also increases but less than plasma volume (see p. 1142). Immediately after hemorrhage, the hematocrit may be normal despite the loss of blood volume (see pp. 585–586). Total RBC volume is ~28 mL/kg body weight

in the adult woman and ~36 mL/kg body weight in the adult man.

Plasma is a pale-white watery solution of electrolytes, plasma proteins, carbohydrates, and lipids. Pink-colored plasma suggests the presence of hemoglobin caused by **hemolysis** (lysis of RBCs) and release of hemoglobin into the plasma. A brown-green color may reflect elevated bilirubin levels (see [Box 46-1](#)). Plasma can also be cloudy in cryoglobulinemias (see [pp. 438–439](#)). The electrolyte composition of plasma differs only slightly from that of interstitial fluid on account of the volume occupied by proteins and their electrical charge (see [Table 5-2](#)).

Plasma proteins at a normal concentration of ~7.0 g/dL account for a colloid osmotic pressure or oncotic pressure of ~25 mm Hg (see [p. 470](#)). Principal plasma proteins are albumin, fibrinogen, globulins, and other coagulation factors. The molecular weights of plasma proteins range up to 970 kDa ([Table 18-1](#)). The plasma concentration of **albumin** ranges from 3.5 to 5.5 g/dL, which provides the body with a total plasma albumin pool of ~135 g. Albumin is synthesized by the liver at a rate of ~120 mg/kg body weight per day and, due to catabolism, has a half-life in the circulation of ~20 days. Urinary losses of albumin are normally negligible (<20 mg/day; see [p. 470](#)). Plasma concentration of albumin is typically decreased in hepatic cirrhosis (see [p. 569](#)). Hepatic synthesis of albumin is strongly enhanced by a low plasma colloid osmotic pressure.

TABLE 18-1
Major Plasma Proteins*

PROTEIN FRACTIONS OF HUMAN PLASMA	MOLECULAR WEIGHT (kDa)	FUNCTION
Transferrin	62	Binds T ₃ and T ₄ Binds vitamin A
Albumin	69	Oncotic pressure Binds steroids, T ₃ , bilirubin, bile salts, fatty acids
α ₁ -antitrypsin (α ₁ AT)	54	Protease inhibitor Deficiency causes emphysema
α ₂ -macroglobulin	725	Broad-spectrum protease inhibitor Synthesized by liver
Haptoglobin	100	Binds hemoglobin
β-lipoprotein = low-density lipoprotein (LDL)	380	Binds lipid
Transferrin	80	Binds iron
Complement C3	185	Third component of complement system
Fibrinogen	340	Clotting protein Precursor of fibrin
Immunoglobulin A (IgA)	160	Mucosal immunity Synthesized by plasma cells in exocrine glands
Immunoglobulin D (IgD)	170	Synthesized by B lymphocytes
Immunoglobulin E (IgE)	190	Synthesized by B lymphocytes Binds to mast cells or basophils
Immunoglobulin G (IgG)	150	Humoral immunity Synthesized by plasma cells
Immunoglobulin M (IgM)	970	Humoral immunity Synthesized by B lymphocytes

*The proteins are listed in the approximate order of decreasing electrophoretic mobility.

Many plasma proteins are involved in blood coagulation through coagulation cascades, the end point of which is the cleavage of **fibrinogen** into fibrin monomers that further assemble into a fibrin polymer. The fibrinogen molecule is a dimer of identical heterotrimers, each composed of Aα-, Bβ-, and γ chains. Fibrinogen is synthesized only by the liver (see [Table 46-3](#)) and circulates in plasma at concentrations of 150 to 300 mg/dL. The acute-phase response ([Box 18-1](#)) greatly enhances fibrinogen synthesis. During clotting, the cross-linked polymers of fibrin form strands that trap red and white cells, platelets, and plasma inside the thrombus (i.e., blood clot). Subsequent interaction of myosin and actin in the platelets of the clot allows the clot to shrink to a plug that expels a slightly yellow-tinged fluid. This residual fluid is **serum**, which differs principally from plasma by the absence of fibrinogen and other coagulation factor.

However, serum still contains albumin, antibodies, and other proteins. Note that *plasma* can also form a clot, but a plasma clot does not retract because it lacks platelets.

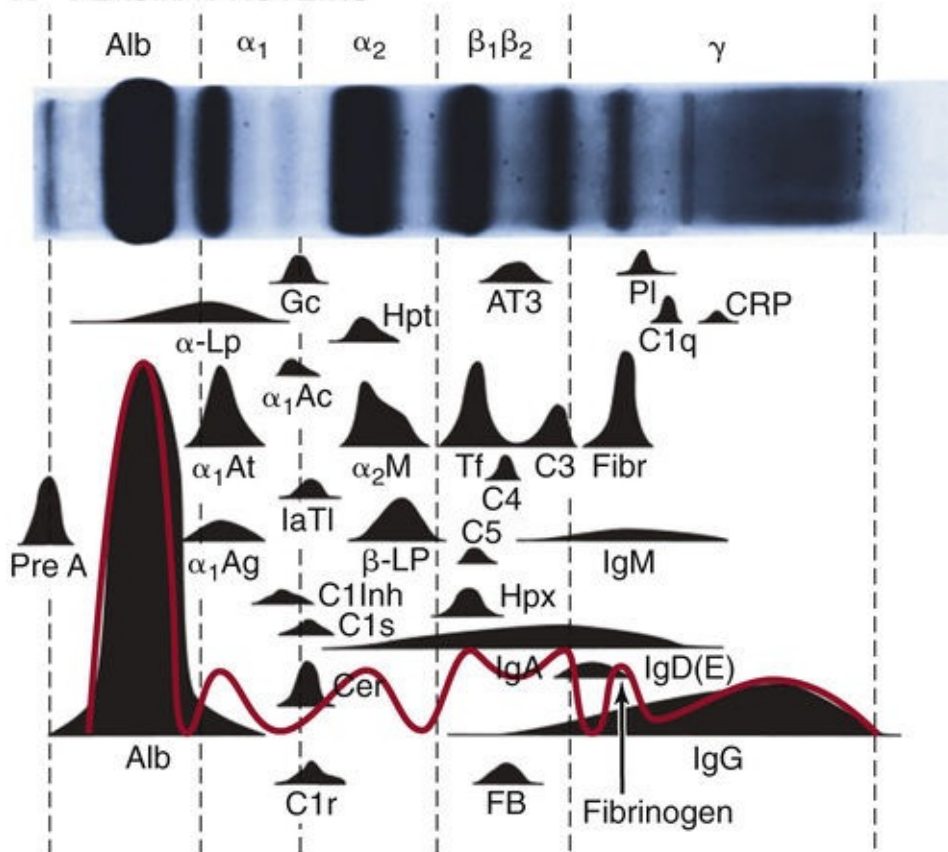

Box 18-1

Erythrocyte Sedimentation Rate

Almost any acute stress to the body (trauma, infection, disease) induces a reaction called the **acute-phase response**. During the course of several hours, in response to inflammatory cytokines the liver rapidly synthesizes and secretes into the circulatory system a number of proteins that aid in the host response to the threat. Among these proteins is fibrinogen (see p. 429), which causes RBCs to cluster and increases their effective density. When anticoagulated blood from a patient with hyperfibrinogenemia is placed in a glass tube, the RBCs fall more quickly under the influence of gravity than when the blood is from a healthy subject. After 1 hour, this sedimentation leaves a layer of clear plasma on the top of the tube (≤ 15 mm thick for normal blood and often >40 mm thick in certain inflammatory disorders). This rate of fall is called the **erythrocyte sedimentation rate (ESR)**. Although it is nonspecific because so many different conditions can cause it to increase, the ESR is still widely used by clinicians to assess the presence and severity of inflammation. It is a simple technique, easily performed in a physician's office. As an example of its utility, a patient with an inflammatory process that naturally waxes and wanes, such as lupus erythematosus, may present with nonspecific complaints such as fatigue, weakness, and achiness. An elevated ESR would suggest that these complaints are due to the reactivation of the disease and not just to a poor night's sleep or depression.

Subtraction of the albumin and fibrinogen moiety from total protein concentration yields the concentration of all the proteins grouped as **globulins**. Electrophoresis can be used to fractionate plasma proteins. The electrophoretic mobility of a protein depends on its molecular weight (size and shape) as well as its electrical charge. Plasma proteins comprise the following in decreasing order of electrophoretic mobility (Fig. 18-2A): albumin, α_1 -globulins, α_2 -globulins, β -globulins, fibrinogen, and γ -globulins. The three most abundant peaks are albumin, fibrinogen, and γ -globulins. The γ -globulins include the immunoglobulins or antibodies, which can be separated into IgA, IgD, IgE, IgG, and IgM. Immunoglobulins are synthesized by B lymphocytes and plasma cells.

A PLASMA PROTEINS

B SERUM PROTEINS

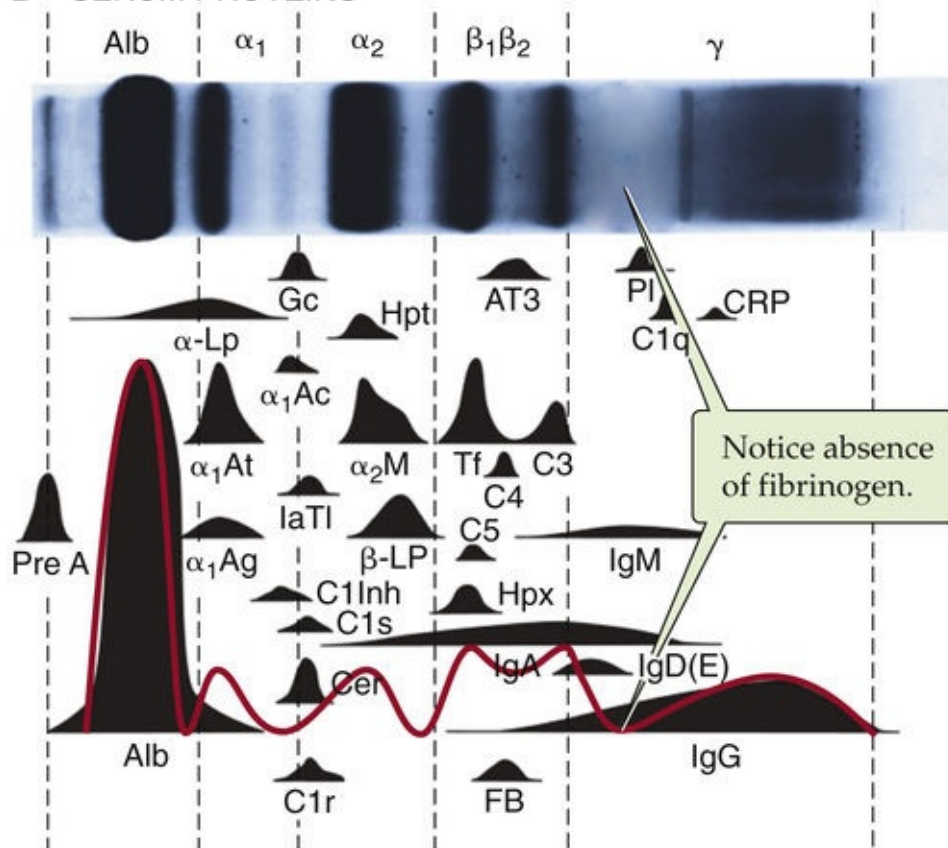

FIGURE 18-2 Electrophoretic pattern of human plasma and serum proteins. Normal concentration ranges are as follows: total protein, 6 to 8 g/dL; albumin, 3.1 to 5.4 g/dL; α_1 -globulins, 0.1 to 0.4 g/dL; α_2 -globulins, 0.4 to 1.1 g/dL; β -globulins, 0.5 to 1.2 g/dL; γ -globulins, 0.7 to 1.7 g/dL.

Clinical laboratories most often perform electrophoresis of blood proteins on *serum* instead of plasma (see Fig. 18-2B). Table 18-1 shows the major protein components that are readily resolved by

electrophoresis. Proteins present in plasma at low concentrations are identified by immunological techniques, such as radioimmunoassay (see [p. 976](#)) or enzyme-linked immunosorbent assay. Not listed in [Table 18-1](#) are several important carrier proteins present in plasma: ceruloplasmin (see [p. 970](#)), transcobalamin (see [p. 937](#)), corticosteroid-binding globulin (CBG; see [p. 1021](#)), insulin-like growth factor (IGF)–binding proteins (see [p. 996](#)), sex hormone–binding globulin (SHBG or TeBG; see [pp. 1119–1120](#)), thyroid-binding globulin (see [pp. 1008–1009](#)), and vitamin D–binding protein (see [p. 1064](#)). The liver synthesizes most of the globulins and coagulation factors.  **N18-1**

Bone marrow is the source of most blood cells

If you spread a drop of anticoagulated blood thinly on a glass slide, you can detect under the microscope the cellular elements of blood. In such a **peripheral blood smear**, the following mature cell types are easily recognized: erythrocytes; granulocytes divided in neutrophils, eosinophils, and basophils; lymphocytes; monocytes; and platelets ([Fig. 18-3](#)).

A NEUTROPHIL

B EOSINOPHIL

C BASOPHIL

D LYMPHOCYTE

E MONOCYTE

F PLATELETS

FIGURE 18-3 Cellular elements in a peripheral blood smear. Erythrocytes (average diameter, $\sim 7.5\ \mu\text{m}$) are present in all panels. The cellular elements are not represented according to their abundance. (From Goldman L, Ausiello D: Cecil's textbook of medicine, ed 22, Philadelphia, 2004, WB Saunders.)

Hematopoiesis is the process of generation of all the cell types present in blood. Because of the diversity of cell types generated, hematopoiesis serves multiple roles ranging from the carriage of gases to immune responses and hemostasis. Pluripotent **long-term hematopoietic stem cells (LT-HSCs)** constitute a population of **adult stem cells** found in bone marrow that are multipotent and able to self-renew. The **short-term hematopoietic stem cells (ST-HSCs)** give rise to **committed stem cells** or progenitors, which after proliferation are able to differentiate into lineages that in turn give rise to **burst-forming units (BFUs)** or **colony-forming units (CFUs)**, each of which ultimately will produce one or a limited number of mature cell types: erythrocytes, the megakaryocytes that give rise to platelets, eosinophils, basophils, neutrophils, monocytes-macrophages/dendritic cells, and B or T lymphocytes and natural killer cells ([Fig. 18-4](#)). Soluble factors known as **cytokines** guide the development of each lineage. The research of Donald Metcalf demonstrated the importance of a family of hematopoietic cytokines that stimulate colony formation by progenitor cells, the **colony-stimulating factors**. The main colony-stimulating factors are granulocyte-macrophage colony-stimulating factor (GM-CSF; see [p. 70](#)), granulocyte colony-stimulating factor (G-CSF), macrophage colony-stimulating factor (M-CSF), interleukin-3 (IL-3) and IL-5 (see [p. 70](#)), thrombopoietin (TPO), and erythropoietin (EPO; see [pp. 431–433](#)).

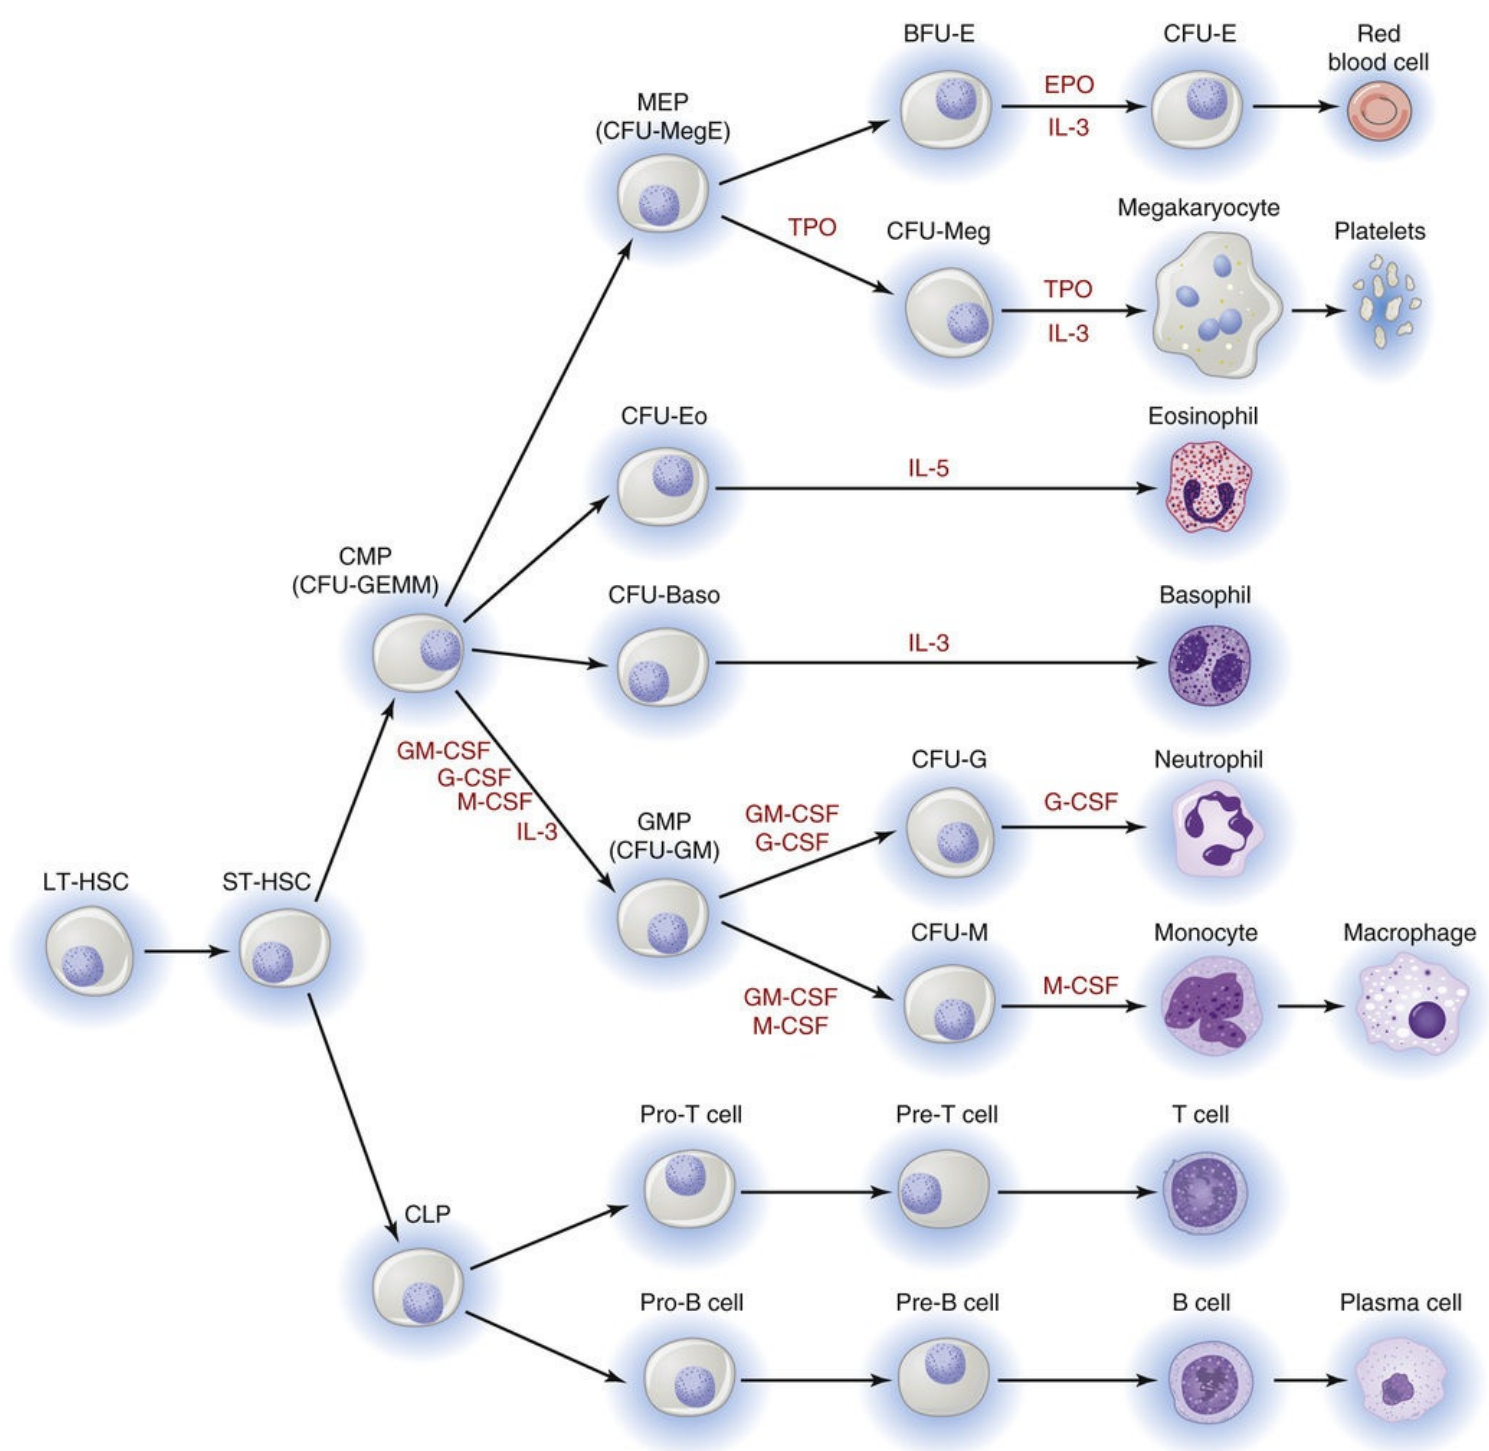

FIGURE 18-4 Hematopoietic lineages. CFU, colony forming unit—with suffixes -Baso (basophilic), -E (erythroid), -Eo (eosinophil), -G (granulocyte), -GEMM (granulocyte, erythrocyte, megakaryocyte, macrophage), -GM (granulocyte/macrophage), -M (macrophage), -Meg (megakaryocyte), -MegE (megakaryocyte/erythroid); CMP, common myeloid progenitor; CLP, common lymphoid progenitor; GMP, granulocyte-macrophage progenitor; MEP, megakaryocyte-erythroid progenitor.

GM-CSF is a glycoprotein that stimulates proliferation of a common myeloid progenitor and promotes the production of neutrophils, eosinophils, and monocytes-macrophages. Recombinant GM-CSF (sargramostim [Leukine]) is used clinically after bone marrow transplantation and in certain acute leukemias.

G-CSF and **M-CSF** are glycoproteins that guide the ultimate development of granulocytes and monocytes-macrophages/dendritic cells, respectively. Recombinant G-CSF (filgrastim [Neupogen]) is used therapeutically in neutropenia (e.g., after chemotherapy). M-CSF is also required for osteoclast development (see p. 1057 and Fig. 52-4).

IL-3 (also known as multi-CSF) has a broad effect on multiple lineages. The liver and the kidney constitutively produce this glycoprotein. **IL-5** (colony-stimulating factor, eosinophil), a homodimeric glycoprotein, sustains the terminal differentiation of eosinophilic precursors.

TPO binds to a TPO receptor called c-Mpl, which is the cellular homolog of the viral oncogene *v-mpl* (murine myeloproliferative leukemia virus). On stimulation by TPO, the Mpl receptor induces an increase in the number and size of megakaryocytes—the cells that produce platelets—which thereby greatly augments the number of circulating platelets.

EPO,  **N18-2** which is homologous to TPO, is produced by the kidney and to a lesser extent by the liver. This cytokine supports **erythropoiesis** or red cell development ([Fig. 18-5](#)). As described on [pages 93–94](#), hypoxia increases the abundance of the α subunit of hypoxia-inducible factor 1 (HIF-1 α), which enhances production of EPO messenger RNA. Although EPO is not absolutely required for early commitment of progenitor cells to the erythroid lineage, it is essential for the differentiation of burst-forming unit–erythroid cells (BFU-Es) to colony-forming unit–erythroid cells (CFU-Es) or **proerythroblasts** (also known as pronormoblasts), which still lack hemoglobin. The further maturation of cells downstream of proerythroblasts does not require EPO. Recombinant EPO has proved effective in the treatment of anemia. Hemoglobin first appears at the stage of **polychromatic erythroblasts** and is clearly evident in **orthochromatic erythroblasts**. The subsequent exocytosis of the nucleus produces **reticulocytes** (see [Fig. 18-5](#)), whereas the loss of ribosomes and mitochondria yields mature erythrocytes, which enter the circulation. The mature erythrocyte has a life span of ~120 days. Immature reticulocytes may also appear in the circulation when erythropoiesis is heavily activated.

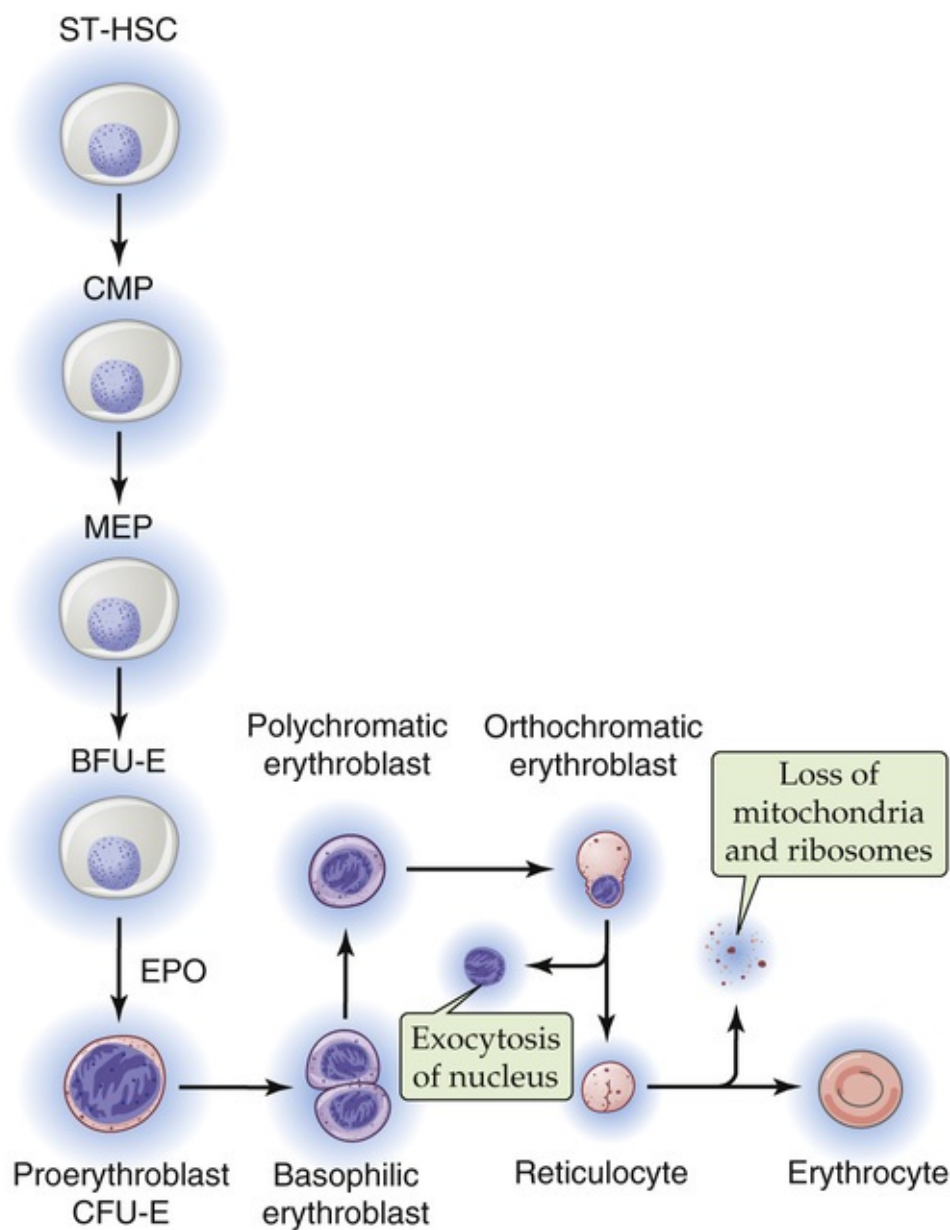

FIGURE 18-5 Erythropoiesis. CMP, common myeloid progenitor; MEP, megakaryocyte-erythroid progenitor.

N18-2

Erythropoietin

Contributed by Walter Boron

Erythropoietin (EPO) is a ~34-kDa glycoprotein made mainly in the kidney by fibroblast-like type I interstitial cells in the cortex and outer medulla (see p. 730). EPO is a growth factor related to other cytokines, and it acts through a tyrosine kinase–associated receptor (see pp. 70–71) to stimulate the production of proerythroblasts in the bone marrow as well as the development of red cells from their progenitor cells. In fetal life, the liver rather than the kidney produces EPO. Even in the adult, Kupffer cells in the liver produce some EPO.

Four lines of evidence indicate that the stimulus for EPO synthesis is a decrease in *local* P_{O_2} . First, EPO synthesis increases with anemia. Second, EPO production increases with lowered renal blood flow. Third, EPO synthesis increases with central hypoxia (i.e., low arterial P_{O_2}), such as may occur with

pulmonary disease or with living at high altitude (see p. 1231). In all three of these cases, local P_{O_2} falls as tissues respond to a decrease in O_2 delivery by extracting more O_2 from each volume of blood that passes through the kidney. Finally, EPO production increases when hemoglobin has a high O_2 affinity. Here, the renal cells must lower P_{O_2} substantially before O_2 dissociates from hemoglobin. Thus, mutant hemoglobins with high O_2 affinities, stored blood (which has low 2,3-DPG levels), and alkaline blood all lead to increased EPO production.

Besides local hypoxia, several hormones and other agents stimulate EPO production. For example, prostaglandin E_2 (PGE_2) and adenosine appear to stimulate EPO synthesis by increasing intracellular levels of cAMP. Norepinephrine and thyroid hormone also stimulate EPO release. Finally, androgens stimulate—whereas estrogens inhibit—EPO synthesis, which explains at least in part why women in their childbearing years have lower hematocrit levels than men do.

Because the kidneys are the major source of EPO, renal failure leads to reduced EPO levels and anemia. The development of recombinant EPO has had a major impact in ameliorating the anemia of chronic renal failure.

RBCs are mainly composed of hemoglobin

As evidenced by the magnitude of the hematocrit, RBCs are the most abundant elements in blood. RBCs are non-nucleated biconcave cells with a diameter of $\sim 7.5\ \mu\text{m}$ and a volume of $\sim 90\ \text{fL}$ ($90 \times 10^{-15}\ \text{L}$). Maintaining the shape of the RBC is a cytoskeleton that is anchored to the plasma membrane by glycophorin and the “band 3” Cl-HCO_3 exchanger (see [Fig. 2-9](#)). The distinctive shape of the RBC provides a much larger surface-to-volume ratio than that of a spherical cell; this maximizes diffusion area and minimizes intracellular diffusion distances for gas exchange. The RBC performs three major tasks: (1) carrying O_2 from the lungs to the systemic tissues, (2) carrying CO_2 from tissues to the lungs, and (3) assisting in the buffering of acids and bases.

[Table 18-2](#) lists the properties of RBCs that are routinely determined in the clinical laboratory. The most important constituent of the RBC is **hemoglobin**. Globin synthesis begins in the proerythroblast (see [Fig. 18-5](#)). By the end of the orthochromatic-erythroblast stage, the cell has synthesized all the hemoglobin it will carry. Normal blood hemoglobin content is $\sim 14.0\ \text{g/dL}$ in the adult female and $\sim 15.5\ \text{g/dL}$ in the adult male. The hemoglobin concentration in red cell cytosol is extremely high, $\sim 5.5\ \text{mM}$. The mean cell hemoglobin concentration is $\sim 35\ \text{g/dL}$ RBCs, or about five times the concentration of proteins in plasma. Enclosure of hemoglobin in red cells has the advantage of minimizing the loss of hemoglobin from the plasma through filtration across the blood capillary walls. The structure and various chemical forms of hemoglobin, as well as the carriage of O_2 and CO_2 by hemoglobin, are discussed in [Chapter 29](#).

TABLE 18-2
Typical Blood Cell Parameters

RBC count (10 ⁶ /μL blood)	4.0 (female); 4.5 (male)
Hematocrit (%)	40 (female); 45 (male)
Hemoglobin (g/dL blood)	14.0 (female); 15.5 (male)
Mean red cell volume, MCV (fL/cell)	90
Mean red cell hemoglobin, MCH (pg/cell)	30
Mean cell hemoglobin concentration, MCHC (g/dL RBCs)	35
Red cell distribution width, RDW (%)	13
WBC count (10 ³ /μL blood)	8
Platelet count (10 ³ /μL blood)	300

Because the mature RBCs contain no nucleus or other organelles, they can neither synthesize proteins nor engage in oxidative metabolism. The RBC can engage in two metabolic pathways: glycolysis, which consumes 90% of glucose uptake; and the pentose shunt (see Fig. 58-1), which consumes the remaining 10% of glucose. The cell generates its ATP exclusively by glycolysis. An important constituent of the RBC is **2,3-diphosphoglycerate (2,3-DPG)**. RBCs use DPG mutase to convert 1,3-diphosphoglycerate (1,3-DPG), part of the normal glycolytic pathway (see Fig. 58-6A), into 2,3-DPG. In RBCs, the cytosolic concentration of 2,3-DPG is normally 4 to 5 mM, about the same as the concentration of hemoglobin. 2,3-DPG acts on hemoglobin by reducing the O₂ affinity of hemoglobin (see pp. 654–655).

Erythrocytes contain **glutathione** at ~2 mM, more than any other cell of the body outside the hepatocyte (see p. 955). A high ratio of reduced glutathione (GSH) to oxidized glutathione (GSSG) protects the RBC against oxidant damage. Glutathione reductase regenerates GSH from GSSG in a reaction that consumes reduced nicotinamide adenine dinucleotide phosphate (NADPH). The RBC generates all its NADPH from the glycolytic intermediate glucose-6-phosphate through the pentose-shunt pathway (see Fig. 58-1).

RBCs carry two cytoplasmic isoforms of **carbonic anhydrase** (see p. 656),  **N18-3** CA I and CA II. These enzymes, which rapidly interconvert CO₂ and HCO₃⁻, play a critical role in carrying metabolically produced CO₂ from the systemic tissues to the pulmonary capillaries for elimination in the exhaled air (see pp. 655–657). CA II has one of the fastest known enzymatic turnover rates.

N18-3

Carbonic Anhydrases

Contributed by Walter Boron

Overview

The carbonic anhydrases (CAs) are a family of zinc-containing enzymes with at least 16 members among mammals; eTable 18-1 lists some of these isoforms. Physiologically, the CAs catalyze the interconversion of CO₂ and HCO₃⁻ although they also can cleave aliphatic and aromatic ester linkages. CA I is present mainly in the cytoplasm of erythrocytes. CA II is a ubiquitous cytoplasmic enzyme. CA IV is a GPI-linked enzyme (see p. 13) found, for example, on the outer surface of the apical membrane of the renal proximal tubule (see pp. 828–829). A hallmark of many CAs is their inhibition by sulfonamides (e.g., acetazolamide).

Reaction Catalyzed by CAs

Before we consider the action of CA, it is instructive to examine the interconversion of CO₂ and HCO₃⁻ in

the absence of enzyme. When $[\text{CO}_2]$ increases,

CO_2 can also form HCO_3^- by directly combining with OH^- , a reaction that becomes important at high pH values, when $[\text{OH}^-]$ is also high:

Because the dissociation of H_2O replenishes the consumed OH^- , the two mechanistically distinct pathways for HCO_3^- formation are functionally equivalent. Of course, both reaction sequences are reversible. However, in the absence of CA, the overall speed of the interconversion between CO_2 and HCO_3^- is slow at physiological pH. In fact, it is possible to exploit this slowness experimentally to generate $\text{CO}_2/\text{HCO}_3^-$ solutions that are temporarily “out of equilibrium” **NE 28-4**. Unlike normal (i.e., equilibrated) solutions, such out-of-equilibrium solutions can have virtually any combination of $[\text{CO}_2]$, $[\text{HCO}_3^-]$, and pH in the physiological range.

Structural biologists have solved the crystal structures of several CAs. At the reaction site, three histidines coordinate a zinc atom that, along with a threonine, plays a critical role in binding CO_2 and HCO_3^- . In CA II, the fastest of the CAs, a fourth histidine acts as a proton acceptor/donor. Extensive site-directed mutagenesis studies have provided considerable insight into the mechanism of the CA reaction. The CAs have the *effect* of catalyzing the slow CO_2 hydration in Equation NE 18-1. Actually, these enzymes catalyze the top reaction in Equation NE 18-2, the direct combination of CO_2 with OH^- to form HCO_3^- . CA II catalyzes *both* reactions in Equation NE 18-2:

CA II has one of the highest turnover numbers of any known enzyme: Each second, one CA II molecule can convert >1 million CO_2 molecules to HCO_3^- ions. In the erythrocyte, this rapid reaction is important for the carriage of CO_2 from the peripheral blood vessels to the lungs (see pp. 655–657). In the average cell, CAs are important for allowing the rapid buffering of H^+ by the $\text{CO}_2/\text{HCO}_3^-$ buffer pair.

Another role of CAs may be in minimizing the pH changes that occur on membrane surfaces that contain transporters that move H^+ or CO_3^{2-} . For example, the extrusion of H^+ from the cell by an Na-H

exchanger would generate a low pH at the outer surface of the cell. CA IV, with its extracellular catalytic domain, would consume much of the extruded H^+

and thereby minimize the fall in surface pH.

Preliminary data suggest that the electrogenic Na/HCO_3 cotransporters (NBCe1 and NBCe2; see p. 122), and perhaps also the other Na^+ -coupled “ HCO_3^- ” transporters (the electroneutral NBCs NBCn1 and NBCn2, the Na^+ -driven Cl/HCO_3 exchanger NDCBE; see p. 124), actually move CO_3^{2-} . As CO_3^{2-} enters the cell, the following reaction would not only replenish the CO_3^{2-} but would also generate H^+ on the outer surface of the cell:

The consequence would be a buildup of H^+ on the extracellular surface, just as in the case of an Na/H exchanger. An extracellular CA like CA IV would consume this newly generated H^+ :

The net reaction (summing Equation NE 18-5 and Equation NE 18-6) would be as follows:

Thus, when a transporter like NBCe1 appears to transport 2 HCO_3^- into the cell, what is really happening is that 1 CO_3^{2-} is being transported by the NBCe1, and 1 CO_2 and 1 H_2O are entering the cell by another mechanism. CA enzymes on both the extra- and intracellular surfaces of the cell minimize the pH changes (by consuming or generating H^+ , as necessary) generated by NBCs and H^+ transporters.

CA Deficiency in Humans

For a discussion of genetic deficiencies of CAs in humans, see Box 39-1. The homozygous absence of normal CA II causes **CA II deficiency syndrome**, characterized by osteopetrosis, renal tubular acidosis, and cerebral calcification. At least seven different mutations can cause genetic defects. The mutation that is common in patients of Arabic descent causes mental retardation but less severe osteopetrosis. Other patients may carry two different mutations. Indeed, the first three patients described with CA II deficiency syndrome, sisters in the same family, were compound heterozygotes, having received one mutation from their mother and a second from their father.

Although **CA I deficiency** exists, the homozygous condition has no obvious consequences because CA I and CA II normally contribute about equally to the CA activity in RBCs.

Nontraditional CAs

Three soluble CAs—VIII, X, and XI—are unusual in that they lack one or more of the three homologous histidine residues that enzymatically active CAs use to coordinate Zn^{2+} . In addition, two receptor tyrosine phosphatases—RPTP β and RPTP γ —have nontraditional CA domains at the location of the ligand-binding site. It is likely that these RPTPs are CO_2 and/or HCO_3^- sensors.

eTABLE 18-1
Some Human CAs*

ISOFORM	MOLECULAR MASS (kDa)	CELLULAR LOCATION	TISSUE DISTRIBUTION	RELATIVE ACTIVITY	SENSITIVITY TO SULFONAMIDES (e.g., ACZ)
I	29	Cytosol	RBCs and GI tract	15%	High
II	29	Cytosol	Nearly ubiquitous	100%	High
III	29	Cytosol	8% of soluble protein in slow-twitch (type I) muscle	1%	Low
IV	35	Extracellular surface of membrane (GPI linked)	Widely distributed, including acid-transporting epithelia	~100%	Moderate
VA, VB	35, 36	Mitochondria (soluble)	Mitochondria	~20%, ~70%	Moderate
VI	39-42	Secreted	Saliva, milk	~25%	High
VII	29	Cytosol	Cytosol	~70%	Very high
IX	54/58	Catalytic domain on extracellular surface [†]	Certain cancers	~100%	High
XII	44	Catalytic domain on extracellular surface [†]	Certain cancers	~30%	(Binds ACZ with unknown affinity)
CAXIII	29	Cytosol	Widely distributed	~10%	High
XIV	54	Catalytic domain on extracellular surface [†]	Kidney, heart, skeletal muscle, brain, retinal pigment epithelium, certain cancers	~100%	Moderate

*Several additional CAs have been cloned. In some cases they have not been functionally characterized.

[†]Integral membrane protein with one membrane-spanning segment.

ACZ, acetazolamide; GI, gastrointestinal.

CO_2 carriage also depends critically on the **Cl-HCO_3^- exchanger AE1** (see pp. 124–125 and 656) in the RBC membrane. The transporter was originally known as band 3 protein because of its position on a sodium dodecyl sulfate–polyacrylamide gel of RBC membrane proteins. AE1 is the most abundant membrane protein in RBCs, with ~1 million copies per cell. One AE1 molecule can transport as many as 50,000 ions per second—it is one of the fastest known transporters. AE1 and most other members of the SLC4 family of HCO_3^- transporters are blocked by a disulfonic stilbene known as DIDS.

The **water channel AQP1** (see p. 110) is the second most abundant membrane protein in RBCs, with ~200,000 copies per cell. AQP1 appears to contribute more than half of the CO_2 permeability of the RBC

membrane (see pp. 655–657).

Leukocytes defend against infections

Table 18-3 summarizes the relative abundance of various leukocytes in the blood. These WBCs are in two major groups: the granulocytes, on the one hand, and the lymphocytes and monocytes, on the other. **Granulocytes** are so named because of their cytoplasmic granules, which on a blood smear stained with Giemsa stain or Wright stain appear red (eosinophils), blue (basophils), or intermediate (neutrophils). The nuclear material is irregularly shaped in the form of the letter S or Z. The name *polymorphonuclear leukocytes* applies to all three types of granulocytes, but often is used to refer specifically to neutrophils. The average diameter of a neutrophil is ~12 µm, smaller than that of a monocyte (14 to 20 µm) or eosinophil (~13 µm), somewhat larger than that of a basophil (~11 µm), and much larger than that of a lymphocyte (6 to 10 µm). Granulocytes have a brief life span in the blood (<12 hours), but on activation can migrate into the tissues.

TABLE 18-3

Leukocytes*

	COUNT (10 ³ /µL BLOOD)	DIFFERENTIAL COUNT (%)
Total leukocytes	7.4	100
Neutrophils	4.4	59 (56 segmented, 3 band)
Lymphocytes	2.5	34
Monocytes	0.3	4
Eosinophils	0.2	3
Basophils	0.04	0.5

*Listed in order of abundance.

Neutrophils

The most abundant leukocytes, neutrophils are identified on the basis of the shape of the nucleus as mature *segmented neutrophils* (56% of leukocytes) and immature *band neutrophils* (3% of leukocytes). Segmented neutrophils have at least two lobes separated by a thin filament, whereas band neutrophils have a nucleus of more uniform thickness. Neutrophils have two types of granules (specific and azurophilic) that contain lysosomal enzymes, peroxidase, collagenase, and other enzymes capable of digesting foreign material. In the presence of a chemotactic attractant, neutrophils approach foreign substances, such as bacteria, to phagocytose them within a phagocytic vacuole. By a process known as degranulation, granules merge with the vacuole and empty their contents into the vacuole. Bacteria are destroyed within the vacuole by the action of hydrogen peroxide (H₂O₂) and the superoxide anion radical (O₂⁻; see p. 1238).

Eosinophils

The granules of eosinophils contain **major basic protein (MBP)**, which is toxic to parasites, as well as other enzymes. These cells are important in the response to parasites and viruses. Eosinophils also play a role in allergic reactions.

Basophils

Basophils, the least common granulocytes, are a major source of the cytokine IL-4, which in turn

stimulates B lymphocytes to produce IgE antibodies. The granules—which nearly obscure the nucleus—contain histamine, heparin, and peroxidase. Like eosinophils, basophils also play a role in allergic reactions.

Lymphocytes

Like the monocytes discussed next, lymphocytes do not have granules. Lymphocytes come in different classes, although they cannot be distinguished in a blood smear. The lymphocyte precursors originate in the bone marrow where lineage commitment occurs.

T lymphocytes or T cells, which represent 70% to 80% of peripheral lymphocytes in blood, undergo maturation primarily in the *thymus*. T lymphocytes are responsible for cell-mediated immunity.

B lymphocytes or B cells, which represent 10% to 15% of peripheral lymphocytes in blood, undergo maturation in *bone marrow* and peripheral lymphoid tissue. When B cells interact with antigen in the presence of T cells and macrophages, B cells can transform into **plasma cells**, which abundantly make and secrete antibodies that are directed against specific antigens. Thus, B cells are responsible for humoral immunity.

The remaining lymphocytes in blood include a variety of classes, such as the natural killer cells.

Monocytes

Because they migrate from the bone marrow to peripheral tissues, monocytes are not abundant in blood. Rather, monocytes spend most of their long life in peripheral tissues, where they develop into larger macrophages (20 to 40 μm in diameter). The **macrophage** (from the Greek *macros* [large] + *phagein* [eat]) serves two functions: (1) the phagocytosis of pathogens or cellular debris, and (2) the presentation of antigens to lymphocytes.

Platelets are nucleus-free fragments

Platelets form in the bone marrow by budding off from large cells called **megakaryocytes**, the maturation of which depends on TPO and IL-3. Each megakaryocyte can produce up to a few thousand platelets. Normal blood contains 150,000 to 450,000 platelets per microliter. A feedback mechanism operates between platelets and megakaryocytes, controlling platelet production. Platelets carry receptors for TPO that are able to bind and remove TPO from the plasma. Thus, a hypoplastic marrow generating few megakaryocytes leads to **thrombocytopenia** (platelet shortage) and thereby little removal of TPO, which in turn stimulates megakaryocyte production and corrects the lack of platelets. Conversely, a hyperplastic marrow creating many megakaryocytes leads to **thrombocytosis** (platelet excess) and thereby greater TPO removal, which ultimately turns off megakaryocyte production.

The life span of platelets is about 10 days. In their unactivated state, these nucleus-free fragments are disk shaped and 2 to 3 μm in diameter (Fig. 18-6). The external coat is rich in platelet receptors, which are glycoproteins. A circumferential band of microtubules composed of tubulin provides an inner skeleton. Actin and myosin contractile filaments are present in the platelet interior. In addition to mitochondria, lysosomes, and peroxisomes, platelets have two types of special organelles: α granules and, less abundantly, dense-core granules. The **α granules** store von Willebrand factor, platelet fibrinogen, and clotting factor V. The fibrinogen inside the platelets actually originates in the liver, which secretes it into the blood plasma, where megakaryocytes and platelets then endocytose the fibrinogen. The **dense-core granules** store ATP, ADP, serotonin, and Ca^{2+} . As discussed below, platelets are essential for

hemostasis (see [p. 439](#)).

FIGURE 18-6 Discoid platelet.

Blood Viscosity

The Poiseuille equation (see [Equation 17-9](#)) is based on several important assumptions (see [pp. 416–418](#)). On [p. 416](#), we considered the first five, and here we consider the sixth: whether the viscosity of whole blood is constant in a newtonian sense (see [pp. 416–418](#)).

Whole blood has an anomalous viscosity

Water and saline solutions are homogeneous or newtonian liquids. For these, the relationship between shear stress (force needed to move one lamina faster than its neighbor) and shear rate (velocity gradient between laminae) is linear and passes through the origin ([Fig. 18-7](#), blue line). Viscosity (see [Equation 17-12](#)) is the slope of this line. The relationship of shear stress to shear rate for a non-newtonian fluid, such as latex house paint, is nonlinear. Blood plasma (see [Fig. 18-7](#), yellow line) and serum are nearly newtonian. However, normal *whole blood* is *non-newtonian*: it has a nonlinear shear stress–to–shear rate relationship that intersects the y-axis above the origin (see [Fig. 18-7](#), red curve). In other words, one has to apply some threshold force (i.e., the yield shear stress) before the fluid will move at all. At lower forces, the fluid is immobile. However, at higher shear rates (such as those achieved physiologically after the velocity of blood flow has increased sufficiently), the relationship between shear stress and shear rate assumes the newtonian ideal, with a slope that corresponds to a viscosity of ~ 3.2 centipoise (cP).

FIGURE 18-7 Anomalous viscosity of blood. To emphasize deviations from linearity, we plot the square roots of shear stress (force/area) and shear rate ($\Delta v/\Delta x$).

The concept of yield shear stress can best be understood by comparing two familiar viscous solutions: honey and mayonnaise. If one estimates the effort needed to stir a pot of honey or a jar of mayonnaise with a spoon, one might assume that their apparent viscosity is the same because each solution offers about the

same resistance to deformation. However, with use of a more modest deforming force, such as gravity, a striking difference between the two fluids emerges. As one removes the spoon from the pot of honey, gravity causes the honey to drip from the spoon in a continuous stream. In contrast, a glob of mayonnaise stays attached to the spoon. The velocity of the mayonnaise is zero because its yield shear stress is greater than the force of gravity. Honey is a newtonian fluid that behaves similarly at low and high forces of deformation. Mayonnaise is similar to blood in that its viscosity appears to be infinite at low forces of deformation.

Blood viscosity increases with the hematocrit and the fibrinogen plasma concentration

In practice, the effective viscosity of whole blood depends on several physiological factors: (1) fibrinogen concentration, (2) hematocrit, (3) vessel radius, (4) linear velocity, and (5) temperature. As noted previously, the viscosity of whole blood in the linear (or newtonian) region of [Figure 18-7](#) is ~ 3.2 cP, assuming a typical fibrinogen concentration of 260 mg/dL, a hematocrit of 40%, and a temperature of 37°C. We will now see how each of these five factors influences the viscosity of blood.

Fibrinogen

Fibrinogen is a major protein component of human plasma (see [p. 429](#)) and is a key element in the coagulation cascade. The main reason for the non-newtonian behavior of blood is the interaction of this fibrinogen with RBCs. Thus, plasma (which contains fibrinogen but not RBCs) is newtonian, as is a suspension of washed RBCs in saline (without fibrinogen). However, the simultaneous presence of fibrinogen and blood cells causes the nonlinear behavior illustrated by the red curve in [Figure 18-7](#). At normal hematocrits, fibrinogen and, perhaps, low-density lipoproteins (see [p. 968](#)), electrophoretically seen as β -lipoproteins, are the only plasma proteins capable of creating a yield shear stress.

At normal hematocrits, the absence of fibrinogen (in congenital afibrinogenemia) eliminates the yield shear stress altogether. **N18-4** Conversely, hyperfibrinogenemia elevates yield shear stress and, in the extreme, leads to a clustering of RBCs that increases their effective density. This increased effective density, in turn, causes the RBCs to settle toward the bottom of a vertical tube—easily measured as an increased **erythrocyte sedimentation rate** (see [p. 430](#)). Note that fibrinogen levels tend to increase with age and with smoking.

N18-4

Effect of Fibrinogen on Blood Viscosity

Contributed by Emile Boulpaep

As shown by [Figure 18-7](#), at very low shear rates (x-axis), the viscosity of whole blood (the value of shear stress divided the shear rate for the red curve) is greater than at high shear rates because of the non-newtonian nature of whole blood. The “yield shear stress” (the intercept at the y-axis) is the minimum force (i.e., shear stress) that one needs to apply to achieve any blood flow (i.e., shearing) at all.

The yield shear stress increases with the square of the fibrinogen concentration. Fibrinogen is a large glycoprotein (molecular weight $\cong 340$ kDa) that is a hexamer composed, in turn, of a dimer of three chains, α , β , γ .

All known *congenital* fibrinogen disorders cause fibrinogen levels to be low. **Congenital afibrinogenemia** is a rare autosomal recessive disorder that leads to severely impaired hemostasis. As would be expected—because of the lack of fibrinogen—this disease is associated with near-newtonian behavior of whole-blood viscosity. **Congenital hypofibrinogenemia** is a rare genetic condition caused by mutations in one of the three fibrinogen chain genes (α , β , γ). As a result, heterozygotes exhibit poor assembly and secretion of mature fibrinogen by the liver.

Acquired alterations in fibrinogen levels include both hypofibrinogenemia and hyperfibrinogenemia. Hypofibrinogenemia can result from liver failure. Elevated fibrinogen levels are part of the acute-phase reaction during inflammation. Higher fibrinogen levels are associated with higher risk of ischemic heart disease—although there is not necessarily a cause-and-effect relationship.

Hematocrit

Increases in hematocrit elevate blood viscosity by two mechanisms (Fig. 18-8). One prevails at physiological hematocrits, the other at higher hematocrits. Starting from values of 30%, raising the hematocrit increases the interactions among RBCs—both directly and by proteins such as fibrinogen—and thereby increases viscosity. The reason is that forcing two RBCs closer together at higher hematocrits makes them more likely to stick to each other. At hematocrits $>60\%$, the cells are so tightly packed that further increases lead to cell-cell interactions that increasingly deform the RBCs, thereby increasing viscosity. In patients with polycythemia, not only is viscosity high, but the yield stress can be >4 -fold higher than normal (see Fig. 18-7). Obviously, the combination of a high hematocrit and a high fibrinogen level can be expected to lead to extremely high viscosities.

FIGURE 18-8 Dependence of viscosity on hematocrit.

Vessel Radius

In reasonably large vessels (radius greater than ~ 1 mm), blood viscosity is independent of vessel radius

Fig. 18-9). However, the viscosity decreases steeply at lower radii. This Fahraeus-Lindqvist phenomenon has four major causes.

FIGURE 18-9 Dependence of viscosity on vessel radius.

Poiseuille observed not only that RBCs move faster in the center of an arteriole or venule than at the periphery but also that the *concentration* of RBCs is greater at the center. Indeed, very near the wall, he observed a “transparent space” occupied only by plasma (Fig. 18-10A). This axial accumulation of RBCs occurs because the plasma imparts a spin to an erythrocyte caught between two layers of plasma sliding past one another at different velocities (see Fig. 17-5B). This spin causes the cell to move toward the center of the vessel, much like a billiard ball curves when struck off center (see Fig. 18-10A, inset of upper drawing). One consequence of axial accumulation is that local viscosity is lowest in the cell-poor region near the vessel wall and greatest in the cell-enriched core. The net effect in smaller vessels is that the overall viscosity of the blood is *decreased* because the cell-poor plasma (low intrinsic viscosity) moves to the periphery where the shearing forces are the greatest, whereas the cell-enriched blood (high intrinsic viscosity) is left along the central axis where the shearing forces are least. A second consequence of axial accumulation is that branch vessels preferentially skim the plasma (plasma skimming) from the main stream of the parent vessel, which leads to a lower hematocrit in branch vessels. However, some anatomical sites prevent skimming by means of an arterial cushion (see Fig. 18-10A, lower drawing).

A AXIAL ACCUMULATION

B LIMITED NUMBER OF LAMINAE IN SMALL VESSEL

C TANK TREADING OF RED BLOOD CELLS

D DEFORMATION OF RED BLOOD CELLS

The Poiseuille equation does not hold in vessels small enough to contain only a few RBCs in their cross section. Hagen's derivation of the equation assumes an infinite number of concentric laminae inside the vessel. In reality, a lamina can be no smaller than the thickness of an erythrocyte, which severely limits the number of laminae in small vessels (see [Fig. 18-10B](#)). If we were to re-derive a Poiseuille-like equation to model a small vessel, it would predict a viscosity that is *lower* than that predicted by the Poiseuille equation for a large vessel.

In vessels (e.g., capillaries) so small that their diameter is about the size of a single erythrocyte, we can no longer speak of the friction between concentric laminae. Instead, in small capillaries, the membrane of the RBC rolls around the cytoplasm in a movement called tank treading, similar to that of the track of a bulldozer (see [Fig. 18-10C](#)). As two treading erythrocytes shoot down a capillary, they spin the bolus of plasma trapped between them (bolus flow).

In vessels smaller than an erythrocyte, highly deformed—literally bullet-shaped—RBCs squeeze through the capillaries, so that the effective viscosity falls even farther below that of the bulk solution (see [Fig. 18-10D](#)). Under these conditions, a layer of plasma separates the erythrocytes from the capillary wall. The cells automatically “focus” themselves to the centerline of the capillary and maintain a fixed distance between two successive cells.

Velocity of Flow

As for an ideal fluid (see [Fig. 17-6A](#)), the dependence of flow on pressure is linear for blood *plasma* ([Fig. 18-11](#), gold curve). However, for *whole blood*, the pressure-flow relationship deviates slightly from linearity at velocities close to zero, and the situation is even worse for polycythemia. These deviations at very low flows have two explanations. First, at low flows, the shear rate is also low, which causes the whole blood (like mayonnaise) to behave in a non-newtonian manner (see [Fig. 18-7](#)) and to have a high apparent viscosity. In fact, as was already seen, one must apply a threshold force to get the blood to move at all. Thus, the red and green curves in [Figure 18-11](#) have shallower slopes at low flows than at high flows. The second reason for the nonlinear pressure-flow relationship is that the tendency for RBCs to move to the center of the stream—thereby lowering viscosity—requires a modest flow. After this axial accumulation “saturates,” however, the relationship becomes linear.

FIGURE 18-11 Pressure-flow relationships over a range of hematocrits. The slope of the linear portion of each curve is $1/\text{resistance}$; resistance (or viscosity) increases from plasma to normal whole blood to polycythemic blood.

Temperature

Cooling normal whole blood from 37°C to 0°C increases its viscosity ~2.5-fold. However, physiologically, this effect is negligible in humans except during intense cooling of the extremities. On the other hand, in some patients, the presence of **cryoglobulins** in the blood can cause an abnormal rise in viscosity even with less intense cooling of limbs. Cryoglobulins are immunoglobulins that precipitate at a temperature that is <37°C but can partially resolubilize on warming. Different cryoglobulins are associated with infections, particularly hepatitis C, as well as with several autoimmune and lymphoproliferative disorders. High blood viscosity from the precipitated cryoglobulins can lead to vessel obstruction and local thrombosis.

Hemostasis and Fibrinolysis

We have already noted that two essential requirements of the circulatory system are that the blood must be a liquid and that it must not leak through the walls of the blood vessels. Meeting these two requirements is the job of the fibrinolytic and hemostatic machinery. Blood is normally in a liquid state inside blood vessels because it does not come into contact with negatively charged surfaces (e.g., the collagen beneath endothelial cells) that activate an *intrinsic* coagulation pathway, nor does it contact tissue factors (e.g., released from damaged tissue) that activate an *extrinsic* pathway. Furthermore, thrombolytic pathways keep the coagulation pathways in check. Indeed, plasma contains proteins that can be converted to proteases that digest fibrin and thereby lyse blood clots.

Hemostasis (from the Greek *hemos* [blood] + *stasis* [standing]), or the prevention of hemorrhage, can be achieved by four methods: (1) vasoconstriction, (2) increased tissue pressure, (3) formation of a platelet plug in the case of capillary bleeding, and (4) coagulation or clot formation.

Vasoconstriction contributes to hemostasis because it raises the critical closing pressure—as we discuss on [page 454](#)—and thus collapses vessels that have an intravascular pressure below the critical closing pressure. Vessel constriction is also promoted by chemical byproducts of platelet plug formation and of coagulation. For example, activated platelets release the vasoconstrictors thromboxane A_2 (TXA₂; see [p. 64](#)) and serotonin (5-HT; see [p. 315](#)). Moreover, thrombin, a major product of the clotting machinery, triggers the endothelium to generate endothelin 1 (ET-1; see [p. 480](#)), the most powerful physiological vasoconstrictor.

Increased tissue pressure contributes to hemostasis because it decreases transmural pressure (see [p. 414](#)), which is the difference between intravascular pressure and tissue pressure. Transmural pressure is the main determinant of blood vessel radius. Given the fourth-power relationship between flow and blood vessel radius (see [Equation 17-9](#)), an increase in tissue pressure that causes radius to decrease by a factor of 2 would diminish flow by a factor of 16. We all take advantage of this principle when we press a finger against a small cut to stop the bleeding. A tourniquet increases extravascular pressure and can thus halt an arterial hemorrhage in a limb. Finally, surgeons routinely make use of this principle when applying hemostatic clamps to close off “bleeders.”

In the next two sections, we discuss the third and fourth methods of hemostasis, platelet plug formation and coagulation.

Platelets can plug holes in small vessels

In a highly controlled fashion, platelets plug small breaches in the vascular endothelium. Plug formation is a process that includes adhesion, activation, and aggregation.

Adhesion

Platelets do not adhere to themselves, to other blood cells, or to endothelial membranes. One preventive factor may be the negative surface charge on both platelets and endothelial cells. In the case of endothelial cells, the negative surface charge reflects the presence of proteoglycans, mainly heparan sulfate. Platelet adhesion occurs in response to an increase in the shearing force (see [p. 415](#)) at the surface of platelets or endothelial cells and in response to vessel injury or humoral signals.

Platelet adhesion—the binding of platelets to themselves or to other components—is mediated by

platelet receptors, which are glycoproteins in the platelet membrane. These platelet receptors are integral membrane proteins belonging to a class of matrix receptors known as integrins (see [p. 17](#)). They are usually heterodimers linked by disulfide bonds. One ligand naturally present in the blood plasma is **von Willebrand factor (vWF)**,  **N18-5** a glycoprotein made by endothelial cells and megakaryocytes. vWF is found in Weibel-Palade bodies of the endothelial cells and in α granules of platelets. High shear, certain cytokines, and hypoxia all trigger the release of vWF from endothelial cells. vWF binds to the platelet receptor known as glycoprotein Ib/Ia (Gp Ib/Ia), which is a dimer of Gp Ib linked to Gp Ia.

A breach of the endothelium exposes platelet receptors to ligands that are components of the subendothelial matrix. These ligands include **collagen**, which binds to Gp Ia/IIa, and **fibronectin** and **laminin** (see [p. 17](#)), both of which bind to Gp Ic/IIa.

N18-5

Von Willebrand Disease

Contributed by Emile Boulpaep, Walter Boron

Von Willebrand disease is named for the Finnish internist **Erik Adolf von Willebrand** (1870–1949). In 1925 von Willebrand saw a 5-year-old patient from the Åland Islands in the Sea of Bothnia between Finland and Sweden. Four of her siblings had died from bleeding at an early age and both her mother and father came from families with histories of bleeding. Von Willebrand went to the Åland Islands and found that 23 of 66 family members had bleeding problems. In his report of the family in 1926, von Willebrand concluded that this was an unknown form of hemophilia. He called it **pseudohemophilia**. It is also known as **vascular hemophilia** and **angiohemophilia**.

Activation

The binding of these ligands—or of certain other agents (e.g., thrombin) that we will discuss below—triggers a conformational change in the platelet receptors that initiates an intracellular signaling cascade, which leads to an exocytotic event known as the release reaction or platelet activation. The signal-transduction cascade involves the activation of phospholipase C (see [p. 58](#)) and an influx of Ca^{2+} . Activated platelets exocytose the contents of their **dense storage granules**, which include ATP, ADP, serotonin, and Ca^{2+} . Activated platelets also exocytose the contents of their **α granules**, which contain several proteins, including a host of growth factors and three hemostatic factors: vWF (see above) and two clotting factors that we will discuss below, clotting factor V and fibrinogen. Activated platelets also use cyclooxygenase (see [pp. 62–64](#)) to initiate the breakdown of arachidonic acid to thromboxane A_2 , which they release. Platelet activation is also associated with marked cytoskeletal and morphological changes as the platelet extends first a broad lamellipodium and then many finger-like filopodia.

Aggregation

Signaling molecules released by activated platelets amplify the platelet activation response. ADP (which binds to P2Y₁₂ receptors on platelets), serotonin, and thromboxane A_2 all activate additional platelets, and this recruitment promotes platelet aggregation. Aspirin, an inhibitor of cyclooxygenase, inhibits clotting by reducing the release of thromboxane A_2 . Another antiplatelet agent—clopidogrel—acts by inhibiting the P2Y₁₂ receptors on the platelet surface. As noted before, vWF released by activated platelets binds to the platelet receptor Gp Ib/Ia, thereby activating even more platelets and forming

molecular bridges between platelets. Platelet activation also induces a conformational change in Gp IIb/IIIa, another platelet receptor, endowing it with the capacity to bind fibrinogen. Thus, as a result of the conformational change in Gp IIb/IIIa, the fibrinogen that is always present in blood forms bridges between platelets and participates in the formation of a platelet plug. As we will see below, when cleaved by thrombin, fibrinogen also plays a critical role in clotting.

A controlled cascade of proteolysis creates a blood clot

A **blood clot** is a semisolid mass composed of both platelets and fibrin and—entrapped in the mesh of fibrin—erythrocytes, leukocytes, and serum. A **thrombus** is also a blood clot, but the term is usually reserved for an *intravascular* clot. Thus, the blood clot formed at the site of a skin wound would usually not be called a thrombus. The relative composition of thrombi varies with the site of **thrombosis** (i.e., thrombus formation). A higher proportion of platelets is present in clots of the arterial circulation, whereas a higher proportion of fibrin is present in clots of the venous circulation.

Platelet plug formation and blood clotting are related but distinct events that may occur in parallel or in the absence of one other. As we will see below, activated platelets can release small amounts of some of the factors (e.g., Ca^{2+}) that play a role in blood clotting. Conversely, as we have already noted, some clotting factors (e.g., thrombin and fibrinogen) play a role in platelet plug formation. Thus, molecular crosstalk between the machinery involved in platelet plug formation and clot formation helps coordinate hemostasis.

The cardiovascular system normally maintains a precarious balance between two pathological states. On the one hand, inadequate clotting would lead to the leakage of blood from the vascular system and, ultimately, to hypovolemia. On the other hand, overactive clotting would lead to thrombosis and, ultimately, to cessation of blood flow. The cardiovascular system achieves this balance between an antithrombotic (anticoagulant) and a prothrombotic (procoagulant) state by a variety of components of the vascular wall and blood. Promoting an antithrombotic state is a normal layer of endothelial cells, which line all luminal surfaces of the vascular system. Promoting a prothrombotic state are events associated with vascular damage: (1) the failure of endothelial cells to produce the proper antithrombotic factors, and (2) the physical removal or injury of endothelial cells, which permits the blood to come into contact with thrombogenic factors that lie beneath the endothelium. Also promoting a prothrombotic state is the activation of platelets by any of the ligands that bind to platelet receptors, as discussed above. For instance, as platelets flow past artificial mechanical heart valves, the shearing forces can activate the platelets.

According to the classical view, two distinct sequences can precipitate coagulation: the intrinsic pathway and the extrinsic pathway. It is the intrinsic pathway that becomes activated when blood comes into contact with a negatively charged surface—in the laboratory we can mimic this process by putting blood into a glass test tube. The extrinsic pathway is activated when blood comes in contact with material from damaged cell membranes. In both cases, the precipitating event triggers a chain reaction that converts precursors into activated factors, which in turn catalyze the conversion of other precursors into other activated factors, and so on. Most of these “precursors” are zymogens that give rise to “activated factors” that are serine proteases. Thus, *controlled proteolysis* plays a central role in amplifying the clotting signals. However, the cascades do not occur in the fluid phase of the blood, where the concentration of each of these factors is low. In the case of the intrinsic pathway, the chain reaction occurs mainly at the membrane of activated platelets. In the case of the extrinsic pathway, the reactions occur mainly at a “tissue factor” that is membrane bound. Both pathways converge on a **common pathway** that

culminates in generation of thrombin and, ultimately, “stable” fibrin. [Table 18-4](#) provides the names, synonyms, and properties of the procoagulant and anticoagulant factors in various parts of the clotting scheme.

TABLE 18-4
Procoagulant and Anticoagulant Factors

NAME	ALTERNATE NAMES	PROPERTIES
Procoagulant Factors		
Factor I	Fibrinogen	Plasma globulin
Factor Ia	Fibrin	
Factor II	Prothrombin	Plasma α_2 -globulin Synthesis in liver requires vitamin K*
Factor IIa	Thrombin	Serine protease
Factor III (cofactor)	Tissue factor Tissue thromboplastin	Integral membrane glycoprotein; member of type II cytokine receptor family Receptor for factor VIIa Must be present in a phospholipid membrane for procoagulant activity
Factor IV	Ca ²⁺	
Factor V	Labile factor Proaccelerin Accelerator globulin	Plasma protein synthesized by liver and stored in platelets Single-chain protein
Factor Va (cofactor)		Heterodimer held together by a single Ca ²⁺ ion Highly homologous to factor VIIIa
Factor VII	Stable factor Serum prothrombin conversion accelerator (SPCA) Proconvertin	Plasma protein Synthesis in liver requires vitamin K*
Factor VIIa		Serine protease
Factor VIII	Antihemophilic factor (AHF) Factor VIII procoagulant component (FVIII:C)	Plasma protein with phospholipid-binding domain
Factor VIIIa (cofactor)		Highly homologous to factor Va
Factor IX	Christmas factor Plasma thromboplastin component (PTC)	Plasma protein Synthesis in liver requires vitamin K*
Factor IXa		Protease Disulfide-linked heterodimer
Factor X	Stuart factor	Plasma glycoprotein Synthesis in liver requires vitamin K*
Factor Xa		Protease
Factor XI	Plasma thromboplastin antecedent (PTA)	Plasma protein produced by megakaryocytes and stored in platelets
Factor XIa		Protease Disulfide-linked homodimer
Factor XII	Hageman factor (HAF)	Plasma glycoprotein
Factor XIIa		Protease
Factor XIII	Fibrin-stabilizing factor (FSF)	Plasma protein stored in platelets
Factor XIIIa		Transglutaminase Tetramer of two A chains and two B chains
High-molecular-weight kininogen	HMWK Fitzgerald factor	Plasma protein stored in platelets Kallikrein clips bradykinin from HMWK
Plasma prekallikrein	Fletcher factor Plasma kallikrein precursor	Plasma protein
Plasma kallikrein		Serine protease Kallikrein clips bradykinin from HMWK
von Willebrand factor	vWF	Plasma glycoprotein made by endothelial cells and megakaryocytes Stabilizes factor VIIIa Promotes platelet adhesion and aggregation
Anticoagulant Factors		
Tissue factor pathway inhibitor	TFPI	Protease inhibitor produced by endothelial cells GPI linked to cell membrane
Antithrombin III	AT III	Plasma protein Serine protease inhibitor, member of serpin family Inhibits factor Xa and thrombin, and probably also factors XIIa, XIa, and IXa Heparan and heparin enhance the inhibitory action
Thrombomodulin (cofactor)		Glycosaminoglycan on surface of endothelial cell Binds thrombin and promotes activation of protein C
Protein C	Anticoagulant protein C Autoprothrombin IIA	Plasma protein Synthesis in liver requires vitamin K*
Protein C _a	Activated protein C	Serine protease Disulfide-linked heterodimer
Protein S (cofactor)		Plasma protein Synthesis in liver requires vitamin K* Cofactor for protein C

*See [page 970](#) for a discussion of vitamin K.

The proteins of the coagulation cascade have a distinct domain structure, including a signal peptide, a propeptide, an epidermal growth factor (EGF)–like domain, a kringle domain, and a catalytic domain, whereas some other domains are variable among these proteins. The **signal peptide** domain is required for the translocation of the polypeptide into the endoplasmic reticulum, where the signal peptide is cleaved. The **propeptide** or γ -carboxyglutamic acid–rich domain (Gla domain) is rich in glutamic acid residues that undergo γ -carboxylation under the influence of the γ -carboxylase that requires **vitamin K**. The presence of these γ -carboxyglutamic acid residues is required for Ca^{2+} binding. The **EGF-like** domain may appear multiple times and play a role in forming protein complexes. The **kringle** domain is loop structure created by several disulfide bonds that also play a role in forming protein complexes and attaching the protease to its target. The **catalytic** domain confers the serine protease function to the coagulation proteins and is homologous to trypsin, chymotrypsin, and other serine proteases.

Intrinsic Pathway (Surface Contact Activation)

The left branch of [Figure 18-12](#) shows the intrinsic pathway, a cascade of protease reactions initiated by factors that are all present within blood. When in contact with a negatively charged surface such as glass or the membrane of an activated platelet, a plasma protein called factor XII (Hageman factor) can become **factor XIIa**—the suffix *a* indicates that this is the *activated* form of factor XII. A molecule called **high-molecular-weight kininogen (HMWK)**, a product of platelets that may in fact be attached to the platelet membrane, helps anchor factor XII to the charged surface and thus serves as a cofactor. However, this HMWK-assisted conversion of factor XII to factor XIIa is limited in speed. Once a small amount of factor XIIa accumulates, this protease converts prekallikrein to kallikrein, with HMWK as an anchor. In turn, the newly produced **kallikrein** accelerates the conversion of factor XII to factor XIIa—an example of positive feedback. On [pages 553–554](#), we see another example of an interaction between kallikreins and kininogens (e.g., HMWK), in which the proteolytic activity of kallikreins on kininogens leads to the release of small vasodilatory peptides called kinins.

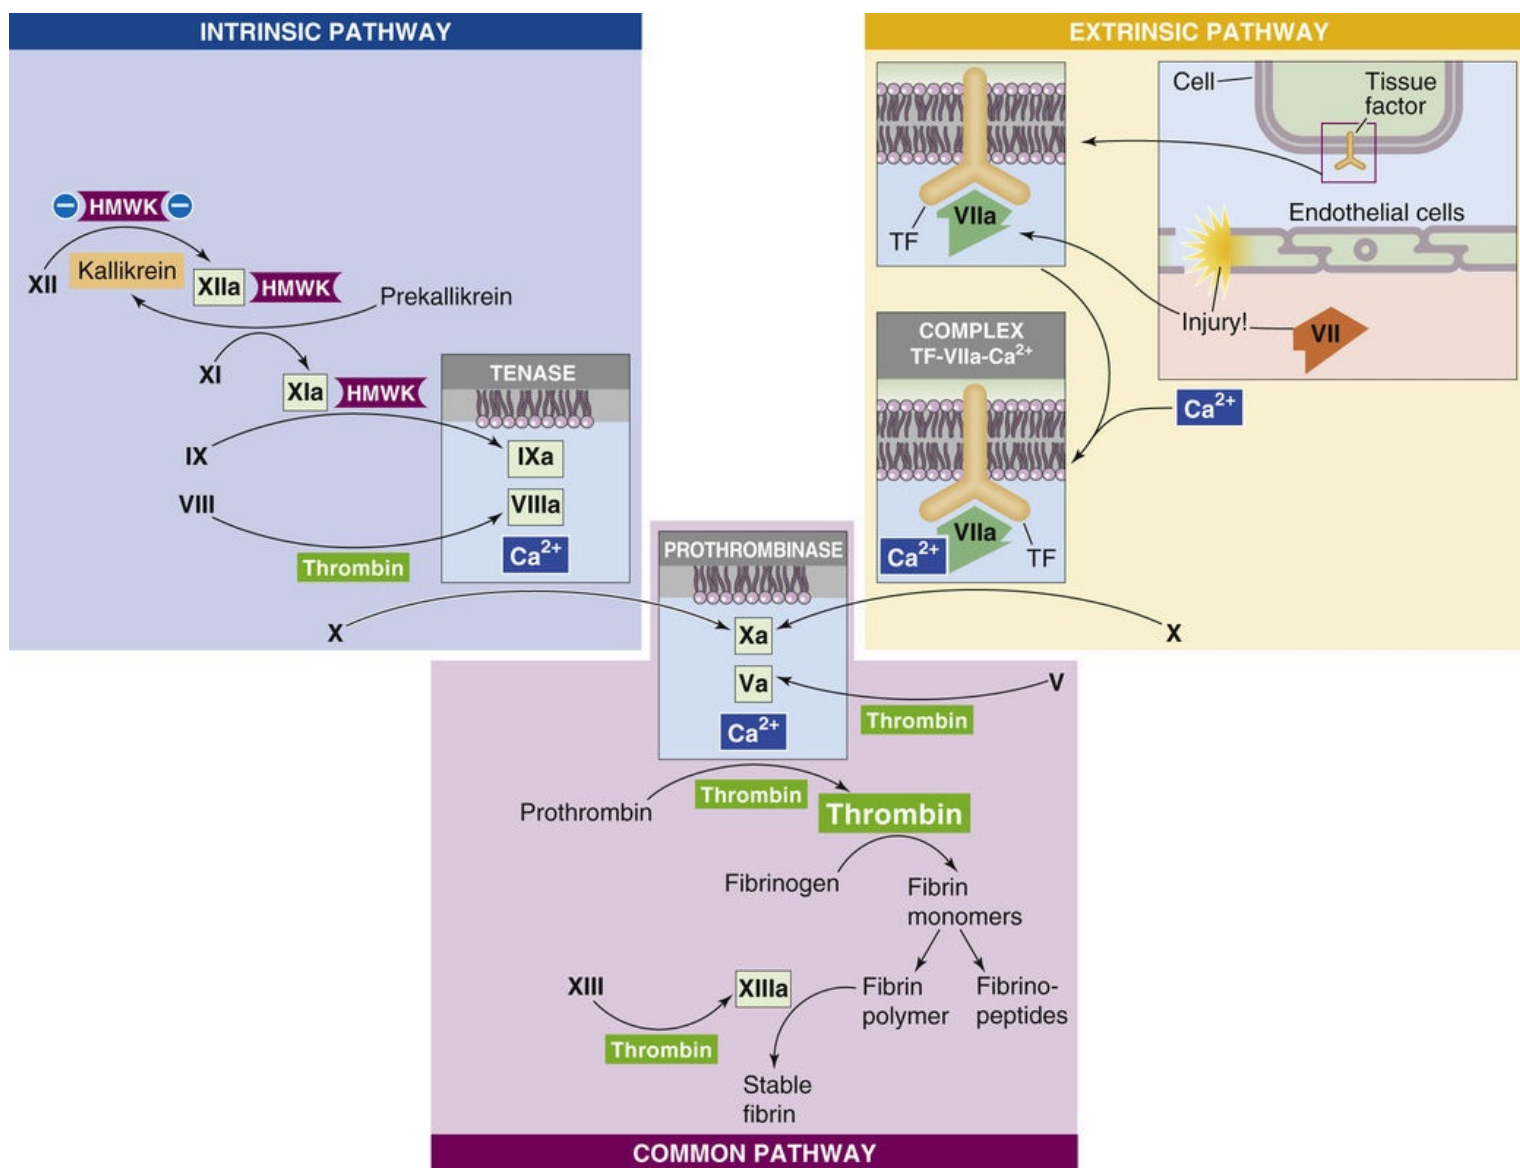

FIGURE 18-12 Coagulation cascade, showing only the procoagulant factors. TF, tissue factor.

In addition to amplifying its own generation by forming kallikrein, factor XIIa (together with HMWK) proteolytically cleaves factor XI to factor XIa. In turn, factor XIa (also bound to the charged surface by HMWK) proteolytically cleaves factor IX (Christmas factor) to factor IXa, which is a protease. Factor IXa and two downstream products of the cascade—factors Xa and, most important, thrombin—proteolytically cleave factor VIII to factor VIIIa, a cofactor in the next reaction. Finally, factors IXa and VIIIa, together with Ca^{2+} (which may come largely from activated platelets) and negatively charged phospholipids, form a trimolecular complex called **tenase**. **Tenase** then converts factor X (Stuart factor) to factor Xa, yet another protease.

Extrinsic Pathway (Tissue Factor Activation)

The right branch of [Figure 18-12](#) shows the extrinsic pathway, a cascade of protease reactions initiated by factors that are outside the vascular system. Nonvascular cells constitutively express an integral membrane protein called **tissue factor** (tissue thromboplastin, or factor III), which is a receptor for a plasma protein called factor VII. When an injury to the endothelium allows factor VII to come into contact with tissue factor, the tissue factor nonproteolytically activates factor VII to factor VIIa. Subsequently, tissue factor, factor VIIa, and Ca^{2+} form a trimolecular complex analogous to tenase. Like tenase, the trimolecular complex of [tissue factor + factor VIIa + Ca^{2+}] proteolytically cleaves the proenzyme factor

X to factor Xa. An interesting feature is that when factor X binds to the trimolecular complex, factor VIIa undergoes a conformational change that prevents it from dissociating from tissue factor.

Regardless of whether factor Xa arises by the intrinsic or extrinsic pathway, the cascade proceeds along the common pathway.

Common Pathway

Factor Xa from either the intrinsic or extrinsic pathway is the first protease of the common pathway (center of [Fig. 18-12](#)). Reminiscent of the conversion of factor VIII to the cofactor VIIIa in the intrinsic pathway, the downstream product thrombin clips factor V to form the cofactor Va. Factor V is highly homologous to factor VIII, and in both cases the proteolytic activation clips a single protein into two peptides that remain attached to one another. Factors Xa and Va, together with Ca^{2+} and phospholipids, form yet another trimolecular complex called **prothrombinase**. Prothrombinase acts on a plasma protein called prothrombin to form thrombin.

Thrombin is the central protease of the coagulation cascade, responsible for three major kinds of actions:

- 1. Activation of downstream components in the clotting cascade.** The main action of thrombin is to catalyze the proteolysis of fibrinogen (see [p. 429](#)) by cleaving the $\text{A}\alpha$ chain, releasing fibrinopeptide A, and cleaving the $\text{B}\beta$ chain, releasing fibrinopeptide B. The release of the fibrinopeptide results in the formation of fibrin monomers that are still soluble. **Fibrin monomers** now composed of α , β , and γ chains then spontaneously polymerize to form a *gel* of **fibrin polymers** that traps blood cells. Thrombin also activates factor XIII to factor XIIIa, which mediates the covalent cross-linking of the α and γ chains of fibrin polymers to form a *mesh* called **stable fibrin** that is even less soluble than fibrin.
- 2. Positive feedback at several upstream levels of the cascade.** Thrombin can catalyze the formation of new thrombin from prothrombin and can also catalyze the formation of the cofactors Va and VIIIa.
- 3. Paracrine actions that influence hemostasis.** First, thrombin causes endothelial cells to release nitric oxide, prostaglandin I_2 (PGI_2), ADP, vWF, and tissue plasminogen activator (see below). Second, thrombin can activate platelets through PAR-1, a protease-activated receptor that belongs to the family of G protein-coupled receptors (see [pp. 51–52](#)). Thus, thrombin is a key part of the molecular crosstalk introduced above between platelet activation and blood clotting, both of which are required for optimal clot formation. On the one hand, thrombin is a strong catalyst for platelet activation, and on the other hand, activated platelets offer the optimal surface for the intrinsic pathway leading to additional thrombin generation.

Coagulation as a Connected Diagram

The concept of independent intrinsic and extrinsic branches converging on a common pathway is becoming obsolete. In such a “branching tree” (see [p. 572](#)), multiple branches converge to form larger downstream branches, eventually converging on a single “trunk”—with no crosstalk between branches. However, coagulation is best conceptualized as a “connected diagram” (see [p. 572](#)) in which the branches may interconnect in both the upstream and downstream directions. One example of interconnections is thrombin's multiple actions just discussed. Another example is the trimolecular complex of [tissue factor + factor VIIa + Ca^{2+}] of the extrinsic pathway, which activates factors IX and XI of the intrinsic pathway. In the other direction, factors IXa and Xa of the intrinsic pathway can activate factor VII of the extrinsic

pathway. Thus, the intrinsic pathway and extrinsic pathway are strongly interconnected to form a *network*.

What parts of this network are most important for coagulation in vivo? Clinical evidence suggests that coagulation depends largely on the extrinsic pathway. Although tissue factor is normally absent from intravascular cells, inflammation can trigger peripheral blood monocytes and endothelial cells to express tissue factor, which increases the risk of coagulation. Indeed, during sepsis, the tissue factor produced by circulating monocytes initiates intravascular thrombosis.  [N18-6](#)

N18-6

Hemophilias

Contributed by Emile Boulpaep

Deficiencies of certain factors affect coagulation. **Hemophilia A** (the most common form of hemophilia) is caused by a deficiency in factor VIII:C. The gene for factor VIII is located on the X chromosome, which explains why females are carriers of hemophilia A, whereas males present with the disease.

Hemophilia B or Christmas disease is caused by a deficiency in factor IX. The very mild **Hemophilia C** is caused by a deficiency in factor XI.

A genetic deficiency of a particular factor does not always result in a clotting defect, however. For instance, factor V as a component of the prothrombinase complex is a procoagulant factor. However, factor V also participates in the inactivation of activated factor VIII (FVIIIa). As a result mutations in factor V gene may produce either hemorrhagic or thrombotic phenotypes. The most common thrombophilic mutation is the factor V Leiden mutation in which factor V is resistant to degradation by activated protein C. The mutation is associated with increased risk of venous thromboembolism.

Anticoagulants keep the clotting network in check

Thus far, our discussion has focused on the coagulation cascade and attendant positive feedback. Just as important are the mechanisms that prevent hemostasis from running out of control. Endothelial cells are the main sources of the agents that help maintain normal blood fluidity. These agents are of two general types, paracrine factors and anticoagulant factors.

Paracrine Factors

Endothelial cells generate prostacyclin (PGI_2 ; see [p. 64](#)), which promotes vasodilation (see [Table 20-8](#)) and thus blood flow and also inhibits platelet activation and thus clotting. Stimulated by thrombin, endothelial cells also produce nitric oxide (see [pp. 66–67](#)). Through cGMP, nitric oxide inhibits platelet adhesion and aggregation.

Anticoagulant Factors

As summarized in [Figure 18-13](#), endothelial cells also generate anticoagulant factors that interfere with the clotting cascade that generates fibrin. [Table 18-4](#) lists these factors.

1. Tissue factor pathway inhibitor (TFPI). TFPI is a plasma protein that binds to the trimolecular complex [tissue factor + factor VIIa + Ca^{2+}] in the extrinsic pathway and blocks the protease activity of factor VIIa. TFPI is glycosylphosphatidylinositol (GPI) linked (see [p. 32](#)) to the endothelial cell membrane, where it maintains an antithrombotic surface.

2. **Antithrombin III (AT III).** AT III binds to and inhibits factor Xa and thrombin. The sulfated glycosaminoglycans (see p. 39) **heparan sulfate** and **heparin** enhance the binding of AT III to factor Xa or to thrombin, thus inhibiting coagulation. Heparan sulfate is present on the external surface of most cells, including endothelial surfaces. Mast cells and basophils release heparin.
3. **Thrombomodulin.** A glycosaminoglycan product of endothelial cells, thrombomodulin can form a complex with thrombin, thereby removing thrombin from the circulation and inhibiting coagulation. In addition, thrombomodulin also binds protein C.
4. **Protein C.** After protein C binds to the thrombomodulin portion of the thrombin-thrombomodulin complex, the thrombin activates protein C. Activated protein C (C_a) is a protease. Together with its cofactor protein S, activated protein C inactivates the cofactors Va and VIIIa, thus inhibiting coagulation.
5. **Protein S.** This is the cofactor of protein C and is thus an anticoagulant.

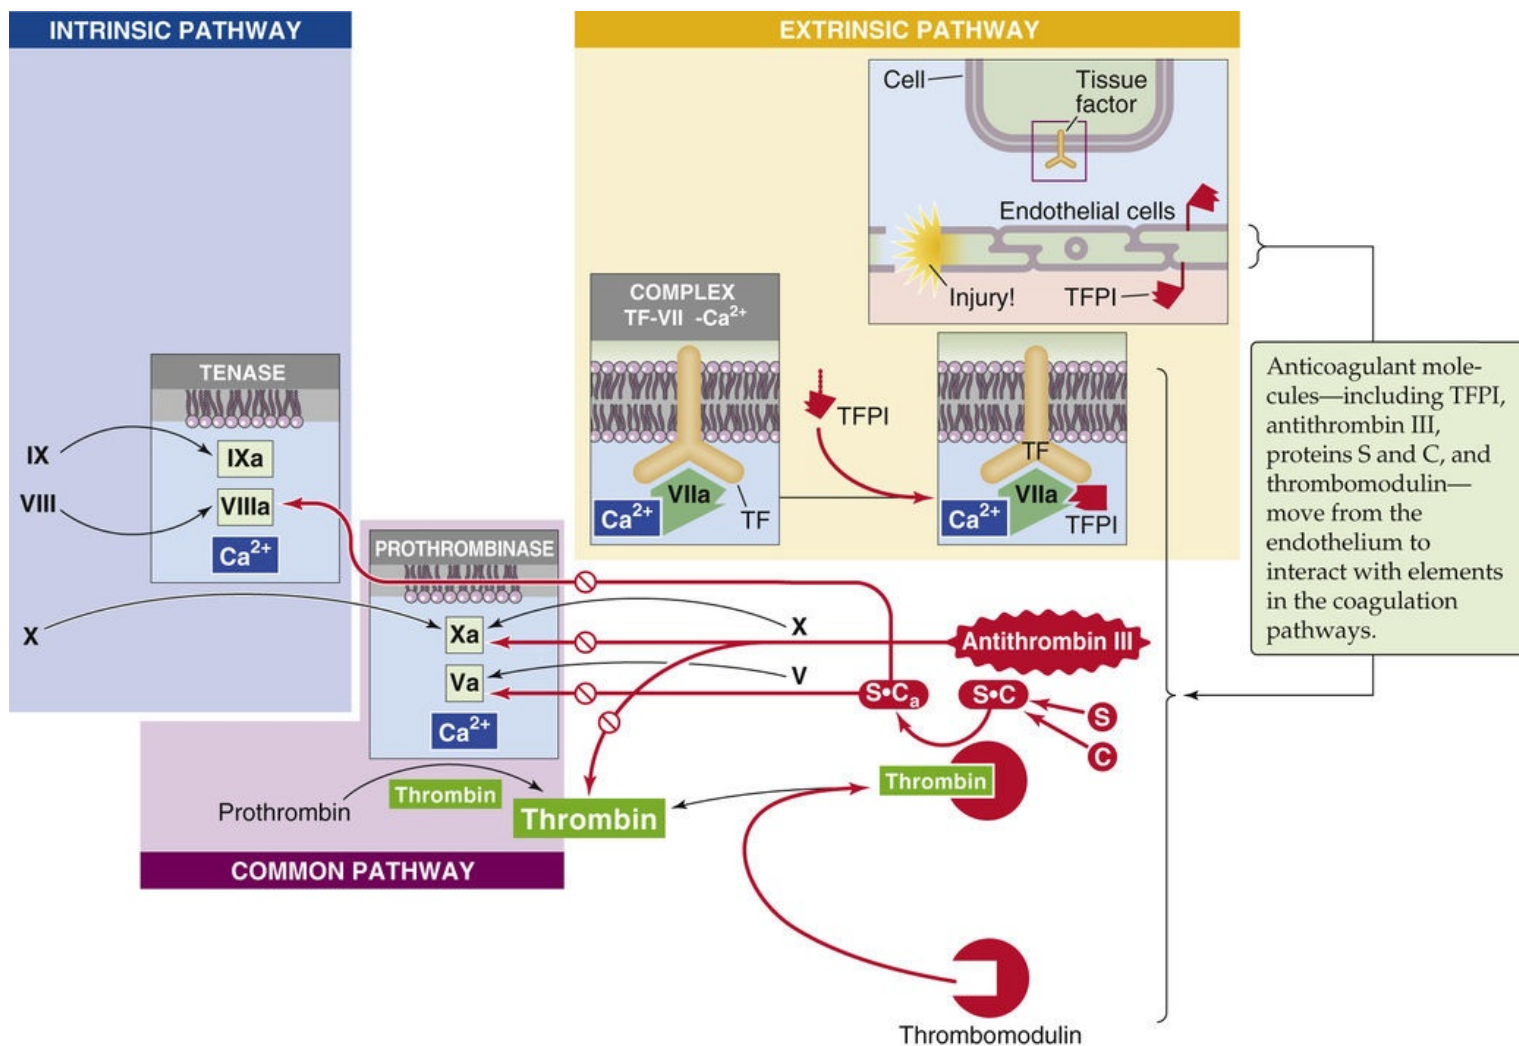

FIGURE 18-13 Abbreviated version of the coagulation cascade, showing the anticoagulant factors. The anticoagulant pathways are indicated in red. TF, tissue factor.

Finally, clearance of activated clotting factors by the Kupffer cells of the liver also keeps hemostasis under control.

Fibrinolysis breaks up clots

As noted on [page 429](#), cross-linked stable fibrin traps RBCs and WBCs as well as platelets in a freshly formed thrombus. Through the interaction of actin and myosin in the platelets, the clot shrinks to a plug and thereby expels serum. After plug formation, fibrinolysis—the breakdown of stable fibrin—breaks up the clot in a more general process known as thrombolysis. As shown in [Figure 18-14](#), the process of fibrinolysis begins with the conversion of plasminogen to plasmin, catalyzed by one of two activators: tissue-type plasminogen activator or urokinase-type plasminogen activator. [Table 18-5](#) summarizes the properties of fibrinolytic factors.

FIGURE 18-14 Fibrinolytic cascade.

TABLE 18-5
Fibrinolytic Factors

NAME	ALTERNATE NAME	PROPERTIES
Tissue-type plasminogen activator	t-PA	Serine protease that catalyzes hydrolysis of plasminogen at the junction between the N-terminal heavy chain and C-terminal light chain N terminus contains two loop structures called kringles
Urokinase-type plasminogen activator	u-PA	Serine protease
Urokinase-type plasminogen activator receptor	u-PAR	Binds to and required for the activity of u-PA
Plasminogen		Single-chain plasma glycoprotein with large N-terminal and small C-terminal domain. N terminus contains five kringles
Plasmin	Fibrinolysin	Serine protease
Plasminogen activator inhibitor 1	PAI-1	Serpin (serine protease inhibitor) In plasma and platelets Forms 1 : 1 complex with t-PA in blood
Plasminogen activator inhibitor 2	PAI-2	Serpin (serine protease inhibitor) Detected only in pregnancy
α ₂ -antiplasmin	α ₂ -AP	Serpin (serine protease inhibitor) Forms 1 : 1 complex with plasmin in blood

The source of **tissue plasminogen activator (t-PA)**, a serine protease, is endothelial cells. t-PA consists of a single peptide chain with two kringles at the N-terminal portion of the molecule and a protease motif in the C-terminal portion. Kringles are loop structures created by three disulfide bonds and serve to anchor the molecule to its substrate. t-PA converts the plasma zymogen plasminogen to the active fibrinolytic protease plasmin. The presence of fibrin greatly accelerates the conversion of plasminogen to plasmin.

Besides t-PA, the other plasminogen activator, **urokinase-type plasminogen activator (u-PA)**, is present in plasma either as a single-chain protein or as the two-chain product of a proteolytic cleavage.

Like t-PA, u-PA converts plasminogen to the active protease plasmin. However, this proteolysis requires that u-PA attach to a receptor on the cell surface called urokinase plasminogen activator receptor (u-PAR).

Plasminogen, mainly made by the liver, is a large, single-chain glycoprotein that is composed of an N-terminal heavy chain (A chain) and a C-terminal light chain (B chain). The N-terminal heavy chain contains five kringles, and the C-terminal light chain contains the protease domain. t-PA cleaves plasminogen at the junction between the heavy and light chains, yielding plasmin. However, the two chains in plasmin remain connected by disulfide bonds.

Plasmin is a serine protease that can break down both fibrin and fibrinogen. The five kringles of the heavy chain of plasminogen are still present in plasmin. These anchors attach to lysine residues on fibrin, holding the protease portion of the molecule in place to promote hydrolysis. Plasmin proteolytically cleaves stable fibrin to fibrin breakdown products. Plasmin can also cleave t-PA between the kringle and protease motifs of t-PA. The C terminus of single-chain t-PA nonetheless retains its protease activity.

The cardiovascular system regulates fibrinolysis at several levels, using both enhancing and inhibitory mechanisms. Catecholamines and bradykinin increase the levels of circulating t-PA. Two *serine protease inhibitors* (serpins) reduce the activity of the plasminogen activators: plasminogen activator inhibitor 1 (PAI-1) and plasminogen activator inhibitor 2 (PAI-2). **PAI-1** complexes with and inhibits both single-chain and two-chain t-PA as well as u-PA. PAI-1 is produced mainly by endothelial cells. **PAI-2** mainly inhibits u-PA. PAI-2 is important in pregnancy because it is produced by the placenta and may contribute to increased risk of thrombosis in pregnancy.

It is of interest that activated protein C, which inhibits coagulation as shown in [Figure 18-13](#), also inhibits PAI-1 and PAI-2, thereby facilitating fibrinolysis. Only one serpin targets plasmin, **α_2 -antiplasmin (α_2 -AP)** made by liver, kidney, and other tissues. When plasmin is not bound to fibrin (i.e., when the plasmin is in free solution), α_2 -AP complexes with and thereby readily inactivates plasmin. However, when plasmin is attached to lysine residues on fibrin, the inhibition by α_2 -AP is greatly reduced. In other words, the very presence of a clot (i.e., fibrin) promotes the breakdown of the clot (i.e., fibrinolysis).

CHAPTER 19

Arteries and Veins

Emile L. Boulpaep

Arterial Distribution and Venous Collection Systems

Hemodynamics is the study of the physical laws of blood circulation. It therefore addresses the properties of both the “content” (i.e., blood) and the “container” (i.e., blood vessels). In [Chapter 18](#), we discussed the properties of the blood. This chapter is primarily concerned with the properties of the blood vessels. The circulation is not a system of rigid tubes. Moreover, the anatomy and functions of the various segments of the vasculature differ greatly from one to another. Because the function of the circulation is to carry substances all over the body, the circulatory system branches out into a network of billions of tiny capillaries. We can think of the **arteries** as a *distribution system*, the **microcirculation** as a *diffusion and filtration system*, and the **veins** as a *collection system*.

Physical properties of vessels closely follow the level of branching in the circuit

The aorta branches out into billions of capillaries that ultimately regroup into a single vena cava ([Fig. 19-1](#), panel 1). At each level of arborization of the peripheral circulation, the values of several key parameters vary dramatically:

1. Number of vessels at each level of arborization
2. Radius of a typical individual vessel
3. Aggregate cross-sectional area of all vessels at that level
4. Mean linear velocity of blood flow within an individual vessel
5. Flow (i.e., volume per second) through a single vessel
6. Relative blood volume (i.e., the fraction of the body's total blood volume present in all vessels of a given level)
7. Circulation (i.e., transit) time between two points of the circuit
8. Pressure profile along that portion of the circuit
9. Structure of the vascular walls
10. Elastic properties of the vascular walls

FIGURE 19-1 Profile of key parameters along the cardiovascular system. Panel 1 (*top*) shows branching of the cardiovascular system, from left side to right side of heart and back to left. Panel 2 shows the variation of aggregate cross-sectional area of all vessels at any level of branching. Panel 3 shows how mean linear velocity of blood varies in typical vessels. Panel 4 shows ways of grouping blood volume in various compartments. Panel 5 shows profile of blood pressure, with superimposed oscillations that represent variations in time.

We discuss parameters 1 to 5 in this section and parameters 6 to 8 in the following two sections. Parameters 9 and 10 are the subject of the second subchapter.

The **number of vessels** at a particular level of arborization ([Table 19-1](#)) increases enormously from a single aorta to $\sim 10^4$ small arteries, $\sim 10^7$ arterioles, and finally $\sim 4 \times 10^{10}$ capillaries. However, only about one fourth of all capillaries are normally open to flow at rest. Finally, all of the blood returns to a single vessel where the superior and inferior venae cavae join.

TABLE 19-1
Key Systemic Vascular Parameters That Vary with Arborization

PARAMETER	AORTA	SMALL ARTERIES*	ARTERIOLES*	CAPILLARIES†	VENA CAVA
Number of units (N)	1	8000	2×10^7	1×10^{10} open (4×10^{10} total)	1
Internal radius (r_i)	1.13 cm	0.5 mm	15 μm	3 μm	1.38 cm
Cross-sectional area ($A_i = \pi r_i^2$)	4 cm^2	$7.9 \times 10^{-3} \text{ cm}^2$	$7.1 \times 10^{-7} \text{ cm}^2$	$2.8 \times 10^{-7} \text{ cm}^2$	6 cm^2
Aggregate cross-sectional area ($A_{\text{total}} = N\pi r_i^2$)	4 cm^2	63 cm^2	141 cm^2	2827 cm^2 ‡	6 cm^2
Aggregate flow (F_{total})	83 cm^3/s (mL/s)	83 cm^3/s	83 cm^3/s	83 cm^3/s	83 cm^3/s
Mean linear velocity ($\bar{v} = F_{\text{total}} / A_{\text{total}}$)	21 cm/s	1.3 cm/s	0.6 cm/s	0.03 cm/s ‡	14 cm/s
Single-unit flow ($F_i = F_{\text{total}} / N = A_i \cdot \bar{v}$)	83 cm^3/s (mL/s)	0.01 cm^3/s	$4 \times 10^{-6} \text{ cm}^3/\text{s}$	$8 \times 10^{-9} \text{ cm}^3/\text{s}$ ‡	83 cm^3/s

*The values in this column are for a representative generation.

†The values in this column are for the smallest capillaries, at the highest level of branching.

‡Assuming that only 25% of the capillaries are open.

The **radius of an individual vessel** (r_i ; see [Table 19-1](#)) declines as a result of the arborization, decreasing from 1.1 cm in the aorta to a minimum of $\sim 3 \mu\text{m}$ in the smallest capillaries. Because the **cross-sectional area** of an individual vessel is proportional to the square of the radius, this parameter decreases even more precipitously.

The aggregate cross-sectional area (see [Table 19-1](#)) at any level of branching is the sum of the single cross-sectional areas of all parallel vessels at that level of branching. That is, it is the area that you would see if you sliced through all of the vessels at the same level of branching in panel 1 of [Figure 19-1](#).

A fundamental law of vessel branching is that at each branch point, the combined cross-sectional area of daughter vessels exceeds the cross-sectional area of the parent vessel. In this process of bifurcation, the steepest increase in total cross-sectional area occurs in the microcirculation (see [Fig. 19-1](#), panel 2). A typical **microcirculation** in the smooth muscle and submucosa of the intestine ([Fig. 19-2](#)) encompasses a first-order arteriole, several orders of progressively smaller arterioles, capillaries, several orders of venules into which the capillaries empty, and eventually a first-order venule. In humans, the maximum cross-sectional area occurs not at the level of the capillaries, but at the “postcapillary” (i.e., fourth-order) venules. Because of anastomoses among capillaries, capillaries only slightly outnumber fourth-order venules, whereas the cross-sectional unit area of each venule is appreciably greater than the area of a capillary. Assuming that only a quarter of the capillaries are usually open, the peak aggregate cross-sectional area of these postcapillary venules can be ~ 1000 -fold greater than the cross section of the parent artery (e.g., aorta), as shown in panel 2 of [Figure 19-1](#).

FIGURE 19-2 Branching in a typical microcirculation, that of the smooth muscle and submucosa of the intestine.

The profile of the **mean linear velocity** of flow (\bar{v}) along a vascular circuit (see Fig. 19-1, panel 3) is roughly a mirror image of the profile of the total cross-sectional area. According to the principle of continuity, which is an application of conservation of mass, **total volume flow** of blood must be the same at any level of arborization. Indeed, as we make multiple vertical slices along the x-axis of panel 1 in Figure 19-1, the aggregate flow for each slice is the same:

$$F_{\text{total}} = \underbrace{A_1 \cdot \bar{v}_1}_{\text{Level 1}} = \underbrace{A_2 \cdot \bar{v}_2}_{\text{Level 2}} = \underbrace{A_3 \cdot \bar{v}_3}_{\text{Level 3}} = \dots$$

(19-1)

As a consequence, \bar{v} must be minimal in the postcapillary venules (~ 0.03 cm/s), where A_{total} is maximal. Conversely, \bar{v} is maximal in the aorta (~ 20 to 50 cm/s). Thus, both A_{total} and \bar{v} values range ~ 1000 -fold from the aorta to the capillaries but are inversely related to one another. The vena cava, with a cross-sectional area $\sim 50\%$ larger than that of the aorta, has a mean linear velocity that is about one third less.

Single-vessel flow, in contrast to total flow, varies by ~ 10 orders of magnitude. In the aorta, the flow is ~ 83 mL/s, the same as the cardiac output (~ 5 L/min). When about 25% of the capillaries are open, a *typical* capillary has a mean linear velocity of 0.03 cm/s and a flow of 8×10^{-9} mL/s (8 pL/s)—10 orders of magnitude less than the flow in the aorta. Within the microcirculation, single-vessel flow has considerable range. At one extreme, a first-order arteriole ($r_i \sim 30$ μm) may have a flow of 20×10^{-6} mL/s. At the other, the capillaries that are closed at any given time have zero flow.

Most of the blood volume resides in the systemic veins

The body's **total blood volume** (V) of about 5 L (see Table 5-1) is not uniformly distributed along the x-axis of panel 1 in Figure 19-1. At any level of branching, the total blood volume is the sum of the volumes of all parallel branches. Table 19-2 summarizes—for a hypothetical 70-kg woman—the distribution of total blood volume expressed as both absolute blood volumes and **relative blood volumes** (percentage of

total blood volume). Panel 4 in [Figure 19-1](#) summarizes four useful ways of grouping these volumes.

TABLE 19-2
Distribution of Blood Volume*

REGION	ABSOLUTE VOLUME (mL)		RELATIVE VOLUME (%)	
Systemic Circulation		4200		84
Aorta and large arteries	300		6.0	
Small arteries	400		8.0	
Capillaries	300		6.0	
Small veins	2300		46.0	
Large veins	900		18	
Pulmonary Circulation		440		8.8
Arteries	130		2.6	
Capillaries	110		2.2	
Veins	200		4.0	
Heart (End Diastole)	360	360	7.2	7.2
Total	5000	5000	100	100

*Values are for a 70-kg woman. For a 70-kg man, scale up the absolute values by 10%.

First, we can divide the blood volume into the *systemic* circulation (where ~85% of blood resides), the *pulmonary* circulation (~10%), and the *heart* chambers (~5%). The pulmonary blood volume is quite adjustable (i.e., it can be much higher than 10%) and is carefully regulated.

Second, as can be seen in the next section, we can divide blood volume into what is contained in the *high-pressure* system (~15%), the *low-pressure* system (~80%), and the heart chambers (~5%).

Third, we can group the blood volumes into those in the *systemic venous system* versus the remainder of the circulation. Of the 85% of the total blood volume that resides in the systemic circulation, about three fourths—or 65% of the total—is on the venous side, particularly in the smaller veins. Thus, the venous system acts as a volume reservoir. Changes in the diameters of veins have a major impact on the amount of blood they contain. For example, an abrupt increase in venous capacity causes pooling of blood in venous segments and may lead to **syncope** (i.e., fainting).

We can also use a fourth approach for grouping of blood volumes—divide the blood into the **central blood volume** (volumes of heart chambers and pulmonary circulation) versus the rest of the circulation. This central blood volume is very adjustable, and it constitutes the filling reservoir for the left side of the heart. Left-sided heart failure can cause the normally careful regulation of the central blood volume to break down.

The **circulation time** is the time required for a bolus of blood to travel either across the entire length of the circulation or across a particular vascular bed. Total circulation time (the time to go from left to right across panel 1 in [Fig. 19-1](#)) is ~1 minute. Circulation time across a single vascular bed (e.g., coronary circulation) may be as short as 10 seconds. Circulation times may be obtained in humans by injection of a substance such as ether into an antecubital vein and measurement of the time to its appearance in the lung (4 to 8 seconds), or by injection of a bitter or sweet substance and measurement of the time to the perception of taste in the tongue (10 to 18 seconds). Although, in the past, circulation time was used clinically as an index of cardiac output, the measurement has little physiological significance. The rationale for determination of circulation time was that a shortening of circulation time could signify an improvement of cardiac output. However, the interpretation is more complicated, because circulation time is actually the ratio of blood volume to blood flow:

$$t = \frac{V}{F}$$

$$\text{Units: } s = \frac{\text{mL}}{\text{mL/s}}$$

(19-2)

Changes in circulation time may thus reflect changes in volume as well as in flow. For instance, a patient in heart failure may have a decreased cardiac output (i.e., F) or an increased blood volume (i.e., V), either of which would contribute to an elevation of transit time.

The intravascular pressures along the systemic circuit are higher than those along the pulmonary circuit

Panel 5 in [Figure 19-1](#) shows the profile of pressure along the systemic and pulmonary circulations. Pressures are far higher in the systemic than in the pulmonary circulation. Although the cardiac outputs of the left and right sides of the heart are the same in the steady state, the total resistance of the systemic circulation is far higher than that of the pulmonary circulation (see [pp. 683–684](#)). This difference explains why the upstream driving pressure averages ~95 mm Hg in the *systemic circulation* but only ~15 mm Hg in the *pulmonary circulation*. [Table 19-3](#) summarizes typical mean values at key locations in the circulation. In both the systemic and pulmonary circulations, the systolic and diastolic pressures decay downstream from the ventricles ([Fig. 19-3](#)). The instantaneous pressures vary throughout each cardiac cycle for much of the circulatory system (see [Fig. 19-1](#), panel 5). In addition, the systemic venous and pulmonary pressures vary with the respiratory cycle, and venous pressure in the lower limbs varies with the contraction of skeletal muscle.

TABLE 19-3
Mean Pressures in the Systemic and Pulmonary Circulations

LOCATION	MEAN PRESSURE (mm Hg)
Systemic large arteries	95
Systemic arterioles	60
Systemic capillaries	25 (range, 35–15)
Systemic venules	15
Systemic veins	15–3
Pulmonary artery	15
Pulmonary capillaries	10
Pulmonary veins	5

A SYSTEMIC CIRCULATION

B PULMONARY CIRCULATION

FIGURE 19-3 Pressure profiles along systemic and pulmonary circulations. In **A** and **B**, the oscillations represent variations in time, not distance. Boxed numbers indicate mean pressures. L, left; Pulm., pulmonary; R, right.

As noted above, the circulation can be divided into a high-pressure and a low-pressure system. The **high-pressure system** extends from the left ventricle in the *contracted state* all the way to the systemic arterioles. The **low-pressure system** extends from the systemic capillaries, through the rest of the systemic circuit, into the right side of the heart, and then through the pulmonary circuit into the left side of the heart in the *relaxed state*. The pulmonary circuit, unlike the systemic circuit, is entirely a low-pressure system; mean arterial pressures normally do not exceed 15 mm Hg, and the capillary pressures do not rise above 10 mm Hg.

Under normal conditions, the steepest pressure drop in the systemic circulation occurs in arterioles, the site of greatest vascular resistance

If we assume for simplicity's sake that the left side of the heart behaves like a constant pressure generator of 95 mm Hg and the right side of the heart behaves like a constant pressure generator of 15 mm Hg, it is the resistance of each vascular segment that determines the profile of pressure fall between the upstream arterial and downstream venous ends of the circulation. In particular, the pressure difference between two points along the axis of the vessel (i.e., the driving pressure difference, ΔP) depends on flow and resistance: $\Delta P = F \cdot R$ (see p. 412). According to Poiseuille's law (see p. 415), the resistance (R_i) of an individual, unbranched vascular segment is inversely proportional to the fourth power of the radius. Thus, the *pressure drop between any two points along the circuit depends critically on the diameter of the vessels between these two points*. However, the steepest pressure drop ($\Delta P/\Delta x$) does *not* occur along the capillaries, where vessel diameters are smallest, but rather along the *precapillary arterioles*. Why? The **aggregate resistance** contributed by vessels of a particular order of arborization depends not only on

their average radius but also on the *number* of vessels in parallel. **N19-1** The more vessels in parallel, the smaller the aggregate resistance (see [Equation 19-3](#)). Although the resistance of a single capillary exceeds that of a single arteriole, capillaries far outnumber arterioles ([Table 19-4](#)). The result is that the aggregate resistance is larger in the arterioles, and this is where the steepest ΔP occurs.

TABLE 19-4
Estimates of Total Arteriolar and Capillary Resistances*

	ARTERIOLES	CAPILLARIES
Internal radius (r_i)	15 μm	4 μm [†]
Individual resistance (R_i)	$\sim 15 \times 10^7$ dyne s/cm ⁵	$\sim 3000 \times 10^7$ dyne s/cm ⁵
Number of units (N)	1×10^7	1×10^{10}
Total resistance ($R_{\text{total}} = R_i/N$)	15 dyne s/cm ⁵	3 dyne s/cm ⁵

*Assuming a blood viscosity of 3 cP and a vessel length of 100 μm .

[†]The value of 4 μm is near the average radius of capillaries.

N19-1

Relative Resistance of Arterioles Versus Capillaries

Contributed by Emile Boulpaep

In Chapter 17, we introduced the concept of how to compute the aggregate resistance of a group of blood vessels (or resistors) arranged in parallel. We used Equation 17-3, shown here as Equation NE 19-1:

$$\frac{1}{R_{\text{total}}} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \dots$$

(NE 19-1)

If we assume that each of N parallel branches has the same resistance R_i (i.e., $R_1 = R_1 = R_2 = R_3 = R_4 = \dots$), then the overall resistance is

$$\frac{1}{R_{\text{total}}} = \frac{1}{R_i} + \frac{1}{R_i} + \frac{1}{R_i} + \dots = \frac{N}{R_i}$$

(NE 19-2)

Thus,

$$R_{\text{total}} = \frac{R_i}{N}$$

(NE 19-3)

If the aorta gives rise to 10^7 arterioles (the N in the above equations), each with a resistance (R_i) of 15×10^7 dyne s/cm⁵, then the total resistance of all the arterioles would be 15 dyne s/cm⁵:

$$R_{\text{total}} = \frac{R_i}{N} = \frac{15 \times 10^7}{10^7} = 15 \text{ dyne s/cm}^5$$

(NE 19-4)

If the same aorta gives rise to 3000×10^7 capillaries (N), each with a resistance (R_i) of 1×10^{10} dyne s/cm⁵, then the total resistance of all the capillaries would be 3 dyne s/cm⁵:

$$R_{\text{total}} = \frac{R_i}{N} = \frac{3000 \times 10^7}{10^{10}} = 3 \text{ dyne s/cm}^5$$

(NE 19-5)

Thus, because the capillaries vastly outnumber the arterioles, their aggregate resistance is less, even though their unit resistance is considerably greater.

Local intravascular pressure depends on the distribution of vascular resistance

We have just seen that the ΔP between an upstream checkpoint and a downstream checkpoint depends on the resistance between these points. What determines the absolute pressure at some location *between* the two checkpoints? To answer this question, we need to know not only the upstream arterial and downstream venous pressures but also the *distribution of resistance* between the two checkpoints. A good example to explain this concept is the distribution of resistance and pressure in the systemic microvasculature. Just how the upstream pressure in the arteriole and the downstream pressure in the venule affect the pressure at the midpoint of the capillary (P_c) depends on the relative size of the upstream and downstream resistances. For the simple circuit illustrated in [Figure 19-4A](#),  **N19-2**

N19-2

Derivation of Equation for Midcapillary Pressure

Contributed by Emile Boulpaep

On page 451 of the text, we present Equation 19-3 (shown here as Equation NE 19-6)

$$P_c = \frac{(R_{\text{post}}/R_{\text{pre}}) \cdot P_a + P_v}{1 + (R_{\text{post}}/R_{\text{pre}})}$$

(NE 19-6)

The capillary pressure (P_c) depends on arteriolar pressure (P_a), venular pressure (P_v), the precapillary

resistance upstream of the capillary bed (R_{pre}), and the postcapillary resistance downstream of the capillary (R_{post}). This equation describes the hydrodynamic equivalent of the electrical voltage drop (“voltage divider”) across each of two resistances in series, such as the pair of resistors shown in Figure 19-4A.

Because of conservation of flow along the vascular circuit, the flow (F) across R_{pre} and R_{post} is, by definition, the same. For each of the two resistive elements, Ohm's law of hydrodynamics (see Equation 17-1) states that

$$P_a - P_c = F \cdot R_{\text{pre}} \quad (\text{NE 19-7})$$

$$P_c - P_v = F \cdot R_{\text{post}} \quad (\text{NE 19-8})$$

Thus, because F is identical in Equations NE 19-7 and NE 19-8,

$$(P_a - P_c)/R_{\text{pre}} = (P_c - P_v)/R_{\text{post}} \quad (\text{NE 19-9})$$

Solving for P_c in the above equation, we get the following:

$$\begin{aligned} (R_{\text{post}}/R_{\text{pre}})(P_a - P_c) &= (P_c - P_v) & (\text{NE 19-10}) \\ (R_{\text{post}}/R_{\text{pre}})P_a - (R_{\text{post}}/R_{\text{pre}})P_c + P_v &= P_c \\ (R_{\text{post}}/R_{\text{pre}})P_a + P_v &= P_c + (R_{\text{post}}/R_{\text{pre}})P_c \\ (R_{\text{post}}/R_{\text{pre}})P_a + P_v &= P_c[1 + (R_{\text{post}}/R_{\text{pre}})] \\ [(R_{\text{post}}/R_{\text{pre}})P_a + P_v]/[1 + (R_{\text{post}}/R_{\text{pre}})] &= P_c \end{aligned}$$

The last in the preceding set of equations is a simple rearrangement of Equation NE 19-6 above.

$$P_c = \frac{(R_{\text{post}}/R_{\text{pre}}) \cdot P_a + P_v}{1 + (R_{\text{post}}/R_{\text{pre}})} \quad (\text{19-3})$$

where P_a is arteriolar pressure, P_v is venular pressure, R_{pre} is precapillary resistance upstream of the capillary bed, and R_{post} is postcapillary resistance downstream of the capillary.

From this equation, we can draw three conclusions about local microvascular pressure. First, even though arteriolar pressure is 60 mm Hg and venular pressure is 15 mm Hg in our example (see [Table 19-3](#)), capillary pressure is not necessarily 37.5 mm Hg, the arithmetic mean. According to [Equation 19-3](#), P_c

would be the arithmetic mean only if the precapillary and postcapillary resistances were identical (i.e., $R_{\text{post}}/R_{\text{pre}} = 1$). The finding that P_c is ~ 25 mm Hg in most vascular beds (see Fig. 19-4A) implies that R_{pre} exceeds R_{post} (i.e., $R_{\text{post}}/R_{\text{pre}} > 1$). Under normal conditions in most microvascular beds, $R_{\text{post}}/R_{\text{pre}}$ ranges from 0.2 to 0.4.

The second implication of Equation 19-3 is that as long as the sum ($R_{\text{pre}} + R_{\text{post}}$) is constant, reciprocal changes in R_{pre} and R_{post} would not alter the total resistance of the circuit and would therefore leave both P_a and P_v constant. However, as $R_{\text{post}}/R_{\text{pre}}$ increases, P_c would increase, thereby approaching P_a (see Fig. 19-4B). Conversely, as $R_{\text{post}}/R_{\text{pre}}$ decreases, P_c would decrease, approaching P_v (see Fig. 19-4C). This conclusion is also intuitive. If we reduced R_{pre} to zero (but increased R_{post} to keep $R_{\text{post}} + R_{\text{pre}}$ constant), no pressure drop would occur along the precapillary vessels, and P_c would be the same as P_a . Conversely, if R_{post} were zero, P_c would be the same as P_v .

The third conclusion from Equation 19-3 is that, depending on the value of $R_{\text{post}}/R_{\text{pre}}$, P_c may be more sensitive to changes in arteriolar than in venular pressure, or vice versa. For example, when the ratio $R_{\text{post}}/R_{\text{pre}}$ is low (i.e., $R_{\text{pre}} > R_{\text{post}}$, as in Fig. 19-4A or C), capillary pressure tends to follow the downstream pressure in large veins. This phenomenon explains why standing may cause the ankles to swell. The elevated pressure in large leg veins translates to an increased P_c , which, as discussed below, leads to increased transudation of fluid from the capillaries into the interstitial spaces (see pp. 467–468). It also explains why elevation of the feet, which lowers the pressure in the large veins, reverses ankle edema.

Vascular resistance varies in time and depends critically on the action of vascular smooth-muscle cells. The major site of control of vascular resistance in the systemic circulation is the *terminal small arteries (or feed arteries) and arterioles*. Figure 19-5 illustrates the effect of vasoconstriction or vasodilation on the pressure profile. Whereas the overall ΔP between source and end point may not vary appreciably during a change in vascular resistance, the *shape* of the local pressure profile may change appreciably. Thus, during arteriolar constriction, the pressure drop between two points along the circuit (i.e., axial pressure gradient, $\Delta P/\Delta x$) is steep and concentrated at the arteriolar site (see Fig. 19-5, green curve). During arteriolar dilation, the gradient is shallow and more spread out (see Fig. 19-5, violet curve).

FIGURE 19-5 Pressure profiles during vasomotion. In this example, we assume that constriction or dilation of terminal arteries and arterioles does not affect the overall driving pressure (ΔP) between aorta and vena cava. This assumption is reasonable in two cases: (1) vasoconstriction or vasodilation is confined to a single parallel vascular bed (e.g., one limb) and does not substantially change total peripheral resistance; and (2) even if total peripheral resistance *does* change, the cardiac pump still maintains constant systemic arterial and venous pressures.

Although the effects of vasoconstriction and vasodilation are greatest in the local arterioles (lighter red band in Fig. 19-5), the effects extend both upstream (darker red band) and downstream (purple and blue bands) from the site of vasomotion because the pressure profile along the vessel depends on the resistance profile. Thus, if one vascular element contributes a greater fraction of the total resistance, a greater fraction of the pressure drop will occur along that element.

Elastic Properties of Blood Vessels

Blood vessels are elastic tubes

The walls of blood vessels consist of three layers: the intima, the media, and the adventitia. Capillaries, which have only an intimal layer of endothelial cells resting on a basal lamina, are the exception. Regardless of the organization of layers, one can distinguish four building blocks that make up the vascular wall: endothelial cells, elastic fibers, collagen fibers, and smooth-muscle cells. [Figure 19-6](#) shows how the relative abundance of these components varies throughout the vascular circuit. In addition to these principal components, fibroblasts, nerve endings, and blood cells invade the intima; other extracellular components (e.g., proteoglycans) may also be present.

FIGURE 19-6 Structure of blood vessels. The values for medium arteries, arterioles, venules, and veins are merely illustrative because the dimensions can range widely. The drawings of the vessels are not to scale.

Endothelial cells form a single, continuous layer that lines all vascular segments. Junctional complexes keep the endothelial cells together in arteries but are less numerous in veins. The organization of the endothelial cell layer in capillaries varies greatly, depending on the organ (see [p. 461](#)). The glomus bodies in the skin and elsewhere are unusual in that their “endothelial cells” exist in multiple layers of cells called **myoepithelioid cells**. These glomus bodies control small arteriovenous shunts or anastomoses (see [p. 570](#)).

Elastic fibers are a rubber-like material that accounts for most of the stretch of vessels at normal pressures as well as the stretch of other tissues (e.g., lungs). Elastic fibers have two components: a core of elastin and a covering of microfibrils. The elastin core consists of a highly insoluble polymer of **elastin**, a protein rich in nonpolar amino acids (i.e., glycine, alanine, valine, proline). After being secreted into the extracellular space, the elastin molecules remain in a random-coil configuration. They

covalently cross-link and assemble into a highly elastic network of fibers, capable of stretching more than 100% under physiological conditions. The **microfibrils**, which are composed of glycoproteins and have a diameter of ~10 nm, are similar to those found in the extracellular matrix in other tissues. In arteries, elastic fibers are arranged as concentric, cylindrical lamellae. A network of elastic fibers is abundant everywhere except in the true capillaries, in the venules, and in the aforementioned arteriovenous anastomoses.

Collagen fibers constitute a jacket of far less extensible material than the elastic fibers, like the fabric woven inside the wall of a rubber hose. Collagen can be stretched only 3% to 4% under physiological conditions. The basic unit of the collagen fibers in blood vessels is composed of type I and type III collagen molecules, which are two of the fibrillar collagens. After being secreted, these triple-helical molecules assemble into fibrils that may be 10 to 300 nm in diameter; these in turn aggregate into collagen fibers that may be several microns in diameter and are visible with a light microscope. Collagen fibers are present throughout the circulation except in the capillaries. Collagen and elastic fibers form a network that is arranged more loosely toward the inner surface of the vessel than at the outer surface. Collagen fibers are usually attached to the other components of the vascular wall with some slack, so that they are normally not under tension. Stretching of these other components may take up the slack on the collagen fibers, which may then contribute to the overall tension.

Vascular smooth-muscle cells (VSMCs) are also present in all vascular segments except the capillaries. In *elastic* arteries, VSMCs are arranged in spirals with pitch varying from nearly longitudinal to nearly transverse-circular; whereas in *muscular* arteries, they are arranged either in concentric rings or as helices with a low pitch. Relaxed VSMCs do not contribute appreciably to the elastic tension of the vascular wall, which is mainly determined by the elastin and collagen fibers. VSMCs exert tension primarily by means of active contraction (see [pp. 238–240 and 459](#)).

Because of the elastic properties of vessels, the pressure-flow relationship of passive vascular beds is nonlinear

Because blood vessels are elastic, we must revise our concept of blood flow, which was based on Poiseuille's law for rigid tubes (see [p. 415](#)). Poiseuille's law predicts a linear pressure-flow relationship ([Fig. 19-7A](#), broken line). However, in reality, the *pressure-flow relationship is markedly nonlinear* in an in vivo preparation of a vascular bed (see [Fig. 19-7A](#), red curve). Starting at the foot of the red curve at a driving pressure of about 6 mm Hg, we see that the curve rises more steeply as the driving pressure increases. The reason is that increase of the driving pressure (i.e., axial pressure gradient) also increases the transmural pressure, causing the vessel to distend. Because radius increases, resistance falls and flow rises more than it would in a rigid tube. Thus, the plot curves upward. The *elastic properties* of vessels are the major cause of such nonlinear pressure-flow relationships in vascular beds exhibiting little or no “active tension.”

FIGURE 19-7 Nonlinear relationships among pressure, flow, and resistance. **N19-8**

N19-8

Nonlinear Relationships Among Pressure, Flow, and Resistance

Contributed by Emile Boulpaep, and Walter Boron

In Figure 19-7A, the broken line shows the theoretical pressure-flow relationship for a rigid tube—flow is directly proportional to driving pressure. For a real vascular bed (red curve), the relationship is

nonlinear. First, the curve does not pass through the origin (i.e., flow is zero until driving pressure exceeds **critical closing pressure**). Second, the curve bends upward because increased transmural pressure widens the vessels. Increasing the vasomotor tone (blue and green curves) has two effects: shifting the critical closing pressure to the right and decreasing the slope (i.e., increasing the resistance once the vessel is open).

In Figure 19-7B, the three curves describe the resistance for the like-colored curves in Figure 19-7A. Under control conditions (no sympathetic stimulation—red curve), the resistance is infinitely high at pressures below the critical closing pressure because the baseline active tension causes the vessel to collapse. Higher driving pressures cause the vessel to dilate, lowering resistance with the fourth power of the radius. Thus, the resistance falls dramatically with increasing driving pressure. Increasing the vasomotor tone (blue and green curves) shifts the pressure-resistance relationships to the right (reflecting the increased critical closing pressures) and up (reflecting the higher resistance throughout).

As *driving* pressure—and thus transmural pressure—increases, vessel radius increases as well, causing resistance (see p. 415) to fall (see Fig. 19-7B, red curve). Conversely, resistance increases toward infinity when driving pressure falls. In Poiseuille's case, of course, resistance would be constant (see Fig. 19-7B, broken line), regardless of the driving pressure. Although many vascular beds behave like the red curves in Figure 19-7A and B, we will see in Chapter 24 that some are highly regulated (i.e., active tension varies with pressure). These special circulations therefore exhibit a pressure-flow relationship that differs substantially from that of a system of elastic tubes.

Contraction of smooth muscle halts blood flow when driving pressure falls below the critical closing pressure

As we have already seen, at low values of driving pressure, resistance rises abruptly toward infinity (see Fig. 19-7B, red curve). Viewed differently, flow totally ceases when the pressure falls below about 6 mm Hg, the critical closing pressure (see Fig. 19-7A, red curve). The stoppage of flow occurs because of the combined action of elastic fibers and *active tension* from VSMCs. Graded increases in active tension—produced, for example, by sympathetic stimulation—shift the pressure-flow relationship to the right and decrease the slope (see Fig. 19-7A, blue and green curves), which reflects an increase in resistance over the entire pressure range (see Fig. 19-7B, blue and green curves). The critical closing pressure also shifts upward with increasing degrees of vasomotor tone. This phenomenon is important in *hypotensive shock*, in which massive vasoconstriction occurs—in an attempt to raise arterial pressure—and critical closing pressures rise to 40 mm Hg or more. As a result, blood flow can stop completely in the limb of a patient in hypotensive shock, despite the persistence of a finite, albeit small, pressure difference between the main artery and vein.

Elastic and collagen fibers determine the distensibility and compliance of vessels

Arteries and veins must withstand very different transmural pressures in vivo (see Table 19-3). Moreover, their relative blood volumes respond in strikingly different ways to increases in transmural pressure (Fig. 19-8). Arteries have a low volume capacity but can withstand large transmural pressure differences. In contrast, veins have a large volume capacity (and are thus able to act as blood reservoirs)

but can withstand only small transmural pressure differences.

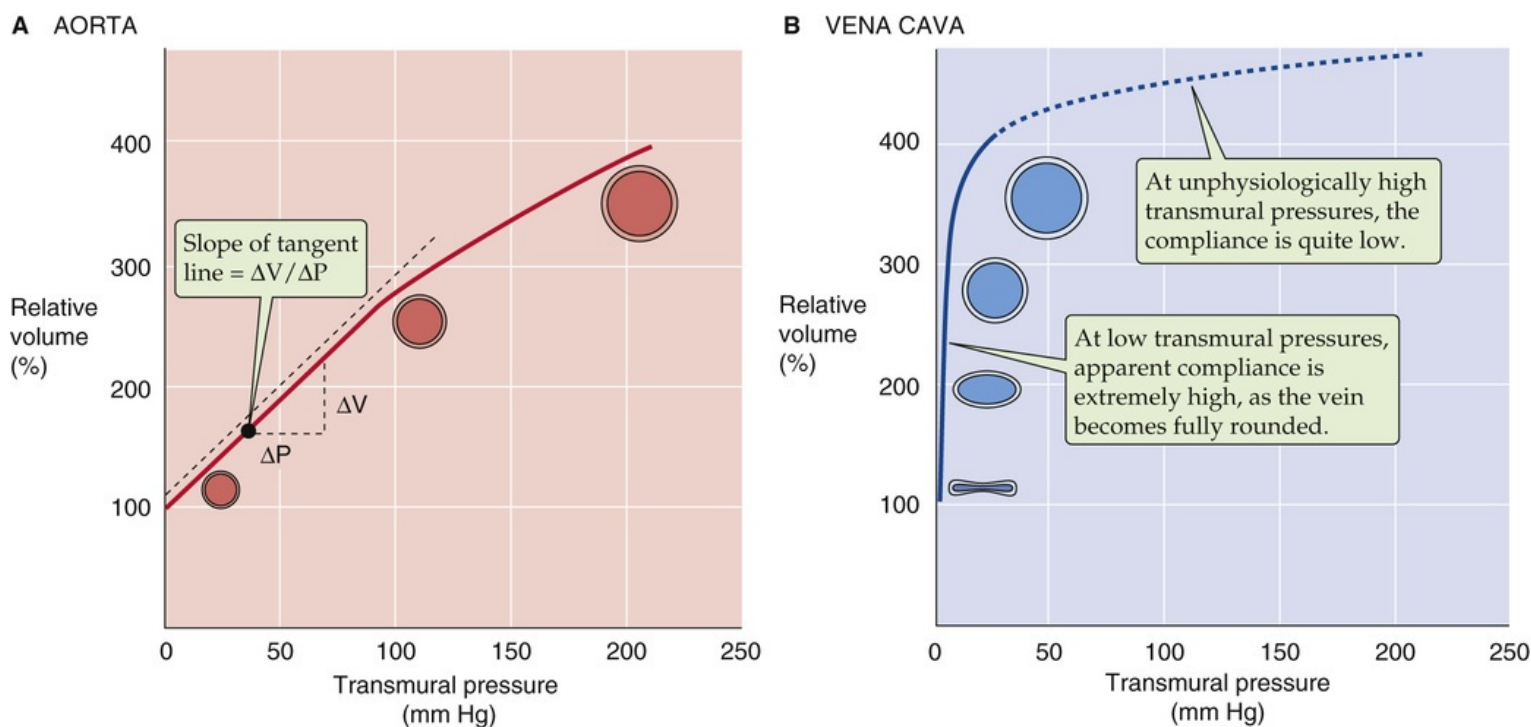

FIGURE 19-8 Compliance of blood vessels. In **A** and **B**, a relative volume of 100% represents the volume in a fully relaxed vessel.

The abundance of structural elements in the vascular walls also differs between arteries and veins (see Fig. 19-6). These disparities contribute to differences in the elastic behavior of arteries and veins. We can study the elastic properties of an isolated blood vessel either by recording the “static” volume change produced by pressurizing the vessel to different levels or, conversely, by recording the “static” pressure change produced by filling the vessel with liquid to different volumes. After the pressure or volume is recorded experimentally, it is important to wait until the vessel has finished responding (i.e., it becomes static) before the measurements are recorded.

The **volume distensibility** expresses the elastic properties of blood vessels. Three measurements are useful for assessment of distensibility. First, the **absolute distensibility** is the change in volume for a *macroscopic* step change in pressure, $\Delta V / \Delta P$. Second, because the unstretched size varies among vessels, it is preferable to normalize the volume change to the initial, unstretched volume (V_0) and thus to use a **normalized distensibility** instead:

$$\text{Normalized distensibility} = \frac{(\Delta V / V_0)}{\Delta P}$$

(19-4)

This ratio is a measurement of the fractional change in volume with a given step in pressure. Third, the most useful index of distensibility is **compliance** (C), which is the slope of the tangent to any point along the pressure-volume diagram in Figure 19-8:

$$C = \frac{\Delta V}{\Delta P}$$

(19-5)

Here, the ΔV and ΔP values are *minute* displacements. The steeper the slope of a pressure-volume diagram, the greater the compliance (i.e., the easier it is to increase volume). In [Figure 19-8](#), the slope—and thus the compliance—decreases with increasing volumes. For such a nonlinear relationship, this variable compliance is the slope of the tangent to the curve at any point. Thus, a compliance reading should always include the transmural pressure or the volume at which it was made. Similar principles apply to the compliance of airways in the lung (see [p. 610](#)).

Differences in compliance cause arteries to act as resistors and veins to act as capacitors

As we increase transmural pressure, arteries increase in volume. As they accommodate the volume of blood ejected with every heartbeat, large, muscular systemic arteries (e.g., femoral artery) increase in radius by about 10%. This change for a typical *muscular* artery is much smaller than the distention that one would observe for *elastic* arteries (e.g., aorta), which have fewer layers of smooth muscle and are not under nervous control. The higher compliance of elastic arteries is evident in the pressure-volume diagram in [Figure 19-8A](#)—obtained after the smooth muscle is relaxed. The compliance of a relaxed elastic artery is substantial: increasing the transmural pressure from 0 to 100 mm Hg (near the normal mean arterial pressure) increases relative volume by ~180%. With further increases in pressure and diameter, compliance decreases only modestly. For example, increase of transmural pressure from 100 to 200 mm Hg increases relative volume by a further ~100 percentage points. Thus, arteries are properly constituted for development and withstanding of high transmural pressures. Because an increase in pressure raises the radius only modestly under physiological conditions, particularly in muscular arteries, the resistance of the artery (inversely proportional to r^4) does not fall markedly. Because muscular arteries have a rather stable resistance, they are sometimes referred to as **resistance vessels**.

Veins behave very differently. The pressure-volume diagram of a vein (see [Fig. 19-8B](#)) shows that compliance is extremely high—far higher than for “elastic arteries”—at least in the low-pressure range. For a relaxed vein, a relatively small increase of transmural pressure from 0 to 10 mm Hg increases volume by ~200%. This high compliance in the low-pressure range is not due to a property of the elastic fibers. Rather, it reflects a change in geometry. At pressures <6 to 9 mm Hg, the vein's cross section is ellipsoidal. A small rise in pressure causes the vein to become circular, without an increase in perimeter but with a greatly increased cross-sectional area. Thus, in their normal pressure range (see [Table 19-3](#)), veins can accept relatively large volumes of blood with little buildup of pressure. Because they act as *volume reservoirs*, veins are sometimes referred to as **capacitance vessels**. The true distensibility or compliance of the venous wall—related to the increase in *perimeter* produced by pressures >10 mm Hg—is rather poor, as shown by the flat slope at higher pressures in [Figure 19-8B](#).

How do veins and elastic arteries compare in response to a sudden increase in volume (ΔV)? When the heart ejects its stroke volume into the aorta, the intravascular pressure increases modestly, from 80 to 120 mm Hg. This change in intravascular pressure—also known as the pulse pressure (see [p. 418](#))—is the same as the change in transmural pressure. We have already seen that venous compliance is low in this “arterial” pressure range. Thus, if we were to challenge a vein with a sudden increase in volume (ΔV) in the arterial pressure range, the increase in transmural pressure (ΔP) would be much higher than in an

artery of equal size. This is indeed the case when a surgeon uses a saphenous vein segment in a coronary artery bypass graft and anastomoses the vein between two sites on a coronary artery, forming a bypass around an obstructed site.

Changes in the volume of vessels during the cardiac cycle are due to changes in radius rather than length. During ejection of blood during systole, the length of the thoracic aorta may increase by only about 1%.  **N19-3**

N19-3

Changes in Vessel Volume

Contributed by Emile Boulpaep, and Walter Boron

The volume (V) of a vessel is the product of its mean cross-sectional area and length (L). Thus, for a cylindrical vessel with a radius of r :

$$V = \pi r^2 L$$

Changes in the volume (ΔV) of a vessel—changes such as those that occur during the cardiac cycle or respiratory cycle—generally are due to changes in radius, rather than in length. During the cardiac cycle, the ejection during systole of a stroke volume of 70 mL of blood causes a substantial increase in the radius of the *thoracic* aorta but causes the length of the thoracic aorta to increase by only ~1%. Moreover, a 1% decrease in the length of the *abdominal* aorta compensates for this increase in the length of the thoracic aorta.

In the case of coiled vessels, an increase in vessel length may make a larger contribution to the volume change. We will discuss two examples, vessels in the uterus and those in “apical” skin.

1. The arteries that supply the uterus form arcuate arteries inside the myometrium, from which arise radial arteries oriented toward the lumen of the uterus. As the radial arteries enter the endometrium, they become coiled spiral arteries. These spiral arteries undergo dramatic changes as the endometrium grows during the endometrial cycle (see pp. 1124–1126). During the proliferative phase of the cycle, the spiral arteries grow toward the lumen of the uterus together with the endometrium. During the luteal/secretory phase, the spiral arteries increase their coiling. On pages 1136–1137, we discuss the role of these spiral arteries in the maternal blood flow during pregnancy. See also Figure 56-6, which shows an unlabeled spiral artery that branches off from the maternal artery.
2. Another example of coiled vessels is the arteriovenous anastomoses (glomus bodies) in apical skin (see pp. 570–571). These vessels act as shunts between arterioles and venules in the dermis and play a role in the control of cutaneous blood flow, and thus heat flow from the “core” and the skin (see pp. 1200–1201).

In the case of pulmonary vessels, increases in lung volume stretch the blood vessels within the parenchyma of the lung, thereby increasing their length. Imagine that lung volume increases from residual volume (1.5 to 1.9 L as shown in Fig. 26-8) to total lung capacity (4.9 to 6.4 L as shown in Fig. 26-8), resulting in a 3.4-fold increase in lung volume. If that volume increase represents a uniform increase in all three axes of the lung, it would correspond to a ~50% increase along each dimension.

Laplace's law describes how tension in the vessel wall increases with transmural pressure

Because compliance depends on the elastic properties of the vessel wall, the discussion here focuses on how an external force deforms elastic materials. When the force vanishes, the deformation vanishes, and the material returns to its original state. The simplest mechanical model of a linearly elastic solid is a spring (Fig. 19-9A). The elongation ΔL is proportional to the **force** (\mathcal{F}), according to **Hooke's law**:

$$\mathcal{F} = k \cdot \Delta L$$

(19-6)

where k is a constant. If an elastic body requires a larger force to achieve a certain deformation, it is stiffer or less compliant. The largest stress that the material can withstand while remaining elastic is the **elastic limit**. If it is deformed beyond this limit, the material reaches its yield point and, eventually, its breaking point.

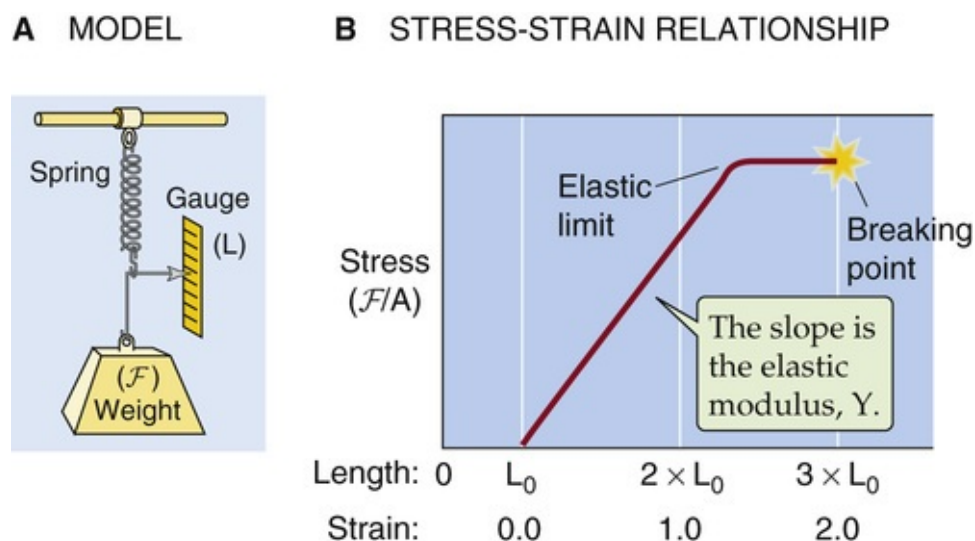

FIGURE 19-9 Elastic properties of a spring.

Stress is the force per unit cross-sectional area (\mathcal{F}/A). Thus, if we pull on an elastic band—stretching it from an initial length L_0 to a final length L —the stress is the force we apply, divided by the area of the band in cross section. **Strain** is the fractional increase in length, that is, $\Delta L/L_0$ or $(L - L_0)/L_0$ (see Fig. 19-9B). An equation analogous to Hooke's law describes the relationship between stress and strain:

$$\underbrace{\frac{\mathcal{F}}{A}}_{\text{Stress}} = Y \underbrace{\left(\frac{L - L_0}{L_0} \right)}_{\text{Strain}}$$

(19-7)

The proportionality factor, the Young **elastic modulus** (Y), **N19-4** is the force per cross-sectional

area required to stretch the material to twice its initial length and also the slope of the strain-stress diagram in [Figure 19-9B](#). Thus, the stiffer a material is, the steeper the slope, and the greater the elastic modulus. For example, collagen is >1000-fold stiffer than elastin ([Table 19-5](#)).

TABLE 19-5
Elastic Moduli (Stiffness) of Materials

MATERIAL	ELASTIC MODULUS (dynes/cm ²)*
Smooth muscle	10 ⁴ or 10 ⁵
Elastin	4 × 10 ⁶
Rubber	4 × 10 ⁷
Collagen	1 × 10 ¹⁰
Wood	10 ¹⁰ to 10 ¹²

N19-4

Young Modulus

Contributed by Emile Boulpaep, and Walter Boron

The elastic modulus used in Equation 19-7 in the text is the elastic modulus measured in an experiment in which one *stretches* an object. The **tensile elastic modulus**, also called the Young elastic modulus, is expressed by the term *Y* (for Young). *Y* is a measure of the force needed to stretch a material. If the material that we stretch has a uniform cross-sectional area *A*, the **stress** is the force we apply, normalized to the cross-sectional area ($\frac{F}{A}$). Stress is given in units of force per area, such as dynes per square centimeter or newtons per square meter. One **pascal** (Pa) is 1 N/m². Because 1 N = 10⁵ dynes and 1 m² = 10⁴ cm², 1 Pa = 10 dyne/cm².

The elongation that results from the stress that we apply is expressed as a **strain** or the change in length of the material normalized to its initial length ($\frac{[L - L_0]}{L_0}$). The relationship between stress and strain is given by Equation 19-7 (shown here as Equation NE 19-11):

$$\frac{\frac{F}{A}}{\text{Stress}} = Y \underbrace{\left(\frac{L - L_0}{L_0} \right)}_{\text{Strain}}$$

(NE 19-11)

Because strain is dimensionless (i.e., length divided by length), the coefficient *Y* has the same units as stress: dynes per square centimeter, or newtons per square meter = pascals.

Table 19-5 in the text gives the elastic moduli in dynes per square centimeter, whereas in engineering elastic moduli are often given in pascals. For further comparison, the elastic modulus of cortical long bone, such that of the femur, is 2 × 10¹⁰ Pa or 2 × 10¹¹ dyne/cm², and that of most types of steel is only an order of magnitude larger, ~2 × 10¹¹ Pa or 2 × 10¹² dyne/cm².

Finally, the elastic modulus of materials can also be obtained by measuring the degree of bending of a material under a given weight. For example, one could suspend a beam between two fixed points at either end of the beam, with the weight placed in the middle. The deflection of the beam is described by an equation analogous to Equation 19-7 (which is only valid for the *tensile* elastic modulus).

Because the elastic and collagen fibers in blood vessels are not arranged as simple linear springs, the stresses and strains that arise during the pressurization or filling of a vessel occur, at least in principle, along three axes (Fig. 19-10): (1) an elongation of the circumference (θ), (2) an elongation of the axial length (x), and (3) a compression of the thickness of the vessel wall in the direction of the radius (r). In fact, blood vessels actually change little in length during distention, and the thinning of the wall is usually not a major factor. Thus, we can describe the elastic properties of a vessel by considering only what happens along the circumference.

FIGURE 19-10 Three axes of vessel deformation. N19-9

The transmural pressure (ΔP) is the distending force that tends to increase the circumference of the vessel. Opposing this elongation is a force inside the vessel wall. It is convenient to express this wall **tension** (T) as the force that must be applied to bring together the two edges of an imaginary slit, of unit length L , cut in the wall along the longitudinal axis of the vessel (Fig. 19-11). Note that in using tension (*units*: dynes per centimeter) rather than stress (*units*: dynes per square centimeter), we assume that the thickness of the vessel wall is constant.

FIGURE 19-11 Laplace's law. The circumferential arrows that attempt to bring together the edges of an imaginary slit along the length of the vessel represent the constricting force of the tension in the wall. The radial arrows that push the wall outward represent the distending force. At equilibrium, the two sets of forces balance.

The equilibrium between ΔP and T depends on the vessel radius and is expressed by a law derived independently by Thomas Young and the Marquis de Laplace in the early 1800s. **N19-5** For a cylinder,

N19-5

Laplace's Law

Contributed by Emile Boulpaep, and Walter Boron

In **N19-9**, we point out that, although one could consider as many as three axes of stress-strain relationships for a blood vessel, the most important is the circumferential stress-strain relationship. Laplace's law illustrates how the circumferential geometry of an elastic tube depends on the balance of the *distending force*, which is generated by the transmural pressure (ΔP) that pushes the wall outward, and the *constricting force* from elastic components within the wall that pulls the wall inward. We can compute the distending force acting on a vessel (vessel length = L) from ΔP . For a blood vessel, ΔP is the transmural pressure, which is the difference between the intravascular pressure and the tissue pressure (see Fig. 17-4). The pressure is simply the force (\mathcal{F}) divided by the inner surface area of the vessel wall, which is (A_{surface}), $2\pi \cdot r \cdot L$. Because we disregard the changes in the thickness of the wall, the present treatment assumes a single radius (r), which is roughly equivalent to the midwall radius. Thus,

$$\mathcal{F}_{\text{distending}} = \Delta P \cdot A_{\text{surface}} = \Delta P \cdot 2\pi \cdot r \cdot L$$

(NE 19-12)

If we normalize this distending force per unit length of vessel, \mathcal{F}/L (in dynes per centimeter), we have the following:

$$\frac{\mathcal{F}_{\text{distending}}}{L} = \Delta P \cdot 2\pi \cdot r$$

(NE 19-13)

The **constricting force** that balances the distending force is the circumferential stress in the wall of the vessel. This stress is the force that must be applied to bring together the two edges of an imaginary slit of length L that has been cut through the vessel wall, along the longitudinal axis of the vessel wall (see Fig. 19-11). You can imagine that, as we cut through the vessel wall, we see that the cross-sectional area cut through the wall (A_{slit}) is $A_{\text{slit}} = h \cdot x$, where h is the thickness of the wall. This cross-sectional area is highlighted in yellow in Figure 19-10 and is labeled “ A_{slit} .” The **circumferential stress** is the force acting over the area A_{slit} . However, because we lack information about thickness of the wall, and thus about A_{slit} , we will ignore the dimension of thickness and instead will focus on the **constricting force per unit length** of the slit rather than per unit area. Thus, instead of working with the circumferential stress ($\mathcal{F}/A_{\text{slit}}$) of the vessel, we will instead work with the circumferential tension (\mathcal{F}/L , in dynes per centimeter):

$$\frac{\mathcal{F}_{\text{constricting}}}{L} = T$$

(NE 19-14)

In order for the system to be in equilibrium, the work done by the distending force must balance the work done by the constricting force. Work is force times displacement. The work done by the distending force (see Equation NE 19-13) is done over a displacement in the radial axis (Δr), as shown in Figure 19-10:

$$\begin{aligned} \text{Distending work} &= \mathcal{F} \cdot \Delta r \\ &= \Delta P \cdot 2\pi \cdot r \cdot \Delta r \end{aligned}$$

(NE 19-15)

The work done by the constricting force (see Equation NE 19-14) is done over a displacement in the circumferential axis and has the magnitude $2\pi \cdot \Delta r$:

$$\text{Constricting work} = T \cdot 2\pi \cdot \Delta r \quad \text{(NE 19-16)}$$

Based on the principles of virtual work and conservation of energy, we conclude that—at equilibrium—the distending work (see Equation NE 19-15) is the same as the constricting work (see Equation NE 19-16):

Distending work = Constricting work

(NE 19-17)

$$\Delta P \cdot 2\pi \cdot r \cdot \Delta r = T \cdot 2\pi \cdot \Delta r$$

Simplifying this equation yields the **law of Young/Laplace** for a cylinder:

$$\Delta P = T/r \quad (\text{NE 19-18})$$

or

$$T = \Delta P \cdot r$$

As we shall see on page 613, Equation 27-6 describes Laplace's law for a sphere, such as a balloon. In this case, the equation of Young and Laplace becomes:

$$\Delta P = 2T/r \quad (\text{NE 19-19})$$

Here, ΔP is the pressure distending the balloon (i.e., the difference between the internal and external pressures), T is the tension within the wall of the balloon, and r is the radius of the balloon. If the sphere were instead a soap bubble, T would be the surface tension.

N19-9

Axes of Vessel Deformation

Contributed by Emile Boulpaep, and Walter Boron

Figure 19-10 in the text shows the three axes along which deformation can occur during the filling of a blood vessel: **circumferential (θ)**, **longitudinal (x)**, and **radial (r)**. Therefore, as a blood vessel is distended by blood filling its lumen, we can consider three stresses and three strains, each with a different orientation. The three strains are as follows:

1. An elongation of the circumference ($\Delta\theta = \Delta 2\pi r$), where r is the average of the vessel's inner radius (r_1) and outer radius (r_2) as shown in Fig. 17-4)
2. An elongation of the length of the vessel (Δx)
3. A compression of the thickness of the vessel wall (Δh) in the direction of the radius; that is, a change in the *difference* between outer and inner radii, $\Delta(r_2 - r_1)$

As noted in **N19-3**, blood vessels actually change little in length during distention, and therefore we can disregard the strain-stress along the axis x of Figure 19-10. Although thinning of the wall does occur during blood vessel distention, the radial stress from wall compression is usually far less than the

circumferential stress; therefore, we will also ignore the strain-stress along the axis r . Thus, we are left to consider only the strain-stress relationship along the circumferential axis (θ), which is given by Laplace's law in Equation 19-8:

$$T = \Delta P \cdot r$$

Note that in the above equation, **stress** (i.e., force per unit area) is replaced by **tension** (i.e., force per unit length).

$$T = \Delta P \cdot r$$

(19-8)

Thus, for a given transmural pressure, the wall tension in the vessel gets larger as the radius increases.

The vascular wall is adapted to withstand wall tension, not transmural pressure

In [Figure 19-8](#), we plotted the volume of a vessel against transmural pressure, finding that the slope of this relationship is compliance. However, this sort of analysis does not provide us with direct information on the spring-like properties of the materials that make up the vessel wall. With Laplace's law ($T = \Delta P \cdot r$), we can transform the pressure-volume relationship into the same kind of “elastic diagram” that we used in [Figure 19-9B](#) to understand the properties of a rubber band.

[Figure 19-12A](#) is a replot of the pressure-volume diagrams in [Figure 19-8A and B](#). In [Figure 19-12B](#), we reverse the coordinate system so that volume is now on the x-axis and pressure on the y-axis. Finally, in [Figure 19-12C](#), we convert volume to radius on the x-axis and use Laplace's law to convert pressure into wall tension on the y-axis. The plots in [Figure 19-12C](#) are analogous to a stress-strain diagram for a rubber band (see [Fig. 19-9B](#)). Thus, stretching the radius of the aorta (solid red curve) causes a considerable rise in wall tension, which reflects the aorta's moderate compliance. The vena cava, on the other hand, fills over a wide range of radii before any wall tension develops, which reflects the shape change that makes it *appear* to be very compliant at the low pressures that are physiological for a vein. However, further stretching of the vein's radius results in a steep rise in wall tension, which reflects the inherently limited compliance of veins. 🍷[N19-6](#)

A PRESSURE-VOLUME DIAGRAM

B VOLUME-PRESSURE DIAGRAM

C RADIUS-TENSION DIAGRAM

FIGURE 19-12 Elastic diagram (tension versus radius) of blood vessels. In **A**, the curves are replots of the curves in [Figure 19-8, A and B](#). In **B**, the plot is the result of reversing the two axes in **A**. In **C**, the solid red and blue curves are transformations of the curves in **B**. If we solve for r , the x-axis of **B** (volume) becomes the radius in **C**; if we use Laplace's law ($T = \Delta P \cdot r$) to solve for T , the y-axis of **B** (transmural pressure) becomes tension in **C**.

N19-6

Length-Tension Versus Strain-Stress Diagrams

Contributed by Emile Boulpaep, and Walter Boron

In Figure 19-12C of the text, we plot the wall tension of a cylindrical blood vessel against its radius (r , in millimeters). This **wall tension** is the force per unit length (T , in dynes per centimeter) of an imaginary slit in the wall of the blood vessel (see Fig. 19-10). The radius in Figure 19-12C is related by a constant (2π) to the *length* of the circumference of the vessel ($2\pi r$). Thus, the x-axis is really a length, so that Figure 19-12C is really a **length-tension** diagram similar to that shown for passive tension in muscle (see Fig. 9-9C). Note, however, that in Figure 9-9C, what we plotted on the y-axis was the percent of maximum active force, not the wall tension (in which the force is normalized to the length of an imaginary slit in the vessel).

In contrast, an engineer studying the elastic properties of a solid would use a **strain-stress** diagram, as shown in Figure 19-9B, which differs from a length-tension diagram on both the y- and x-axes. On the y-axis of a strain-stress diagram, we plot the force, normalized to the cross-sectional area of the material—we define this parameter as **stress** (dynes per square centimeter). On the x-axis, we plot the fractional change in the length of the material—we define this dimensionless parameter as the **strain**. The following equation (which reproduces Equation 19-7) shows that the relationship between stress and strain is linear:

$$\frac{F}{A} = Y \left(\frac{L - L_0}{L_0} \right)$$

Stress Strain

(NE 19-20)

Note that the proportionality constant in this equation is the **Young elastic modulus (Y)**, which is a characteristic of a particular material, as shown in Table 19-5.

It would be advantageous to convert the length-tension diagram in Figure 19-12C into a true strain-stress diagram because that would allow us to estimate the Young elastic modulus for the blood vessel wall, which in turn would give us insight into the material that makes up the wall. This conversion requires that we (1) convert the y-axis from wall tension (dynes per centimeter) to stress (dynes per square centimeter), and (2) convert the x-axis from absolute length (centimeters) to fractional change in length (dimensionless). Starting from the definition of stress, we get

$$\begin{aligned}
 \underbrace{\frac{F}{A_{\text{slit}}}}_{\text{Stress}} &= \frac{F}{(\text{Length of slit}) \times (\text{Wall thickness})} \\
 &= \frac{F}{(\text{Length of slit})} \times \frac{1}{(\text{Wall thickness})} \\
 &= \frac{\text{Wall tension}}{\text{Wall thickness}} \\
 &\quad \text{(NE 19-21)}
 \end{aligned}$$

We see that we can obtain the stress by dividing wall tension (y-axis in Fig. 19-12C) by the wall thickness. Note that the experimental data of Figure 19-12C were obtained on vessels of an experimental animal with vessel diameters that were about half those of the human aorta or vena cava. Assuming that wall thickness of both the aorta and vena cava in the experimental animal were 0.1 cm, we can convert the y-axis of Figure 19-12C to units of stress (dynes per square centimeter) simply by dividing the wall tension by 0.1 cm. We will perform this conversion separately for the aorta and vena cava and, in the process, compute the Young elastic modulus for the materials that constitute the wall of the aorta and vena cava.

Aorta

Because the length-tension diagram in Figure 19-12C was not linear, the resulting strain-stress diagram will also be nonlinear. Therefore, we will analyze the relationship between strain and stress at two different points along the curve (i.e., at two different degrees of elongation of the circumference of the vessel wall).

For an elongation of the vessel-wall circumference from a radius of 3.15 mm (the intersection of the curve with the x-axis) to a radius of 4 mm, the fractional change in length is $(L - L_0)/L_0 = (4 - 3.15)/3.15 = 0.27$, or a change of 27%. Achieving this elongation requires that we increase the wall tension from zero to 21,500 dyne/cm. Viewed another way, assuming a wall thickness of 0.1 cm, we must increase the stress from zero to $(21,500 \text{ dyne/cm})/(0.1 \text{ cm})$ or 215,000 dyne/cm². Inserting the preceding values into Equation NE 19-20 yields an elastic modulus (Y) of $\sim 800,000 \text{ dyne/cm}^2$. Referring to Table 19-5, we see that this value is intermediate between the elastic modulus of smooth muscle and that of elastin, suggesting that both smooth muscle and elastin contribute to the elastic properties of the vessel wall in this low range of elongation of the vessel-wall circumference.

For an elongation of the vessel-wall circumference from a radius of 6 mm (the red point on the red curve in Fig. 19-12C) to a radius of 6.1 mm, the fractional change in length is $(6.1 - 6.0)/6.0 = 0.017$, or a change of 1.7%. Achieving this elongation requires that we increase the wall tension from 120,000 dyne/cm to 140,000 dyne/cm, an increase in wall tension of 20,000 dyne/cm. Viewed another way, and assuming a wall thickness of 0.1 cm, we must increase the stress by $(20,000 \text{ dyne/cm})/(0.1 \text{ cm})$ or 200,000 dyne/cm². Inserting the preceding values into Equation NE 19-20 yields an elastic modulus (Y) of $\sim 12,000,000 \text{ dyne/cm}^2$. This estimated elastic modulus somewhat exceeds the typical elastic modulus of elastin, indicating the likely recruitment—in this range of elongation—of some material with a higher elastic modulus (i.e., collagen).

This analysis confirms the conclusion that we reached on page 458. Thus, depending on the degree of stretch, different materials of different elastic modulus contribute to the overall **elastic diagram** of the aorta.

Vena Cava

For an elongation of the vessel-wall circumference from a radius of 3 mm to a radius of 6 mm, the fractional change in length is $(L - L_0)/L_0 = (6 - 3)/3 = 1$, or a change of 100%. Achieving this elongation requires that we increase the wall tension from zero to ~ 1000 dyne/cm. Assuming a wall thickness of 0.1 cm, we must increase the stress from zero to $(1000 \text{ dyne/cm})/(0.1 \text{ cm})$ or $10,000 \text{ dyne/cm}^2$. Inserting the preceding values into Equation NE 19-20 yields an elastic modulus (Y) of $\sim 100,000 \text{ dyne/cm}^2$, which is in the range of the elastic modulus for pure smooth muscle (see Table 19-5). However, because smooth muscle is arranged in parallel with elastin, it is impossible to pull on one without pulling on the other. Thus, the elastic modulus of $\sim 100,000 \text{ dyne/cm}^2$ is unrealistically low. In fact, the stress that we are applying in this range of elongation does not place any increased strain on the smooth muscle and elastic fibers of the vessel wall. Rather, the small increase in wall stress is merely that required to change the geometry of the vena cava from ellipsoidal (i.e., collapsed) to circular (i.e., fully rounded), as discussed on page 455.

For an elongation of the vessel-wall circumference from a radius of 6.8 mm (the blue point on the blue curve in Fig. 19-12C) to a radius of 6.9 mm, the fractional change in length is $(6.9 - 6.8)/6.8 = 0.015$, or a change of 1.5%. Achieving this elongation requires that we increase the wall tension from 20,000 dyne/cm to 40,000 dyne/cm, an increase in wall tension of 20,000 dyne/cm. Assuming a wall thickness of 0.1 cm, we must increase the stress by $(20,000 \text{ dyne/cm})/(0.1 \text{ cm})$ or $200,000 \text{ dyne/cm}^2$. Inserting the preceding values into Equation NE 19-20 yields an elastic modulus (Y) of $\sim 13,600,000 \text{ dyne/cm}^2$. The estimated elastic modulus of the vena cava in this range of elongation of the circumference somewhat exceeds the typical elastic modulus of elastin, which indicates—as in the case of the aorta—the recruitment of a material with a higher elastic modulus (i.e., collagen).

What does Laplace's law (see [Equation 19-8](#)) tell us about the wall tension necessary to withstand the pressure inside a blood vessel? On the plot of tension versus radius for the aorta in [Figure 19-12C](#), we have chosen a single point at a radius of 6 mm; because the aorta is relatively stiff, stretching it to this radius produces a wall tension of 120,000 dyne/cm. According to Laplace's law, exactly one *pressure*—200,000 dyne/cm² or 150 mm Hg—satisfies this combination of r and T . In [Figure 19-12C](#), this pressure is indicated by the *slope* of the red broken line that connects the origin with our point. In a similar exercise for the vena cava, we assume a radius of ~ 6.7 mm, which is similar to the one we chose for the aorta; because the vena cava is readily deformed in this range, expanding it to this radius produces a wall tension of only 12,000 dyne/cm (blue broken line). This combination of r and T yields a much lower pressure—18,000 dyne/cm², or 13.5 mm Hg. Thus, comparing vessels of *similar size*, Laplace's law tells us that a high wall tension is required to withstand a high pressure.

Comparing two vessels of very *different size* reveals a disparity between wall tension and pressure. A large vein, such as the vena cava, must resist only 10 mm Hg in transmural pressure but is equipped with a fair amount of elastic tissue. A capillary, on the other hand, which must resist a transmural pressure of 25 mm Hg, does not have any elastic tissue at all. Why? The key concept is that what the vessel really has to withstand is not pressure but *wall tension*. According to Laplace's law (see [Equation 19-8](#)), wall tension is the product of transmural pressure and radius ($\Delta P \cdot r$). Hence, wall tension in a capillary (10 dyne/cm) is much smaller than that in the vena cava (18,000 dyne/cm), even though the capillary is at a higher pressure. [Table 19-6](#) shows that the amount of elastic tissue correlates extremely well with wall tension but very poorly with transmural pressure. The higher the tension that the vessel wall must bear, the greater is its complement of elastic tissue.

TABLE 19-6
Comparison of Wall Tensions and Elastic-Tissue Content in Various Vessels

	MEAN TRANSMURAL PRESSURE ΔP (mm Hg)	RADIUS (r)	WALL TENSION T (dynes/cm)	ELASTIC TISSUE*
Aorta	95	1.13 cm	140,000	++++
Small arteries	90	0.5 cm	60,000	+++
Arterioles	60	15 μ m	1200	+
Capillaries	25	3 μ m	10	0
Venules	15	10 μ m	20	0
Veins	12	>0.02 cm	320	+
Vena cava	10	1.38 cm	18,000	++

*The number of plus signs is a relative index of the amount of elastic tissue.

Elastin and collagen separately contribute to the wall tension of vessels

The solid red and blue curves in [Figure 19-12C](#) are quite different from the linear behavior predicted by Hooke's law (see [Fig. 19-9B](#)). With increasing stretch, the vessel wall resists additional deformation more; that is, the slope of the relationship becomes steeper. The increasing slope (i.e., increasing elastic modulus) of the radius-tension diagram of a blood vessel is due to the heterogeneity of the elastic material of the vascular wall. Elastic and collagen fibers have different elastic moduli (see [Table 19-5](#)). We can quantitate the separate contributions of elastic and collagen fibers by “chemical dissection.” After selective digestion of elastin with elastase, which unmask the behavior of collagen fibers, the length-tension relationship is very steep and closer to the linear relationship expected from Hooke's law ([Fig. 19-13, orange](#) curve). After selective digestion of collagen fibers with formic acid, which unmask the behavior of elastic fibers, the length-tension relationship is fairly flat (see [Fig. 19-13](#), violet curve). The orange curve (collagen) is steeper than the violet curve (elastin) because collagen is stiffer than elastin (see [Table 19-5](#)). In a normal vessel (see [Fig. 19-13](#), red curve), modest degrees of stretch elongate primarily the elastin fibers along a relatively flat slope. Progressively greater degrees of stretch recruit collagen fibers, resulting in a steeper slope.

FIGURE 19-13 Chemical dissection of elastic moduli of collagen and elastin.

Aging reduces the distensibility of arteries

With aging, important changes occur in the elastic properties of blood vessels, primarily arteries. We can look at these age relationships for arteries from two perspectives, the pressure-volume curve and the radius-tension curve.

The most obvious difference in aortic pressure-volume curves with increasing age is that the curves shift to progressively higher volumes (Fig. 19-14A), which reflects an increase in diameter. In addition, the compliance of the aorta first rises during growth and development to early adulthood and then falls during later life. After early adulthood, two unfavorable changes occur. First, arteriosclerotic changes reduce the vessel's compliance per se. Thus, during ventricular ejection, a normal-sized increase in aortic volume (ΔV) in a young adult produces a relatively small pulse pressure (ΔP) in the aorta. In contrast, the same change in aortic volume in an elderly individual produces a much larger pulse pressure. Second, because blood pressure frequently rises with age, the older person operates on a flatter portion of the pressure-volume curve, where the compliance is even lower than at lower pressures. Thus, a normal-sized increase in aortic volume produces an even larger pulse pressure.

A PRESSURE–VOLUME DIAGRAM

B RADIUS–TENSION DIAGRAM

FIGURE 19-14 Effect of aging on arteries. In **A** and **B**, a relative radius of 100% represents the fully relaxed value. In **A**, the white triangles show the expected change in transmurial pressure (*blue line*) for the increase in aortic blood volume (*red line*) produced by each heartbeat—assuming a diastolic pressure of 80 mm Hg.

The second approach for assessment of the effects of age on the elastic properties of blood vessels is to examine the radius-tension diagram (see Fig. 19-14B). Because of the progressive, diffuse fibrosis of vessel walls with age, and because of an increase in the amount of collagen, the maximal slope of the radius-tension diagram increases with age. In addition, with age, these curves start to bend upward at lower radii, as the same degree of stretch recruits a larger number of collagen fibers. Underlying this phenomenon is an increased cross-linking among collagen fibers (see p. 1239) and thus less slack in their connections to other elements in the arterial wall. Thus, even modest elongations challenge the stiffer collagen fibers to stretch.

Active tension from smooth-muscle activity adds to the elastic tension of vessels

Although we have been treating blood vessels as though their walls are purely elastic, the **active tension** (see pp. 238–240) from VSMCs also contributes to wall tension. Stimulation of VSMCs can reduce the internal radius of muscular feed arteries by 20% to 50%. Laplace's law ($T = \Delta P \cdot r$) tells us that as the VSMC shortens—thereby reducing vessel radius against a constant transmural pressure—there is a decrease in the tension that the muscle must exert to maintain that new, smaller radius.

For a blood vessel in which both passive elastic components and active smooth-muscle components contribute to the total tension, the radius-tension relationship reflects the contributions of each. **N19-7** The red curve in Figure 19-15 shows such a compounded (passive + active) radius-tension diagram for an artery in which the sympathetic neurotransmitter norepinephrine (see p. 342) has maximally stimulated the VSMCs. The green curve shows a passive radius-tension relationship for just the elastic component of the tension (after the active component is eliminated by poisoning of the VSMCs with potassium cyanide). Of course, the green curve is the radius-tension diagram on which we have focused the previous figures (e.g., see Fig. 19-12C). Subtraction of the green from the red curve in Figure 19-15 yields the *active*

length-tension diagram (blue curve) for the vascular smooth muscle.

FIGURE 19-15 Active versus passive tension. The relative radius of 100% is that of an excised vessel maximally stimulated by norepinephrine (*red curve*, total tension) but not “stressed” (i.e., transmural pressure is 0). When the vessel is maximally poisoned with potassium cyanide, the baseline radius is ~150% (*green curve*, passive tension), which reflects its relaxed state. The blue curve is just the active (i.e., smooth-muscle) component of tension.

N19-7

Stability of Vessels with Combined Active and Passive Tension

Contributed by Ridder Emile Boulpaep

Figure 19-15 in the text shows that total vascular wall tension from active and passive elements (*red curve*) is a rising function of relative radius (i.e., length). We can compare the active, passive, and total tensions of a blood vessel wall with those of skeletal muscle, which are shown in Figure 9-9C. Active tensions in both skeletal muscle and vascular smooth-muscle cells (VSMCs) plotted against length exhibit a maximum, as shown for skeletal muscle in Figure 9-9D and for VSMCs by the blue curve in Figure 19-15. However, note that the plot of the *total* tension of skeletal muscle against length (*orange curve* in Fig. 9-9C) exhibits a plateau or a maximum, whereas the plot of total tension of VSMCs against length rises monotonically throughout (*red curve* in Fig. 19-15). The latter phenomenon is due to the increasingly large *passive* tension component (*green curve* in Fig. 19-15), which rises very steeply as one stretches the wall of the blood vessel.

The absence of a plateau in the total-tension versus radius curve for a blood vessel wall is of great benefit for the stability of a blood vessel over a wide range of transmural pressures. We can make this point more clearly by considering a length-tension diagram similar to the red curve in Figure 19-15, but in which we plot the absolute radius on the x-axis. The solid red curve in Figure 19-12C is just such a plot. Here, the dashed red line represents the particular transmural pressure of 150 mm Hg that satisfies

the physical equilibrium of that vessel at a wall tension of 120,000 dyne/cm and a radius of 6 mm. We could draw a family of dashed lines in Figure 19-15—each one representing one transmural pressure and passing through the origin (zero tension and zero radius) and intersecting various points on the rising red curve. Each of these dashed lines would represent one of a wide range of transmural pressures that can be in physical equilibrium, each with its own wall tension and vessel radius.

We now return to the red curve in Figure 19-15, which represents a vessel whose VSMCs have been maximally stimulated by norepinephrine. Note that in this plot, the x-axis starts with 100%, rather than zero. This 100% represents the “unloaded” diameter in which the transmural pressure is zero. This is also the minimum radius that the vessel can achieve under the current conditions of norepinephrine stimulation. Now let us assume that we extend the x-axis of Figure 19-15 to the left to 0% to obtain the true origin of a diagram such as that in Figure 19-12 (tension = 0, radius = 0). Because we have drawn Figure 19-15 for an artery of an experimental animal, we will assume that the 100% radius corresponds to 3 mm = 0.3 cm.

Just as we introduced the concept of drawing a family of dashed lines in Figure 19-12C, we can draw a family of dashed lines in Figure 19-15, with its x-axis artificially extended to the left to 0%. The table below shows the coordinates of the end points of just such a family of dashed lines. In each row we show the coordinates of the origin (columns 1 and 2), the coordinates of the intersection of the dashed line with the red curve (columns 3 and 4), and finally the appropriate equilibrium pressure in two different units (columns 5 and 6) computed from Laplace's law (i.e., $P = T/r$). For example, the first row of data pertains to the unloaded condition. Here, the dashed line is horizontal and connects the new origin at 0% with 100% (i.e., the old origin). Note that the slope is the transmural pressure, which is zero. Another example is the last row of data, which corresponds to a radius of 200%, or twice the initial radius of 100%. Here, the dashed line has a slope of 275 mm Hg, which is the transmural pressure necessary for the physical equilibrium between the radius of 200% and wall tension of 220,000 dyne/cm. Thus, the table shows that the system can be in equilibrium for transmural pressures ranging from zero to 275 mm Hg, and even beyond.

Coordinates of the Origin		Coordinates of Intersection of Dashed Line with Red Curve		Equilibrium Pressure = Slope of Dashed Line = T/r	
Tension (dynes/cm)	Radius	T (dynes/cm)	Radius	P (dynes/cm ²)	P (mm Hg)
0	0% = 0 cm	0	100% = 0.3 cm	0	0
0	0% = 0 cm	10,000	120% = 0.36 cm	28,000	20
0	0% = 0 cm	30,000	140% = 0.42 cm	71,000	54
0	0% = 0 cm	68,000	160% = 0.48 cm	142,000	106
0	0% = 0 cm	120,000	180% = 0.54 cm	222,000	167
0	0% = 0 cm	220,000	200% = 0.6 cm	367,000	275

We will now use two examples to illustrate why it is important for blood vessels to contain elastic material with a reasonably high elastic modulus. That is, the green curve in Figure 19-15 must be reasonably steep.

First, consider the hypothetical case in which the active tension of smooth muscle (analogous to the blue curve in Fig. 19-15) peaks at a wall tension of 100,000 dyne/cm at a radius of 190% = 0.57 cm and then falls very steeply to a wall tension of zero at a radius of 195%. If we now summed this new hypothetical blue curve and the existing green curve in Figure 19-15, we would obtain a red curve that reaches a maximum total wall tension of ~150,000 dyne/cm at a radius of 190% and then falls off at higher radii. At the maximum wall tension, the transmural pressure (P) would be 197 mm Hg. Any transmural pressure in excess of 197 mm Hg (i.e., a pressure of $P + \Delta P$) would further dilate the vessel to a radius in excess of 190% (i.e., a radius of $r + \Delta r$). The total wall tension required for equilibrium, according to Laplace's law, would be $T_{\text{required}} = (P + \Delta P) \times (r + \Delta r)$, which would have to be >150,000

dyne/cm. In fact, the actual tension (T_{actual}) has already passed its peak of 150,000 dyne/cm. Accordingly, $T_{\text{required}} = (P + \Delta P) \times (r + \Delta r) > T_{\text{actual}}$ and a **blowout** would result (see Fig. 19-16B, panel 2).

Second, consider another hypothetical case in which smooth-muscle tension is perfectly constant. That is, the blue curve for active tension (analogous to the blue curve in Fig. 19-15) is a flat horizontal line that might have a wall tension, for example, of 100,000 dyne/cm, irrespective the size of the vessel. If we now summed this new hypothetical blue curve and the existing green curve in Figure 19-15, we would obtain a red curve that would be the same as the green curve, but upwardly displaced by 100,000 dyne/cm. Thus, this new red curve would be flat between a radius of 0% and a radius of 140%. Beyond a radius of 140%, this new red curve would rise with the same slope as the green curve. Let us now assume a starting radius of 140% (0.42 cm) and a wall tension of 100,000 dyne/cm, which would be in physical equilibrium—according to Laplace's law—at a transmural pressure of 178 mm Hg. If the transmural pressure then fell to <178 mm Hg (i.e., a pressure of $P - \Delta P$), the vessel would tend to narrow below a radius of 140% (i.e., a radius of $r - \Delta r$). The total wall tension required for equilibrium, according to Laplace's law, would be $T_{\text{required}} = (P - \Delta P) \times (r - \Delta r)$, which would have to be <100,000 dyne/cm. In fact, the actual tension (T_{actual}) is 100,000 dyne/cm. Accordingly, $T_{\text{required}} = (P - \Delta P) \times (r - \Delta r) < T_{\text{actual}}$ and a complete vessel **collapse** would result (see Fig. 19-16B, panel 3).

Elastic tension helps stabilize vessels under vasomotor control

Consider a vessel initially stretched to a radius that is 80% greater than the unstressed radius (i.e., 180 versus 100 on the x-axis of Fig. 19-15). As we inject more fluid into the vessel, the radius increases (i.e., the vessel is more “stressed”). As a result, total wall tension must increase (see Fig. 19-15, red curve). The opposite, of course, would happen if we were to withdraw some fluid from the vessel. During such changes in total wall tension, what are the individual contributions of vascular smooth-muscle tension and the passive connective tissue tension? In Figure 19-16, we consider two extreme examples, one in which the vessel has only elastic elements and another in which it has only a fixed (i.e., isotonic) active tension.

First, consider a vessel lacking smooth muscle, so that only elastic elements contribute to total wall tension (see Fig. 19-16A). If we increase transmural pressure from P (panel 1) to $P + \Delta P$ (panel 2), thereby increasing the radius from r to $r + \Delta r$, wall tension will automatically increase from T to $T + \Delta T$.

This increase in tension allows the vessel to reach a new equilibrium, according to Laplace's law:

$$T + \Delta T = (P + \Delta P) \cdot (r + \Delta r)$$

(19-9)

Conversely, a decrease in pressure must lead to a decrease in radius and a decrease in tension (panel 3). To achieve either the stable inflation of panel 2 or the stable deflation of panel 3, ΔT cannot be zero. In other words, the passive radius-tension diagram (see Fig. 19-15, green curve) cannot have a slope of zero. The vessel wall must have some elasticity.

Second, consider a hypothetical case in which *no elastic fibers* are present and in which the total tension T is kept constant by active elements (i.e., VSMCs) alone. For example, this would be approximately the case for the blue curve in Figure 19-15, between relative radii of 180% and 200%. At the start (see Fig. 19-16B, panel 1), we will assume that the smooth-muscle tension exactly balances the $P \cdot r$ product. However, when we now increase pressure (panel 2), the automatic adaptation of tension that we saw in the previous example would *not* occur. Indeed any increase in pressure would make the product $(P + \Delta P) \cdot (r + \Delta r)$ exceed the fixed T of the VSMCs. As a result, the vessel would blow out. Conversely, any decrease in pressure would make the product $(P - \Delta P) \cdot (r - \Delta r)$ fall below the fixed T and lead to full collapse of the vessel (panel 3). This type of instability does in fact occur in **arteriovenous anastomoses**, which are characterized by poor elastic tissue and abundant myoepithelioid cells.

A real vessel, whose wall contains both elastic and smooth-muscle elements, can be stable (i.e., neither blown out nor collapsed) over a wide range of radii. The role of elastic tissue in vessels is therefore not only to withstand high transmural pressures, but also to stabilize the vessel. Thus, elastic tissue ensures a graded response when smooth-muscle tone changes. If vessels had only smooth muscle—and no elastic fibers—they would be like those in panels 2 and 3 of Figure 19-16B, and tend to be either completely open or completely closed.

An imbalance between passive and active elastic components in blood vessels can be important in disease. For example, when the passive, elastic fibers of a blood vessel are reduced or damaged, vessels tend to become larger, as in **aneurysms** and **varicosities**. If the radius exceeds the value compatible with the physical equilibrium governed by Laplace's law, a blowout may occur.

A second pathological example is seen when smooth muscle has undergone maximal stimulation and, conversely, passive elastic elements have regressed. This is the case in **Raynaud disease**, in which exposure to cold leads to extreme constriction of arterioles in the extremities, particularly the fingers. Vessel closure occurs because active smooth-muscle tension dominates the radius-tension diagram.

CHAPTER 20

The Microcirculation

Emile L. Boulpaep

The microcirculation serves both nutritional and non-nutritional roles

The primary function of the cardiovascular system is to maintain a suitable environment for the tissues. The microcirculation is the “business end” of the system. The capillary is the principal site for exchange of gases, water, nutrients, and waste products. In most tissues, capillary flow exclusively serves these **nutritional** needs. In a few tissues, however, a large portion of capillary flow is **non-nutritional**. For example, in the glomeruli of the kidneys, capillary flow forms the glomerular filtrate (see [p. 739](#)). Blood flow through the skin, some of which may shunt through arteriovenous anastomoses, plays a key role in temperature regulation (see [pp. 1200–1201](#)). Capillaries also serve other non-nutritional roles, such as signaling (e.g., delivery of hormones) and host defense (e.g., delivery of platelets). In the first part of this chapter, we discuss the nutritional role of capillaries and examine how gases, small water-soluble substances, macromolecules, and water pass across the endothelium. In the last two subchapters, we discuss lymphatics as well as the regulation of the microcirculation.

The morphology and local regulatory mechanisms of the microcirculation are designed to meet the particular needs of each tissue. Because these needs are different, the structure and function of the microcirculation may be quite different from one tissue to the next.

The microcirculation extends from the arterioles to the venules

The microcirculation is defined as the blood vessels from the first-order arteriole to the first-order venule. Although the details vary from organ to organ, the principal components of an idealized microcirculation include a single arteriole and venule, between which extends a network of true capillaries ([Fig. 20-1](#)). Sometimes a metarteriole—somewhat larger than a capillary—provides a shortcut through the network. Both the arteriole and the venule have vascular smooth-muscle cells (VSMCs). Precapillary sphincters—at the transition between a capillary and either an arteriole or a metarteriole—control the access of blood to particular segments of the network. Sphincter closure or opening creates small local pressure differences that may reverse the direction of blood flow in some segments of the network.

FIGURE 20-1 Idealized microcirculatory circuit.

Arteries consist of an inner layer of endothelium, an internal elastic lamina, and a surrounding sheath of at least two continuous layers of innervated VSMCs (see [p. 453](#)). The inner radius of **terminal arteries** (called feed arteries in muscle) may be as small as $25\ \mu\text{m}$. **Arterioles** (inner radius, 5 to $25\ \mu\text{m}$) are similar to arteries but have only a *single* continuous layer of VSMCs, which are innervated. **Metarterioles** are similar to arterioles, but of shorter length. Moreover, their VSMCs are discontinuous and are not usually innervated. The **precapillary sphincter** is a small cuff of smooth muscle that usually is not innervated but is very responsive to local tissue conditions. Relaxation or contraction of the precapillary sphincter may modulate tissue blood flow by an order of magnitude or more. Metarterioles and precapillary sphincters are not found in all tissues.

True capillaries (inner radius, 2 to $5\ \mu\text{m}$) consist of a single layer of endothelial cells surrounded by a basement membrane, a fine network of reticular collagen fibers, and—in some tissues—pericytes. The endothelial cells have a smooth surface and are extremely thin (as little as 200 to 300 nm in height), except at the nucleus. The thickness and density of the capillary **basement membrane** vary among organs. Where large transcapillary pressures occur or other large mechanical forces exist, the basement membrane is thickest. Some endothelial cells have, on both luminal and basal surfaces, numerous **pits** called **caveolae** (see [pp. 42–43](#)) that are involved in ligand binding. Fluid-phase and receptor-mediated endocytosis (see [pp. 41–42](#)) can result in 70-nm **caveolin-coated vesicles**. In addition, the cytoplasm of capillary endothelial cells is rich in other endocytotic (pinocytotic) **vesicles** that contribute to the transcytosis of water and water-soluble compounds across the endothelial wall. In some cases, the endocytotic vesicles are lined up in a string and even appear linked together to form a **transendothelial channel**.

Linking endothelial cells together are **interendothelial junctions** (Fig. 20-2) where the two cell membranes are ~10 nm apart, although there may be constricted regions where the space or **cleft** between the two cells forms **adhering junctions** only ~4 nm wide. **Tight junctions** (see pp. 43–44) may also be present in which the apposed cell membranes appear to fuse, and **claudins** 1, 3, and 5 (CLDN1, CLDN3, CLDN5; see pp. 43–44) as well as **occludin** seal the gap. CLDN5 is quite specific for endothelial cells. Occludin is not found in all endothelia.

FIGURE 20-2 Capillary endothelial junctions. This electron micrograph shows the interendothelial junction between two endothelial cells in a muscle capillary. Arrows point to tight junctions. (From Fawcett DW: A Textbook of Histology, 12th ed. New York, Chapman & Hall, 1994, p 964.)

Some endothelial cells have membrane-lined, cylindrical conduits—**fenestrations**—that run completely through the cell, from the capillary lumen to the interstitial space. These fenestrations are 50 to 80 nm in diameter and are seen primarily in tissues with large fluid and solute fluxes across the capillary walls (e.g., intestine, choroid plexus, exocrine glands, and renal glomeruli). A thin diaphragm often closes the perforations of the fenestrae (e.g., in intestinal capillaries).

The endothelia of the sinusoidal capillaries in the liver, bone marrow, and spleen have very large fenestrations as well as **gaps** 100 to 1000 nm wide *between* adjacent cells. Vesicles, transendothelial channels, fenestrae, and gaps—as well as structures of intermediate appearance—are part of a spectrum of regulated permeation across the endothelial cells.

Capillaries fall into three groups, based on their degree of leakiness (Fig. 20-3).

- 1. Continuous capillary.** This is the most common form of capillary, with interendothelial junctions 10 to 15 nm wide (e.g., skeletal muscle). However, these clefts are absent in the blood-brain barrier (see p. 284), whose capillaries have narrow tight junctions.
- 2. Fenestrated capillary.** In these capillaries, the endothelial cells are thin and perforated with fenestrations. These capillaries most often surround epithelia (e.g., small intestine, exocrine glands).
- 3. Discontinuous capillary.** In addition to fenestrae, these capillaries have large gaps. Discontinuous capillaries are found in sinusoids (e.g., liver).

FIGURE 20-3 Three types of capillaries.

At their distal ends, true capillaries merge into **venules** (inner radius, 5 to 25 μm), which carry blood back into low-pressure veins that return blood to the heart. Venules have a discontinuous layer of VSMCs and therefore can control local blood flow. Venules may also exchange some solutes across their walls.

Capillary Exchange of Solutes

The exchange of O_2 and CO_2 across capillaries depends on the diffusional properties of the surrounding tissue

Gases diffuse by a **transcellular route** across the two cell membranes and cytosol of the endothelial cells of the capillary with the same ease that they diffuse through the surrounding tissue. In this section, we focus primarily on the exchange of O_2 . Very similar mechanisms exist for the exchange of CO_2 , but they run in the opposite direction. Arterial blood has a relatively high O_2 level. As blood traverses a systemic capillary, the principal site of gas exchange, O_2 diffuses across the capillary wall and into the tissue space, which includes the interstitial fluid and the neighboring cells.

The most frequently used model of gas exchange is August Krogh's **tissue cylinder**, a volume of tissue that a single capillary supplies with O_2 ([Fig. 20-4A](#)). The cylinder of tissue surrounds a single capillary. According to this model, the properties of the tissue cylinder govern the rate of diffusion of both O_2 and CO_2 . The radius of a tissue cylinder in an organ is typically half the average spacing from one capillary to the next, that is, half the mean intercapillary distance. Capillary density and therefore mean intercapillary distance vary greatly among tissues. Among systemic tissues, capillary density is highest in tissues with high O_2 consumption (e.g., myocardium) and lowest in tissues consuming little O_2 (e.g., joint cartilage). Capillary density is extraordinarily high in the lungs (see [p. 684](#)).

FIGURE 20-4 Delivery and diffusion of O_2 to systemic tissues. **A** shows Krogh's tissue cylinder, which consists of a single capillary (radius r_c) surrounded by a concentric cylinder of tissue (radius r_t) that the capillary supplies with O_2 and other nutrients. Blood flow into the capillary is F_{in} , and blood flow out of the capillary is F_{out} . The lower panel of **A** shows the profile of partial pressure of O_2 (P_{O_2}) along the longitudinal axis of the capillary and the radial axis of the tissue cylinder.

The Krogh model predicts how the concentration or partial pressure of oxygen (P_{O_2}) within the capillary lumen falls along the length of the capillary as O_2 exits for the surrounding tissues (see Fig. 20-4A). The P_{O_2} within the capillary at any site along the length of the capillary depends on several factors:

1. The concentration of **free O_2** in the arteriolar blood that feeds the capillary. This dissolved $[O_2]$, which is the same in the plasma and the cytoplasm of the **red blood cells (RBCs)**, is proportional to the partial pressure of O_2 (see p. 647) in the arterioles.
2. The **O_2 content** of the blood. Less than 2% of the total O_2 in arterial blood is dissolved; the rest is bound to hemoglobin inside the RBCs. Each 100 mL of arterial blood contains ~ 20 mL of O_2 gas, or 20

volume%—the **O₂ content** (see [Table 29-3](#)).

3. The capillary blood flow (F).
4. The **radial diffusion coefficient** (D_r), which governs the diffusion of O₂ out of the capillary lumen. For simplicity, we assume that D_r is the same within the blood, the capillary wall, and the surrounding tissue and that it is the same along the entire length of the capillary.
5. The capillary radius (r_c).
6. The **radius of tissue cylinder** (r_t) that the capillary is supplying with O₂.
7. The **O₂ consumption** by the surrounding tissues (\dot{Q}_{O_2}).
8. The **axial distance** (x) along the capillary.

The combination of all these factors accounts for the shape of the concentration profiles within the vessel and the tissue. Although this model appears complicated, it is actually based on many simplifying assumptions. [N20-1](#)

N20-1

Limitations of Krogh's Tissue-Cylinder Model

Contributed by Emile L. Boulpaep

Krogh's tissue-cylinder model (see Fig. 20-4A), which describes O₂ and CO₂ exchange between the capillary and surrounding tissue, is based on several simplifying—but critical—assumptions.

1. The model assumes that the capillary displays cylindrical symmetry around a central axis, so that only two spatial dimensions must be considered (i.e., x and r in Fig. 20-4A).
2. The model is correct only for the idealized case of capillaries that run in parallel, start and end in the same plane, and carry blood in the same direction.
3. The model neglects any longitudinal diffusion of gas along the x -axis within the tissue and the blood. In other words, Krogh assumes that blood flow is the sole mode for gas to move along the x -axis.
4. The model requires that the capillary wall itself does not constitute a rate-limiting barrier to O₂ or CO₂ transport; that is, the permeability of the endothelial membranes to these gases is similar to the diffusion properties of the bulk phase. In other words, as stated in point 4 on page 464, the radial diffusion coefficient (D_r) is uniform within the blood vessel, the vessel wall, and the surrounding tissue.
5. Krogh assumes that there is no O₂ flow into or out of the tissue cylinder across the cylinder's outer boundary (i.e., beyond the radius, r_t). In a regular array of identical tissue cylinders, each neighboring

tissue cylinder would have the same P_{O_2} at its outer boundary (see Fig. 20-4C). Therefore, there would be no P_{O_2} difference to drive O_2 diffusion from one tissue cylinder to another.

6. The model assumes a steady state. There are no transients; P_{O_2} is a function of position, not of time.
7. The O_2 consumption of the tissue must be constant.
8. The upstream P_{O_2} in the capillary must be constant.

Investigators have generated more complicated models that include different geometries of capillary distribution and also incorporate (1) the effects of pH and P_{CO_2} changes on the O_2 affinity of hemoglobin (see pp. 652 and 653–654, as well as Fig. 29-5); (2) the effects of changes in oxygen solubility on the O_2 content of the blood; and (3) the effects of changes in the amount of hemoglobin and its affinity for O_2 , which even more strongly affects the O_2 content of the blood.

The O_2 extraction ratio of a whole organ depends primarily on blood flow and metabolic demand

In principle, beginning with a model like Krogh's but more complete, one could sum up the predictions for a single capillary segment and then calculate gas exchange in an entire tissue. However, it is more convenient to pool all the capillaries in an organ and to focus on a single arterial inflow and single venous outflow. The difference in concentration of a substance in the arterial inflow and venous outflow of that organ is the **arteriovenous (a-v) difference** of that substance. For example, if the arterial O_2 content ($[O_2]_a$) entering the tissue is 20 mL O_2 /dL blood and the venous O_2 content leaving it ($[O_2]_v$) is 15 mL O_2 /dL blood, the O_2 a-v difference for that tissue is 5 mL O_2 gas/dL blood.

For a substance like O_2 , which *exits* the capillaries, another way of expressing the amount that the tissues remove is the **extraction ratio**. This parameter is merely the a-v difference *normalized* to the arterial content of the substance. Thus, the extraction ratio of oxygen (E_{O_2}) is

$$E_{O_2} = \frac{[O_2]_a - [O_2]_v}{[O_2]_a} \quad (20-1)$$

Thus, in our example,

$$E_{O_2} = \frac{20 \text{ mL } O_2/\text{dL} - 15 \text{ mL } O_2/\text{dL}}{20 \text{ mL } O_2/\text{dL}} = \frac{5}{20} = 25\% \quad (20-2)$$

In other words, the muscle in this example removes (and burns) 25% of the O_2 presented to it by the

arterial blood.

What are the factors that determine O_2 extraction? To answer this question, we return to the hypothetical Krogh cylinder. The same eight factors that influence the P_{O_2} profiles in [Figure 20-4A](#) also determine the whole-organ O_2 extraction. Of these factors, the two most important are capillary flow (item 3 in the list above) and metabolic demand (item 7). The O_2 extraction ratio decreases with increased flow but increases with increased O_2 consumption. These conclusions make intuitive sense. Greater flow supplies more O_2 , so the tissue needs to extract a smaller fraction of the incoming O_2 to satisfy its fixed needs. Conversely, increased metabolic demands require that the tissue extract more of the incoming O_2 . These conclusions are merely a restatement of the Fick principle (see [p. 423](#)), which we can rewrite as

$$\underbrace{[O_2]_a - [O_2]_v}_{\substack{\text{Related to} \\ \text{extraction ratio}}} = \frac{\dot{Q}_{O_2}}{F}$$

(20-3)

The term on the left is the a-v difference. The extraction ratio is merely the a-v difference normalized to $[O_2]_a$. Thus, the Fick principle confirms our intuition that the extraction ratio should increase with increasing metabolic demand but decrease with increasing flow.

Another important factor that we have so far ignored is that not all of the capillaries in a tissue may be active at any one time. For example, skeletal muscle contains roughly a half million capillaries per gram of tissue. However, only ~20% are perfused at rest (see [Fig. 20-4B](#)). During exercise, when the O_2 consumption of the muscle increases, the resistance vessels and precapillary sphincters dilate to meet the increased demand. This vasodilation increases muscle blood flow and the density of perfused capillaries (see [Fig. 20-4C](#)). This response is equivalent to decreasing the tissue radius of Krogh's cylinder because each perfused capillary now supplies a smaller region. Other things being equal, reduced diffusion distances cause P_{O_2} in the tissue to increase.

The velocity of blood flow in the capillaries also increases during exercise. All things being equal, this increased velocity would cause P_{O_2} to fall *less steeply* along the capillary lumen. For example, if the velocity were infinite, P_{O_2} would not fall at all! In fact, because O_2 consumption rises during exercise, P_{O_2} actually falls *more steeply* along the capillary.

According to Fick's law, the diffusion of small water-soluble solutes across a capillary wall depends on both the permeability and the concentration gradient

Although the endothelial cell is freely permeable to O_2 and CO_2 , it offers a significant barrier to the exchange of lipid-insoluble substances. Hydrophilic solutes that are smaller than albumin can traverse the capillary wall by **diffusion** via a paracellular route (i.e., through the clefts and interendothelial junctions as well as gaps and fenestrae, if these are present).

The amount of solute that crosses a particular surface area of a capillary per unit time is called a **flux**.

It seems intuitive that the flux ought to be proportional to the magnitude of the concentration difference across the capillary wall and that it ought to be bigger in leakier capillaries (Fig. 20-5). These ideas are embodied in a form of Fick's law: **N20-2**

FIGURE 20-5 Diffusion of a solute across a capillary wall.

N20-2

Fick's Law

Contributed by Emile Boulpaep

The passive movement of a small solute (X) across any surface can be described by Fick's law:

$$J_x = -D \frac{\partial [X]}{\partial z}$$

(NE 20-1)

where J_x is the **flux** of solute (*units*: $\text{moles} \cdot \text{cm}^{-2} \cdot \text{s}^{-1}$), assuming a positive J_x in the direction of increasing distance z . D is the **diffusion coefficient** in $\text{cm}^2 \cdot \text{s}^{-1}$, and $\partial[X]/\partial z$ is the **concentration gradient** of X (*units*: $\text{moles} \cdot \text{cm}^{-3} \cdot \text{cm}^{-1}$) along the z axis. In the case of a solute crossing a capillary wall (see Fig. 20-5), we assume that the concentration of the solute in the bulk phase of the capillary ($[X]_c$), as well as in the bulk phase of the interstitial fluid ($[X]_{if}$), is constant and uniform. We also assume that the diffusion distance along the axis of diffusion (z) is equal to the thickness of the capillary wall (a). We can then rewrite Fick's law as

$$J_X = -D_X \frac{[X]_{if} - [X]_c}{z_{if} - z_c} = D_X \frac{[X]_c - [X]_{if}}{a}$$

(NE 20-2)

Because the wall thickness (a) is hard to determine, one often combines the terms D_X and a into a single **permeability coefficient** P (*units*: $\text{cm} \cdot \text{s}^{-1}$), defined as $P_X = D_X/a$. The permeability coefficient is an expression of the ease with which a solute crosses a membrane, driven by the concentration difference. Therefore, the flux of a solute becomes

$$J_X = P_X \cdot ([X]_c - [X]_{if})$$

(NE 20-3)

Equation NE 20-3 is the same as Equation 20-4.

$$J_X = P_X \cdot ([X]_c - [X]_{if})$$

(20-4)

In [Figure 20-5](#) and [Equation 20-4](#), J_X is the flux of the solute X (*units*: $\text{moles}/[\text{cm}^2 \text{ s}]$), assuming a positive J_X with flow out of the capillary, into the interstitial fluid. $[X]_c$ and $[X]_{if}$ are the dissolved concentrations of the solute in the capillary and interstitial fluid, respectively. Because the capillary wall thickness a (*units*: cm) is difficult to determine, we combined the diffusion coefficient D_X (*units*: cm^2/s) and wall thickness into a single term (D_X/a) called P_X , the **permeability coefficient** (*units*: cm/s). Thus, P_X expresses the ease with which the solute crosses a capillary by diffusion.

Because, in practice, the surface area (S) of the capillary is often unknown, it is impossible to compute the *flux* of a solute, which is expressed per unit area. Rather, it is more common to compute the *mass flow* (\dot{Q}), which is simply the amount of solute transferred per unit time (*units*: moles/s):

$$\dot{Q} = S \cdot J_X = S \cdot P_X \cdot ([X]_c - [X]_{if})$$

(20-5)

The whole-organ extraction ratio for small hydrophilic solutes provides an estimate of the solute permeability of capillaries

How could we estimate the permeability coefficient for a solute in different capillaries or for different solutes in the same capillary? Unfortunately, it is difficult to determine permeability coefficients in single capillaries. Therefore, investigators use an indirect approach that begins with measurement of the *whole-organ* extraction ratio for the solute X. As we have already seen for O_2 (see [Equation 20-1](#)), the extraction ratio (E_X) is a normalized a-v difference for X:

$$E_x = \frac{[X]_a - [X]_v}{[X]_a} \quad (20-6)$$

Thus, E_x describes the degree to which an organ removes a solute from the circulation. Unlike the situation for O_2 , the extraction ratio for small hydrophilic solutes depends not only on total organ blood flow (F) but also on the overall “exchange properties” of all of its capillaries, expressed by the product of permeability and total capillary area ($P_x \cdot S$). The dependence of E_x on the $P_x \cdot S$ product and F is described by the following equation:

$$E_x = 1 - e^{-(P_x S / F)} \quad (20-7)$$

Therefore, by knowing the whole-organ extraction ratio for a solute and blood flow through the organ, we can calculate the product $P_x \cdot S$. The second column of [Table 20-1](#) lists the $P_x \cdot S$ products for a single solute (inulin), determined from [Equation 20-7](#), for a number of different organs. Armed with independent estimates of the capillary surface area (see [Table 20-1](#), column 3), we can compute P_x (column 4). P_x increases by a factor of ~4 from resting skeletal muscle to heart, which reflects a difference in the density of fluid-filled interendothelial clefts. Because a much greater fraction of the capillaries in the heart are open to blood flow (i.e., S is ~10-fold larger), the $P_x \cdot S$ product for heart is ~40-fold higher than that for resting skeletal muscle.

TABLE 20-1
 $P_x \cdot S$ Products for Various Capillary Beds

TISSUE	$P_x S$ FOR INULIN* ($10^{-3} \text{ cm}^3/\text{s}$) (MEASURED)	S , CAPILLARY SURFACE AREA* (cm^2) (MEASURED)	P_x PERMEABILITY TO INULIN ($\times 10^{-6} \text{ cm/s}$) (CALCULATED)
Heart	4.08	800	5.1
Lung	3.80	950	4.0
Small intestine	1.79	460	3.9
Diaphragm	0.76	400	1.9
Ear	0.34	58	5.9
Skeletal muscle at rest	0.09	75	1.2

*All calculations are normalized for 1 g of tissue from rabbits.
Adapted from Wittmers LE, Barlett M, Johnson JA: Estimation of the capillary permeability coefficients of inulin in various tissues of the rabbit. *Microvasc Res* 11:67–78, 1976.

The **cerebral vessels** have unique characteristics that constitute the basis of the blood-brain barrier (see [p. 284](#)). The tight junctions of most brain capillaries do not permit any paracellular flow of hydrophilic solutes; therefore, they exhibit a very low permeability to sucrose or inulin, probably because of the abundant presence of CLDN5 and occludin. In contrast, the *water* permeability of cerebral vessels is similar to that of other organs. Therefore, a large fraction of water exchange in cerebral vessels must occur through the endothelial cells.

Whole-organ $P_x \cdot S$ values are not constant. First, arterioles and precapillary sphincters control the number of capillaries being perfused and thus the available surface area (S). Second, in response to a variety of signaling molecules (e.g., cytokines), endothelial cells can reorganize their cytoskeleton,

thereby changing their shape. This deformation widens interendothelial clefts and increases P_x . One example is the increased leakiness that develops during inflammation in response to the secretion of histamine by mast cells and basophilic granulocytes.  **N20-3**

N20-3

Effect of Inflammation on Capillary Leakiness

Contributed by Emile Boulpaep

Endothelial tight junctions are regulated by a wide variety of signaling mechanisms, including cytokines; extracellular $[Ca^{2+}]$; G proteins; intracellular $[cAMP]$ and $[Ca^{2+}]$; serine, threonine, and tyrosine kinases; and proteases. The increased endothelial permeability induced by the inflammatory response can result from two general mechanisms. First, increased tension caused by actomyosin/cytoskeletal contractility can change the shape of cells and pull individual endothelial cells apart. Second, intercellular adhesion can be decreased by breakdown or modulation of the intercellular junctions.

Histamine increases vascular permeability by causing transitory gaps of 100 to 400 nm between adjacent endothelial cells. These gaps occur without any detectable increased tension within the cells. Instead, histamine alters the adhering junctions between endothelial cells, particularly the adhesions that are based on vascular endothelial cadherin (VE-cadherin; see “Cadherin Terminology” below). Among the cell-cell adhesion molecules (see p. 17), the type I cadherins (i.e., E-, N-, and P-cadherin) associate with cortical actin filaments via α - and β -catenin, whereas VE-cadherin is a type II cadherin that is linked not only to cortical actin by α - and β -catenin, but also to the intermediate filament protein vimentin (see p. 23) via γ -catenin and desmoplakin. Endothelial cells respond to histamine with an increase in intracellular $[Ca^{2+}]$, which stimulates the tyrosine phosphorylation of VE-cadherin and γ -catenin. How these phosphorylation events affect the link of VE-cadherin with the vimentin cytoskeleton is not known.

Cadherin Terminology

E-cadherin (in epithelial cells)

N-cadherin (in nerve and muscle cells)

P-cadherin (in placental and epidermal cells)

VE-cadherin (in vascular endothelial cells)

Small polar molecules have a relatively low permeability because they can traverse the capillary wall only by diffusing through water-filled pores (small-pore effect)

Having compared the permeabilities of a single hydrophilic solute (inulin) in several capillary beds, we can address the selectivity of a single capillary wall to several solutes. [Table 20-2](#) shows that the permeability coefficient falls as molecular radius rises. For *lipid-soluble* substances such as CO_2 and O_2 , which can diffuse through the *entire* capillary endothelial cell and not just the water-filled pathways, the permeability is much larger than for the solutes in [Table 20-2](#). Early physiologists had modeled

endothelial permeability for hydrophilic solutes on the basis of two sets of pores:  **N20-4** large pores with a diameter of ~10 nm or more and a larger number of **small pores** with an equivalent radius of 3 nm. Small water-soluble, polar molecules have a relatively low permeability because they can diffuse only by a paracellular path through interendothelial clefts or other water-filled pathways, which constitute only a fraction of the total capillary area. **Discontinuities** or gaps in tight-junction strands could form the basis for the small pores. Alternatively, the molecular sieving properties of the small pores may reside in a **fiber matrix** ([Fig. 20-6](#)) that consists of either a meshwork of glycoproteins in the paracellular clefts (on the abluminal side of the tight junctions) or the glycocalyx on the surface of the endothelial cell (on the luminal side of the tight junctions). The endothelium-specific, calcium-dependent adhesion molecule **VE-cadherin** (CDH5; see [p. 17](#)) and **platelet/endothelial cell adhesion molecule 1 (PECAM1, or CD31 antigen)** are important glycoprotein components of the postulated fiber matrix in the paracellular clefts. In fact, the small-pore effect is best explained by an arrangement of discontinuities in the tight junctional strands in series with a fiber matrix on either side of the tight junction.

TABLE 20-2
Permeability Coefficients for Lipid-Insoluble Solutes*

SUBSTANCE	RADIUS OF EQUIVALENT SPHERE† (nm)	PERMEABILITY (cm/s)
NaCl	0.14	310×10^{-6}
Urea	0.16	230×10^{-6}
Glucose	0.36	90×10^{-6}
Sucrose	0.44	50×10^{-6}
Raffinose	0.56	40×10^{-6}
Inulin	1.52	5×10^{-6}

Pore Theory

Contributed by Emile Boulpaep

The “pore theory” has been the main model of capillary permeability for a long time. Many studies have attempted to relate the permeability of solutes of various molecular weights to the geometry of hypothetical fluid-filled transendothelial channels, clefts, fenestrations, and gaps (see p. 462). Investigators have used the whole-organ extraction of molecular probes to estimate the size of a pore that would be necessary to allow movement of these probes at the observed rates. The result can then be used to estimate the number or density of pores, assuming that they have a fixed size and geometry. However, structural studies of capillary endothelial cells of various organs have failed to corroborate the initial formulation of the pore theory. Electron microscopic examination reveals that, in tissues such as muscle, transendothelial channels and the junctions between endothelial cells would allow the passage of substances of a molecular radius of 5 nm, exceeding that of inulin. The fenestrae in other tissues—such as the intestine, the kidney, and some glands—have even wider openings, 60 to 80 nm in diameter. However, except in glomerular capillaries, these openings are mostly covered by a thin diaphragm (see p. 727). Thus, the diverse overall geometry, size, and number of the transendothelial channels, clefts, and fenestrae in endothelia do not agree with the limited sets of pores that have been postulated based on

pore theory. On the other hand, investigators measuring solute exchange at the level of a single perfused capillary—which is a far simpler system than a whole organ—are beginning to resolve the discrepancy between whole-organ permeability measurements and the images obtained by electron microscopy.

N20-16

Stokes-Einstein Radius

Contributed by Emile Boulpaep

The Stokes-Einstein radius is the radius of a spherical molecule that would have a diffusion coefficient equivalent to that of the lipid-insoluble substance (which itself may not be spherical).

Interendothelial clefts are wider—and fenestrae are more common—at the venular end of the capillary than at its arteriolar end, so that P_x increases along the capillary. Therefore, if the transcapillary concentration difference ($[X]_c - [X]_{if}$) were the same, the solute flux would actually be larger at the venous end of the microcirculation.

Small proteins can also diffuse across interendothelial clefts or through fenestrae. In addition to molecular size, the *electrical charge* of proteins and other macromolecules is a major determinant of their apparent permeability coefficient. In general, the flux of negatively charged proteins is much smaller than that of neutral macromolecules of equivalent size, whereas positively charged macromolecules have the highest apparent permeability coefficient. Fixed negative charges in the endothelial glycocalyx exclude macromolecules with negative charge and favor the transit of macromolecules with positive charge. Selective permeability based on the electrical charge of the solute is a striking feature of the filtration of proteins across the glomerular barrier of the nephron (see pp. 742–743).

The diffusive movement of solutes is the dominant mode of transcapillary exchange. However, the convective movement of water can also carry solutes. This **solvent drag** is the flux of a dissolved solute that is swept along by the bulk movement of the solvent. Compared with the diffusive flux of a small solute with a high permeability coefficient (e.g., glucose), the contribution of solvent drag is minor.

The exchange of macromolecules across capillaries can occur by transcytosis (large-pore effect)

Macromolecules with a radius >1 nm (e.g., plasma proteins) can cross the capillary, at a low rate, through wide intercellular clefts, fenestrations, and gaps—when these are present. However, it is caveolae (see p. 461) that are predominantly responsible for the large-pore effect that allows transcellular translocation of macromolecules. The **transcytosis** of very large macromolecules by vesicular transport involves (1) equilibration of dissolved macromolecules in the capillary lumen with the fluid phase inside the open

vesicle; (2) pinching off of the vesicle; (3) vesicle shuttling to the cytoplasm and probably transient fusion with other vesicles within the cytoplasm, allowing intermixing of the vesicular content; (4) fusion of vesicles with the opposite plasma membrane; and (5) equilibration with the opposite extracellular fluid phase.

Although one can express the transcytotic movement of macromolecules as a *flux*, the laws of diffusion (see [Equation 20-4](#)) do not govern transcytosis. Nevertheless, investigators have calculated the “apparent permeability” of typical capillaries to macromolecules ([Table 20-3](#)). The resulting “permeability”—which reflects the total movement of the macromolecule, regardless of the pathway—falls off steeply with increases in molecular radius, a feature called **sieving**. This sieving may be the result of steric hindrance when large macromolecules equilibrate across the neck of nascent vesicles or when a network of glycoproteins in the glycocalyx above the vesicle excludes the large macromolecules. In addition, sieving of macromolecules according to molecular size could occur as macromolecules diffuse through infrequent chains of fused vesicles that span the full width of the endothelial cell. N20-5

Fast Versus Slow Pathways for Exchange of Macromolecules Across Capillary Walls

Contributed by Emile Boulpaep

Classical transcytosis provides a relatively **slow pathway**. A **fast pathway** is provided by the infrequent transient chains of fused vesicles that happen to span the full width of the endothelial cell. Any degree of differential diffusion through this fast pathway will manifest itself as **sieving**.

Transcytosis is not as simple as the luminal loading and basal unloading of ferryboats—the cell may process some of the cargo. Although the luminal surface of endothelial cells avidly takes up ferritin (750 kDa), only a tiny portion of endocytosed ferritin translocates to the opposite side of the cell (see [Table 20-3](#)). The remainder stays for a time in intracellular compartments, where it is finally broken down.

Both transcytosis and chains of fused vesicles are less prominent in brain capillaries. The presence of continuous tight junctions and the low level of transcytosis account for the blood-brain barrier's much lower apparent permeability to macromolecules.

Capillary Exchange of Water

Fluid transfer across capillaries is convective and depends on net hydrostatic and osmotic forces (i.e., Starling forces)

The pathway for fluid movement across the capillary wall is a combination of transcellular and paracellular pathways. Endothelial cell membranes express constitutively active **aquaporin 1** (AQP1) water channels (see [p. 110](#)). It is likely that AQP1 constitutes the principal *transcellular* pathway for water movement. The interendothelial clefts, fenestrae, or gaps may be the anatomical substrate of the *paracellular* pathway.

Whereas the main mechanism for the transfer of gases and other solutes is *diffusion*, the main mechanism for the net transfer of fluid across the capillary membrane is **convection**. As first outlined in 1896 by Ernest Starling, [N20-6](#) the two driving forces for the convection of fluid—or bulk water movement—across the capillary wall are the transcapillary hydrostatic pressure difference and *effective* osmotic pressure difference, also known as the colloid osmotic pressure or oncotic pressure difference (see [p. 128](#)).

N20-6

Ernest Henry Starling

Contributed by Emile Boulpaep

Ernest Starling (1866–1927) was born in London and educated at Guy's Hospital Medical School (MB, 1889). Upon graduation, he became a demonstrator in physiology at Guy's. In 1890 he began part-time work at University College, London, where he soon began a lifelong association with Sir William M. Bayliss.

Starling was professor of physiology at University College, London, where he did pioneering work in two cardiovascular areas, the heart and the microcirculation. His name is attached to Starling's law of the heart, which describes the dependence of stroke volume on end-diastolic volume (see pp. 524–526) and the Starling equation, which describes the movement of fluid across the capillary wall (see pp. 467–468). In addition, Starling and Bayliss together introduced the concept of a *hormone* and coined the term as part of their discovery of secretin, the first hormone identified. He and Bayliss also showed that intestinal peristalsis is a ganglionic reflex.

Starling's textbook *Principles of Human Physiology* (1912; 14th edition with Sir Charles A. Evans, 1968) was a standard physiology textbook in the first half of the 20th century.

Whonamedit? Ernest Henry Starling. <http://www.whonamedit.com/doctor.cfm/1188.html>
[Accessed May 2015].

The **hydrostatic pressure difference** (ΔP) across the capillary wall is the difference between the

intravascular pressure (i.e., capillary hydrostatic pressure, P_c) and the extravascular pressure (i.e., interstitial fluid hydrostatic pressure, P_{if}). Note that the term *hydrostatic* includes all sources of intravascular pressure, not only that derived from gravity; we use it here in opposition to *osmotic*.

The **colloid osmotic pressure difference ($\Delta\pi$)** across the capillary wall is the difference between the intravascular colloid osmotic pressure caused by plasma proteins (π_c) and the extravascular colloid osmotic pressure caused by interstitial proteins and proteoglycans (π_{if}). A positive ΔP tends to drive water *out of* the capillary lumen, whereas a positive $\Delta\pi$ attracts water *into* the capillary lumen.

Starling's hypothesis to describe the volume flow (F) or volume flux (J_V) of fluid across the capillary wall is embodied in the following equation, which is similar to [Equation 5-26](#):

$$J_V = L_p \left[\underbrace{(P_c - P_{if})}_{\substack{\Delta P \\ \text{Hydrostatic} \\ \text{pressure} \\ \text{difference}}} - \sigma \underbrace{(\pi_c - \pi_{if})}_{\substack{\Delta \pi \\ \text{Colloid osmotic} \\ \text{pressure} \\ \text{difference}}} \right] = F/S_f$$

Net filtration pressure
(i.e., net driving force)
(20-8)

[Table 20-4](#) describes the terms in this equation. The equation is written so that the flux of water leaving the capillary is positive and that of fluid entering the capillary is negative.

TABLE 20-4
Terms in the Starling Equation

TERM	DEFINITION	UNITS
J_V	Volume flux across the capillary wall	$\text{cm}^3 \cdot \text{cm}^{-2} \cdot \text{s}^{-1}$ or $[\text{cm}^3/(\text{cm}^2 \cdot \text{s})]$
L_p	Hydraulic conductivity*	$\text{cm} \cdot \text{s}^{-1} \cdot (\text{mm Hg})^{-1}$ or $[\text{cm}/(\text{s} \cdot \text{mm Hg})]$
P_c	Capillary hydrostatic pressure	mm Hg
P_{if}	Tissue (interstitial fluid) hydrostatic pressure	mm Hg
π_c	Capillary colloid osmotic pressure caused by plasma proteins	mm Hg
π_{if}	Tissue (interstitial fluid) colloid osmotic pressure caused by interstitial proteins and proteoglycans	mm Hg
σ	Average colloid osmotic reflection coefficient	(dimensionless, varies between 0 and 1)
F	Flow of fluid across the capillary wall	cm^3/s
S_f	Functional surface area	cm^2

*Alternatively, the leakiness of the capillary wall to water may be expressed in terms of water permeability (P_f ; units: cm/s). [N20-7](#) In this case, the hydrostatic and osmotic forces are given in the units of osmolality.

The **hydraulic conductivity (L_p)** [N20-7](#) is the proportionality constant that relates the net driving force to J_V and expresses the total permeability provided by the ensemble of AQP1 channels and the paracellular pathway.

N20-7

Hydraulic Conductivity Versus Water Permeability Coefficient

Contributed by Emile Boulpaep

The **hydraulic conductivity** (L_p) is the coefficient that relates water flux J_v (*units*: $\text{cm}^3 \cdot \text{cm}^{-2} \cdot \text{s}^{-1}$) to the net driving force in units of pressure (ΔP or $\Delta\pi$; *units*: mm Hg).

$$J_v = L_p \left[\underbrace{(P_c - P_{if})}_{\substack{\Delta P \\ \text{Hydrostatic} \\ \text{pressure} \\ \text{difference}}} - \sigma \underbrace{(\pi_c - \pi_{if})}_{\substack{\Delta\pi \\ \text{Colloid osmotic} \\ \text{pressure} \\ \text{difference}}} \right]$$

Net filtration pressure
(i.e., net driving force)

(NE 20-4)

Thus, the units of L_p are $\text{cm} \cdot \text{s}^{-1} \cdot (\text{mm Hg})^{-1}$. These are the terms used in Equation 20-8 and in Table 20-4.

The **water permeability coefficient** or osmotic permeability coefficient or filtration coefficient (P_f) is the coefficient that relates water flux (J_v ; *units*: $\text{moles} \cdot \text{cm}^{-2} \cdot \text{s}^{-1}$) to the net driving force of water in units of concentration difference ($\Delta[X]$; *units*: $\text{moles} \cdot \text{cm}^{-3}$):

$$J_v = P_f \Delta[X] \quad (\text{NE 20-5})$$

Thus, the units of P_f are $\text{cm} \cdot \text{s}^{-1}$.

What is the relationship between the two proportionality factors L_p and P_f ? It can be shown that

$$P_f = \left(\frac{RT}{V_w} \right) L_p$$

(NE 20-6)

Here, R is the universal gas constant ($0.082055 \text{ atm} \cdot \text{L} \cdot \text{mole}^{-1} \cdot \text{K}^{-1}$) = $62.4 \text{ mm Hg} \cdot \text{L} \cdot \text{mole}^{-1} \cdot \text{K}^{-1}$), T is the absolute temperature, and V_w is the partial molar volume of water ($0.018 \text{ L} \cdot \text{mole}^{-1}$). Note that the P_f - L_p conversion factor depends on temperature. At 37°C ,

$$\frac{RT}{V_w} = \frac{62.4(\text{mm Hg})\text{L} \cdot \text{mole}^{-1} \cdot \text{K}^{-1} \cdot 310\text{K}}{0.018\text{L} \cdot \text{mole}^{-1}} = 1,074,667 \text{ mm Hg}$$

(NE 20-7)

Thus, at 37°C ,

$$P_f = (1,074,667 \text{ mm Hg}) L_p \quad (\text{NE 20-8})$$

This conversion makes sense because multiplying L_p , which is in units of $\text{cm} \cdot \text{s}^{-1} \cdot (\text{mm Hg})^{-1}$ by (mm Hg) yields $\text{cm} \cdot \text{s}^{-1}$, which are the units of P_f .

According to van't Hoff's law, the theoretical colloid osmotic pressure difference ($\Delta\pi_{\text{theory}}$) is proportional to the protein concentration difference ($\Delta[X]$):

$$\Delta\pi_{\text{theory}} = RT\Delta[X]$$

(20-9)

However, because capillary walls exclude proteins *imperfectly*, the observed colloid osmotic pressure difference ($\Delta\pi_{\text{obs}}$) is less than the ideal. The ratio $\Delta\pi_{\text{obs}}/\Delta\pi_{\text{theory}}$ is the **reflection coefficient (σ)**  **N20-8** that describes how a semipermeable barrier excludes or “reflects” solute X as water moves across the barrier, driven by hydrostatic or osmotic pressure gradients.

N20-8

Reflection Coefficient

Contributed by Emile Boulpaep

Lest we forget ... she is still here!

If a semipermeable membrane excludes a solute (X) *perfectly*, then a concentration difference of the solute X ($\Delta[X]$) generates an osmotic pressure difference that is exactly the same as the theoretically predicted value (see Equation 20-9, reproduced here):

$$\Delta\pi_{\text{theory}} = RT\Delta[X]$$

(NE 20-9)

Here, R is the gas constant ($0.082055 \text{ atm} \cdot \text{L} \cdot \text{mole}^{-1} \cdot \text{K}^{-1}$) and T is the absolute temperature (K). Equation NE 20-9 is known as **van't Hoff's law**. Because RT at 37°C equals $25.4 \text{ atm} \cdot \text{L} \cdot \text{mole}^{-1}$ or $19,332 \text{ mm Hg} \cdot \text{L} \cdot \text{mole}^{-1}$, an osmotic pressure difference of 1 mM should exert an ideal osmotic pressure ($\Delta\pi_{\text{theory}}$) of 19.3 mm Hg (see p. 128).

If, on the other hand, the membrane excludes the solute *imperfectly*, the observed osmotic pressure ($\Delta\pi_{\text{obs}}$) is less than the ideal. The **reflection coefficient for solute X (σ)** is the ratio of the observed to the predicted osmotic pressure:

$$\sigma = \frac{\Delta\pi_{\text{obs}}}{\Delta\pi_{\text{theory}}}$$

(NE 20-10)

The reflection coefficient is the property of a semipermeable membrane that causes the *observed* osmotic pressure (π_{obs})—generated by a concentration difference $\Delta[X]$ —to be less than the theoretical osmotic pressure for an ideal membrane (π_{theory}). The reflection coefficient is dimensionless and ranges between 0 and 1. When $\sigma = 1$, the membrane excludes the solute perfectly and is an ideal osmometer. When $\sigma = 0$, the membrane treats the solute the same as water, and the solute generates no osmotic pressure.

Because the capillary endothelium has multiple “permeability” pathways for macromolecules, and because the permeability is different for different macromolecules, the σ in Equation 20-8 (reproduced here)

$$J_V = L_p \left[\underbrace{(P_c - P_{if})}_{\substack{\Delta P \\ \text{Hydrostatic} \\ \text{pressure} \\ \text{difference}}} - \sigma \underbrace{(\pi_c - \pi_{if})}_{\substack{\Delta \pi \\ \text{Colloid osmotic} \\ \text{pressure} \\ \text{difference}}} \right]$$

Net filtration pressure
(i.e., net driving force)

(NE 20-4)

is actually the *average* reflection coefficient of proteins by the capillary wall.

The value of σ can range from 0 to 1. When σ is zero, the moving water perfectly “entrains” the solute, which moves with the water and exerts no osmotic pressure across the barrier. When σ is 1, the barrier completely excludes the solute as the water passes through, and the solute exerts its full or ideal osmotic pressure. To the extent that σ exceeds zero, the membrane sieves out the solute. The σ for plasma proteins is nearly 1.

Because small solutes such as Na^+ and Cl^- freely cross the endothelium, their σ is zero, and they are not included in the Starling equation for the capillary wall (see Equation 20-8). Thus, changing the intravascular or interstitial concentrations of such “crystalloids” does *not* create a net effective osmotic driving force across the capillary wall. (Conversely, because plasma membranes have an effective $\sigma_{\text{NaCl}} = 1$, NaCl gradients *do* shift water between the *intracellular and interstitial* compartments.)

The net driving force in the Starling equation (see Equation 20-8), $[(P_c - P_{if}) - \sigma (\pi_c - \pi_{if})]$, has a special name, the **net filtration pressure**. **Filtration** of fluid from the capillary into the tissue space occurs when the net filtration pressure is positive. In the special case where σ for proteins is 1, the fluid leaving the capillary is protein free; this process is called ultrafiltration. Conversely, **absorption** of fluid from the tissue space into the vascular space occurs when the net filtration pressure is negative. At the arterial end of the capillary, the net filtration pressure is generally positive, so that filtration occurs. At the venous end, the net filtration pressure is generally negative, so that absorption occurs. However, as is discussed below, some organs do not adhere to this general rule.

In the next four sections, we examine each of the four Starling forces that constitute the net filtration pressure: P_c , P_{if} , π_c , and π_{if} .

Capillary blood pressure (P_c) falls from ~35 mm Hg at the arteriolar end to ~15 mm Hg at the venular end

Capillary blood pressure is also loosely called the capillary *hydrostatic* pressure, to distinguish it from

capillary *colloid osmotic* pressure. It is possible to record P_c only in an exposed organ, ideally in a thin tissue (e.g., a mesentery) that allows good transillumination. One impales the lumen of the capillary with a fine micropipette (tip diameter $< 5\ \mu\text{m}$) filled with saline and heparin. The micropipette lumen connects to a manometer, which has a sidearm to a syringe. Immediately after the impalement, blood begins to rise slowly up the pipette. A pressure reading at this time would underestimate the actual P_c because pipette pressure is less than P_c . The syringe makes it possible to apply just enough pressure to the pipette lumen to reach true pressure equilibrium—when fluid flows neither from nor to the pipette. By use of this **null-point** approach, the recorded pressure is the true P_c . In the human skin, P_c is $\sim 35\ \text{mm Hg}$ at the arteriolar end and $\sim 15\ \text{mm Hg}$ at the venular end.

When the arteriolar pressure is $60\ \text{mm Hg}$ and the venular pressure is $15\ \text{mm Hg}$, the midcapillary pressure is not the mean value of $37.5\ \text{mm Hg}$ but only $25\ \text{mm Hg}$ (Table 20-5, top row). The explanation for the difference is that normally the precapillary upstream resistance exceeds the postcapillary downstream resistance ($R_{\text{post}}/R_{\text{pre}}$ is typically 0.3 ; see pp. 451–452). However, the midcapillary pressure is not a constant and uniform value. In the previous chapter, we saw that P_c varies with changes in R_{pre} and R_{post} (see Equation 19-3). P_c also varies with changes in four other parameters: (1) upstream and downstream pressure, (2) location, (3) time, and (4) gravity.

TABLE 20-5
Effect of Upstream and Downstream Pressure Changes on Capillary Pressure*

	P_a (mm Hg)	P_c (mm Hg)	P_v (mm Hg)
Control	60	25	15
Increased arteriolar pressure	70	27	15
Increased venular pressure	60	33	25

*Constant $R_{\text{post}}/R_{\text{pre}} = 0.3$.

Arteriolar (P_a) and Venular (P_v) Pressure

Because R_{post} is less than R_{pre} , P_c follows P_v more closely than P_a (see p. 451). Thus, increasing P_a by $10\ \text{mm Hg}$ —at a constant $R_{\text{post}}/R_{\text{pre}}$ of 0.3 —causes P_c to rise by only $2\ \text{mm Hg}$ (see Table 20-5, middle row). On the other hand, increasing P_v by $10\ \text{mm Hg}$ causes P_c to rise by $8\ \text{mm Hg}$ (see Table 20-5, bottom row).

Location

Capillary pressure differs markedly among tissues. For example, the high P_c of glomerular capillaries in the kidney, $\sim 50\ \text{mm Hg}$ (see p. 744), is required for ultrafiltration. The retinal capillaries in the eye must also have a high P_c because they bathe in a vitreous humor that is under a pressure of $\sim 20\ \text{mm Hg}$ (see pp. 360–361). A higher P_c is needed to keep the capillaries patent in the face of the external compressing force. The pulmonary capillaries have unusually *low* P_c values, 5 to $15\ \text{mm Hg}$, which minimizes the ultrafiltration that otherwise would lead to the accumulation of edema fluid in the alveolar air spaces (see p. 684).

Time

Capillary blood pressure varies considerably from moment to moment at any given site, depending on the

arteriolar diameter and tone of the precapillary sphincter (i.e., R_{pre}). In individual capillaries, these fluctuations lead to times of net filtration and other times of net fluid absorption.

Gravity

Finally, the effect of gravity on P_c is the same as that discussed for arterial and venous pressure. Thus, a capillary bed below the level of the heart has a higher P_c than a capillary bed at the level of the heart.

Interstitial fluid pressure (P_{if}) is slightly negative, except in encapsulated organs

The interstitium consists of both a solid and a liquid phase. The solid phase is made up of collagen fibers and proteoglycans. In the liquid phase, only a small fraction of interstitial water is totally “free” and capable of moving under the influence of convective forces. Most of the water is trapped in gels (e.g., proteoglycans), in which both water and small solutes move by diffusion. It was once thought that P_{if} in the liquid phase is slightly above barometric pressure throughout the interstitium, but more recent measurements indicate that P_{if} is subatmospheric in many tissues.

Estimation of P_{if} is very difficult because the probe used to make the measurement is far larger than the interstitial space; thus, the measurement itself can alter P_{if} . If one inserts a probe percutaneously and immediately uses a null-point method  **N20-9** to measure P_{if} (as outlined above for capillary pressure), the values are +1 to +2 mm Hg. However, during the next 4 to 5 hours, the measured value drops to -1 to -2 mm Hg. Arthur Guyton implanted a perforated, hollow plastic sphere under the skin to provide a long-term record of P_{if} (Fig. 20-7). After the wound has healed, the pressure inside the sphere may be as low as -2 to -10 mm Hg after 1 or 2 weeks. Another approach, the wick-in-needle technique, also yields subatmospheric values.

FIGURE 20-7 Long-term measurement of interstitial fluid pressure using an implanted capsule.

N20-9

Null-Point Technique for Measuring Interstitial Pressure

Contributed by Emile Boulpaep

As pointed out on pages 469–470, measuring interstitial pressure (P_{if}) is technically challenging. If one measures P_{if} by inserting a small needle percutaneously and immediately recording the pressure needed to force fluid out of the needle and into the interstitial fluid, one obtains values of +1 to +5 mm Hg. However, this approach suffers from some weaknesses. First, the very act of pushing fluid out of the needle distorts the narrow interstitial spaces during this brief measurement. Second, the interstitial fluid is actually in several microcompartments that are separated by connective tissue; the fluid injected cannot communicate freely among all of these microcompartments. As a result, one would have to wait a very long time for the distortions to dissipate.

A “null-point” method overcomes some of the aforementioned difficulties. In this case, the experimenter makes upward and downward adjustments to the pressure inside the probe in an effort to avoid any net movement of fluid into or out of the interstitial fluid (i.e., out of or into the needle). In brief experiments, this null-point method for measuring P_{if} (see p. 469), yields values of +1 to +2 mm Hg. However, during the next 4 to 5 hours, the measured value drops to –1 to –2 mm Hg. Thus, the short-term measurements of P_{if} —even those using a null-point method—are intrinsically flawed. As outlined in the text, Guyton overcame these shortcomings by obtaining a long-term record of P_{if} .

A value of –2 mm Hg is a reasonable average in *loose tissues*, such as the lung and subcutaneous tissue. P_{if} is slightly negative because of fluid removal by the lymphatics (see below). Inside *rigid enclosed compartments*, such as the bone marrow or brain, P_{if} is positive. It is also positive in *encapsulated*

organs such as the kidney, where P_{if} is +1 to +3 mm Hg within the parenchyma. Expansion of high-pressure vessels in the kidney pushes the interstitial fluid against an unyielding fibrous capsule, raising P_{if} . The same principle applies to skeletal muscle, which is surrounded by layers of fascia. In some cases, it is not the interstitial fluid but another specialized compartment that provides the pressure around the capillaries. For renal glomerular capillaries, it is Bowman's space (see pp. 743–744)—filled with glomerular filtrate to a pressure of about +10 mm Hg—that is the relevant outside compartment. For pulmonary capillaries, the relevant outside compartment is the alveolus, the pressure of which varies during the respiratory cycle (see p. 622).

P_{if} is also sensitive to the addition of fluid to the interstitial compartment. When small amounts of fluid are added to the interstitial compartment, the interstitium behaves like a low-compliance system, so that P_{if} rises steeply for the small amount of added fluid. Adding more fluid disrupts the solid phase of collagen fibers and the gel of proteoglycans, so that large volumes can now accumulate with only small additional pressure increases. In this high-volume range, the interstitial compartment thus behaves like a high-compliance system. This high compliance is especially high in loose subcutaneous tissues, which can accommodate more edema fluid (Box 20-1) than can muscle.

Box 20-1

Interstitial Edema

Edema (from the Greek *oidema* [swelling]) is characterized by an excess of salt and water in the extracellular space, particularly in the interstitium. Edema may be associated with any disease leading to salt retention and expansion of the extracellular fluid volume—in particular, renal, cardiac, and hepatic disease (see p. 838). However, interstitial edema can also occur without overall salt and water retention because of microcirculatory alterations that affect the Starling forces. Regardless of the cause, the resulting edema can be either generalized (e.g., widespread swelling of subcutaneous tissue, often first evident in facial puffiness) or localized (e.g., limited to the dependent parts of the body). In this box, we focus on how edema can result from changes in parameters that are included in the Starling equation.

Hydrostatic Forces

When a person is **standing** for a sustained time, venous pressure and thus capillary pressure (P_c) in the legs increase because of gravity. The result is movement of fluid into the tissue space. In most cases, the lymphatic system can take up the extra interstitial fluid and return it to the vascular space, maintaining proper fluid balance. The return of fluid requires contractions of the leg muscles to compress the veins and lymphatics and to propel the fluid upward through the valves in these vessels and toward the heart (see pp. 474–476). If the standing person does not contract these muscles, the transudation of fluid can exceed the lymphatic return, causing interstitial edema.

An organ that is particularly sensitive to proper fluid balance is the lung. Slight increases in the hydrostatic pressure of the pulmonary capillaries (pulmonary hypertension) can lead to **pulmonary edema**. This condition decreases lung compliance (making lung inflation more difficult; see p. 610) and also may severely compromise gas exchange across the pulmonary capillary bed (see pp. 661–663). Left-sided heart failure causes blood to back up into the vessels of the lung, which raises pulmonary vascular pressures and causes pulmonary edema.

In right-sided heart failure, blood backs up into the systemic veins. As a result, there is a rise in central venous pressure (i.e., the pressure inside the large systemic veins leading to the right side of the heart),

causing an increase in the P_c in the lower extremities and abdominal viscera. Fluid transudated from the hepatic and intestinal capillaries may leave the interstitial space and enter the peritoneal cavity, a condition called **ascites**. 📌N20-18

Colloid Osmotic Forces

In **nephrotic syndrome**, a manifestation of a number of renal diseases, protein is lost in the urine. The result is a fall in plasma colloid osmotic pressure, a decrease in the ability of the capillaries to retain fluid, and generalized peripheral edema.

In **pregnancy**, synthesis of plasma proteins by the mother does not keep pace with the expanding plasma volume and nutritional demands of the fetus. As a result, maternal plasma protein levels fall. The same occurs in **protein malnutrition**. Although it is less severe than in nephrotic syndrome, the lower capillary colloid osmotic pressure nevertheless leads to edema in the extremities.

The opposite effect is seen in dehydration. A deficit of salt and water causes an *increase* in the plasma protein concentration, increasing the capillary colloid osmotic pressure and thus pulling fluid out of the interstitial space. The result is reduced turgor of the interstitial space. This effect is easily noticed by pinching the skin, which is unable to spring back to its usual firm position.

Properties of the Capillary Wall

Inflammation causes the release of vasodilators, such as histamine and cytokines, into the surrounding tissue. Vasodilation increases the number of open capillaries and therefore the functional surface area (S_p). Cytokines also cause widening of interendothelial clefts and a fall in the reflection coefficient (σ) for proteins. The net effect is enhanced filtration of fluid from capillary lumen to interstitium, so that tissue swelling is one of the hallmarks of inflammation.

Severe head injuries can result in **cerebral edema**, a result of the breakdown of the normally tight endothelial barrier of the cerebral vessels (see pp. 285–286). Because the rigid skull prevents expansion of the brain, cerebral edema can lead to occlusion of the cerebral microcirculation.

During ischemia—when blood flow to a tissue is severely reduced or completely stopped—blood vessels deteriorate, which causes hydraulic conductivity (L_p) to increase and reflection coefficient to decrease. Once blood flow is reestablished (**reperfusion**), these changes lead to local edema. If the increased leakiness is substantial, large quantities of plasma proteins freely move into the interstitial space, dissipating the colloid osmotic gradient across the capillary wall and aggravating the edema.

Lymphatic Drainage

Lymphatic drainage may become impaired after lymph nodes are removed in cancer surgery or when lymph nodes are obstructed by malignant neoplasms. The reduction in the lymphatic drainage leads to local edema upstream from the affected nodes.

N20-18

Transcapillary Refill

Contributed by Emile Boulpaep

The opposite of the changes responsible for interstitial edema occurs when there is significant hemorrhage. During severe hemorrhagic hypotension, capillary pressure drops and fluid moves from the tissue space into the vascular space, as discussed on pages 585–586. This fluid movement—known as

transcapillary refill—helps replace the fluid lost in the hemorrhage and thereby serves as a compensatory mechanism for blood loss. The amount of fluid that can be replaced from the interstitium of the skeletal muscle is significant. Because this fluid is cell free, it lowers the hematocrit of the blood, a condition known as **hemodilution**.

Capillary colloid osmotic pressure (π_c), which reflects the presence of plasma proteins, is ~25 mm Hg

The colloid osmotic pressure difference across the capillary endothelium is due solely to the plasma proteins, such as albumin, globulins, and fibrinogen. Total plasma protein concentration is ~7.0 g/dL, which corresponds to ~1.5 mM of protein. According to van't Hoff's law (see [Equation 20-9](#)), these proteins would exert an osmotic pressure of ~28 mm Hg if perfectly reflected by the capillary wall ($\sigma = 1$). The σ is indeed close to 1 for the principal plasma proteins—albumin (3.5 to 5.5 g/dL) and the globulins (2.0 to 3.5 g/dL)—so that the actual colloid osmotic pressure ($\sigma\pi_c$) in capillaries is ~25 mm Hg. This value is the same as if osmotically active solutes were present at ~1.3 mM. Note that because of the very definition of colloid osmotic pressure, we have ignored the osmotic effects of the small solutes in plasma, which have an *osmolality* of 290 mOsm (see [p. 105](#)). 🟡N20-10

N20-10

Total Osmotic Pressure versus Colloid Osmotic Pressure of Plasma

Contributed by Emile Boulpaep

The **total osmotic pressure** of blood plasma that contains ~290 milliosmoles/L of solutes can be computed from the van't Hoff equation (see Equation 20-9, reproduced here):

$$\Delta\pi_{\text{theory}} = RT\Delta[X]$$

(NE 20-9)

As described in 🟡N20-8, RT can be expressed as 19,332 mm Hg · L · mole⁻¹. Thus, for a $\Delta[X]$ of 0.29 moles/L (i.e., 290 mOsm),

$$\begin{aligned}\Delta\pi_{\text{theory}} &= RT\Delta[X] \\ &= \left(\frac{19,332 \text{ mm Hg} \cdot \text{L}}{\text{mole}}\right) \times \left(0.29 \frac{\text{mole}}{\text{L}}\right) = 5597 \text{ mm Hg}\end{aligned}$$

(NE 20-11)

This pressure of 5597 mm Hg corresponds to 7.4 atm. If distilled water were on the opposite side of the capillary endothelium, and if the capillary wall reflected all of the solutes in the blood plasma (i.e., if the wall were perfectly impermeable to all solutes, but permeable to water), then the osmotic pressure difference across the capillary wall would be 7.4 atm. However, these conditions are not valid. First,

most of the solutes in blood plasma are also in the interstitial fluid at approximately the same concentrations. Second, even when small concentration differences exist across the capillary wall for these small solutes such as Na^+ or Cl^- (sometimes called crystalloids), these solutes do not exert any *effective* osmotic pressure across the capillary wall because they pass with great ease through the capillary wall. That is, these crystalloids have a reflection coefficient (σ **N20-8**) of zero.

As stated in the text (see p. 470), the **colloid osmotic pressure** (π_c) of blood plasma is only 25 mm Hg, which is minuscule compared to the total osmotic pressure (5597 mm Hg). The colloid osmotic pressure is generated solely by the concentration difference across the capillary wall of solutes with a reflection coefficient of ~ 1 , that is, the proteins in the blood plasma. The concentration difference for these proteins is ~ 1.3 mM. Thus,

$$\begin{aligned}\pi_c &= RT\Delta[X] \\ &= (19.3 \text{ mm Hg/mM}) \times (1.3 \text{ mM}) \\ &= 25 \text{ mm Hg} \\ &\text{(NE 20-12)}\end{aligned}$$

π_c does vary appreciably along the length of the capillary. Indeed, most capillary beds filter $<1\%$ of the fluid entering at the arteriolar end. Thus, the loss of protein-free fluid does not measurably concentrate plasma proteins along the capillary and does not appreciably raise π_c .

Because clinical laboratories report plasma protein concentrations in grams per deciliter and not all proteins have the same molecular weight, a plasma protein concentration of 7 g/dL can produce different π_c values, depending on the protein *composition* of the plasma. Because albumin has a much lower molecular weight than γ -globulin, replacement of 1 g of the heavier γ -globulin with 1 g of the lighter albumin raises π_c . Whereas van't Hoff's law (see [Equation 20-9](#)) predicts a *linear* relationship between osmotic pressure and concentration, colloid osmotic pressure actually increases more steeply, even when the albumin/globulin ratio is held constant at 1.8 ([Fig. 20-8](#), orange curve). **N20-11** Obviously, the steepness of the curve varies from one plasma protein to the next because all have different molecular weights.

FIGURE 20-8 Dependence of colloid osmotic pressure on the concentration of plasma proteins. The point on the orange curve indicates that normal plasma, a mixture of proteins at a concentration of 7 g/dL, has a colloid osmotic pressure (π_c) of 25 mm Hg.

N20-11

Effects of Changes in Plasma H₂O on Colloid Osmotic Pressure

Contributed by Emile Boulpaep

The curves in Figure 20-8 show a nonlinear dependence of colloid osmotic pressure on the concentration of plasma proteins. The nonlinearity of the curves becomes clinically significant when a gain or loss of plasma water alters the plasma protein concentration. As expected, identical increases or decreases in plasma H₂O—caused by gain or loss in extracellular fluid—exert changes in colloid osmotic pressure that are of opposite sign. However, the changes in colloid osmotic pressure are not identical in magnitude.

For instance, if we assume a normal plasma volume of 3000 mL and a plasma protein concentration of 7.0 g/dL, then a 300-mL loss of plasma H₂O will increase plasma protein concentration to 7.78 g/dL (a gain of 0.78 g/dL), whereas a 300-mL gain of plasma H₂O will decrease plasma protein concentration to 6.36 g/dL (a loss of 0.64 g/dL). These two identical changes in plasma H₂O do *not* result in the same change in colloid osmotic pressure. First, the absolute change in plasma protein concentration is less for 300 mL of overhydration than for 300 mL of dehydration. Second, because the “Normal plasma” curve in Figure 20-8 is nonlinear, the change in colloid osmotic pressure is larger in the direction of increased protein concentration (i.e., during dehydration, when the curves in Fig. 20-8 are becoming steeper) than

in the direction of decreased protein concentration (i.e., during an equivalent overhydration).

Not only does π_c vary markedly with protein composition and concentration, the reflection coefficient for colloids also varies widely among organs. The lowest values for σ (i.e., greatest leakiness) are in discontinuous capillary beds (e.g., liver); intermediate values are in muscle capillaries; and the highest values ($\sigma = 1$) are in the tight, continuous capillary beds of the brain.

The plasma proteins do more than just act as osmotic agents. Because these proteins also carry negative charges, the **Donnan effect**  **N20-12** (see Fig. 5-15) causes an increase in both the concentrations of cations (see p. 104) and the colloid osmotic pressure in the capillary lumen.

N20-12

Donnan Effect Across the Capillary Wall

Contributed by Emile Boulpaep

Plasma proteins do more than act as osmotic agents. They also carry net negative charges. Thus, albumin and other plasma proteins can act as the counterbalancing anion for some of the cations in blood plasma. Because the endothelium is relatively impermeable to proteins, the protein concentration in the interstitial fluid is lower than that in the capillary. The result is a “Donnan effect” (see p. 104) across the endothelial wall, so that at equilibrium the composition of cations and anions in the interstitial fluid is not identical to that in the protein-free plasma of the capillary (see Table 5-2). If we make the simplifying assumption that the capillary wall excludes all proteins from the interstitial fluid, the equilibrium concentration ratios for monovalent cations and anions are as follows:

$$\frac{[\text{Cation}^+]_{\text{Interstitial Fluid}}}{[\text{Cation}^+]_{\text{Protein-free Plasma}}} \cong 0.95 \quad (\text{for monovalent cations})$$
$$\frac{[\text{Anion}^-]_{\text{Interstitial Fluid}}}{[\text{Anion}^-]_{\text{Protein-free Plasma}}} \cong 1.05 \quad (\text{for monovalent anions})$$

(NE 20-13)

Thus, the Donnan effect causes the capillary lumen to contain higher concentrations of cations and lower concentrations of anions than the protein-free solution of the interstitium.

As noted on page 129, it is a general property of a Gibbs-Donnan equilibrium that, after the permeant ions achieve the predicted electrochemical equilibrium across a barrier separating two compartments, the compartment containing the impermeant ions has a higher osmolality than the compartment from which the impermeant ions are excluded (see Fig. 5-15). Thus, just as the presence of impermeant proteins in the cytoplasm leads to cell swelling because of Donnan forces, the presence of impermeant anions in the capillary lumen leads to the movement of water from the interstitium into the capillary lumen.

Note that the water movement we have chosen to discuss so far is *not* due to the osmotic pressure exerted by the plasma proteins per se. Rather, we are considering the osmotic pressure difference that arises from the unequal distribution of Na^+ and Cl^- between capillary lumen (c) and interstitial fluid (if). By analogy to the calculation shown in Equation 5-31, we can calculate the theoretically predicted osmotic force ($\Delta\pi_{\text{theory}}$) caused by the difference in the osmolalities of small, permeant ions (ΔOsm):

$$\Delta\pi_{\text{theory}} = RT\Delta\text{Osm} \quad (\text{NE 20-14})$$

Of course, it was the Gibbs-Donnan equilibrium that set up this difference in total osmolality across the capillary wall. Because the major small ions on either side of the capillary wall are Na^+ and Cl^- ,

$$\Delta\pi_{\text{theory}} = RT \left[([\text{Na}^+]_{\text{c}} + [\text{Cl}^-]_{\text{c}}) - ([\text{Na}^+]_{\text{if}} + [\text{Cl}^-]_{\text{if}}) \right] \quad (\text{NE 20-15})$$

Using the values in Table 5-2 for protein-free plasma and interstitial fluid, we have the following:

$$\begin{aligned} \Delta\pi_{\text{theory}} &= RT \left[([153\text{mM}]_{\text{c}} + [110\text{mM}]_{\text{c}}) - ([145\text{mM}]_{\text{if}} + [116\text{mM}]_{\text{if}}) \right] \\ \Delta\pi_{\text{theory}} &= RT [2\text{mM}] \end{aligned} \quad (\text{NE 20-16})$$

Because RT at 37°C equals $19,332 \text{ mm Hg/M}$, an osmolality difference of 1 mM exerts an ideal osmotic pressure of 19.332 mm Hg . Thus, the Gibbs-Donnan equilibrium for Na^+ and Cl^- causes a theoretical osmotic pressure difference of

$$\Delta\pi_{\text{theory}} = 38.7 \text{ mm Hg (due to } \text{Na}^+ \text{ and } \text{Cl}^-) \quad (\text{NE 20-17})$$

Physiologically, the osmotic difference of 38.7 mm Hg caused by the unequal distribution of small ions is of no consequence for water movement across the capillary wall because the capillary does not *reflect* Na^+ or Cl^- (i.e., $\sigma_{\text{Na}} = \sigma_{\text{Cl}} = 0$), and therefore these solutes generate no *effective* osmotic pressure. See  **N20-8** for a discussion of the reflection coefficient (σ).

As introduced on page 128 and discussed more fully on page 469, the only *effective* osmotic pressure difference across the capillary wall is that caused directly by the plasma proteins themselves, acting as solutes. This *effective* osmotic pressure difference is the **colloid osmotic pressure**, which tends to pull water into the capillary lumen.

$$\Delta\pi = \pi_{\text{c}} - \pi_{\text{if}} \cong 25 \text{ mm Hg (due to colloids)} \quad (\text{NE 20-18})$$

As shown in Table 20-6, the physiological force opposing the colloid osmotic pressure ($\Delta\pi$) is the difference between the capillary hydrostatic pressure (P_{c}) and the interstitial hydrostatic fluid pressure (P_{if}).

In the preceding discussion, we saw that because the capillary wall is freely permeable to Na^+ and Cl^-

, the only transmural concentration differences that count are those for the colloids. What would happen if the capillary wall were an ideal osmotic membrane, permeable to water but not to any solutes (i.e., neither ions nor proteins)? In such a hypothetical case, the total osmotic pressure difference across the capillary wall would be the sum of the $\Delta\pi_{\text{small ions}}$ (or 38.7 mm Hg) caused by the small ions and the $\Delta\pi$ (or 25 mm Hg) caused by the colloids, which totals ~64 mm Hg. Of course, the hydrostatic pressure difference ($P_c - P_{if}$) would never be large enough to prevent the net movement of water into the lumen of the typical capillary.

Interstitial fluid colloid osmotic pressure (π_{if}) varies between 0 and 10 mm Hg among different organs

It is difficult to measure the interstitial fluid colloid osmotic pressure because it is virtually impossible to obtain uncontaminated samples. As a first approximation, we generally assume that π_{if} is the same as the colloid osmotic pressure of *lymph*. The protein content of lymph varies greatly from region to region; for example, it is 1 to 3 g/dL in the legs, 3 to 4 g/dL in the intestine, and 4 to 6 g/dL in the liver. Such lymph data predict that π_{if} ranges from 3 to 15 mm Hg. However, the protein concentration in the interstitial fluid is probably somewhat higher than in the lymph. A total-body average value for π_{if} is ~3 mm Hg, substantially less than the value of 25 mm Hg for π_c in the capillary lumen.

The π_{if} appears to increase along the axis of the capillary (Table 20-6). The lowest values are near the arteriolar end, where the interstitium receives protein-free fluid from the capillary as the result of filtration. The highest values are near the venular end, where the interstitium loses protein-free fluid to the capillary as the result of absorption.

TABLE 20-6
Typical Values of Transcapillary Driving Forces for Fluid Movement in Loose, Nonencapsulated Tissue

	CAPILLARY BLOOD PRESSURE (P_c)	INTERSTITIAL FLUID PRESSURE (P_{if})	EFFECTIVE CAPILLARY COLLOID OSMOTIC PRESSURE ($\sigma\pi_c$)	EFFECTIVE INTERSTITIAL FLUID COLLOID OSMOTIC PRESSURE ($\sigma\pi_{if}$)	NET FORCE
Arteriolar end	+35 mm Hg	-2 mm Hg	+25 mm Hg	+0.1 mm Hg*	+12 mm Hg
Venular end	+15 mm Hg	-2 mm Hg	+25 mm Hg	+3 mm Hg	-5 mm Hg

*The low effective colloid osmotic pressure prevails only in the subcalyx fluid compartment (see Fig. 20-10B).

The Starling principle predicts ultrafiltration at the arteriolar end and absorption at the venular end of most capillary beds

The idealized forces acting on fluid movement across a capillary are shown in Figure 20-9A. Using the Starling equation and the values in Table 20-6, we can calculate the net transfer of fluid (J_v) at both the arteriolar and venular ends of a typical capillary:

$$J_v = L_p[(P_c - P_{if}) - (\sigma\pi_c - \sigma\pi_{if})]$$

$$\text{Arteriolar end: } J_v = L_p[(35 - (-2)) - (25 - 0.1)]$$

$$= L_p(+12 \text{ mm Hg})$$

$$\text{Venular end: } J_v = L_p[(15 - (-2)) - (25 - 3)]$$

$$= L_p(-5 \text{ mm Hg})$$

(20-10)

A INDIVIDUAL HYDROSTATIC AND OSMOTIC PRESSURES

The vertical distance between the *upper yellow line* (P_c) and the *lower yellow line* (P_{if}) is the net hydrostatic force.

The vertical distance between the *upper red line* (π_c) and the *lower red line* (π_{if}) is the net osmotic force.

B NET FILTRATION PRESSURE

FIGURE 20-9 Starling forces along a capillary. In **A**, the yellow lines are idealized profiles of capillary (P_c) and interstitial (P_{if}) hydrostatic pressures. The red lines are idealized capillary (π_c) and interstitial (π_{if}) colloid osmotic pressures. In **B**, the net filtration pressure is $(P_c - P_{if}) - \sigma(\pi_c - \pi_{if})$.

The net filtration pressure is thus positive (favoring filtration) at the arteriolar end, and it gradually makes the transition to negative (favoring absorption) at the venular end (see [Fig. 20-9B](#)). At the point where the filtration and reabsorptive forces balance each other, an equilibrium exists, and no net movement of water occurs across the capillary wall.

Net filtration pressure varies—sometimes considerably—among tissues. For example, in the intestinal mucosa, P_c is so much lower than π_c that absorption occurs continually along the entire length of the capillary. On the other hand, in glomerular capillaries, P_c exceeds π_c throughout most of the network, so that filtration may occur along the entire capillary (see [pp. 745–746](#)). Hydraulic conductivity also can affect the filtration/absorption profile along the capillary. Because the interendothelial clefts become larger toward the venular end of the capillary, L_p increases along the capillary from the arteriolar to the venular end.

Ignoring glomerular filtration in the kidney, Landis and Pappenheimer calculated a filtration of ~20 L/day at the arteriolar end of the capillary and an absorption of about 16 to 18 L/day at the venular end, for a net *filtration* of about 2 to 4 L/day from blood to interstitial fluid. This 2 to 4 L of net filtration does not occur uniformly in all capillary beds. The *flow* of fluid across a group of capillaries (F) is the product of the *flux* (J_v) and the functional surface area (S_f): $F = J_v \cdot S_f$. Thus, net filtration of fluid in an organ depends not only on the net filtration pressure and the hydraulic conductivity of the capillary wall (terms that contribute to J_v) but also on the surface area of capillaries that happen to be perfused. For example, exercise recruits additional open capillaries in muscle, raising S_f and thereby increasing filtration.

For continuous capillaries, the endothelial barrier for fluid exchange is more complex than considered by Starling

The contribution of Landis and Pappenheimer was to insert experimentally measured values into the Starling equation (see [Equation 20-8](#)) and to calculate the total-body filtration and absorption rates and, by difference, net filtration. Because the estimate of 2 to 4 L for the net filtration rate agreed so well with total lymph flow, the scientific public accepted the entire Landis-Pappenheimer analysis. However, for continuous capillaries, the Landis-Pappenheimer estimates of filtration and absorption are far higher than those indicated by the modern experimental data. Two major reasons for the discrepancy have emerged. First, Starling's assumptions about the nature of the capillary barrier were overly simplistic. Namely, he assumed that a single barrier separated two well-defined, uniform compartments ([Fig. 20-10A](#)). Thus, according to [Equation 20-8](#), the dependence of J_v on net filtration pressure ought to be linear, as indicated by the plot in the inset of [Figure 20-10A](#). Second, Landis and Pappenheimer used (1) P_c values that are valid only at the level of the heart (i.e., ignoring gravity), (2) P_c values that are not subject to the vagaries of vasomotion, (3) unrealistically low values of π_{if} (which would predict a greater absorption), and (4) P_{if} and π_{if} values that are invariant. 🟡**N20-13**

A CLASSICAL STARLING MODEL

B REVISED MODEL: FILTRATION

C REVISED MODEL: ABSORPTION

FIGURE 20-10 Models of fluid exchange across continuous endothelia with interendothelial junctions. N20-13

Assumptions of Landis and Pappenheimer

Contributed by Emile Boulpaep

Direct measurements of the four parameters of the Starling equation (P_c , P_{if} , π_c , π_{if}) in organs with low lymph flow such as skeletal muscle indicate that $P_c > [P_{if} + \sigma (\pi_c - \pi_{if})]$ throughout the length of the capillary. These values would predict unrealistically high net filtration rates that are incompatible with the observed low lymph flow.

Landis and Pappenheimer had estimated only 2 to 4 L of net total-body filtration (excluding renal glomerular filtration), which agreed well with total lymph flow, because of the particular values that they used in the classical Starling equation.

1. Landis and Pappenheimer used arterial and venous values of P_c that can be correct only at the level of the heart. As shown in Figure 17-8 on page 418, gravity can add 95 mm Hg to the transmural pressure in feed arteries of the dependent limb and can raise P_c to 90 to 100 mm Hg, which predicts filtration throughout the length of the capillary.
2. Landis and Pappenheimer ignored dynamic changes in P_c . Vasomotion causes P_c to cycle between high and low values, creating alternating periods of filtration and reabsorption.
3. Landis and Pappenheimer assumed low arterial values of π_{if} .
4. Landis and Pappenheimer assumed that values of P_{if} and π_{if} were clamped in time, whereas the rate of filtration itself determines P_{if} and π_{if} . At high filtration rates, P_{if} tends to rise, opposing further filtration. At high filtration rates, π_{if} tends to fall, also opposing further filtration.

In reality, as noted on page 472, net total-body filtration (excluding renal glomerular filtration) is even much less than the 2 to 4 L estimated by Landis and Pappenheimer because the endothelial barrier is not a single membrane separating two well-stirred clamped compartments and the barrier effectively exhibits osmotic asymmetry. Placing the protein osmotic barrier at the glycocalyx and considering a dynamic range of subglycocalyx colloid osmotic pressures (π_{sg}) independent of bulk π_{if} carries important implications. First, the net filtration pressure is far less than expected from the Starling equation, and this explains why actual lymph flows are less than the net filtration rates postulated from bulk values of P_c , P_{if} , π_c , and π_{if} . Second, during reversal of flow (i.e., absorption), protein in the subcalyx fluid should quickly concentrate to prevent all absorption. Thus, overall fluid balance of the interstitium is primarily maintained not by venous absorption but by lymphatic function.

A revised model has emerged for fluid exchange across continuous endothelia (see [p. 462](#)) with interendothelial junctions (see [p. 461](#)) to account for discrepancies between the classical Starling predictions and the modern data. The revised model has two major features. First, the primary barrier for colloid osmotic pressure—that is, the semipermeable “membrane” that reflects proteins but lets water and small solutes pass—is not the *entire* capillary but only the luminal glycocalyx, in particular the glycocalyx overlying the paracellular clefts (see [Fig. 20-10B](#)). Second, the abluminal surface of the glycocalyx is not in direct contact with the bulk interstitial fluid but is bathed by the **subglycocalyx fluid** at the top of the long paracellular cleft—a third compartment. Thus, the flow across the glycocalyx barrier depends not on P_{if} and π_{if} in the bulk interstitial fluid but on the comparable parameters in the subglycocalyx fluid (P_{sg} and π_{sg}):

$$J_V = L_p[(P_c - P_{sg}) - \sigma(\pi_c - \pi_{sg})]$$

(20-11)

Let us now examine the predictions of this equation for three states.

1. During ultrafiltration (i.e., J_V is positive). Here, the hydrostatic pressure in the subglycocalyx fluid—that is, the fluid in direct contact with the abluminal surface of the glycocalyx—is higher than that in the bulk interstitial fluid (i.e., $P_{sg} > P_{if}$ in [Fig. 20-10B](#)). Thus, fluid moves from the subglycocalyx space, along the paracellular cleft, to the bulk interstitial fluid. Moreover, as long as protein-free ultrafiltrate enters the subglycocalyx space, the colloid osmotic pressure in the subglycocalyx fluid is low ($\pi_{sg} < \pi_{if}$). Both the rise in P_{sg} and the fall in π_{sg} tend to oppose filtration. Because proteins enter the interstitium through the large-pore pathway (see [p. 467](#)), π_{if} in the bulk interstitial compartment is about that of lymph. However, at high rates of ultrafiltration, this π_{if} has no osmotic effect on the glycocalyx barrier because the protein cannot diffuse against the convective flow of fluid from lumen to interstitium. On the other hand, if the ultrafiltration rate is low, interstitial proteins can diffuse from the bulk interstitial space into the paracellular cleft, raising π_{sg} and promoting more ultrafiltration.

2. When net flow falls to nearly zero (i.e., J_v is ~ 0). Here, the parameters in the subglycocalyx fluid (i.e., P_{sg} and π_{sg}) should thus be very close to their values in the bulk interstitial fluid (i.e., P_{if} and π_{if}), and the revised model simplifies to the classical Starling model (see [Fig. 20-10A](#)).

3. During absorption (i.e., reversal of flow, where J_v is negative). Here, water and small solutes move from the subglycocalyx space to the capillary lumen, leaving behind and thereby concentrating the protein in the subglycocalyx space (see [Fig. 20-10C](#)). The resulting rise of π_{sg} (see [Equation 20-11](#)) opposes further absorption and, indeed, can quickly bring it to a halt. This effect explains why the plot is nearly flat in the left lower quadrant of the inset between [Figure 20-10B and C](#).

Thus, a more sophisticated understanding of the structure of the endothelial barrier for proteins correctly makes two predictions. First, the fluxes are smaller than predicted by Starling for bulk driving forces because the actual driving force across the glycocalyx barrier (see [Equation 20-11](#)) is smaller than the net driving force in the Starling equation (see [Equation 20-8](#)). Second, the magnitude of the flux for a given net driving force is greater for ultrafiltration than for absorption—osmotic asymmetry or rectification.

Lymphatics

Lymphatics return excess interstitial fluid to the blood

Lymphatics arise in the interstitium as small, thin-walled channels of endothelial cells that then join together to form increasingly larger vessels ([Fig. 20-11](#)). The **initial lymphatics** (previously called terminal lymphatics) are similar to capillaries but with many interendothelial junctions that behave like one-way microvalves, also called **primary lymph valves**. Anchoring filaments tether the initial lymphatics to surrounding connective tissue. The walls of the larger **collecting lymphatics** are similar to those of small veins, consisting of endothelium and sparse smooth muscle. The large lymphatic vessels, like the veins, have **secondary lymph valves** that restrict retrograde movement of lymph. Lymph nodes are located along the path of the collecting lymphatics. The large lymphatics ultimately drain into the left and right subclavian veins.

A EXPANSION PHASE

B COMPRESSION PHASE

FIGURE 20-11 Flow of lymph into initial and collecting lymphatics.

At the level of the initial lymphatics, interendothelial junctions have few tight junctions or adhesion molecules connecting neighboring endothelial cells. As a result, flaps of endothelial cells can overlap with each other and act as the microvalve discussed above. Although initial lymphatics may appear collapsed and show no contractile activity, a pressure gradient from the interstitial fluid to the lymphatic lumen deforms the endothelial cells so that the microvalves open and fluid enters the initial lymphatic during the expansion phase (see [Fig. 20-11A](#)). During this time, the secondary lymph valves are closed.

External pressure (e.g., from skeletal muscle) shuts the microvalves and causes fluid to enter larger lymphatics through the now open secondary lymph valves (see [Fig. 20-11B](#)).

Most organs contain both initial and collecting lymphatics, but skeletal muscle and intestine have only

initial lymphatics within their tissue. Lymphatics are absent from the brain. They are most prevalent in the skin and the genitourinary, respiratory, and gastrointestinal tracts.

As we have already seen, filtration at the arteriolar end of capillaries is estimated to exceed absorption at the venular end by 2 to 4 L/day. However, fluid does not normally accumulate in the interstitium because this excess fluid and protein move into the lymphatics. Thus, each day, the lymphatics return to the circulation 2 to 4 L of interstitial fluid, maintaining a steady state. In a model of congenital lymphedema, mice with genetic absence of initial lymphatics have elevated P_{if} and π_{if} as well as interstitial volume expansion (i.e., edema), a finding that emphasizes the role of the lymphatics in returning fluid and protein from the interstitial space to the blood.

Flow in Initial Lymphatics

Hydrostatic pressure in the initial lymphatics (P_{lymph}) ranges from -1 mm Hg to $+1$ mm Hg. Inasmuch as the mean interstitial fluid pressure is somewhat more *negative* than these values, what provides the driving force for interstitial fluid to move into the terminal lymphatics? Transient increases in P_{if} temporarily raise P_{if} above P_{lymph} . Indeed, increases in mean P_{if} cause an increase in lymph flow (Fig. 20-12).

FIGURE 20-12 Dependence of lymph flow on interstitial pressure.

Because the interstitium exhibits a variable compliance (see p. 470), fluid added to the interstitium in its low-compliance range raises the P_{if} substantially, providing the driving force for fluid to enter the lymphatics. In this same range of P_{if} values, lymphatic flow is especially sensitive to increases in P_{if} (steep portion of curve in Fig. 20-12). Thus, lymphatic efflux nicely matches the excess capillary filtration, so that the interstitial fluid volume changes very little. The situation is very different if the interstitium is already expanded and in its high-compliance range. In this case, fluid added to the interstitium raises the already elevated P_{if} only moderately (e.g., from $+2$ to $+4$ mm Hg). In this range of P_{if} values, lymphatic uptake is not very responsive to increases in P_{if} (flat portion of the curve in Fig. 20-

12). Thus, in this case, lymphatic return does not compensate well for the excess capillary filtration, so that interstitial fluid volume increases further (i.e., edema begets more edema).

Intermittent compression and relaxation of lymphatics occur during respiration, walking, and intestinal peristalsis. When P_{lymph} in a downstream segment falls below that in an upstream segment, fluid aspiration produces unidirectional flow. This suction may be largely responsible for the subatmospheric values of the P_{if} observed in many tissues.

Flow in Collecting Lymphatics

Pressures in the collecting lymphatics range from +1 to +10 mm Hg, and they increase progressively with each valve along the vessel. As P_{lymph} rises in the collecting lymphatic vessels, smooth muscle in the lymphatic walls actively contracts by an intrinsic **myogenic** mechanism that, as discussed below, also plays a role in blood vessels. Thus, downstream occlusion of a lymphatic vessel increases P_{lymph} and hence the frequency of smooth-muscle contractions, whereas an upstream occlusion does the opposite. Because of the presence of one-way valves, smooth-muscle contraction drives lymph toward the veins. The rhythmic contraction and relaxation of VSMCs that we will discuss for blood vessels—**vasomotion**—also occurs in lymphatics and is essential for the propulsion of lymph.

In addition to vasomotion, passive processes also propel lymph toward the blood. As is the case for the initial lymphatics, skeletal muscle contraction, respiratory movements, and intestinal contractions all passively compress the collecting lymphatics. This intermittent pumping action moves lymph into the veins.

Transport of Proteins and Cells

Proteins that entered interstitial fluid from the capillary cannot return to the circulation because of the adverse chemical gradient across the capillary endothelial wall. The buildup of these macromolecules in the interstitium creates a diffusional gradient from the interstitium to the lymph that complements the convective movement of these macromolecules (along with fluid) into the lymphatic system. In an average person, the lymphatics return 100 to 200 g of proteins to the circulation each day. Even before lymph reaches lymph nodes, it contains leukocytes—which had moved from the blood into the interstitium—but no RBCs or platelets. Cycles of lymphatic compression and relaxation not only enhance fluid movement but also greatly increase the leukocyte count of lymph.

The circulation of extracellular fluids involves three convective loops: blood, interstitial fluid, and lymph

Extracellular fluid moves in *three convective loops* (Fig. 20-13). The first is the **cardiovascular loop**. Assuming a cardiac output of 5 L/min, the convective flow of blood through the circulation at rest is 7200 L/day. The second is the **transvascular loop**, in which fluid moves out of the capillaries at their arteriolar end and into the capillaries at their venular end. Not counting the kidney, whose glomeruli filter a vast amount of fluid (see p. 739), Landis and Pappenheimer estimated that all the other tissues of the body filter ~20 L/day at the arteriolar end of their capillaries and reabsorb 16 to 18 L at the venular end. As noted above (see pp. 472–474), both the filtration and absorption values are probably vast overestimates. Nevertheless, the difference between filtration and absorption, 2 to 4 L/day, is a reasonable estimate of the third fluid loop, the **lymphatic loop**.

	Lymph flow (3rd loop)	Entry into capillary (2nd loop)	Exit from capillary (2nd loop)
FLUID	2-4 L/day	16-18 L/day	20 L/day
PROTEIN	95-195 g/day	5 g/day	100-200 g/day
GLUCOSE			20 g/day

FIGURE 20-13 Convective loops of extracellular fluid and protein.

In addition to convective exchange, a *diffusional exchange* of water and solutes also occurs across the capillaries. The diffusional exchange of **water** occurs at a much higher rate than does convective

movement. Using deuterium oxide as a marker, investigators have found that this diffusional exchange is $\sim 80,000$ L/day across all of the body's systemic capillaries. This value is about an order of magnitude greater than blood flow in the cardiovascular loop and three orders of magnitude larger than the convective flow in the transvascular filtration/absorption loop of the microcirculation. However, the diffusion of water molecules is an *exchange* process that does not contribute appreciably to the *net* movement of water. In other words, every day, 80,000 L of water diffuses out of the capillaries and 80,000 L diffuses back.

For **small solutes** that can diffuse across the capillary endothelium, the traffic is quite different from the convective loops for water. Take glucose as an example. The plasma contains ~ 100 mg/dL glucose, RBCs have little glucose, and the cardiac output of *plasma* is ~ 2.75 L/min (assuming a hematocrit of 45%). Therefore, each day, the heart pumps ~ 4000 g of glucose. This glucose can enter the interstitium by two mechanisms. First, glucose is dissolved in the water filtered from the arteriolar end of the capillaries. Each day, this filtration process carries $20 \text{ L} \times 100 \text{ mg/dL} = 20 \text{ g}$ of glucose into the interstitium. Second, each day, $\sim 20,000$ g of glucose enters the interstitium by diffusion. Convection can supply only a small fraction of the ~ 400 g of glucose that the body consumes each day. Instead, diffusion supplies the majority of the glucose. Nevertheless, the 400 g/day of metabolized glucose is a minuscule fraction of the amount that enters the interstitium by diffusion. Thus, most of the glucose that diffuses into the interstitium diffuses back out again.

Protein traffic provides yet another pattern of circulatory loops. Plasma contains 7 g/dL of proteins, and—assuming a plasma volume of 3 L in a 70-kg human—total plasma protein content is ~ 210 g. Given a cardiac *plasma* output of 2.75 L/min, the heart pumps $\sim 277,000$ g of protein through the circulation every day. Of this protein, 100 to 200 g—nearly the entire plasma content of proteins—moves daily across the capillary walls through the large-pore system via a transcellular route (see [p. 467](#)) and to a lesser extent by solvent drag (see [p. 467](#)). Because only very small amounts of filtered protein return to the circulation by solvent drag at the venular end of capillaries (~ 5 g/day), nearly all of the filtered protein (95 to 195 g/day) depends on the convective lymphatic loop for its ultimate recovery.

Regulation of the Microcirculation

The active contraction of vascular smooth muscle regulates precapillary resistance, which controls capillary blood flow

Smooth-muscle tone in arterioles, metarterioles, and precapillary sphincters (see pp. 459–460) determines the access resistance to the capillary beds. This resistance upstream of the capillary bed is also known as the afferent or **precapillary resistance** (R_{pre}). The overall resistance of a microcirculatory bed is the sum of R_{pre} , the resistance of the capillary bed itself (R_{cap}), and the efferent or **postcapillary resistance** (R_{post}).

How do these resistances influence the flow of blood (F_{cap}) through a capillary bed? We can answer this question by rearranging the Ohm's law–like expression that we introduced as [Equation 17-1](#):

$$F_{\text{cap}} = \frac{\Delta P}{R_{\text{total}}} = \frac{P_a - P_v}{R_{\text{pre}} + R_{\text{cap}} + R_{\text{post}}} \quad (20-12)$$

P_a is the pressure just before the beginning of the precapillary resistance, and P_v is the pressure just after the end of the postcapillary resistance. Because the aggregate R_{cap} is small, and $R_{\text{post}}/R_{\text{pre}}$ is usually ~ 0.3 , R_{pre} is usually much greater than $R_{\text{cap}} + R_{\text{post}}$. Because R_{pre} is the principal determinant of total resistance, capillary flow is roughly inversely proportional to R_{pre} . Thus, modulating the contractility of VSMCs in *precapillary* vessels is the main mechanism for adjusting perfusion of a particular tissue.

Smooth-muscle cells can function as a syncytium when they are coupled through gap junctions (unitary smooth muscle), or they can function independently of one another as do skeletal muscle fibers (multiunit smooth muscle; see p. 243). Most vascular smooth muscle has a multiunit organization. In contrast to skeletal muscle, VSMCs receive multiple excitatory as well as inhibitory inputs (see p. 251). Moreover, these inputs come not only from chemical synapses (i.e., neural control) but also from circulating chemicals (i.e., humoral control). The actual contraction of VSMCs may follow smooth-muscle electrical activity in the form of action potentials, slow waves of depolarization, or graded depolarizations without spikes. VSMCs can show spontaneous rhythmic variations in tension leading to periodic changes in vascular resistance and microcirculatory flow in a process called **vasomotion**. These spontaneous, rhythmic smooth-muscle contractions result either from pacemaker currents or from slow waves of depolarization and associated $[\text{Ca}^{2+}]_i$ increases in the VSMCs (see p. 244). Humoral agents can also directly trigger contraction of VSMCs via increases in $[\text{Ca}^{2+}]_i$ without measurable fluctuations in membrane potential (pharmacomechanical coupling; see p. 247).

VSMCs rely on a different molecular mechanism of contraction than skeletal muscle does, although an increase in $[\text{Ca}^{2+}]_i$ is the principal trigger of contraction in both cases. Whereas an increase in $[\text{Ca}^{2+}]_i$ in skeletal muscle elicits contraction by interacting with troponin C, an increase in $[\text{Ca}^{2+}]_i$ in VSMCs elicits contraction by activating calmodulin (see p. 60). The Ca^{2+} -calmodulin (Ca^{2+} -CaM) complex activates

myosin light-chain kinase (MLCK; see [p. 247](#)), which in turn phosphorylates the regulatory myosin light chain (MLC) on each myosin head (see [p. 247](#)). Phosphorylation of MLC allows the myosin to interact with actin, producing contraction. Relaxation occurs when MLC phosphatase dephosphorylates the MLC. In addition to changes in $[Ca^{2+}]_i$, changes in the activity of MLCK itself can modulate the contraction of VSMCs. Phosphorylation of MLCK by cAMP-dependent protein kinase (protein kinase A, or PKA) or cGMP-dependent protein kinase (protein kinase G, or PKG) inactivates the enzyme and thus *prevents* contraction. Thus, intracellular Ca^{2+} , cAMP, and cGMP are the principal second messengers responsible for modulating vascular tone.

Contraction of Vascular Smooth Muscle

The following changes promote contraction:

- $\uparrow[Ca^{2+}]_i \rightarrow \uparrow Ca^{2+}\text{-CaM} \rightarrow \uparrow \text{MLCK activity} \rightarrow \uparrow \text{phosphorylation of MLC} \rightarrow \text{VSMC contraction.}$
- $\downarrow[cAMP]_i \rightarrow \downarrow \text{PKA} \rightarrow \downarrow \text{phosphorylation of MLCK} \rightarrow \uparrow \text{MLCK activity} \rightarrow \uparrow \text{phosphorylation of MLC} \rightarrow \text{VSMC contraction.}$
- $\downarrow[cGMP]_i \rightarrow \downarrow \text{PKG} \rightarrow \downarrow \text{phosphorylation of MLCK} \rightarrow \uparrow \text{MLCK activity} \rightarrow \uparrow \text{phosphorylation of MLC} \rightarrow \text{VSMC contraction.}$

Relaxation of Vascular Smooth Muscle

The following changes promote relaxation:

- $\downarrow[Ca^{2+}]_i \rightarrow \downarrow Ca^{2+}\text{-CaM} \rightarrow \downarrow \text{MLCK activity} \rightarrow \downarrow \text{phosphorylation of MLC} \rightarrow \text{VSMC relaxation.}$
- $\uparrow[cAMP]_i \rightarrow \uparrow \text{PKA} \rightarrow \uparrow \text{phosphorylation of MLCK} \rightarrow \downarrow \text{MLCK activity} \rightarrow \downarrow \text{phosphorylation of MLC} \rightarrow \text{VSMC relaxation.}$
- $\uparrow[cGMP]_i \rightarrow \uparrow \text{PKG} \rightarrow \uparrow \text{phosphorylation of MLCK} \rightarrow \downarrow \text{MLCK activity} \rightarrow \downarrow \text{phosphorylation of MLC} \rightarrow \text{VSMC relaxation.}$

Various membrane proteins (channels, transporters, and receptors) play a role in controlling the tone of VSMCs. Together with their associated signal-transduction pathways, these membrane proteins lead to either contraction (i.e., vasoconstriction) or relaxation (i.e., vasodilation). [Table 20-7](#) lists neural mechanisms of VSMC regulation. [Table 20-8](#) lists paracrine/endocrine mechanisms of VSMC regulation.

TABLE 20-7

Neural Mechanisms Underlying the Contraction and Relaxation of Vascular Smooth Muscle

Vasoconstriction
Vasoconstriction in Most Blood Vessels (e.g., skin)
Sympathetic release of NE → α ₁ -AR on VSMC → Gα _{q/11} → ↑PLC → ↑[Ca ²⁺] _i → VSMC contraction
Vasoconstriction in Some Blood Vessels
Sympathetic release of NE → α ₂ -AR on VSMC → Gα _{i/o} → ↓AC → ↓[cAMP] _i → ↓PKA → ↓MLCK phosphorylation → VSMC contraction
Vasoconstriction in Some Blood Vessels
Sympathetic release (cotransmission) of NE + other neurotransmitters (e.g., ATP and NPY) → multiple receptors: α ₁ -AR + P2X + Y1R
Vasodilation
Vasodilation in Most Blood Vessels (e.g., muscle)
Adrenal medulla release of epinephrine → β ₂ -AR on VSMC → Gα _s → ↑AC → ↑[cAMP] _i → ↑PKA → ↑MLCK phosphorylation → VSMC relaxation
Vasodilation in Blood Vessels of Erectile Tissue
Parasympathetic co-release of multiple neurotransmitters a) ACh → presynaptic M ₂ muscarinic receptor on noradrenergic neurons → Gα _i → ↓AC → ↓[cAMP] _i in neuron → reduced adrenergic activity b) ACh → M ₃ muscarinic receptor on endothelial cell → Gα _q → PLC → ↑Ca ²⁺ → ↑NOS → ↑[NO] → NO diffusion to VSMC → NO receptor inside VSMC → ↑sGC → ↑[cGMP] _i → ↑PKG → ↑MLCK phosphorylation → VSMC relaxation c) NO co-release → ↑sGC inside VSMC → ↑[cGMP] _i d) VIP co-release → VIPR1 and VIPR2 on VSMC → Gα _s → ↑AC → ↑[cAMP] _i → ↑PKA → ↑MLCK phosphorylation → relaxation
Vasodilation in Blood Vessels of Salivary Gland
Parasympathetic release of ACh → M ₃ receptor on gland cell → Gα _{q/11} → ↑[kallikrein] → ↑[bradykinin] → B ₂ receptor on endothelial cell → NO release
Vasodilation in Blood Vessels of Sweat Gland
Sympathetic cholinergic release of ACh → M ₃ receptor on gland cell → Gα _{q/11} → ↑[kallikrein] → ↑[bradykinin] → B ₂ receptor on endothelial cell → NO release
Vasodilation in Blood Vessels of Muscle (Anticipatory Response)
Sympathetic cholinergic release (cotransmission) of ACh + other neurotransmitters a) ACh → presynaptic M ₂ muscarinic receptor on noradrenergic neurons → Gα _i → ↓AC → ↓[cAMP] _i in neuron → ↓NE release by neuron → ↓vasoconstriction b) mNO, NPY, VIP, CGRP → receptors on VSMC

AC, adenylyl cyclase; IP₃, inositol trisphosphate; K_{ATP} channel, ATP-sensitive K⁺ channel; P2Y, purinergic G protein–coupled receptor; PLA₂, phospholipase A₂; PLC, phospholipase C; SERCA2, sarcoplasmic and endoplasmic reticulum Ca ATPase 2; SR, sarcoplasmic reticulum.

Tissue metabolites regulate local blood flow in specific vascular beds, independently of the systemic regulation

VSMCs not only control the resistance of arterioles (i.e., R_{pre}) and thus local blood flow, they also control the resistance of small terminal arteries and thereby play an important role in regulating systemic arterial blood pressure. In [Chapter 23](#), we discuss this control of arterial blood pressure (a whole-body function) via VSMCs of small arteries and arterioles, both of which are under the control of *central* mechanisms—the autonomic nervous system and systemic humoral agents (e.g., angiotensin II). However, the subject of the present discussion is *local regulatory mechanisms* that use the arterioles to regulate blood flow through specific vascular beds. These local control mechanisms can override any of the neural or systemic humoral influences.

Mechanisms of local control involve (1) myogenic activity, and (2) local chemical and humoral factors. **Myogenic regulation** refers to an *intrinsic* mode of control of activity in which stretch of the VSMC membrane activates stretch-sensitive nonselective cation channels. The result is a depolarization that affects pacemaker activity, thereby eliciting contraction of the VSMC.

The most prominent **chemical factors** are interstitial P_{O_2} , P_{CO_2} , and pH as well as local concentrations of K^+ , lactic acid, ATP, ADP, and adenosine ([Table 20-9](#)). Total osmolality may also make a contribution. The local regulation of VSMCs by *interstitial* P_{O_2} , P_{CO_2} , and pH is distinct from the regulation of systemic blood pressure by the peripheral chemoreceptors, which respond to changes in *arterial* P_{O_2} , P_{CO_2} , and pH (see [pp. 710–713](#)) and initiate a complex neural reflex that modulates VSMC activity (see [p. 544](#)). In the case of *local* control, chemical changes in interstitial fluid act *directly* on the VSMCs through one of the three aforementioned principal second-messenger systems (i.e., intracellular Ca^{2+} , cAMP, cGMP). Changes that typically accompany increased metabolism (e.g., low P_{O_2} , high P_{CO_2} , and low pH) vasodilate vessels in the systemic circulation. Such local changes in P_{O_2} , P_{CO_2} , and pH have opposite effects in the pulmonary circulation (see [p. 687](#)).

TABLE 20-9
Local Metabolic Changes That Cause Vasodilation in the Systemic Circulation

CHANGE	MECHANISM
↓ P_{O_2}	↓ $[ATP]_i$, ↑ adenosine release, ↑ PGI_2 release, ↑ NO release
↑ P_{CO_2}	↓ pH_o
↓ pH	↓ pH_o
↑ $[K^+]_o$ N20-17	Transient hyperpolarization → closes voltage-gated Ca^{2+} channels
↑ [Lactic acid] _o	Probably ↓ pH_o
↓ $[ATP]_i$	Opens K_{ATP} channels
↑ $[ATP]_o$	Activates purinergic receptors P2Y
↑ [ADP] _o	Activates purinergic receptors P2Y
↑ [Adenosine] _o	Activates adenosine receptor A_2

Note: The subscript *i* refers to intracellular levels, and the subscript *o* refers to interstitial levels.
 K_{ATP} channel, ATP-sensitive K^+ channel.

N20-17

Vasodilation Caused by Increases in $[K^+]_o$

Contributed by Emile Boulpaep

Why does a transient increase in $[K^+]_o$ cause a transient paradoxical hyperpolarization, rather than the

depolarization that one might expect from the Nernst equation (see Equation 6-5)?

First of all, the effect is transient because the increase in $[K^+]_o$ is short-lived—the ensuing vasodilation will wash away the excess extracellular K^+ .

Second, the rise in $[K^+]_o$ causes V_m (membrane potential) to become more negative (a hyperpolarization) even though E_K (the equilibrium potential for K^+) becomes more positive (see Equation 6-5). The reason is that the K^+ conductance of VSMCs depends largely on inwardly rectifying K^+ channels (Kir channels; see Fig. 7-20). A peculiar property of Kir channels is that an increase in $[K^+]_o$ not only causes E_K to shift to more positive values, but also increases the slope conductance (i.e., the slope of the current voltage relationship at E_K). VSMCs normally do not live at E_K , but at more positive voltages (−30 to −40 mV), reflecting the contributions from other conductances (e.g., Na^+) with more positive equilibrium potentials. In the text, we introduced Equation 6-12 (shown here as Equation NE 20-19):

$$V_m = \frac{G_K}{G_m} E_K + \frac{G_{Na}}{G_m} E_{Na} + \frac{G_{Ca}}{G_m} E_{Ca} + \frac{G_{Cl}}{G_m} E_{Cl} \dots$$

(NE 20-19)

Here, G_K , G_{Na} , G_{Ca} , G_{Cl} , etc. represent membrane conductances for each ion, whereas G_m represents the total membrane conductance. Thus, G_K/G_m represents the fractional conductance for K^+ . Therefore, the equation tells us that V_m not only depends on the various equilibrium potentials, but also on their respective fractional conductances. Thus, if an increase in $[K^+]_o$ simultaneously causes (1) a slight decrease in the absolute value of E_K and (2) a larger increase G_K , the absolute value of the product $(G_K/G_m)E_K$ will be larger. Because $(G_K/G_m)E_K$ is a negative number, the net effect is that the computed value of V_m is more negative (i.e., a hyperpolarization).

In principle, a second phenomenon can contribute to the hyperpolarization. The increase in $[K^+]_o$ will enhance the activity of the electrogenic Na-K pump, resulting an increase in the pump's outward current, and therefore a hyperpolarization.

Because blood flow itself can wash out the metabolic intermediates listed above, vasomotion (see [p. 475](#)) can arise from a local feedback system. For example, if interstitial P_{O_2} falls as a result of increased local O_2 consumption, the ensuing vasodilation will increase O_2 delivery to the metabolizing cells and in turn will tend to cause the local interstitial P_{O_2} to increase. As the P_{O_2} now increases, vascular tone will increase. The timing of release and washout of the chemical factors determines the frequency of the vasomotion. The interstitial fluid volume around the active cells—the volume in which vasoactive metabolites are distributed—also affects this periodicity because it affects the time lag for the concentration of vasoactive substances to rise or to fall. Finally, spontaneous fluctuations in metabolism may confer an additional periodicity to vasomotion.

The endothelium of capillary beds is the source of several vasoactive compounds, including nitric oxide, endothelium-

derived hyperpolarizing factor, and endothelin

Table 20-10 lists several endothelial factors that act on blood vessels.

TABLE 20-10
Vasoactive Agents Produced by Endothelial Cells

VASODILATORS	VASOCONSTRICTORS
Nitric oxide (NO)	Endothelin (ET)
Endothelium-derived hyperpolarizing factor (EDHF)	Endothelium-derived constricting factor 1 (EDCF ₁)
Prostacyclin (PGI ₂)	Endothelium-derived constricting factor 2 (EDCF ₂)

Nitric Oxide

Originally called endothelium-derived relaxing factor (EDRF), nitric oxide (NO) is a potent vasodilator. NO also inhibits platelet aggregation, induces platelet disaggregation, and inhibits platelet adhesion. Bradykinin and acetylcholine both stimulate the NO synthase III (NOS III, or eNOS) isoform of NOS (see p. 66) that is constitutively present in endothelial cells. Increases in shear stress—the force acting on the endothelial cell along the axis of blood flow—can also stimulate the enzyme. NOS III, which depends on both Ca²⁺ and CaM for its activity, catalyzes the formation of NO from arginine. NO, a lipophilic gas with a short half-life, exits the endothelial cells, diffuses locally, and enters VSMCs. Inside the VSMC is the “receptor” for NO, a soluble guanylyl cyclase (see pp. 66–67) that converts GTP to cyclic GMP (cGMP). cGMP-dependent protein kinase (i.e., PKG) then phosphorylates MLCK (see p. 247), SERCA Ca pumps (see p. 118), and BK_{Ca} K⁺ channels (see Table 6-2, family No. 2). Phosphorylation *inhibits* the MLCK, thus leading to a net decrease in the phosphorylation of MLC and a decrease in the interaction between myosin and actin. Phosphorylation *activates* SERCA, thereby decreasing [Ca²⁺]_i. Finally, phosphorylation *activates* BK_{Ca}, causing hyperpolarization. By these three complementary effects, the NO released by endothelial cells relaxes VSMCs, producing vasodilation.

The NO-mediated cascade is one of the most important mechanisms for vasodilation in the circulatory system. Physicians have used exogenous organic nitrates (e.g., nitroglycerin) for decades to dilate peripheral vessels for relief of the pain of angina pectoris. These powerful vasodilators exert their activity by breaking down chemically, thereby releasing NO near VSMCs. A similar pathway of NO-mediated smooth-muscle relaxation is involved in the physiology of penile erection (see p. 1106) as demonstrated by the action of drugs for erectile dysfunction such as Viagra (sildenafil), which inhibit the phosphodiesterase 5 enzyme to decrease hydrolysis of cGMP and thus raise [cGMP]_i.

Endothelium-Derived Hyperpolarizing Factor

In addition to releasing NO, endothelial cells release another relaxing factor in response to acetylcholine, endothelium-derived hyperpolarizing factor (EDHF). EDHF causes VSMC relaxation by making the membrane potential more negative.

Prostacyclin (Prostaglandin I₂)

Prostacyclin synthase (see Fig. 3-11) metabolizes arachidonic acid to the vasodilator prostacyclin (prostaglandin I₂, or PGI₂). This agent acts by increasing [cAMP]_i and promoting the phosphorylation of MLCK, which ultimately decreases the phosphorylation of MLCs. PGI₂ is especially important for

dilation of pulmonary vessels at birth (see [p. 1162](#)).

Endothelins

Endothelial cells produce 21-residue peptides that cause an extremely potent and long-lasting **vasoconstriction** in most VSMCs. Many acute and chronic pathological conditions, including hypoxia, promote the release of endothelin (ET), which exists as three isopeptides: ET-1, ET-2, and ET-3. The precursor of **ET-1** is *preproendothelin*, which the endothelial cell converts first to *proendothelin* and then to the mature *endothelin*, which it releases. The ET receptor subtype for vasoconstriction is ET_A. Other ET receptors also exist. ET_{B1} mediates vasodilation, ET_{B2} mediates vasoconstriction, and ET_C has as yet no clearly defined function. ET_A receptors predominate in high-pressure parts of the circulation, whereas ET_B receptors predominate in low-pressure parts of the circulation.

The binding of an ET to any ET receptor subtype ultimately results in an increase in $[Ca^{2+}]_i$. In the *vasoconstriction* response, ET-1 binding to ET_A receptors acts through the phospholipase C pathway to generate inositol trisphosphate, to release Ca^{2+} from intracellular stores, and to raise $[Ca^{2+}]_i$ (see [p. 60](#)). In a second, delayed phase, which is not well understood, Ca^{2+} entering from the outside contributes to the increase in $[Ca^{2+}]_i$.  **N20-14** The increased $[Ca^{2+}]_i$ activates Ca^{2+} -CaM, stimulating MLCK to phosphorylate MLCs and culminating in contraction.

N20-14

Delayed $[Ca^{2+}]_i$ Increase in Response to Endothelin

Contributed by Emile Boulpaep

Endothelin may mediate the second, delayed phase of $[Ca^{2+}]_i$ increase through multiple pathways, including Ca^{2+} channels, nonselective cation channels, kinases, and other second-messenger systems.

Thromboxane A₂

Endothelial cells and platelets metabolize arachidonic acid via the cyclooxygenase pathway to produce thromboxane A₂ (TXA₂; see [p. 64](#)). This agent activates TXA₂/prostaglandin H₂ (TP) receptors, which leads to opening of L-type Ca channels and a consequent increase in $[Ca^{2+}]_i$. In addition, TP activation increases the levels of superoxide anion radical O_2^- (see [p. 1238](#)) in VSMCs. In turn, O_2^- reacts with NO, thereby reducing the vasodilating effect of NO.

Other Endothelial Factors

In some systemic arteries of the dog, *anoxia* produces an unexpected effect: an endothelium-dependent *increase* in tension mediated by a putative factor, EDCF₁ (endothelium-derived constricting factor 1). In some dog arteries, rapid *stretch* evokes a contraction that is also endothelium dependent. This putative factor, EDCF₂, could be a superoxide anion because superoxide dismutase prevents the contractions.

Autoregulation stabilizes blood flow despite large fluctuations in systemic arterial pressure

As we saw in [Chapter 17](#), the pressure-flow relationship of an idealized rigid vessel is linear ([Fig. 20-14](#), gray line). In most real (i.e., elastic) vessels, however, increases in pressure cause a dilation that reduces resistance and leads to a steeper-than-linear flow (see [Fig. 20-14](#), red curve). However, some vascular beds behave very differently. Despite large changes in the systemic arterial pressure—and thus large changes in the driving pressure—these special vascular beds maintain local blood flow within a narrow range. This phenomenon is called **autoregulation**. These vascular beds behave more or less like rigid tubes at very low and at very high perfusion pressures (see [Fig. 20-14](#), purple curve). However, in the physiological pressure range over which autoregulation occurs, changes in perfusion pressure have little effect on flow. Instead, increases in *pressure* lead to increases in *resistance* that keep blood flow within a carefully controlled range.

FIGURE 20-14 Autoregulation of blood flow.

Autoregulatory behavior takes time to develop and is due to an active process. If the perfusion pressure were to increase abruptly, we would see that immediately after the pressure increase, the pressure-flow diagram would look much like the one for the rigid tube in [Figure 20-14](#). However, the vascular arteriolar tone then slowly adjusts itself to produce the characteristic autoregulatory pressure-flow diagram. The contraction of VSMCs that underlies autoregulation is *autonomous*; that is, it is entirely local and independent of neural and endocrine mechanisms. Both myogenic and metabolic mechanisms play an important role in the adjustments of smooth-muscle tone during autoregulation. For example, the stretch of VSMCs that accompanies the increased perfusion pressure triggers a **myogenic contraction** that reduces blood flow. Also, the increase in P_{O_2} (or decrease in P_{CO_2} , or increase in pH) that accompanies increased perfusion pressure triggers a metabolic vasoconstriction that reduces blood flow (see [Table 20-9](#)).

Autoregulation is useful for at least two reasons. First, with an increase in perfusion pressure, autoregulation avoids a waste of perfusion in organs in which the flow is already sufficient. Second, with a decrease in perfusion pressure, autoregulation maintains capillary flow and capillary pressure. Autoregulation is very important under these conditions for organs that are very sensitive to ischemia or hypoxia (particularly the heart, brain, and kidneys) and for organs whose job it is to filter the blood (again, the kidney).

Blood vessels proliferate in response to growth factors by a

process known as angiogenesis

In adults, the anatomy of the microcirculation remains rather constant. Notable exceptions are the growth of new vessels during wound healing, inflammation, and tumor growth and in the endometrium during the menstrual cycle. Increased capillary density is important in physical training (see pp. 1220–1222) and in acclimatization to altitude (see p. 1232).

The development of new vessels is called **angiogenesis**. The first step is dissolution of the venular basement membrane at a specific site, followed by activation and proliferation of previously quiescent endothelial cells. The new cells, attracted by growth factors, migrate to form a tube. Eventually, the budding tubes connect with each other, allowing the flow of blood and the development of vascular smooth muscle as the new microvascular network establishes itself. Angiogenesis relies on a balance between positive and negative regulation. The body normally produces some factors that promote angiogenesis and others that inhibit it (Table 20-11).

TABLE 20-11
Agents That Affect Vascular Growth

PROMOTERS	INHIBITORS
Vascular endothelial growth factor (VEGF)	Endostatin
Fibroblast growth factors (FGFs)	Angiostatin
Angiopoietin 1 (ANGPT1)	Angiopoietin 2 (ANGPT2)

Promoters of Vessel Growth

The principal peptides that induce angiogenesis are two polypeptides: vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF). Both interact with endothelium-specific receptor tyrosine kinases (see pp. 68–70). **VEGF**—related to platelet-derived growth factor (PDGF) and a mitogen for vascular endothelial cells—is produced by fibroblasts and, frequently, by cancer cells. Activated coagulation factor VII (FVIIa; see p. 442) promotes VEGF production.

FGF mediates many cellular responses during embryonic, fetal, and postnatal development. At least 22 different FGFs exist in humans. FGF2 (also known as basic fibroblast growth factor or bFGF) has particular angiogenic activity.

VEGF and FGF2 promote expression of NOS. The resulting NO promotes proliferation and migration of endothelial cells as well as differentiation of vascular tubes.

The difficulty in achieving targeted delivery of these growth factors is a major obstacle in their therapeutic use. One approach has been to link the growth factor to small beads delivered into the coronary circulation. Clinical trials with local or systemic administration of FGF2 to patients with ischemic heart disease have shown mixed efficacy. A recombinant, humanized monoclonal antibody against VEGF (Avastin) is being used in patients with advanced non–small-cell lung cancer.

Other growth factors have indirect angiogenic effects that are distinct from those of VEGF or FGF. **Angiopoietins** (ANGPT1 and ANGPT2) are proteins that act through a receptor tyrosine kinase (Tie2) expressed almost exclusively in endothelial cells. ANGPT1 is required for *embryonic* vascular development, and ANGPT2—normally an antagonist of ANGPT1 at the Tie2 receptor—is required for *postnatal* angiogenic remodeling. **Angiogenin**,  **N20-15** a member of the ribonuclease (RNase) family, is normally present in plasma, but at levels too low to produce proliferative effects. Plasma angiogenin levels rise in cancer patients. Regulated surface receptors on endothelial cells bind angiogenin, which after endocytosis translocates to the nucleus, where its RNase activity is essential for its angiogenic

effect.

N20-15

Angiogenin

Contributed by Emile Boulpaep

Although initially identified in the media of cultured tumor cells, angiogenin is present in normal plasma and it is a mitogen for normal endothelial cells. **Angiogenin**—a soluble 14-kDa protein—mediates a number of functions in addition to angiogenesis. For example, angiogenin is a microbicidal agent that plays a role in innate immunity.

Angiogenin belongs to a superfamily of **ribonucleases (RNases; see p. 98)**. RNase A is the prototype of that family, and angiogenin has been classified as **RNase 5**. Critical structural differences between angiogenin and the other RNases are apparent in the ribonucleolytic site and the receptor-binding site. The ribonucleolytic activity and angiogenic activity of angiogenin can be separated because the protein can be modified and as a result retain its ribonucleolytic activity but lose its angiogenic activity.

Angiogenin-responsive endothelial cells express a specific receptor on the cell membrane. After binding to the receptor, some angiogenin is rapidly endocytosed and translocated to the nucleus. Indeed, angiogenin contains a specific nuclear-localization sequence. In addition, another portion of the angiogenin bound to its receptor may trigger a number of intracellular signaling cascades. Both pathways lead to cell growth and neovascularization. Angiogenin plays a role in vascularization not only in malignancies, but also in nonmalignant pathologic conditions (e.g., in diabetic retinopathy).

Inhibitors of Vessel Growth

The concept of antiangiogenesis was first advanced by Judah Folkman as a strategy to stop the growth of tumors. He and his colleagues have described two peptides, angiostatin and endostatin, that are inhibitors of angiogenesis.

Angiostatin is a kringle-containing fragment of plasminogen, a key fibrinolytic protein (see [p. 446](#)). Angiostatin arises by proteolytic cleavage of plasminogen by connective tissue enzymes, such as matrix metalloproteinases and elastase. Angiostatin inhibits angiogenesis by enhancing apoptosis of endothelial cells and inhibiting migration and tube formation, rather than by affecting proliferation. Recombinant angiostatin is being tested in patients with advanced lung cancer.

Endostatin is a peptide breakdown product of collagen XVIII. It is produced by the extracellular matrix of tumors.

We can illustrate the importance of angiogenesis by highlighting three clinical situations in which angiogenesis plays an important role. First, enhancement of vessel growth is important during coronary artery disease, when chronic ischemia of the heart leads to the development of new vessels and thus collateral circulation. Second, angiogenesis enhances the blood supply to a tumor, thereby promoting its growth and opening the principal route by which tumor cells exit the primary tumor during metastasis. Oncologists are exploring the use of angiogenesis inhibitors to treat cancer. Third, angiogenesis may also be important in diabetic retinopathy, in which blood vessel proliferation can cause blindness.

CHAPTER 21

Cardiac Electrophysiology and the Electrocardiogram

W. Jonathan Lederer

Different cardiac cells serve different and very specialized functions, but all are electrically active. The heart's electrical signal normally originates in a group of cells high in the right atrium that depolarize spontaneously; it then spreads throughout the heart from cell to cell ([Fig. 21-1](#)). As this action potential propagates through the heart—sometimes carried by cells that form specialized conducting pathways and sometimes by the very cells that generate the force of contraction—it assumes different appearances within the different cardiac cells ([Fig. 21-2](#)). Based on the speed of the upstroke, we can characterize action potentials as either **slow** (sinoatrial and atrioventricular nodes) or **fast** (atrial myocytes, Purkinje fibers, and ventricular myocytes).

FIGURE 21-1 Conduction pathways through the heart. A section through the long axis of the heart is shown.

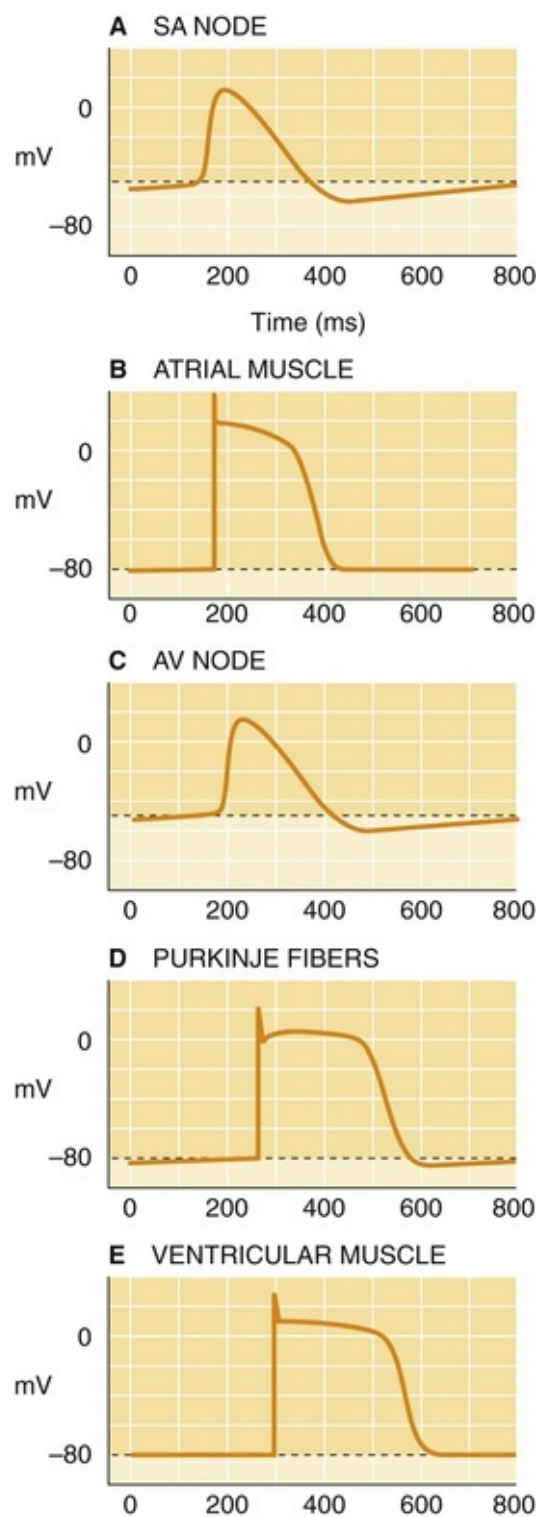

FIGURE 21-2 Cardiac action potentials. The distinctive shapes of action potentials at five sites along the spread of excitation are shown.

Because the excitation of cardiac myocytes triggers contraction—a process called *excitation-contraction coupling* (see p. 229)—the propagation of action potentials must be carefully timed to synchronize ventricular contraction and thereby optimize the ejection of blood. This chapter focuses on the membrane currents responsible for the generation and transmission of action potentials in heart tissue. We also examine how to record the heart's electrical flow by placing electrodes on the surface of the body to create one of the simplest and yet one of the most useful diagnostic tools available to the clinician—the electrocardiogram.

Electrophysiology of Cardiac Cells

The cardiac action potential starts in specialized muscle cells of the sinoatrial node and then propagates in an orderly fashion throughout the heart

The cardiac action potential originates in a group of cells called the **sinoatrial (SA) node** (see [Fig. 21-1](#)), located in the right atrium. These cells depolarize spontaneously and fire action potentials at a regular, intrinsic rate that is usually between 60 and 100 times per minute for an individual at rest. Both parasympathetic and sympathetic neural input can modulate this intrinsic **pacemaker** activity, or *automaticity* (see pp. [397–398](#)).

Because cardiac cells are electrically coupled through gap junctions ([Fig. 21-3A](#)), the action potential propagates from cell to cell in the same way that an action potential in nerve conducts along a single long axon. A spontaneous action potential originating in the SA node will conduct from cell to cell throughout the right atrial muscle and spread to the left atrium. The existence of discrete conducting pathways in the atria is still disputed. About one tenth of a second after its origination, the signal arrives at the **atrioventricular (AV) node** (see [Fig. 21-1](#)). The impulse does not spread directly from the atria to the ventricles because of the presence of a fibrous **atrioventricular ring**. Instead, the only available pathway is for the impulse to travel from the AV node to the **His-Purkinje fiber system**, a network of specialized conducting cells that carries the signal to the muscle of both ventricles.

A CURRENT FLOW THROUGH GAP JUNCTIONS

B ELECTROTONIC SPREAD OF CURRENT

C THRESHOLD AND RATE OF PROPAGATION OF ACTION POTENTIAL

FIGURE 21-3 Conduction in the heart. **A**, An action potential conducting from left to right causes intracellular current to flow from fully depolarized cells on the left, through gap junctions, and into cell A. Depolarization of cell A causes current to flow from cell A to cell B (I_{AB}). Part of I_{AB} discharges the capacitance of cell B (depolarizing cell B), and part flows downstream to cell C. **B**, Subthreshold

The cardiac action potential conducts from cell to cell via gap junctions

The electrical influence of one cardiac cell on another depends on the voltage difference between the cells and on the resistance of the gap junction connecting them. A **gap junction** (see p. 205) is an **electrical synapse** (see Fig. 21-3A) that permits electrical current to flow between neighboring cells. According to Ohm's law, the current flowing between cell A and the adjacent cell B (I_{AB}) is proportional to the voltage difference between the two cells (ΔV_{AB}) but inversely proportional to the electrical resistance between them (R_{AB}):

$$I_{AB} = \frac{V_A - V_B}{R_{AB}} = \frac{\Delta V_{AB}}{R_{AB}} \quad (21-1)$$

When R_{AB} is very small (i.e., when the cells are tightly coupled), the gap junctions are minimal barriers to the flow of depolarizing current.

Imagine that several interconnected cells are initially all at their normal resting potentials (see Fig. 21-3B). An action potential propagating from the left of cell A now injects depolarizing current into cell A. As a result, the cell depolarizes to V_A , which is now somewhat positive compared with V_B . Thus, a small depolarizing current (i.e., positive charges) will also move from cell A to cell B and depolarize cell B. In turn, current flowing from cell B will then depolarize cell C. By this process, the cells closest to the current source undergo the greatest depolarization.

Imagine that the injected current, coming from the active region of the heart to the left, depolarizes cell A just to its threshold (see Fig. 21-3C, red curve) but that cell A has not yet fired an action potential. At this instant, the current passing from cell A to cell B cannot bring cell B to its threshold. Of course, cell A will eventually fire an action potential and, in the process, depolarize enough to inject enough current into cell B to raise cell B to its threshold. Thus, the action potential propagates down the chain of cells, but relatively slowly. On the other hand, if the active region to the left injects *more* current into cell A (see Fig. 21-3C, blue curve)—producing a larger depolarization in cell A—the current passing from cell A to cell B will be greater and sufficient to depolarize cell B beyond its voltage threshold for a regenerative action potential. However, at this instant, the current passing from cell B to cell C is still not sufficient to trigger an action potential in cell C. That will have to wait until the active region moves closer to cell C, but the wait is not as long as in the first example (red curve in Fig. 21-3C). Thus, the action potential propagates more rapidly in this second example (blue curve in Fig. 21-3C).

In principle, we could make the action potential propagate more rapidly down the chain of cells in two ways. First, we could allow more ion channels to open in the active region of the heart, so that depolarizing current is larger (blue curve in Fig. 21-3C). Second, we could lower the threshold for the regenerative action potential (“more negative threshold” in Fig. 21-3C), so that even the small current represented by the red curve is now sufficient to trigger cell B.

Just as in a nerve axon conducting an action potential, the intracellular and extracellular currents in

heart muscle must be equal and opposite. In the active region of the heart (to the left of cell A in [Fig. 21-3B](#)), cells have reached threshold and their action potentials provide the *source* of current that depolarizes cells that are approaching threshold (e.g., cells A and B). As cell A itself is depolarizing to and beyond threshold, its Na^+ and Ca^{2+} channels are opening, enabling these cations (i.e., positive charge) to enter. The positive charge that enters cell A not only depolarizes cell A but also produces a flow of positive charge to cell B—**intracellular current**. This flow of positive charge discharges the membrane capacitance of cell B, thereby depolarizing cell B and releasing extracellular positive charges that had been associated with the membrane. The movement of this extracellular positive charge from around cell B toward the extracellular region around cell A constitutes the **extracellular current**. The flow of intracellular current from cell A to cell B and the flow of extracellular current from around cell B to around cell A are equal and opposite. It is the flow of this *extracellular* current in the heart that gives rise to an instantaneous electrical vector, which changes with time. Each point on an **electrocardiogram (ECG)** is the sum of the many such electrical vectors, generated by the many cells of the heart.

Cardiac action potentials have as many as five distinctive phases

The initiation time, shape, and duration of the action potential are distinctive for different parts of the heart, reflecting their different functions (see [Fig. 21-2](#)). These distinctions arise because the myocytes in each region of the heart have a characteristic set of channels and anatomy. Underlying cardiac action potentials are four major time-dependent and voltage-gated membrane currents ([Table 21-1](#)):  **N21-1**

TABLE 21-1

Major Cardiac Membrane Currents That Are Time Dependent and Voltage Gated

CURRENT	NAME	CHANNEL PRO TEIN	HUMAN GENE SYMBOL	REVERSAL PO TENTIAL OF CURRENT (mV)	INHIBITORS
I_{Na}	Na^+ current	Nav1.5 (voltage-gated Na^+ channel)	<i>SCN5A</i>	+60	TTX Local anesthetics
I_{Ca}	Ca^{2+} current	Cav1.2 (L-type Ca^{2+} channel)	<i>CACNA1C</i>	+120	Nifedipine Verapamil
I_{K}	I_{to}	Kv4.3 + KChIP2	<i>KCND3 + KNCIP2</i>	−100	Tedisamil
	Repolarizing I_{Kr}	Kv11.1 (HERG) + miRP1*	<i>KCNH2 + KCNE2</i>	−100	Ba^{2+} Cs^+ TEA Dofetilide E4031
	Repolarizing I_{Ks}	Kv7.1 (KvLQT1) + minK*	<i>KCNQ1 + KCNE1</i>	−100	HMR1556 L-768, 673 Benzopyran chromanol
	I_{K1}	Kir2.1 Kir2.2	<i>KCNJ2</i> <i>KCNJ12</i>	−100	Ba^{2+} ML133
	G protein–activated $I_{\text{K,ACh}}$	Kir3.4 (GIRK4)*	<i>KCNJ5</i>	−100	
	ATP-sensitive current, K_{ATP}	Kir6.1 + SUR1 or SUR2* Kir6.2 + SUR1 or SUR2*	<i>KCNJ8 + ABCC8</i> or <i>ABCC9</i> <i>KCNJ11 + ABCC8</i> or <i>ABCC9</i>	−100	Glibenclamide
I_{f} (Na^+ + K^+)	Pacemaker current	HCN4	<i>HCN4</i>	−35	Cs^+

*These are heteromultimeric channels.

GIRK, G protein–activated inwardly rectifying K^+ channel; HERG, human ether-à-go-go–related gene (related to Kv family of K^+ channel genes); KChIP2, Kv channel–interacting protein 2; TEA, tetraethylammonium; TTX, tetrodotoxin.

Cardiac Ion Channels

Contributed by W. Jonathan Lederer

The number of distinct ion channels found in heart cells has grown dramatically with the development of new tools. While the cellular and organ-level function follows the presentation in the text and this webnote, important subtleties in the detailed function can depend on the additional channel subtypes that may be expressed at varying levels and that can change under stress or during disease. For example, heart cells express not only the “cardiac” sodium channel (Nav1.5) but also other sodium channel types (e.g., Nav1.4, which is normally found in skeletal muscle; see Table 7-1). In addition to the L-type Ca^{2+} channel, cardiac myocytes may also express the T-type Ca^{2+} channel (see Table 7-2). In many diseases, the expression of the T-type Ca^{2+} channel increases. Ventricular and atrial myocytes may express K^{+} channels in a diversity much greater than described in the text. Moreover, the array of K^{+} channels often changes in disease processes. eFigure 21-1 lists some of the prominent channels and how they contribute to the cardiac action potential.

FIGURE 21-1 Membrane currents that underlie the cardiac action potential. The action potential time course is shown at top left with typical currents shown below on the left. The time course of inward (blue) and outward (green) currents is shown. The components of each channel type shown are presented on the right. (From George AL Jr: *J Clin Invest* 123:75–83, 2013.)

George AL Jr. Molecular and genetic basis of sudden cardiac death. *J Clin Invest*. 2013;123:75–83.

1. The **Na^+ current** (I_{Na}) is responsible for the rapid **depolarizing** phase of the action potential in atrial and ventricular muscle and in Purkinje fibers.
2. The **Ca^{2+} current** (I_{Ca}) is responsible for the rapid **depolarizing** phase of the action potential in the SA node and AV node; it also triggers contraction in all cardiomyocytes.
3. The **K^+ current** (I_K) is responsible for the **repolarizing** phase of the action potential in all cardiomyocytes.
4. The **pacemaker current** (I_f) is responsible, in part, for pacemaker activity in SA nodal cells, AV nodal cells, and Purkinje fibers.

Besides these four currents, channels carry numerous other currents in heart muscle. In addition, two *electrogenic* transporters  **N21-2** carry current across plasma membranes: the type 1 Na-Ca exchanger (NCX1; see pp. 123–124) and the Na-K pump (see pp. 115–117).

N21-2

Cardiac Currents Carried by Electrogenic Transporters

Contributed by W. Jonathan Lederer

In addition to the channels listed in Table 21-1, numerous other channels are present in heart muscle. The distribution of this large array of time- and voltage-dependent membrane currents (see Table 21-1) differs in each of the different cardiac cell types. In addition, there are yet *other* membrane channels (not shown in Table 21-1) that are responsible for “background” currents that we have not discussed, that are *not* gated by voltage, and that are *not* time dependent. These background currents can be modulated by diverse factors and help to shape the action potential.

In addition to all of the channels, cardiac cells have two *electrogenic* transporters that also carry current across the plasma membranes: the Na-Ca exchanger and the Na-K pump.

Na-Ca Exchanger

The Na-Ca exchanger (NCX; see pp. 123–124 and 126) is an electrogenic transporter that normally moves three Na⁺ ions into the cell in order to *extrude* one Ca²⁺ ion, using the electrochemical gradient for Na⁺ as an energy source for transport. Under these conditions, the Na-Ca exchanger produces an inward or depolarizing current (i.e., a net inward movement of positive charge). However, if this electrochemical gradient reverses, as it *transiently* does early during the cardiac action potential (due to the positive V_m), the Na-Ca exchanger may be able to reverse and mediate *entry* of Ca²⁺ and a net outward current. Later during the cardiac action potential, the Na-Ca exchanger returns to its original direction of operation (i.e., Ca²⁺ extrusion and inward current). During the plateau phase of the action potential, the inward current mediated by the Na-Ca exchanger tends to prolong the action potential.

Na-K Pump

The Na-K pump is also an electrogenic transporter, normally moving two K⁺ ions into the cell for every three Na⁺ ions that it transports out of the cell, using ATP as an energy source (see pp. 115–117). Therefore, this pump produces an outward or hyperpolarizing current. Cardiotonic steroids (such as digoxin and ouabain) inhibit the Na-K pump and thereby cause an increase in [Na⁺]_i. This inhibition also reduces the outward current carried by the pump and therefore depolarizes the cell.

Traditionally, the changes in **membrane potential (V_m)** during the cardiac action potential are divided into separate phases, as illustrated in [Figure 21-4A](#) for cardiac action potentials from the SA node and in [Figure 21-4B](#) for those from ventricular muscle.

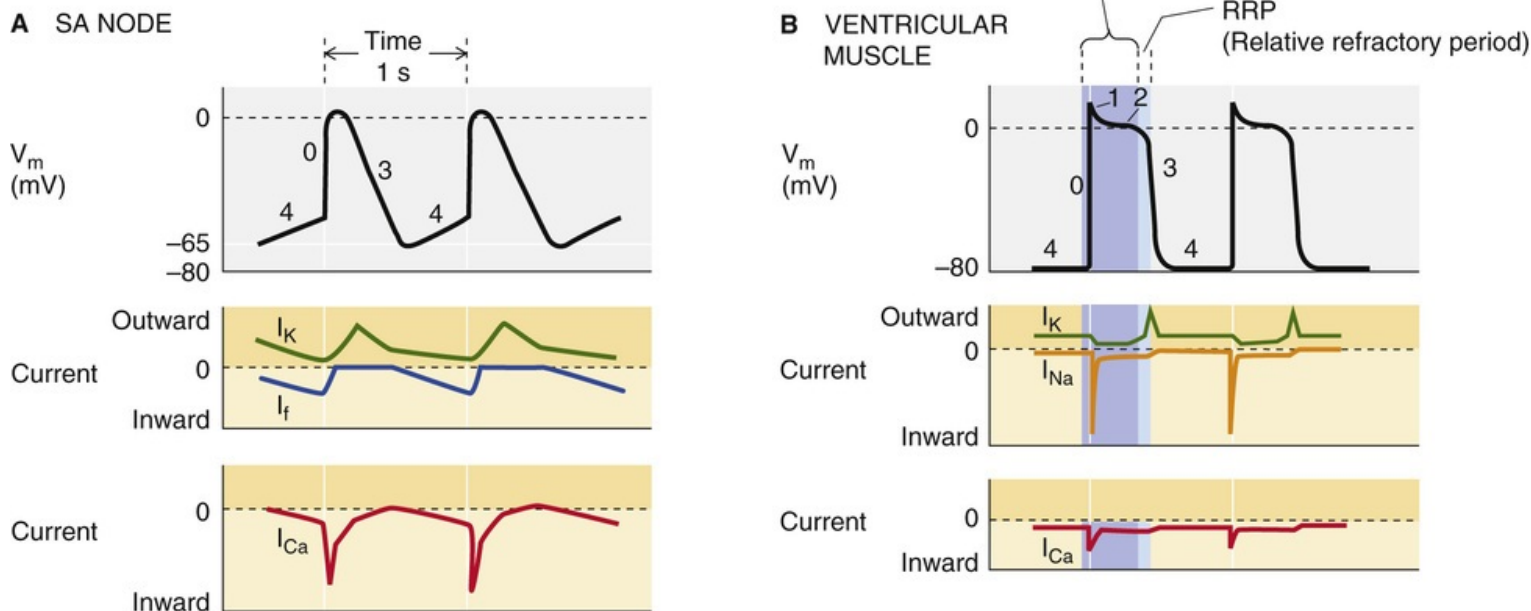

FIGURE 21-4 Phases of cardiac action potentials. The records in this figure are idealized. I_K , I_{Na} , I_{Ca} , and I_f are currents through K^+ , Na^+ , Ca^{2+} , and nonselective cation channels, respectively.

Phase 0 is the upstroke of the action potential. If the upstroke is due only to I_{Ca} (see Fig. 21-4A), it will be slow. If the upstroke is due to both I_{Ca} and I_{Na} (see Fig. 21-4B), it will be fast.

Phase 1 is the rapid repolarization component of the action potential (when it exists). This phase is due to almost total inactivation of I_{Na} or I_{Ca} and may also depend on the activation of a minor K^+ current not listed previously, called I_{to} (for transient outward current).

Phase 2 is the plateau phase of the action potential, which is prominent in ventricular muscle. It depends on the continued entry of Ca^{2+} or Na^+ ions through their major channels and on a minor membrane current due to the Na-Ca exchanger NCX1. **N21-2**

Phase 3 is the repolarization component of the action potential. It depends on I_K (see Table 21-1).

Phase 4 constitutes the electrical diastolic phase of the action potential. V_m during phase 4 is termed the **diastolic potential**; the most negative V_m during phase 4 is the **maximum diastolic potential**. In SA and AV nodal cells, changes in I_K , I_{Ca} , and I_f produce pacemaker activity during phase 4. Purkinje fibers also exhibit pacemaker activity but use only I_f . Atrial and ventricular muscle have no time-dependent currents during phase 4.

The Na^+ current is the largest current in the heart

The Na^+ current (see Table 21-1) is the largest current in heart muscle, which may have as many as 200 Na^+ channels per square micrometer of membrane. These channels are abundant in ventricular and atrial muscle, in Purkinje fibers, and in specialized conduction pathways of the atria. This current is not present in SA or AV nodal cells.

The channel that underlies I_{Na} is a classic voltage-gated Na^+ channel, with both α and β_1 subunits (see pp. 182–185). The unique cardiac α subunit (Nav1.5) has several phosphorylation sites that make it sensitive to stimulation by cAMP-dependent protein kinase (see p. 57). **N21-3**

N21-3

Cardiac Na⁺ Channels

Contributed by W. Jonathan Lederer, Emile Boulpaep, Walter Boron

The channel that underlies I_{Na} is a classic voltage-gated Na⁺ channel, with both an α and β_1 subunit (see p. 187 and Fig. 7-12A). The cardiac α subunit differs from the brain α subunit in having a long cytoplasmic loop connecting the first and second repeats of its six membrane-spanning segments. This long loop has several phosphorylation sites, and it conveys a unique quality to the cardiac channel: phosphorylation by cAMP-dependent protein kinase (protein kinase A, or PKA; see p. 57) *stimulates* the cardiac channel, but *inhibits* the brain channel.

At the negative resting potentials of the ventricular muscle cells, the Na⁺ channels are closed. However, these channels rapidly activate (in 0.1 to 0.2 ms) in response to local depolarization produced by conducted action potentials and produce a massive inward current that underlies most of the rapid upstroke of the cardiac action potential (phase 0 in Fig. 21-4B). If V_m remains at a positive level, these channels close in a time-dependent process known as **inactivation**. This process, which is slower than activation but still fairly rapid (half-time, ~1 ms), is partly responsible for the rapid repolarization of the action potential (phase 1). At the potentials maintained during the plateau of the cardiac action potential—slightly positive to 0 mV during phase 2—a very small but important component of this current remains ($I_{Na,late}$). The sustained level of I_{Na} helps prolong phase 2.  **N21-4**

N21-4

Late Na⁺ Current

Contributed by W. Jonathan Lederer

Although the primary purpose of I_{Na} in ventricular and atrial myocytes is to support the rapid depolarization of the membrane potential during the upstroke of the cardiac action potential and to provide the inward current needed for rapid conduction, there are other aspects of its function. A small residual fraction of the I_{Na} channels may incompletely inactivate or exist in a distinct kinetic mode following phase 1 of the action potential. This enables these channels to contribute current, now dubbed $I_{Na,late}$, that lingers long into phases 2 and 3 of the ventricular and atrial action potentials. Both the inward current and the Na⁺ influx attributed to $I_{Na,late}$ can contribute to changes in myocyte behavior that are proarrhythmic. Since many disease conditions enhance $I_{Na,late}$ there is an intense effort to identify and test therapeutic agents that block $I_{Na,late}$ with minimal impact on the early or normal I_{Na} (Maier and Sossalla, 2013). The specific post-translational modifications of the Na⁺ channel protein subunits that underlie the late Na⁺ channel state remain unknown but are under active investigation.

Reference

Maier LS, Sossalla S. The late Na current as a therapeutic target: Where are we? *J Mol Cell Cardiol.* 2013;61:44–50.

In cardiac tissues other than the SA and AV nodes, the regenerative spread of the conducted action potential depends in large part on the *magnitude* of I_{Na} (see Fig. 21-3C). The depolarization produced by the Na^+ current not only activates I_{Na} in neighboring cells but also activates other membrane currents in the same cell, including I_{Ca} and I_{K} . For example, unlike in skeletal muscle, in which the action potential duration is relatively short, in cardiac myocytes the depolarization—initiated by Nav1.5—activates the L-type cardiac Ca^{2+} channel (Cav1.2; see next section), which greatly prolongs the depolarizing phase of the cardiac action potential due to its long-duration opening events. Local anesthetic **antiarrhythmic drugs**, such as lidocaine, work by partially blocking I_{Na} .

The Ca^{2+} current in the heart passes primarily through L-type Ca^{2+} channels

The Ca^{2+} current (I_{Ca} ; see Table 21-1) is present in all cardiac myocytes. The L-type Ca^{2+} channel (Cav1.2; see pp. 190–193) is the dominant one in the heart. T-type Ca^{2+} channels, with different biophysical and pharmacological properties, are also present but in smaller amounts.

In the SA node, the role of I_{Ca} , like that of the other time- and voltage-dependent membrane currents, is to contribute to pacemaker activity. In both the SA and AV nodes, I_{Ca} is the inward current source that is responsible for the upstrokes (phase 0) of the SA and AV nodal action potentials. Because the nodal cells lack the larger I_{Na} , their upstrokes are slower than those in atrial and ventricular muscle (compare A and B of Fig. 21-4). Therefore, the smaller I_{Ca} discharges the membrane capacitance of neighboring cells in the SA and AV nodes less rapidly, so that the speed of the conducted action potential is much slower than that of any other cardiac tissue. This feature in the AV node leads to an **electrical delay** between atrial contraction and ventricular contraction that permits more time for the atria to empty blood into the ventricles.

Although it is smaller, I_{Ca} sums with I_{Na} during the upstroke of the action potentials of the ventricular and atrial muscle and the Purkinje fibers. In this way, it increases the velocity of the conducted action potential in these tissues. Like I_{Na} , I_{Ca} produces virtually no current at very negative potentials because the channels are closed. At more positive values of V_{m} , the Ca^{2+} channels rapidly *activate* (in ~ 1 ms) and, by a completely separate and time-dependent process, *inactivate* (half-time, 10 to 20 ms). **N21-5** A small I_{Ca} remains during phase 2 of the action potential, helping to prolong the plateau. In atrial and ventricular muscle cells, the Ca^{2+} entering via L-type Ca^{2+} channels activates the release of Ca^{2+} from the sarcoplasmic reticulum (SR) by calcium-induced Ca^{2+} release (see pp. 242–243). **Blockers of L-type Ca^{2+} channels**—therapeutic agents such as verapamil, diltiazem, and nifedipine—act by inhibiting I_{Ca} .

N21-5

Time Course of Ca^{2+} Current in Ventricular Muscle

Contributed by W. Jonathan Lederer

In Figure 21-4B, the lower panel (red trace) illustrates the time course of the Ca^{2+} current during an action potential in a ventricular myocyte.

During phase 4, at rest, where V_{m} is maximally negative, the Ca^{2+} channels are mostly closed and I_{Ca} is a very small inward current. Following the depolarization produced by the very fast Na^+ channel during

phase 0, the Ca^{2+} channels *activate* (in ~ 1 ms), producing the rapid downstroke of the red I_{Ca} record in Figure 21-4B.

Next, by a completely separate and time-dependent process, the Ca^{2+} channels *inactivate* at positive potentials (half-time, 10 to 20 ms), producing the slower decay of inward current toward the end of phase 1 in Figure 21-4B. Along with the inactivation of the Na^+ channels and the opening of the Kv4.3 channels that underlie I_{to} , the inactivation of Ca^{2+} channels contributes to the small repolarization that defines phase 1 (see Fig. 21-4B). Note that, for both activation and inactivation, the cardiac Ca^{2+} channels are about an order of magnitude slower than cardiac Na^+ channels.

During phase 2 of the action potential, a small I_{Ca} remains, helping to prolong the plateau. This phase is represented by the flat portion of the red I_{Ca} record displaced below the dashed zero-current line in Figure 21-4B.

During phase 3, as V_{m} returns to negative potentials, two things happen to Ca^{2+} channels. First, the still-active Ca^{2+} channels (which were activated by positive V_{m} values) will go through a process of *deactivation* (caused by negative V_{m} values). Second, the Ca^{2+} channels that had been inactivated during phase 2 now begin to *recover from inactivation*. The net effect is that a minuscule Ca^{2+} current remains during phase 4 ... which takes us back to the beginning of this discussion.

The repolarizing K^+ current turns on slowly

Cardiac action potentials last two orders of magnitude longer than action potentials in skeletal muscle because the repolarizing K^+ current turns on very slowly and—in the case of atrial myocytes, Purkinje fibers, and ventricular myocytes—with a considerable delay. The **repolarizing K^+ current** (I_{K} ; see Table 21-1) is found in all cardiac myocytes and is responsible for repolarizing the membrane at the end of the action potential (phase 3 in Fig. 21-4A, B). Two currents underlie I_{K} —a relatively rapid component (I_{KR}) carried by heteromeric HERG/miRP1 channels and a relatively slow component (I_{KS}) carried by heteromeric KvLQT1/minK channels (see Box 7-3). **N21-6** The I_{K} membrane current is very small at negative potentials. With depolarization, it slowly activates (20 to 100 ms) but does not inactivate. In SA and AV nodal cells, it contributes to pacemaker activity by slowly deactivating at the diastolic voltage.

N21-6

Cardiac K^+ Currents

Contributed by W. Jonathan Lederer, Emile Boulpaep, Walter Boron

Table 21-1 lists five K^+ currents:

- I_{to} —the transient outward current—occurs during phase 1 of the action potential. Along with the inactivation of the Na^+ channels and (a bit later) the inactivation of Ca^{2+} channels, I_{to} contributes to the small repolarization that defines phase 1 (see Fig. 21-4B). The Shaker-type K^+ channel (see pp. 193–196) Kv4.3 carries I_{to} .
- I_{KR} —the rapid repolarizing K^+ current—is the current arising from heteromultimeric channels composed of HERG and miRP subunits.

- I_{Ks} —the slow repolarizing K^+ current—arises from different heteromultimeric channels composed of KvLQT1 and minK subunits. In older terminology, the *delayed-rectifier K^+ current* is the sum of I_{Kr} and I_{Ks} .
- I_{K1} —the inward-rectifying current that prevails at the resting potential. The channels are members of the Kir family (*KCNJ* genes). The channels close during phase 0, and re-open at the end of phase 3.
- GIRK—the G protein-activated, inwardly rectifying K^+ channels (also part of the Kir family; see pp. 197–198)—open in response to ACh. Like many K^+ channels, the GIRK channels are comprised of two different GIRK subunits clustered as tetramers.
- K_{ATP} —the K^+ channels inhibited by intracellular ATP (like GIRKs, part of the IR family of K^+ channels; see pp. 197–198)—contribute to the background K^+ current. The K_{ATP} channel is a tetramer comprised of two different subunits, as is the case for the GIRK K^+ channels and the channels that give rise to the I_{Kr} and I_{Ks} currents.

In addition to I_K , several other K^+ currents are present in cardiac tissue.

Early Outward K^+ Current (A-type Current)

Atrial and ventricular muscle cells have some early transient outward current (I_{to}). This current is activated by depolarization but rapidly inactivates. It contributes to phase 1 repolarization and is analogous to the A-type currents (see p. 193) seen in nerves. A Kv4.3 channel mediates the A-type current in heart and certain other cells.

G Protein-Activated K^+ Current

Acetylcholine activates muscarinic receptors and, through the $\beta\gamma$ subunits of a G protein, activates an outward K^+ current mediated by GIRK K^+ channels (see pp. 197–198). This current is prominent in SA and AV nodal cells, where it decreases pacemaker rate by cell hyperpolarization. When activated, this current also slows the conduction of the action potential through the AV node.

K_{ATP} Current

ATP-sensitive K^+ channels (K_{ATP} ; see p. 198), activated by low intracellular [ATP], are present in abundance and may play a role in electrical regulation of contractile behavior. These channels are octamers, consisting of four subunits (Kir6.1 or Kir6.2) forming the pore of an inward-rectifier channel and four sulfonylurea receptors (SUR1 or SUR2).

The I_f current is mediated by a nonselective cation channel

The pacemaker current (I_f) is found in SA and AV nodal cells and in Purkinje fibers (see Fig. 21-4A, blue curve). The channel underlying this current is a nonspecific cation channel called **HCN** (for hyperpolarization activated, cyclic nucleotide gated; see pp. 162–165), with HCN4 being dominant in the adult heart. Because the HCN channels conduct both K^+ and Na^+ , the reversal potential of I_f is around

–20 mV, between the Nernst potentials for K^+ (about –90 mV) and Na^+ (about +50 mV). The HCN channels have the unusual property (hence the subscript f , for “funny” current) that they do not conduct at positive potentials but are activated by *hyperpolarization* at the end of phase 3. The activation is slow (100 ms), and the current does not inactivate. Thus, I_f produces an inward, *depolarizing* current as it slowly activates at the end of phase 3. The I_f current is not the only current that contributes to pacemaker activity; in SA and AV nodal cells, I_{Ca} and I_K also contribute significantly to the phase 4 depolarization.

Different cardiac tissues uniquely combine ionic currents to produce distinctive action potentials

The shape of the action potential differs among different cardiac cells because of the unique combination of various currents—both the voltage-gated/time-dependent currents discussed in the preceding four sections and the “background” currents—present in each cell type. **N21-7** In Chapter 6, we introduced Equation 6-12, which describes V_m in terms of the conductances for the different ions (G_{Na} , G_K , G_{Ca} , G_{Cl}) relative to the total membrane conductance (G_m) and the equilibrium potentials (E_{Na} , E_K , E_{Ca} , E_{Cl}):

$$V_m = \frac{G_K}{G_m} E_K + \frac{G_{Na}}{G_m} E_{Na} + \frac{G_{Ca}}{G_m} E_{Ca} + \frac{G_{Cl}}{G_m} E_{Cl} \dots \quad (21-2)$$

N21-7

Contribution of Ionic Currents to the Action Potential

Contributed by W. Jonathan Lederer

Equation 21-2 gives V_m in terms of the weighted conductances of the various ions. Another, less general, way of expressing this concept is the Goldman-Hodgkin-Katz (GHK) equation, which we introduced in Chapter 6. The GHK equation (given as Equation 6-9 and reproduced here) relates V_m to the cellular permeability to different ions (P_{Na} , P_K , P_{Cl}), as well as to the intracellular and extracellular concentrations of these ions:

$$V_{rev} = \frac{RT}{F} \ln \left(\frac{P_K [K^+]_o + P_{Na} [Na^+]_o + P_{Cl} [Cl^-]_i}{P_K [K^+]_i + P_{Na} [Na^+]_i + P_{Cl} [Cl^-]_o} \right)$$

Several assumptions underlie the GHK equation, including that (1) the voltage varies linearly with distance through the membrane (constant-field assumption), (2) the ions move independently of one another, (3) the ions are driven only by their electrochemical gradients, (4) the permeabilities are constant, and (5) the total membrane current is zero (i.e., the individual ionic currents sum to zero and V_m is constant). Although we derived this GHK equation with these assumptions—which are not strictly true during the action potential—the equation nevertheless embodies the notion that changes in permeabilities and concentrations of specific ions will affect the shape of the action potential.

Therefore, as the relative contribution of a particular membrane current becomes dominant, V_m approaches the equilibrium potential for that membrane current (Table 21-2). How fast V_m changes during the action potential depends on the magnitude of each of the currents (Equation 21-2). Not only does each current *independently* affect the shape of the action potential, but the voltage- and time-dependent currents interact with one another because they affect—and are affected by— V_m . Other important influences on the shape of the cardiac action potential are the membrane capacitance of each cell and the geometry of the conduction pathway (e.g., AV node, bundle of His, ventricular muscle) as the action potential propagates from cell to cell in this functional syncytium via gap junctions. Therefore, it is easy to understand, at a conceptual level, how a particular cell's unique complement of ion channels, the properties of these channels at a particular instant in time, the intracellular ion concentrations, and the cell's geometry can all contribute to the shape of an action potential. Mathematical Modeling of the Heart

Contributed by W. Jonathan Lederer

In this chapter and throughout the text, reference is often made to mathematical models and the way they are used to test interpretations of data and to integrate specific experimental findings into a larger physiological context. This approach is used increasingly in teaching, drug testing, and experimental investigations, and will be used in the future in personalized medicine. In heart and other organs, tissues, and cells, the primary weakness of mathematical models is model validation: How do we know that the choice of unknown or uncertain variables placed into the mathematical model is optimal and unprejudiced? This selection is now being done through optimization programs and approaches that, if successful, can be used to improve personalized medicine. Courses are available to begin the application of “systems biology” methods for all.

Powerful resources are available on the Web. The Virtual Cell is a modeling environment for physicians, scientists, and students who seek to investigate quantitative relationships in biology. This is a National Institutes of Health–funded resource and can be accessed and used without charge. Importantly, there is a growing community of users who share their models and modeling code.

The SA node is the primary pacemaker of the heart

The Concept of Pacemaker Activity

The normal heart has three intrinsic pacemaking tissues: the SA node, the AV node, and the Purkinje fibers. The term **pacemaker activity** refers to the spontaneous time-dependent depolarization of the cell membrane that leads to an action potential in an otherwise quiescent cell. Any cardiac cell with pacemaker activity can initiate the heartbeat. The pacemaker with the highest frequency will be the one to trigger an action potential that will propagate throughout the heart. In other words, the fastest pacemaker sets the heart rate and overrides all slower pacemakers. Thus, cardiac pacemakers have a hierarchy among themselves, based on their intrinsic frequency. Two fundamental principles underlie pacemaker activity. The first is that inward or depolarizing membrane currents interact with outward or hyperpolarizing membrane currents to establish regular cycles of spontaneous depolarization and repolarization. The second is that in a particular cell, these currents interact during phase 4 within a narrow range of diastolic potentials: between -70 and -50 mV in SA and AV nodal cells, and between -90 and -65 mV in Purkinje fibers.

SA Node

The SA node is found in the right atrium and is the primary site of origin of the electrical signal in the mammalian heart (Table 21-3). It is the smallest electrical region of the heart and constitutes the *fastest normal pacemaker*, with an intrinsic rate of about 60 beats/min, or faster in an individual at rest. SA nodal cells are stable oscillators whose currents are always varying with time.  **N21-9** The interactions among three time-dependent and voltage-gated membrane currents (I_{Ca} , I_K , and I_f) control the intrinsic rhythmicity of the SA node. The sum of a *decreasing outward* current (I_K ; green curve in Fig. 21-4A) and two *increasing inward* currents (I_{Ca} and I_f ; red and blue curves in Fig. 21-4A) produces the slow pacemaker depolarization (phase 4) associated with the SA node. The maximum diastolic potential (i.e., the most negative V_m) of the SA nodal cells, which occurs during phase 4 of the action potential, is between -60 and -70 mV. As V_m rises toward the threshold of about -55 mV, I_{Ca} becomes increasingly activated and eventually becomes regenerative, producing the upstroke of the action potential. This depolarization rapidly turns off (i.e., deactivates) I_f , and the whole process begins again.  **N21-10**

TABLE 21-3
Electrical Properties of Different Cardiac Tissues

TISSUE NAME	FUNCTION	PRINCIPAL TIME-DEPENDENT AND VOLTAGE-DEPENDENT CURRENTS	β-ADRENERGIC EFFECT (e.g., EPINEPHRINE)	CHOLINERGIC EFFECT (e.g., ACh)
SA node	Primary pacemaker	I_{Ca} , I_K , I_f	↑ Conduction velocity ↑ Pacemaker rate	↓ Pacemaker rate ↓ Conduction velocity
Atrial muscle	Expel blood from atria	I_{Na} , I_{Ca} , I_K	↑ Strength of contraction	Little effect
AV node	Secondary pacemaker	I_{Ca} , I_K , I_f	↑ Conduction velocity ↑ Pacemaker rate	↓ Pacemaker rate ↓ Conduction velocity
Purkinje fibers	Rapid conduction of action potential Tertiary pacemaker	I_{Na} , I_{Ca} , I_K , I_f	↑ Pacemaker rate	↓ Pacemaker rate
Ventricular muscle	Expel blood from ventricles	I_{Na} , I_{Ca} , I_K	↑ Contractility	Little effect

N21-9

Action Potential of the Sinoatrial Node

Contributed by W. Jonathan Lederer

Figure 21-4A illustrates the phases of the SA node action potential and the underlying currents.

During phase 0 of the action potential, I_{Ca} *activates* regeneratively (see red record in bottom panel of Fig. 21-4A, specifically the rapid downstroke), producing a rapid upstroke of V_m . Underlying I_{Ca} are both T-type and L-type Ca^{2+} channels.

At the transition between phases 0 and 3, I_{Ca} then begins to *inactivate*, a feature that begins the repolarization process. Note that phases 1 and 2 are not seen in the SA node because the inactivation of I_{Ca} combines with the slow activation of I_K to bring about the phase 3 repolarization of the action potential.

As V_m approaches the maximum diastolic potential at the beginning of phase 4, three slow changes in membrane current take place that underlie phase 4 pacemaker activity:

1. I_K deactivates slowly with time (over hundreds of milliseconds), producing a decreasing outward current (see green record in middle panel of Fig. 21-4A, specifically the slow decline of outward current during phase 4).
2. I_{Ca} contributes inward (i.e., depolarizing) current in the following way. Even though V_m has become more negative at the end of phase 3, V_m is still positive enough to keep I_{Ca} *partially activated* (albeit to only a small extent) from the previous action potential. Additionally, at the end of phase 3, V_m is still negative enough to cause I_{Ca} to *recover slowly from inactivation* (remember that recovery from inactivation and activation of I_{Ca} are independent processes). Thus, as I_{Ca} recovers from inactivation over hundreds of milliseconds, there is a small, increasingly inward I_{Ca} that tends to depolarize the SA nodal cells during phase 4 (see red record in lower panel of Fig. 21-4A, specifically the slow downstroke of inward current during phase 4).
3. I_f slowly activates as V_m becomes sufficiently negative at the end of phase 3. The result is a slowly growing inward (i.e., depolarizing) current (see blue record in middle panel of Fig. 21-4A, specifically the rather rapid downstroke of inward current during phase 4).

Thus, during phase 4, the sum of a *decreasing outward* current (I_K) and two *increasing inward* currents (I_{Ca} and I_f) produces the slow pacemaker depolarization associated with the SA node.

As V_m rises from about -65 mV toward the threshold of about -55 mV during the pacemaker depolarization, I_{Ca} becomes increasingly activated and eventually becomes regenerative, producing the rapid upstroke of the action potential ... which takes us back to the beginning of this discussion. Note that the turning off of I_f tends to oppose the rapid upstroke of V_m during phase 0. However, the activation of I_{Ca} overwhelms the turning off of I_f .

N21-10

Control of Pacemaker Activity

Contributed by W. Jonathan Lederer

The interactions of three membrane currents (I_f , $I_{Ca,L}$ [L-type Ca^{2+} channel current], and I_K) contribute to pacemaker activity in SA node and AV node in heart as presented in the text. Two other inward currents are considered possible contributors to pacemaker activity under normal conditions, $I_{Ca,T}$ and I_{NCX} (the T-type Ca^{2+} channel current and the Na-Ca exchanger current, respectively). Mathematical models  **N21-8** and experimental evidence support the roles that these mechanisms could play in influencing pacemaker activity under normal conditions. Active investigations by many laboratories seek to determine the extent to which these additional mechanisms may influence normal and pathological pacemaker activity. The Na-Ca exchanger-dependent contribution has been dubbed *the Ca^{2+} clock*. The essence of the “clock” is the time-dependent subcellular Ca^{2+} release (Ca^{2+} sparks) from the SR in SA and AV nodal cells. When this occurs the subcellular Ca^{2+} sparks activate an inward (depolarizing) I_{NCX} .

The membrane currents discussed in the previous paragraph are under the control of local and circulating agents (e.g., acetylcholine, epinephrine, and norepinephrine) and are also targets for therapeutic agents designed to modulate the heart's rhythm (e.g., Ca^{2+} channel blockers and β -adrenergic blockers).

AV Node

The AV node, located just above the AV ring, is the secondary site of origin of the electrical signal in the mammalian heart. Normally, the AV node may be excited by an impulse reaching it by way of the specialized atrial conduction pathways (see below). Like that of the SA node, the intrinsic rhythmicity of the AV node depends on the interaction of three time-dependent and voltage-gated currents: I_K , I_{Ca} , and I_f . Electrically, the SA and AV nodes share many properties; they have similar action potentials, pacemaker mechanisms, and drug sensitivities and a similarly slow conduction of action potentials. Because the intrinsic pacemaker rate of the AV node is slower (~ 40 beats/min) than that of the SA node, it does not set the heart rate; its pacemaker activity is considered secondary. However, if the SA node should fail, the AV node can assume control of the heart and drive it successfully.

Purkinje Fibers

The His-Purkinje fiber system originates at the AV node with the bundle of His and splits to form the left and right bundle branches (see [Fig. 21-1](#)). The right bundle conducts the electrical signal to the right

ventricle, and the left bundle conducts the signal to the left ventricle. The anatomy of the left bundle is variable, but this bundle frequently divides into two main branches—the left anteroseptal fascicle (or hemibundle) and the left posterolateral fascicle.

Purkinje fiber cells have the slowest intrinsic pacemaker rate (20 beats/min or less). Thus, Purkinje fiber cells become functional pacemakers only if the SA and AV pacemakers fail, and are considered tertiary pacemakers. On the other hand, the bundle of His and the Purkinje fibers are an effective conduction system within the ventricles because they conduct action potentials more quickly than any other tissue within the heart (Table 21-4).

TABLE 21-4
Conduction Velocity in Different Cardiac Tissues

TISSUE	CONDUCTION VELOCITY (m/s)
SA node	0.05
Atrial pathways	1
AV node	0.05
Bundle of His	1
Purkinje system	4
Ventricular muscle	1

The action potential of the Purkinje fibers depends on four time- and voltage-dependent membrane currents: I_{Na} (not present in the SA and AV nodal cells), I_{Ca} , I_K , and I_f . The maximum diastolic potential is about -80 mV. From that negative V_m , these cells produce a very slow pacemaker depolarization (phase 4) that depends on I_f . **N21-11** Because of their low rate of pacemaker depolarization and therefore the uncertainty of reaching the threshold for triggering of an action potential, Purkinje fiber cells are unreliable as pacemakers. Normally, the action potential passing through the AV node activates the Purkinje fiber cells, resulting in a rapid upstroke (phase 0), mediated by I_{Na} and I_{Ca} . Because I_{Na} is large, Purkinje fibers conduct action potentials rapidly.

N21-11

Action Potential of the Purkinje Fiber

Contributed by W. Jonathan Lederer

As pointed out in the text, the action potential of the Purkinje fibers depends on four time- and voltage-dependent membrane currents:

- I_{Na} (not present in the SA and AV nodal cells)
- I_{Ca}
- I_K
- I_f

As in ventricular muscle, the maximum diastolic potential of Purkinje fibers (-80 mV) is sufficiently negative that little if any I_{Na} remains active during phase 4 of the action potential (see orange curve in middle panel of Fig. 21-4B for ventricular muscle).

In contrast to the SA and AV nodes, in Purkinje fibers the maximum diastolic potential also is sufficiently negative that little if any I_{Ca} remains active during phase 4 of the action potential (see red curve in lower panel of Fig. 21-4A for the SA node).

Also in contrast to the SA and AV nodal cells, in Purkinje fiber cells I_K deactivates quickly and does not appear to contribute to pacemaker depolarization during phase 4 of the action potential (see green curve in middle panel of Fig. 21-4A for the SA node).

However, at the more negative values of V_m prevailing in Purkinje fiber cells, I_f activates more fully than in SA or AV nodal cells during phase 4 of the action potential (see blue curve in middle panel of Fig. 21-4A for the SA node). The time-dependent activation of I_f produces an inward (i.e., depolarizing) current that underlies the depolarization of pacemaker activity. However, this pacemaking happens at a very low rate, so that the pacemaker activity of the Purkinje cells does not normally determine the “heart rate” of the ventricles.

Normally, the Purkinje fiber cells are activated by the conducted action potential that passes through the AV node. The rapid upstroke (phase 0) is mediated by I_{Na} and I_{Ca} . The rapid repolarization (phase 1) occurs because of the inactivation of I_{Na} and the activation of I_{to} (see Table 21-1 and p. 485). The plateau (phase 2) mainly reflects a small maintained inward current via I_{Na} and I_{Ca} . Finally, the repolarization (phase 3) begins with the activation of I_K .

As is the case for the other pacemaker tissues in the heart, the intrinsic rhythmicity of the Purkinje fibers is the target of therapeutic agents, neurohormones, and physiological changes (e.g., changes in heart rate).

Atrial and ventricular myocytes fire action potentials but do not have pacemaker activity

The resting potential of atrial and ventricular myocytes is substantially more negative (about -80 mV) than the maximum diastolic potential of SA and AV node pacemaker cells (see Fig. 21-1).

Atrial Muscle

Within each atrium, the action potential spreads among cardiac myocytes via a direct cell-to-cell pathway. The atrial action potential depends on three primary time- and voltage-dependent membrane currents: I_{Na} , I_K , and I_{Ca} . There is no normal spontaneous (i.e., pacemaker) activity in atrial muscle. It has been proposed that atrial muscle has four special conducting bundles (see Fig. 21-1). One, **Bachmann's bundle** (anterior interatrial myocardial band), is interatrial and conducts the cardiac action potential from the SA node to the left atrium. Three other internodal pathways—the anterior, middle, and posterior internodal pathways—appear to conduct the action potential from the SA node to the AV node. Therefore, the first step in propagation of the cardiac action potential is the depolarization of the atria, following a general axis from right to left and downward (Fig. 21-5, step 1).

FIGURE 21-5 Sequence of depolarization in cardiac tissue.

If the conduction path through the AV node is blocked, the ventricles will not be activated electrically and will not contract. The spontaneous activity that can arise in the Purkinje fiber cells may provide the necessary electrical signal to activate the ventricles, but this activation occurs normally only at a very low rate, and Purkinje fiber pacemaker activity is fairly unreliable.

Ventricular Muscle

After the action potential reaches the AV node, it travels to the His-Purkinje fiber network and out into the ventricular muscle. The only normal electrical access between atrial muscle and the ventricles is the AV node. Because of this single electrical connection between the atria and the ventricles, there is a well-defined and orderly sequence of electrical activity through the rapidly conducting His-Purkinje network to the ventricles. Within the ventricular muscle, the action potential conducts from cell to cell. Steps 2 to 6 in [Figure 21-5](#) summarize the sequence of events in ventricular activation, which is completed in ~100 ms:

Step 2: The septum depolarizes from left to right.

Step 3: The anteroseptal region depolarizes.

Step 4: The myocardium always depolarizes from the endocardium (the cells lining the ventricles) toward the epicardium (cells on the outer surface of the heart). The left ventricle depolarizes at the apex while the Purkinje fibers are still in the process of conducting the action potential toward the base of the left ventricle.

Step 5: Depolarization spreads from the apex toward the base, carried by the Purkinje fibers. This spread to the base begins even as the signal in the apex is still spreading from the endocardium to the epicardium. The last region to depolarize is the posterobasal region of the left ventricle.

Step 6: The ventricles are fully depolarized.

Ventricular muscle has three major time- and voltage-gated membrane currents: I_{Na} , I_{Ca} , and I_K (see [Fig. 21-4B](#)). Ventricular muscle has no I_f , and healthy ventricular muscle cells show no pacemaker activity. Starting from a resting potential of -80 mV, the rapid upstroke of the ventricular action potential results from the activation of I_{Na} by an external stimulus (e.g., an impulse conducted to the muscle by a Purkinje fiber or by a neighboring ventricular muscle cell). The Ca^{2+} current is of particular importance to ventricular muscle because it provides the Ca^{2+} influx that activates the release of Ca^{2+} from the SR. The rapid repolarization (phase 1), the plateau (phase 2), and the repolarization (phase 3) all appear to be governed by mechanisms similar to those found in the Purkinje fibers. [N21-11](#) However, the plateau phase is prolonged in ventricular muscle because the inward and outward currents are rather stable during that time (green, orange, and red curves in [Fig. 21-4B](#)).

Once a ventricular muscle cell is activated electrically, it is refractory to additional activation. This **effective refractory period** arises because the inward currents (I_{Na} and I_{Ca}) that are responsible for activation are largely inactivated by the membrane depolarization (see [Fig. 21-4B](#)). The effective refractory period is the same as the *absolute* refractory period in nerve and skeletal muscle. During the effective refractory period, an additional electrical stimulus has no effect on the action potential. At the end of the plateau, the cell begins to repolarize as I_K increases in magnitude. As I_{Ca} and I_{Na} begin to recover from inactivation, the **relative refractory period** begins. During this period, an additional

electrical stimulus can produce an action potential, but a smaller one than usual. Refractoriness provides the heart with a measure of electrical safety because it prevents extraneous pacemakers (which may arise pathologically) from triggering **ectopic beats**. An extrasystolic contraction would make the heart a less efficient pump. Refractoriness also prevents tetanus (see p. 241), a feature observed in skeletal muscle. Tetanus of the heart would mean perpetual systole and no further contractions.

Acetylcholine and catecholamines modulate pacemaker activity, conduction velocity, and contractility

In principle, three mechanisms can slow the firing rate of the SA node (i.e., negative chronotropic effect). First, the steepness of the depolarization during phase 4 can decrease, thereby lengthening the time necessary for V_m to reach threshold (Fig. 21-6A, blue curve). In this way, diastole is longer and the heart rate falls. Second, the maximum diastolic potential can become more negative (see Fig. 21-6B, green curve). In this case, V_m starts phase 4 at a more negative potential and thus takes longer to reach threshold, assuming that the steepness of the phase 4 depolarization has not changed. Third, the threshold for the action potential can become more positive (see Fig. 21-6C, purple curve). Assuming no change in either the maximum diastolic potential (i.e., starting point) or the steepness of the phase 4 depolarization, V_m requires a longer time to reach a more positive threshold. Obviously, a combination of these three mechanisms would have an enhanced effect. Conversely, the SA nodal cells can use each of these three mechanisms in the opposite sense to increase their firing rate (positive chronotropic effect).

A DECREASED RATE OF DEPOLARIZATION

B NEGATIVE SHIFT IN MAXIMUM DIASTOLIC POTENTIAL

C POSITIVE SHIFT IN THRESHOLD

FIGURE 21-6 Modulation of pacemaker activity.

Acetylcholine

The vagus nerve, which is parasympathetic (see p. 339), releases acetylcholine (ACh) onto the SA and AV nodes and slows the intrinsic pacemaker activity by all three mechanisms discussed in the preceding paragraph. First, ACh decreases I_f in the SA node (see Table 21-1), reducing the steepness of the phase 4 depolarization (see Fig. 21-6A). Second, ACh opens GIRK channels, increasing relative K^+ conductance

and making the maximum diastolic potential of SA nodal cells more negative (see Fig. 21-6B). Third, ACh reduces I_{Ca} in the SA node, thereby reducing the steepness of the phase 4 depolarization (see Fig. 21-6A) and also moving the threshold to more positive values (see Fig. 21-6C). All three effects cooperate to lengthen the time for the SA node to depolarize to threshold; the net effect is to lower the heart rate.

The effects of ACh on currents in the AV node are similar to its effects on those in the SA node. However, because the pacemaker normally does not reside in the AV node, the physiological effect of ACh on the AV node is to slow **conduction velocity**. The mechanism is an inhibition of I_{Ca} that also makes the threshold more positive for AV nodal cells. Because it is more difficult for one cell to depolarize its neighbors to threshold, conduction velocity falls.  **N21-12**

N21-12

Effect of Acetylcholine on Purkinje Fiber Conduction Velocity

Contributed by W. Jonathan Lederer

As noted in the text, ACh slows conduction in both the SA and AV nodes. Purkinje fibers are the third (and slowest) group of cells in the heart with intrinsic pacemaker activity. Recent reports suggest that ACh also decreases the intrinsic activity of Purkinje fibers, presumably via a reduction of I_f .

Catecholamines

Sympathetic innervation to the heart is plentiful, releasing mostly norepinephrine. In addition, the adrenal medulla releases epinephrine into the circulation. Catecholamines, which act through β_1 -adrenergic receptors, produce an increase in heart rate by two mechanisms. First, catecholamines increase I_f in the nodal cells, thereby increasing the steepness of the phase 4 depolarization (i.e., opposite to the effect in Fig. 21-6A). Second, catecholamines increase I_{Ca} in all myocardial cells. The increase in I_{Ca} in the SA and AV nodal cells steepens the phase 4 depolarization (i.e., opposite to the effect in Fig. 21-6A) and also makes the threshold more negative (i.e., opposite to the effect in Fig. 21-6C). Note that catecholamines do not appear to change the maximum diastolic potential. They do, however, produce shorter action potentials as a result of the actions they have on several specific currents.

In atrial and ventricular muscle, catecholamines cause an increase in the strength of contraction (**positive inotropic effect**) for four reasons. First, the increased I_{Ca} (i.e., Ca^{2+} influx) leads to a greater local increase in $[Ca^{2+}]_i$ and also a greater Ca^{2+} -induced Ca^{2+} release (see pp. 242–243) from the SR. Second, the catecholamines increase the sensitivity of the SR Ca^{2+} -release channel to cytoplasmic Ca^{2+} (see p. 230). Third, catecholamines also enhance Ca pumping into the SR by stimulation of the SERCA Ca pump (see p. 118), thereby increasing Ca^{2+} stores for later release. Fourth, the increased I_{Ca} presents more Ca^{2+} to SERCA, so that SR Ca^{2+} stores increase over time. The four mechanisms make more Ca^{2+} available to troponin C, enabling a more forceful contraction (Box 21-1).

Box 21-1

Vagal Maneuvers

If a patient has an **atrial tachycardia**, such as **atrial flutter** or **atrial fibrillation**, electrical impulses

from the AV node and above may pummel the ventricles and drive them at a very high rate. The ventricular rate may become so high that the effectiveness of the ventricles' pumping is hindered. Because all impulses activating the ventricles must pass through the AV node, use of ACh to slow impulse conduction through the AV node can slow the ventricular rate. Thus, so-called vagal maneuvers, which increase parasympathetic activity, can also decrease ventricular rate. One example is the release from a **Valsalva maneuver**. During a Valsalva maneuver, one makes a forced expiratory effort against a closed airway (e.g., grunting while lifting a heavy object), raising intrathoracic pressure. Subsequently, opening of the airway allows intrathoracic pressure to fall, so that the now-increased transmural pressure stretches the aorta, stimulating the aortic baroreceptors and triggering a reflex activation of the vagus nerve (see p. 534). Alternatively, massage of the bifurcation of the carotid artery in the neck directly stretches the wall of the carotid sinus, thereby stimulating the baroreceptors. Therefore, by either maneuver, the baroreceptor output signals brainstem centers to stimulate the vagus nerve, thereby slowing the heart.

Digitalis compounds (see p. 117) may also be used to treat supraventricular tachycardias because these drugs may increase vagal tone and decrease sympathetic tone, thereby slowing the conduction of atrial impulses through the AV node. Patients with congestive heart failure may have a low baseline vagal tone and a high baseline sympathetic tone. In these patients, digitalis-like drugs increase myocardial contractility (see p. 530) and cardiac output, causing a reflex increase in vagal tone.  **N21-17**

N21-17

How Does Digitalis Increase Vagal Tone?

Contributed by Emile Boulpaep, Walter Boron

The effect of digitalis drugs to increase vagal tone is probably indirect. Digitalis compounds increase myocardial contractility (see p. 530), which increases cardiac output. The resulting increase in effective circulating volume (see pp. 554–555) relieves high-pressure (see pp. 534–536) and low-pressure baroreceptor reflexes (see pp. 546–547), thereby increasing parasympathetic tone and having the opposite effect on sympathetic tone.

The Electrocardiogram

An ECG generally includes five waves

The electrocardiogram (ECG) is the standard clinical tool used to measure the electrical activity of the heart. It is a recording of the small *extracellular* signals produced by the movement of action potentials through cardiac myocytes. To obtain a standard 12-lead ECG, one places two **electrodes** on the upper extremities, two on the lower extremities, and six on standard locations across the chest. In various combinations, the electrodes on the extremities generate the six limb leads (three standard and three augmented), and the chest electrodes produce the six precordial leads. In a **lead**, one electrode is treated as the positive side of a voltmeter and one or more electrodes as the negative side. Therefore, a lead records the fluctuation in voltage difference between positive and negative electrodes. By variation of which electrodes are positive and which are negative, a standard 12-lead ECG is recorded. Each lead looks at the heart from a unique angle and plane; that is, from what is essentially its own unique point of view.

The fluctuations in extracellular voltage recorded by each lead vary from fractions of a millivolt to several millivolts. These fluctuations are called **waves** and are named with the letters of the alphabet (Fig. 21-7). **N21-13** The **P** wave reflects depolarization of the right and left atrial muscle. The **QRS** complex represents depolarization of ventricular muscle. The **T** wave represents repolarization of both ventricles. Finally, the rarely seen **U** wave may reflect repolarization of the papillary muscle. The shape and magnitude of these waves are different in each lead because each lead views the electrical activity of the heart from a unique position in space. For his discovery of the mechanism of the ECG, Willem Einthoven was awarded the 1924 Nobel Prize in Physiology or Medicine. **N21-14**

FIGURE 21-7 Components of the ECG recording.

Nomenclature and Durations of Electrocardiographic Waves

Contributed by Emile Boulpaep, requested by Walter Boron

The various **waves** of the ECG are named P, Q, R, S, T, and U.

- **P wave:** a small, usually positive, deflection before the QRS complex
- **QRS complex:** a group of waves that may include a Q wave, an R wave, and an S wave; note, however, that not every QRS complex consists of all three waves
- **Q wave:** the initial negative wave of the QRS complex
- **R wave:** the first positive wave of the QRS complex, or the single wave if the entire complex is positive
- **S wave:** the negative wave following the R wave
- **QS wave:** the single wave if the entire complex is negative
- **R' wave:** extra positive wave, if the entire complex contains more than two or three deflections
- **S' wave:** extra negative wave, if the entire complex contains more than two or three deflections
- **T wave:** a deflection that occurs after the QRS complex and the following isoelectric segment (i.e., the ST segment that we will define below)
- **U wave:** a small deflection sometimes seen after the T wave (usually of the same sign as the T wave)

In addition to the totally *qualitative* wave designations defined above, cardiologists may use uppercase and lowercase letters as a gauge of the amplitude of Q, R, and S waves.

- **Capital letters Q, R, S** are used for deflections of relatively large amplitude.
- **Lower case letters q, r, s** are used for deflections of relatively small amplitude. For instance: an **rS** complex indicates a small R wave followed by a large S wave.

The various **intervals** are as follows:

- **PR interval:** measured from the beginning of the P wave to the beginning of the QRS complex; normal duration is between 0.12 and 0.2 second (three to five small boxes on the recording)
- **QRS interval:** measured from the beginning to the end of the QRS complex, as defined above; normal duration is <0.12 second
- **QT interval:** measured from the beginning of the QRS complex to the end of the T wave; the QT

interval is an index of the length of the overall ventricular action potential; duration depends on heart rate because the action potential shortens with increased heart rate

- **R-R interval:** the interval between two consecutive QRS complexes; duration is equal to the duration of the cardiac cycle
- **ST segment:** from the end of the QRS complex to the beginning of the T wave

Willem Einthoven

For more information about Willem Einthoven and the work that led to his Nobel Prize, visit <http://www.nobel.se/medicine/laureates/1924/index.html> (accessed March 2015).

Because the ECG machine uses electrodes attached to the skin to measure the sum of the heart's electrical activity, it requires special amplifiers. The ECG machine also has electrical filters that reduce the electrical noise. Moving the limbs, breathing, coughing, shivering, and faulty contact between the skin and an electrode produce artifacts on the recorded ECG.

Because the movement of charge (i.e., the spreading wave of electrical activity in the heart) has both a three-dimensional **direction** and a **magnitude**, the signal measured on an ECG is a **vector**. The system that clinicians use to measure the heart's three-dimensional, time-dependent electrical vector is simple to understand and easy to implement, but it can be challenging to interpret.

A pair of ECG electrodes defines a lead

To record the complicated time-dependent electrical vector of the heart, the physician or ECG technician constructs a system of leads in two planes that are perpendicular to each other. One plane, the **frontal plane**, is defined by the six **limb leads** (Fig. 21-8A). A perpendicular **transverse plane** is defined by the six **precordial leads** (see Fig. 21-8B). Each lead is an axis in one of the two planes, onto which the heart projects its electrical activity. The ECG recording from a single lead shows how that lead views the time-dependent changes in voltage of the heart.

A FRONTAL PLANE LEADS

B TRANSVERSE PLANE-PRECARDIAL LEADS

FIGURE 21-8 The ECG leads.

Older ECG machines recorded data from the 12 leads one at a time, sequentially. Thus, relatively rare events captured by the recording in one lead might not be reflected in any of the others, which were obtained at different times. Modern ECG machines record from leads synchronously in groups of 3 or 12. Because the real electrical vector of the heart consists of just one time-dependent vector signal, you might think that a three-lead recording would suffice to localize the vector signal in space. In principle, this is true: only two leads in one plane and one lead in another plane are needed to fully define the original electrical vector of the heart at all moments. However, recording from all 12 leads is extremely useful because a signal of interest may be easier to see in one lead than in another. For example, an acute myocardial infarction involving the inferior (diaphragmatic) portion of the heart might be easily visualized in leads II, III, and aVF but go completely undetected (or produce so-called reciprocal changes) in the other leads.

The Limb Leads

One obtains a 12-lead ECG by having the patient relax in a supine position and connecting four electrodes to the limbs (see [Fig. 21-8A](#)). Electrically, the torso and limbs are viewed as an equilateral triangle (Einthoven's triangle) with one vertex on the groin and the other two on the shoulder joints ([Fig. 21-9A](#)). Because the body is an electrical “volume conductor,” an electrical attachment to an arm is electrically equivalent to a connection at the shoulder joint, and an attachment to either leg is equivalent to a connection at the groin. By convention, the left leg represents the groin. The fourth electrode, connected to the right leg, is used for electrical grounding. The three initial limb leads represent the difference between two of the limb electrodes:

- **I** (positive connection to left arm, negative connection to right arm). This lead defines an axis in the frontal plane at 0 degrees (see [Fig. 21-9A, B](#)).
- **II** (positive to left leg, negative to right arm). This lead defines an axis in the frontal plane at 60 degrees.
- **III** (positive to left leg, negative to left arm). This lead defines an axis in the frontal plane at 120 degrees.

A EINTHOVEN'S TRIANGLE

B CIRCLE OF AXES

FIGURE 21-9 Axes of the limb leads. **A**, The frontal plane limb leads behave as if they are located at the shoulders (RA [right arm] and LA [left arm]) and groin (LL [left leg]). Leads I, II, and III are separated from one another by 60 degrees. The augmented leads, referenced to the center of the heart, bisect each of the 60-degree angles formed by leads I, II, and III. **B**, Translating each of the six frontal leads so that they pass through a common point defines a polar coordinate system, providing views of the heart at 30-degree intervals.

An electronic reconstruction of the three-limb connection defines an electrical reference point in the middle of the heart (see Fig. 21-9A) that constitutes the negative connection for the augmented “unipolar” limb leads and for the chest leads. The three augmented unipolar limb leads compare one limb electrode to the average of the other two:

- **aVR** (positive connection to *right* arm, negative connection is electronically defined in the middle of the heart): The axis defined by this limb lead in the frontal plane is -150 degrees (see Fig. 21-9B). The *a* stands for augmented, and the *V* represents unipolar.
- **aVL** (positive to *left* arm, negative is middle of the heart): The axis defined by this limb lead in the frontal plane is -30 degrees.
- **aVF** (positive to left leg [*foot*], negative is middle of the heart): The axis defined by this limb lead in the frontal plane is +90 degrees.

Thus, the positive and negative ends of these six leads define axes every 30 degrees in the frontal plane (see Fig. 21-9B).

The Precordial Leads

The precordial leads lie in the transverse plane, perpendicular to the plane of the frontal leads. The positive connection is one of six different locations on the chest wall (see Fig. 21-8B), and the negative connection is electronically defined in the middle of the heart by averaging of the three limb electrodes. The resultant leads are named V_1 to V_6 , where the *V* stands for unipolar:

- **V_1** : fourth intercostal space to the right of the sternum
- **V_2** : fourth intercostal space to the left of the sternum
- **V_4** : fifth intercostal space at the midclavicular line

- V_3 : halfway between V_2 and V_4
- V_6 : fifth intercostal space at the midaxillary line
- V_5 : halfway between V_4 and V_6

It is also possible, on rare occasions, to generate **special leads** by employing the same negative connection used for the unipolar limb and precordial leads and a positive “probe” connection. Special leads that are used include esophageal leads and an intracardiac lead (e.g., that used to obtain a recording from the His bundle).

A simple two-cell model can explain how a simple ECG can arise

We can illustrate how the ECG arises from the propagation of action potentials through the functional syncytium of myocytes by examining the electrical activity in two neighboring cardiac cells, A and B, connected by gap junctions (Fig. 21-10A). The depolarization and action potential begin first in cell A (V_A in Fig. 21-10A, green record). The current from cell A then depolarizes cell B through the gap junctions and a brief time later triggers an action potential in cell B (V_B). If we subtract the V_B record from the V_A record, we obtain a record of the intracellular voltage *difference* $V_A - V_B$ (see Fig. 21-10B).

A ACTION POTENTIALS OF TWO SEPARATE CELLS

Two intracellular electrodes record normal action potentials displaced in time.

B SUBTRACTED ACTION POTENTIALS

Subtracted intracellular voltage records show the equivalent of a QRS complex and T wave.

C DEPOLARIZATION MOVING TOWARD POSITIVE ELECTRODE

Extracellular voltage recorded with wave moving toward positive electrode.

D DEPOLARIZATION MOVING PERPENDICULAR TO ELECTRODE AXIS

Extracellular voltage recorded with wave moving perpendicular to axis of electrodes.

E DEPOLARIZATION MOVING AWAY FROM POSITIVE ELECTRODE

Extracellular voltage recorded with wave moving away from positive electrode.

FIGURE 21-10 Two-cell model of the ECG.

We have already seen that according to Ohm's law (see [Equation 21-1](#)), the *intracellular* current from cell A to cell B (I_{AB}) is proportional to $(V_A - V_B)$. The *extracellular* current flowing from the region of cell B to the region of cell A is equal but opposite in direction to the intracellular current flowing from cell A to cell B. Imagine that an extracellular voltmeter has its negative electrode placed to the left of cell A and its positive electrode to the right of cell B (forming a lead with an axis of 0 degrees). During the upswing in the action potential of cell A, while cell B is still at rest, $(V_A - V_B)$ and I_{AB} are both positive, and the voltmeter detects a *positive* difference in voltage (see [Fig. 21-10C](#))—analogous to the QRS complex in a real ECG. Later, during the recovery from the action potential in cell A, while cell B is still depolarized, $(V_A - V_B)$ and I_{AB} are both negative, and the voltmeter would detect a *negative* difference in voltage. From the extracellular voltage difference in [Figure 21-10C](#), we can conclude that when the wave

of depolarization moves *toward* the positive lead, there is a positive deflection in the *extracellular* voltage difference.

If we place the two electrodes at the junction between the two cells, with the positive connection on the bottom and the negative connection on the top, we create a lead with an axis of 90 degrees to the direction of current flow (see [Fig. 21-10D](#)). Under these conditions, we observe no voltage difference because both extracellular electrodes sense the same voltage at each instant in time. Thus, when a lead is perpendicular to the wave of depolarization, the measured deflection on that lead is **isoelectric**.

If we put our extracellular electrodes in yet a third configuration—with the positive electrode on the left and the negative electrode on the right—we observe a *negative* deflection during the depolarization of cell A because the wave of depolarization is moving *away from* the positive electrode (see [Fig. 21-10E](#)).

This simple two-cell model demonstrates that the wave of depolarization behaves like a vector, with both magnitude and direction. Two practical methods to determine the direction (or axis) of the vector are presented in [Box 21-2](#).

Box 21-2

Basic Interpretation of the Electrocardiogram

An ECG provides a direct measurement of the rate, rhythm, and time-dependent electrical vector of the heart. It also provides fundamental information about the origin and conduction of the cardiac action potential within the heart. Because the different parts of the heart activate sequentially, we can attribute the time-dependent changes in the electrical vector of the heart to different regions of the heart. The P wave reflects the atrial depolarization. The QRS complex corresponds to ventricular depolarization. The T wave reflects ventricular repolarization.

ECG paper has a grid of small 1-mm square boxes and larger 5-mm square boxes. The vertical axis is calibrated at 0.1 mV/mm; the horizontal (time) axis, at 0.04 s/mm (small box) or 0.2 s/5 mm (large box). Thus, five large boxes correspond to 1.0 second ([Fig. 21-11](#)). [Table 21-5](#) summarizes the steps for interpretation of an ECG.

FIGURE 21-11 Normal 12-lead ECG recording. The recordings were obtained synchronously, three leads at a time (I, II, and III simultaneously; aVR, aVL, and aVF simultaneously; V₁, V₂, and V₃ simultaneously; and V₄, V₅, and V₆ simultaneously). A 1-mV, 200-ms calibration pulse is visible on the left of each of the three recordings in the top left panel. The leads are marked on the traces. (We thank the Division of Cardiology, University of Maryland School of Medicine, for obtaining this ECG recording from the author.)

TABLE 21-5

Eightfold Approach for Reading an Electrocardiogram

1	Search for P waves.
2	Determine the relationship of P waves and QRS complexes.
3	Identify the pacemaker.
4	Measure the heart rates from different waves (e.g., P-P interval, R-R interval).
5	Characterize the QRS shape (i.e., narrow versus wide).
6	Examine features of the ST segment.
7	Estimate the mean QRS axis (and the axes of the other waves of interest).
8	Examine the cardiac rhythm (e.g., look at a 20- to 30-s ECG record from lead II).

Rate

We can measure rate in two ways. The direct method is to measure the number of seconds between waves of the same type, for example, the R-R interval. The quotient of 60 divided by the interval in seconds is the heart rate in beats per minute.

A quick alternative method is quite popular (Table 21-6). Measure the number of large boxes that form the R-R interval and remember the series 300, 150, 100, 75, 60, 50—which corresponds to an interval of one, two, three, four, five, or six large boxes. Thus, rate = 300/(number of large boxes). For example, if four large boxes separate the R waves, the heart rate is 75 beats/min.

TABLE 21-6
Determination of Heart Rate from the Electrocardiogram

R-R INTERVAL (in number of large boxes of 0.2 s)	CALCULATION	HEART RATE (beats/min)
1	300/1	300
2	300/2	150
3	300/3	100
4	300/4	75
5	300/5	60
6	300/6	50

Rhythm

The determination of rhythm is more complex. One must answer the following questions: Where is the heart's pacemaker? What is the conduction path from the pacemaker to the last cell in the ventricles? Is the pacemaker functioning regularly and at the correct speed? The normal pacemaker is the SA node; the signal then propagates through the AV node and activates the ventricles. When the heart follows this pathway at a normal rate and in this sequence, the rhythm is called a normal sinus rhythm. **N21-18**

Careful examination of the intervals, durations, and segments in the ECG tracing can reveal a great deal about the conducted action potential (see Fig. 21-7). The **P-wave** duration indicates how long atrial depolarization takes. The **PR interval** indicates how long it takes the action potential to conduct through the AV node before activating the ventricles. The **QRS duration** reveals how long it takes for the wave of depolarization to spread throughout the ventricles. The **QT interval** indicates how long the ventricles remain depolarized and is thus a rough measure of the duration of the overall “ventricular” action potential. The QT segment gets shorter as the heart rate increases, which reflects the shorter action potentials that are observed at high rates. In addition, many other alterations in these waves—and the segments separating them—reflect important physiological and pathophysiological changes in the heart.

Vector (or Axis) of a Wave in the Frontal Plane

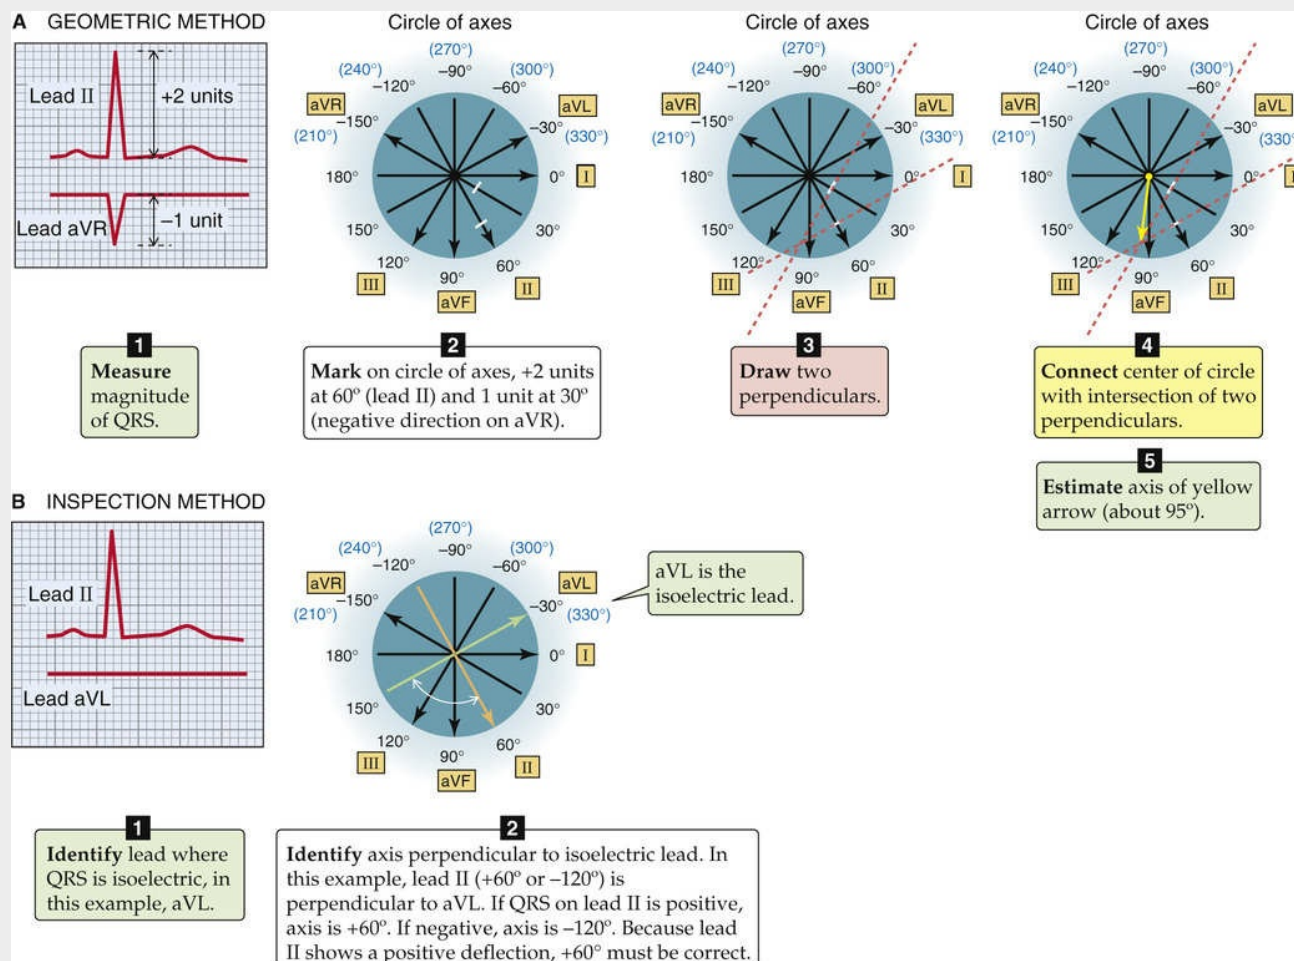

Determination of the vector of current flow through the heart is not just an intellectual exercise but can be of great clinical importance. The normal axis of ventricular depolarization in the frontal plane lies between -30 and +90 degrees. However, this axis can change in a number of pathological situations, including hypertrophy of one or both ventricular walls (a common sequela of severe or prolonged hypertension) and conduction blocks in one or several of the ventricular conducting pathways.

We can use two approaches to measure the axis of a wave within the frontal plane (i.e., with use of limb leads). The first is more accurate but the second is quicker and easier and is usually sufficient for clinical purposes.

The first approach is a **geometric method**. It uses our knowledge of the axes of the different leads and the measured magnitude of the wave projected onto at least two leads in the frontal plane. It involves five

steps:

Step 1: Measure the height of the wave on the ECG records in two leads, using any arbitrary unit (e.g., number of boxes). A *positive deflection* is one that rises above the baseline, and a *negative deflection* is one that falls below the baseline. In the example in Figure 21-12A, we are estimating the axis of the R wave of the QRS complex. The R wave is +2 units in lead II and -1 unit in lead aVR.

Step 2: Mark the height of the measured deflections on the corresponding lead lines on a circle of axes. Any unit of measure will suffice, as long as you use the same unit for both markings. Starting at the center of the circle, mark a *positive deflection* toward the *arrowhead* and a *negative deflection* toward the *tail of the arrow*.

Step 3: Draw lines perpendicular to the lead axes through each of your two marks.

Step 4: Connect the center of the circle of axes (tail of the vector) to the intersection of the two perpendicular lines (head of the vector). In our example, the intersection is close to the aVF axis.

Step 5: Estimate the axis of the vector that corresponds to the R wave, using the “angle” scale of the circle of axes. In this case, the vector is at about 95 degrees, just clockwise to the aVF lead (i.e., 90 degrees).

The second approach is a qualitative **inspection method**. It exploits the varying magnitudes of the wave of interest in recordings from different leads. When the wave is isoelectric (i.e., no deflection, or equal positive and negative deflections), then the electrical vector responsible for that projection must be perpendicular to the isoelectric lead, as we already saw for the two-cell model in Figure 21-10D. The inspection approach requires two steps:

Step 1: Identify a lead in which the wave of interest is isoelectric (or nearly isoelectric). In the example in Figure 21-12B, the QRS complex is isoelectric in aVL (−30 degrees). The vector must be perpendicular (or nearly perpendicular) to that lead (i.e., aVL). In our example, the vector must point 90 degrees from −30 degrees and therefore is at either +60 degrees or −120 degrees. Because the leads in the frontal plane define axes every 30 degrees, every lead has another lead to which it is perpendicular.

Step 2: Identify a lead in which the wave is largely positive. In Figure 21-12B, this would be lead II. The vector must lie roughly in the same direction as the orientation of that lead. Because lead II is at +60 degrees, the axis of the vector of the QRS wave must be about +60 degrees and not −120 degrees.

If the wave of interest is not isoelectric in any lead, then find two leads onto which the projections are of similar magnitude and sign. The vector has an axis halfway between those two leads.

N21-18

Electrocardiographic Rhythm Strip

Contributed by W. Jonathan Lederer

Determining the cardiac “rhythm,” as discussed in Box 21-2, requires observation over a longer time interval than that used to obtain the ECG traces shown in Figure 21-11. The rhythm strip in eFigure 21-2 shows leads V₁, II, and V₅ obtained simultaneously for an extended period.

EFigure 21-2 ECG strip for assessment of heart rhythm. (We thank the Division of Cardiology, University of Maryland School of Medicine, for obtaining this ECG recording from the author.)

The QRS equivalent in the extracellular voltage record of our simplistic two-cell analysis is due to a spreading wave of *depolarization*. The T-wave equivalent is negative compared with the QRS

equivalent, and it reflects the wave of *repolarization*. If cell A has an action potential that is much longer than that of cell B (so that positive current again propagates from A to B after the action potential in B is completed), then the T-wave equivalent will be upright, as it is in most ECGs. Thus, on average, the ventricular myocytes that depolarize last are the first to repolarize. In other words, the B cells have shorter action potentials than the A cells.

What happened to the P wave that we see in a real ECG? The P wave reflects the depolarization of the *atrial* myocytes. In our model, we could represent the P wave by introducing a second pair of myocytes (i.e., the atrial cells) and allowing them to fire their action potentials much earlier than the two ventricular myocytes.

Cardiac Arrhythmias

Any change in cardiac rhythm from the normal sinus rhythm is defined as an **arrhythmia**. Although some arrhythmias are pathological and even life-threatening, others are normal and appropriately adaptive, including sinus tachycardia and sinus arrhythmia.

Sinus tachycardia is a heart rate faster than normal, driven by the sinus node. This arrhythmia is seen in frightened or startled individuals or during normal exercise. Rarely, sinus tachycardia can be pathological—for example, in patients with acute hyperthyroidism (see pp. [1011–1013](#)).

Sinus arrhythmia is the name given to a normal phenomenon: a subtle change in heart rate that occurs with each respiratory cycle. Inspiration accelerates the heart rate (see pp. [547–548](#)); expiration slows it. Deepening of the respirations exaggerates these cyclic changes. The magnitude of the effect can vary significantly among individuals. The heart rate is still under the control of the SA node, but cyclic variations in sympathetic and parasympathetic tone modulate the SA node's pacemaker rate. The loss of sinus arrhythmia can be a sign of autonomic system dysfunction, as may be seen in patients with diabetes.

Although the list of pathological arrhythmias is long, two basic problems are responsible for nearly all arrhythmias: altered conduction and altered automaticity ([Box 21-3](#)).

Box 21-3

Myocardial Infarction

An acute myocardial infarction, or heart attack, begins with the occlusion of a coronary artery. The region of myocardium subserved by that coronary artery is deprived of oxygen and will die unless blood flow resumes shortly. During the initial stages, the myocardial cells are electrically active but their function is impaired, which produces characteristic changes in the ECG. Complete but transient blockade of blood flow to the myocardium—even though it does not lead to cell death—may result in a pattern of ECG changes similar to that seen during the acute phase of myocardial infarction. Because blood flow is regional, the areas of infarction are also regional. Thus, the physician can best observe the changes in electrical activity by examining the specific ECG leads that provide the best view of the involved region of myocardium.

The first electrical change associated with an acute myocardial infarction is **peaking of the T waves**, followed soon after by **T-wave inversion**. These T-wave changes are not specific for infarction and are reversible if blood flow is restored.

The next change, and one that is more characteristic of an acute myocardial infarction, is **elevation of the ST segment**. This change occurs because the myocytes closest to the epicardium become depolarized by the cellular anoxic injury, but they are still electrically coupled. Returning to the two-cell model (Fig. 21-13A), consider the cell on the left (cell A) to be normal and the cell on the right (cell B) to be damaged. Figure 21-13B shows the extracellular current, which is proportional to the differences in the action potentials of the two cells shown in Figure 21-13A. Because cell B has a more positive resting potential than cell A but the same plateau during the action potential, the difference in voltage between cell A and cell B is depressed everywhere but at the ST segment—which makes the ST segment appear elevated. This is also the ECG change that one views with an acute myocardial infarction.

FIGURE 21-13 Two-cell model of a myocardial infarction. **A**, The damaged cell B (blue record) has a lower resting potential, but the plateau of its action potential is at the same level as that of the normal cell A (green record). **B**, After the records in **A** are subtracted, the apparent elevation of the ST segment is the same as the difference in resting potentials; the TP and PR regions are actually depressed.

Brief periods of **coronary artery spasm** can also produce ST elevation, presumably by the same mechanism. Rapid reperfusion of coronary arteries after acute blockage may lead to rapid and complete recovery of the myocardial cells, as indicated by the evanescent nature of the ECG changes.

Ischemia without cell death due to a fixed degree of occlusion (e.g., that caused by a thrombus or atherosclerosis) is often associated with changes in the ECG, typically ST-segment and T-wave changes. However, these changes are quite variable, presumably brought about by altered action potential duration in the affected regions. Patients experiencing exertional chest pain (angina) due to diminished coronary blood flow frequently have ECG changes during the anginal episode that include **ST-segment depression** and T-wave inversion.

With irreversible cell death, the ECG typically shows the evolution of **deep Q waves** (a large negative deflection at the beginning of the QRS complex). Q waves develop only in those leads overlying or near the region of the infarction. The Q waves indicate an area of myocardium that has become electrically silent. Because action potentials cannot propagate into the infarcted area, the net vector of the remaining areas of ventricular depolarization—by default—points *away* from this area. The result is a deep *negative* deflection on the ECG in the appropriate leads. Thus, an inferior wall infarction inscribes deep Q waves in leads II, III, and aVF. An infarction affecting the large muscular anterior wall of the heart will inscribe deep Q waves in some of the precordial leads (V_1 through V_6).

Not all infarctions create deep Q waves; the only visible changes may be T-wave inversion and ST-segment depression. Clinically, these infarctions behave like incomplete infarctions, and patients are at risk of a second, completing event. Therefore, these patients are investigated and treated aggressively to prevent further infarction.

Conduction abnormalities are a major cause of arrhythmias

Disturbances of conduction make up the first major category of cardiac arrhythmias. Conduction disturbances can have multiple causes and can occur at any point in the conduction pathway. Conduction disturbances can be partial or complete. The two major causes of conduction disturbances are depolarization and abnormal anatomy.

If a tissue is injured (e.g., by stretch or anoxia), an altered balance of ionic currents can lead to a **depolarization**. The depolarization, in turn, partially inactivates I_{Na} and I_{Ca} , slowing the spread of current (i.e., slowing conduction). As a result, the tissue may become less excitable (partial conduction block) or completely inexcitable (complete conduction block).

Another type of conduction disturbance is the presence of an aberrant conduction pathway, reflecting **abnormal anatomy**. One such example is an accessory conduction pathway that rapidly transmits the action potential from the atria to the ventricles, bypassing the AV node, which normally imposes a conduction delay. Patients with the common Wolff-Parkinson-White syndrome have a bypass pathway called the bundle of Kent. The existence of a second pathway between the atria and ventricles predisposes affected individuals to supraventricular arrhythmias (see pp. [504–505](#)).

Partial (or Incomplete) Conduction Block

Three major types of partial conduction block exist: slowed conduction, intermittent block, and unidirectional block. We defer the discussion of unidirectional block until we consider re-entry phenomena.

In **slowed conduction**, the tissue conducts all the impulses, but more slowly than normal. **First-degree AV block** reflects a *slowing* of conduction through the AV node. On an ECG, first-degree AV block appears as an unusually long PR interval (compare A and B in [Fig. 21-14](#)).

A—NORMAL SINUS RHYTHM**B—FIRST-DEGREE BLOCK****C—SECOND-DEGREE BLOCK: MOBITZ TYPE I****D—SECOND-DEGREE BLOCK: MOBITZ TYPE II****E—BUNDLE BRANCH BLOCKS****F—THIRD-DEGREE BLOCK****G—DELTA WAVE (WOLFF-PARKINSON-WHITE SYNDROME)****H—ATRIAL FIBRILLATION****I—VENTRICULAR FIBRILLATION**

FIGURE 21-14 Pathological ECGs. In **E**, right bundle branch block is visible in the V₁ or V₂ precordial leads; left bundle branch block is visible in the V₅ or V₆ leads. (Modified from Chernoff HM: Workbook in Clinical Electrocardiography. New York, Medcom, 1972.)

A second example of partial conduction block is **intermittent block**, in which the tissue conducts some impulses but not others. In the AV node, intermittent block leads to **second-degree AV block**, of which there are two types. Both reflect incomplete (i.e., intermittent) coupling of the atria to the ventricles. In a **Mobitz type I block** (or Wenckebach block), the PR interval gradually lengthens from one cycle to the next until the AV node fails completely, skipping a ventricular depolarization (see Fig. 21-14C). With Mobitz type I block, it is most common to see every third or fourth atrial beat fail to conduct to the

ventricles. In a **Mobitz type II block**, the PR interval is constant from beat to beat, but every n th ventricular depolarization is missing. In [Figure 21-14D](#), the first cardiac cycle is normal. However, the second P wave is not followed by a QRS or T. Instead, the ECG record is flat until the third P wave arrives at the expected time, followed by a QRS and a T. Thus, we say that every second QRS is dropped (2:1 block).

Another form of intermittent conduction block, called **rate-dependent block**, reflects disease often seen in the large branches of the His-Purkinje fiber system (i.e., the bundle branches). When the heart rate exceeds a critical level, the ventricular conduction system fails, presumably because a part of the conducting system lacks sufficient time to repolarize. With intermittent failure of the His-Purkinje fiber system, the impulse is left to spread slowly and inefficiently through the ventricles by conducting from one myocyte to the next. Such a failure, whether intermittent or continuous, is known as a **bundle branch block** and appears on the ECG as an intermittently wide QRS complex (see [Fig. 21-14E](#)). Because this block impairs the coordinated spread of the action potential throughout the ventricles, the resulting contraction loses some efficiency.

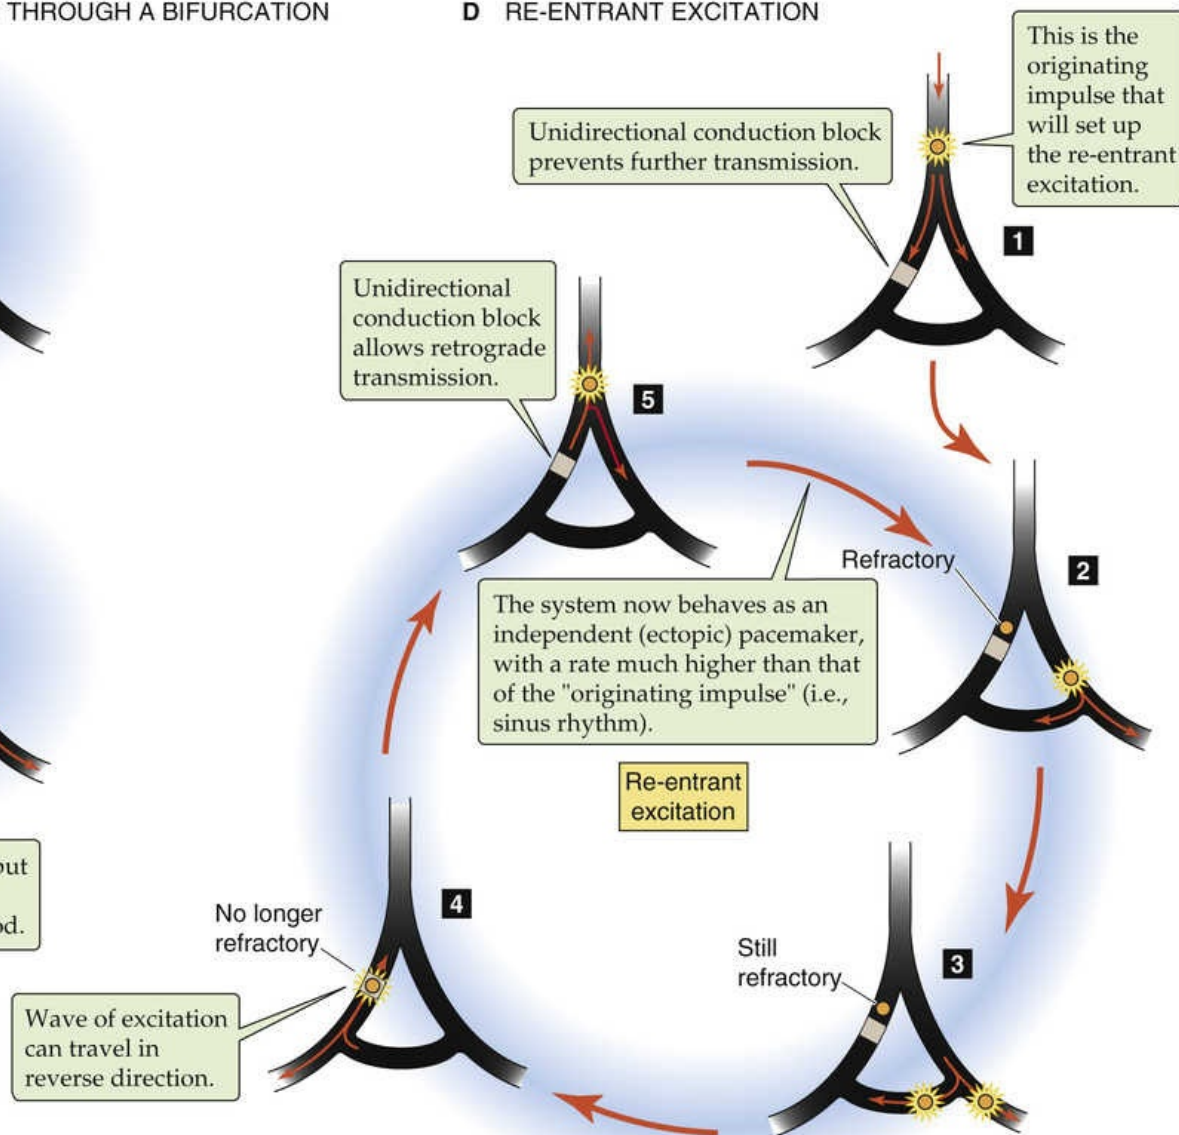

Complete Conduction Block

In complete block, or **third-degree AV block**, no impulses conduct through the affected area, in either direction. For example, **complete block** at the AV node stops any supraventricular electrical impulse from triggering a ventricular contraction. Thus, AV nodal block electrically severs the atria and ventricles, each of which beats under control of its own pacemakers. This situation is called **AV dissociation**. The only ventricular pacemakers that are available to initiate cardiac contraction are the Purkinje fiber cells, which are notoriously unreliable and slow. Thus, cardiac output may fall, and blood pressure along with it. AV dissociation can therefore constitute a medical emergency, and placement of an artificial ventricular pacemaker can prove lifesaving. On an ECG, complete block appears as regularly spaced P waves (i.e., the SA node properly triggers the atria) and as irregularly spaced QRS and T waves that have a low frequency and no fixed relationship to the P waves (see [Fig. 21-14F](#)).

Re-Entry

An independent focus of pacemaker activity can develop as a consequence of a conduction disturbance. This class of conduction disturbance is called re-entry (or re-entrant excitation or circus movement). It is one of the major causes of clinical arrhythmias. It occurs when a wave of depolarization travels in an apparently endless circle. Re-entry has three requirements: (1) a closed conduction loop, (2) a region of unidirectional block (at least briefly), and (3) a sufficiently slow conduction of action potentials around the loop.

Before further considering re-entry, we need to discuss a conduction defect that is essential for re-entry—unidirectional block. **Unidirectional block** is a type of partial conduction block in which impulses travel in one direction but not in the opposite one. Unidirectional block may arise as a result of a local depolarization or may be due to pathological changes in functional anatomy. Normal cardiac tissue can conduct impulses in both directions ([Fig. 21-15A](#)). However, after an asymmetric anatomical lesion develops, many more healthy cells may remain on one side of the lesion than on the other. When conduction proceeds in the direction from the many healthy cells to the few healthy cells, the current from the many may be sufficient to excite the few (right to left in [Fig. 21-15B](#)). On the other hand, when conduction proceeds in the opposite direction, the few healthy cells cannot generate enough current to excite the region of many healthy cells (left to right in [Fig. 21-15B](#)). The result is a unidirectional block.

A NORMAL CONDUCTION IN BOTH DIRECTIONS**B UNIDIRECTIONAL BLOCK****C NORMAL CONDUCTION THROUGH A BIFURCATION****D RE-ENTRANT EXCITATION****FIGURE 21-15** Abnormal conduction.

We return now to the problem of re-entry. Imagine that an impulse is traveling down a bifurcating Purkinje fiber and is about to reach a group of ventricular myocytes—a *closed conduction loop* (see Fig. 21-15C). However, the refractory zones prevent the re-entry of impulses from the right to the left, and vice versa. We now introduce a lesion that causes a *unidirectional conduction block* in the left branch of the Purkinje fiber. When the impulse reaches the fork in the road, it spreads in both directions (see Fig. 21-15D, step 1). However, the impulse cannot continue past the unidirectional block in the left branch. The impulse traveling down the right branch stimulates the distal conducting cells (see Fig. 21-15D, step 2), leaving them in an effective refractory period (see p. 491). When the impulse reaches the ventricular

muscle, it begins to travel back toward the damaged left branch (step 3). At this point, the cells in the normal right branch may still be refractory to excitation. The impulse finally reaches the damaged left branch and travels in a retrograde fashion up this branch, reaching and passing through the region of the unidirectional conduction block (step 4). Finally, the impulse again reaches the bifurcation (step 5). Because enough time has elapsed for the cells at the bifurcation as well as in the right branch to recover from their refractory period, the impulse can now travel retrograde up the main part of the Purkinje fiber as well as orthograde down the right branch—for a second time.

If this re-entrant movement (steps 2 → 5 → 2, and so on) continues, the frequency of re-entry will generally outpace the SA nodal pacemaker (frequency of step 1) and is often responsible for diverse tachyarrhythmias because the fastest pacemaker sets the heart rate. Re-entry excitation may be responsible for atrial and ventricular tachycardia, atrial and ventricular fibrillation, and many other arrhythmias. Re-entry can occur in big loops (see [Fig. 21-15D](#)) or in small loops consisting entirely of myocardial cells.

Accessory Conduction Pathways

Wolff-Parkinson-White (WPW) syndrome, briefly mentioned above (see pp. [501–502](#)), is a common example of an accessory conduction pathway, which in this case provides a short circuit (i.e., bundle of Kent) around the delay in the AV node. The fast accessory pathway is composed not of Purkinje fibers but instead of muscle cells. It conducts the action potential directly from the atria to the ventricular septum, depolarizing some of the septal muscle earlier than if the depolarization had reached it via the normal, slower AV nodal pathway. As a result, ventricular depolarization is more spread out in time than is normal, giving rise to a broader-than-normal QRS complex. The general direction of ventricular depolarization is reversed, so that the events normally underlying the Q wave of the QRS complex have an axis opposite to that normally seen. This early depolarization, or **pre-excitation**, appears as a small, positive **delta wave** at the beginning of the QRS complex (see [Fig. 21-14G](#)). In addition, because the time between atrial depolarization and ventricular depolarization (i.e., beginning of delta wave) is shortened, the interval between the P wave and the QRS complex is shortened.

The aberrant conduction pathway in WPW syndrome also establishes a loop that may meet the requirements for re-entry and may therefore be associated with a **supraventricular tachycardia**. Although in general a benign condition, WPW syndrome is associated with at least one attack of supraventricular tachycardia in at least 50% of affected individuals. The two most common supraventricular tachycardias seen in this population are paroxysmal supraventricular tachycardia and atrial fibrillation (described below). **Paroxysmal supraventricular tachycardia (PSVT)** is a regular tachycardia with a ventricular rate usually exceeding 150 beats/min. Because ventricular depolarization still occurs via the normal conducting pathways, the QRS complex appears normal.

If, during an episode of PSVT, the conduction direction for re-entry is in the reverse direction (i.e., down the accessory pathway and back up through the AV node), the QRS shape may be unusual. This arrangement may produce a PSVT with wide and bizarre QRS complexes because ventricular depolarization does not occur along the normal bundle branches. A small number of people with WPW syndrome have more than one accessory pathway, so that multiple re-entry loops are possible.

Fibrillation

In fibrillation, many regions of re-entrant electrical activity are present, creating electrical chaos that is not associated with useful contraction. **Atrial fibrillation**  [N21-15](#) (see [Fig. 21-14H](#)) is commonly found in elderly patients, sometimes with mitral valve or coronary artery disease, but often without any

evidence of underlying cardiac disease. The re-entry loop within the atria moves wildly and rapidly, generating a rapid succession of action potentials—as many as 500 per minute. This wandering re-entry circuit easily becomes the fastest pacemaker in the heart, outpacing the SA node and bombarding the AV node. Fortunately, the AV node cannot repolarize fast enough to pass along all of these impulses. Only some make it through to the ventricles, resulting in the irregular appearance of QRS complexes without any detectable P waves. The baseline between QRS complexes may appear straight or may show small, rapid fluctuations. Although only some atrial impulses reach the ventricles, the ventricular rate can still be quite high.

N21-15

Atrial Fibrillation

Contributed by W. Jonathan Lederer

Atrial fibrillation (AF) is the most common cardiac arrhythmia. It frequently presents with modest or no symptoms and may be diagnosed on a routine ECG when no clear P wave can be identified on the ECG and the QRS complex occurs at “irregularly irregular” intervals. Compared to ventricular fibrillation with its extreme and rapid lethality, AF has more modest pathology. It is an arrhythmia that depends on altered cellular electrical properties, on tissue organization problems (e.g., fibrosis), and on diverse background issues (e.g., increased blood pressure, increased vascular volume, duration of the fibrillation). Cardioversion works best only when applied early in the course of the disease and often yields only a short-term improvement. Because AF is frequently found in the context of much atrial fibrosis and widespread electrical re-entry sites in both atria, invasive structural changes in the atrial conduction pathways may be beneficial. Conceptually these procedures seek to prevent the electrical activity from multiple re-entry sites from impinging on the AV node. Introducing atrial scars to block conduction out of re-entry regions can help. These are frequently referred to as “maze” ablations and involve procedures such as controlled freezing or radiofrequency destruction in a complex maze pattern in the affected regions of the atria. There is often a Ca^{2+} -dependent component of AF, and therapeutic drugs are often used to mitigate this Ca^{2+} -dependent component.

Because the atria function mainly as a booster pump (see p. 508), many patients tolerate atrial fibrillation without harm and may even be unaware that they have it. Others may suffer greatly from the loss of a coordinated atrial contraction, particularly the elderly or those with coexisting cardiac disease. In most individuals, attempts should be made to convert the rhythm back to normal sinus rhythm if possible, by either electrical or chemical means. If this is not possible, then attempts can be made to at least slow conduction through the AV node. For example, digitalis compounds increase parasympathetic and decrease sympathetic stimulation to the AV node, decreasing the speed of AV conduction and thus reducing the ventricular rate (see p. 493). β -adrenergic blockers or Ca^{2+} channel blockers are also used to control ventricular rate.

Ventricular fibrillation (see Fig. 21-14I) is a life-threatening medical emergency. The heart cannot generate cardiac output because the ventricles are not able to pump blood without a coordinated ventricular depolarization.

Altered automaticity can originate from the sinus node or

from an ectopic locus

The automaticity of any cardiac tissue can change. Pacemaker cells can experience an alteration in or even a complete absence of automaticity. Conversely, other cells that normally have no automaticity (e.g., ventricular muscle) can become “ectopic” pacemakers. These disturbances of automaticity make up the second major category of cardiac arrhythmias.

Depolarization-Dependent Triggered Activity

A positive shift in the maximum diastolic potential brings V_m closer to the threshold for an action potential and can induce automaticity in cardiac tissue that otherwise has no pacemaker activity. The development of depolarization-induced triggered activity depends on the interaction of the Ca^{2+} current (I_{Ca}) and the repolarizing K^+ current (I_{K}). This mechanism can produce a more rapid pacemaker depolarization in the SA or AV nodal cells, causing them to accelerate their pacemakers. It can also increase the intrinsic pacemaker rate in Purkinje fiber cells, which normally have a very slow pacemaker.

Depolarization-induced triggered activity is particularly dramatic in nonpacemaker tissues (e.g., ventricular muscle), which normally exhibit no diastolic depolarization. Factors that significantly prolong action potential duration can cause depolarization-dependent triggered activity. During the repolarization phase, I_{Na} remains inactivated because the cell is so depolarized (Fig. 21-16A). On the other hand, I_{Ca} has had enough time to recover from inactivation and—because the cell is still depolarized—triggers a slow, positive deflection in V_m known as an **early afterdepolarization (EAD)**.  **N21-16** Eventually, I_{K} increases and returns V_m toward the resting potential. Such EADs, if they are larger than the one shown in Figure 21-16A, may trigger an extrasystole. Isolated ventricular extrasystoles (known by many names, including premature ventricular contractions, or PVCs) may occur in normal individuals. Alterations in cellular Ca^{2+} metabolism (discussed in the next section) may increase the tendency of a prolonged action potential to produce an extrasystole. Ironically, a class of drugs used to treat arrhythmias can become *arrhythmogenic* by producing EADs. For example, quinidine can produce this dangerous adverse effect, presumably by inhibiting Na^+ channels and some K^+ channels and thus prolonging the ventricular muscle action potential.

A PROLONGED ACTION POTENTIAL LEADS TO EARLY AFTERDEPOLARIZATION

B PROLONGED ACTION POTENTIAL LEADS TO A "RUN" OF SPONTANEOUS ACTIVITY

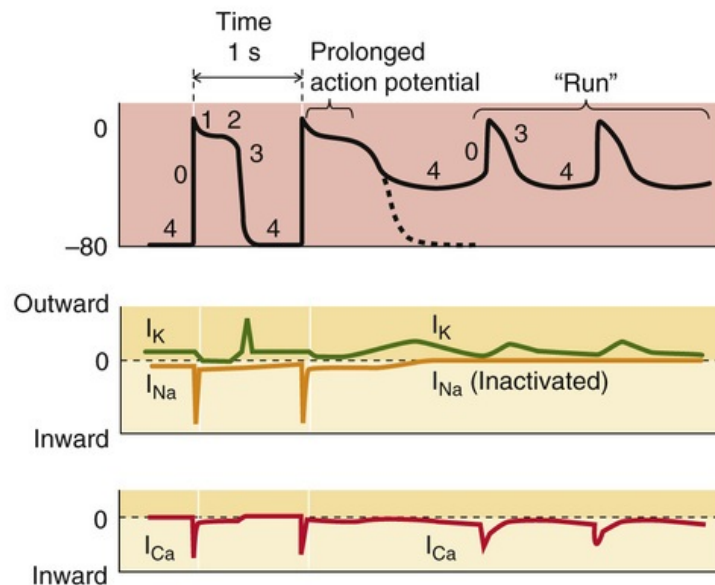

FIGURE 21-16 Abnormal automaticity in ventricular muscle. The records in this figure are idealized. **A**, The prolonged action potential keeps I_{Na} inactivated but permits I_{Ca} and I_K to interact and thereby produce a spontaneous depolarization—the early afterdepolarization. **B**, The afterdepolarization reaches threshold, triggering a sequence of several slow pacemaker-like action potentials that generate extrasystoles.

N21-16

Triggered Activity

Contributed by W. Jonathan Lederer

Both the **early afterdepolarizations** (EADs; see p. 505) and the **delayed afterdepolarizations** (DAD; see p. 506) are the impetus for a form of arrhythmia called **triggered activity**, which is a spontaneous abnormal beat or series of beats.

The natural automaticity generated by pacemaker cells (e.g., in the SA node) can occur without any preceding action potentials. In contrast, triggered activity requires at least one preceding action potential. Thus, if an afterdepolarization occurs but does not reach threshold, the cell will eventually return to its resting potential and no triggered activity will occur. If, however, an afterdepolarization reaches threshold, it can generate an unusual action potential from which another afterdepolarization may or may not arise. Thus, it is possible to generate a train of spontaneous depolarizations before the cell finally returns to its resting potential. In the case of a single unusual action potential, the electrical activity can generate an extrasystole. In the case of a train of depolarizations, the electrical activity can generate a run of extrasystoles.

The difference between EADs and DADs is that the additional depolarization in an *early* afterdepolarization occurs during phase 2 or 3. On the other hand, with a *delayed* afterdepolarization, the additional depolarization takes place during phase 4. The ventricular tachyarrhythmias seen in long QT syndrome (LQTS) are an example of arrhythmias caused by *early* afterdepolarizations. Some digitalis-induced arrhythmias are examples of arrhythmias caused by *delayed* afterdepolarizations.

More than one extrasystole—a **run of extrasystoles** (see Fig. 21-16B)—is pathological. A run of three or more ventricular extrasystoles is the minimal requirement for diagnosis of **ventricular tachycardia**.

This arrhythmia is life-threatening, because it can degenerate into ventricular fibrillation (see Fig. 21-14f), which is associated with no meaningful cardiac output. The heart rate in ventricular tachycardia is much faster than normal, usually between 120 and 150 beats/min (or faster), and the pacemaker driving the heartbeat is located in the ventricle itself. The heart rate in ventricular tachycardia may be so fast that the heart cannot pump blood effectively.

Long QT Syndrome

Patients with long QT syndrome (LQTS) have a prolonged ventricular action potential and are prone to ventricular arrhythmias. In particular, these patients are susceptible to a form of ventricular tachycardia called **torsades de pointes**, or “twisting of the points,” in which the QRS complexes appear to spiral around the baseline, constantly changing their axes and amplitude. LQTS can be congenital or acquired. The congenital form can involve mutations of cardiac Na^+ channels (see pp. 188–189) or K^+ channels (see p. 195). The acquired form of LQTS, which is much more common, can result from various electrolyte disturbances (especially hypokalemia and hypocalcemia) or from prescribed or over-the-counter medications (e.g., several antiarrhythmic drugs, tricyclic antidepressants, and some nonsedating antihistamines when they are taken together with certain antibiotics, notably erythromycin).

Ca^{2+} overload and metabolic changes can also cause arrhythmias

Ca^{2+} Overload

Ca^{2+} overload in the heart has many potential causes. One frequent factor is digitalis intoxication. Another is injury-related cellular depolarization. Ca^{2+} overload occurs when $[\text{Ca}^{2+}]_i$ increases, causing the SR to sequester too much Ca^{2+} . Thus overloaded, the SR begins to cyclically—and spontaneously—dump Ca^{2+} and then take it back up. The Ca^{2+} release may be large enough to stimulate a Ca^{2+} -activated nonselective cation channel and the Na-Ca exchanger (see pp. 123–124).  **N21-2** These current sources combine to produce I_{ti} , a **transient inward current** that produces a **delayed afterdepolarization (DAD)**.  **N21-16** When it is large enough, I_{ti} can depolarize the cell beyond threshold and produce a spontaneous action potential.

Metabolism-Dependent Conduction Changes

During ischemia and anoxia, many cellular events take place, including a fall in intracellular ATP levels. This fall in $[\text{ATP}]_i$ activates the ATP-sensitive K^+ channel (K_{ATP}), which is plentiful in cardiac myocytes. Thus, when $[\text{ATP}]_i$ falls sufficiently, K_{ATP} is less inhibited and the cells tend to become less excitable (i.e., K_{ATP} helps keep V_m close to E_K). The activation of this channel may explain, in part, the slowing or blocking of conduction that may occur during ischemia or in the peri-infarction period.

Electromechanical Dissociation

Rarely, patients being resuscitated from cardiac arrest exhibit a phenomenon called electromechanical dissociation in which the heart's ECG activity is not accompanied by the pumping of blood. In many cases, the basis of electromechanical dissociation is not understood. However, in other cases, the cause is obvious. For example, the heart of a patient with a large pericardial effusion may manifest normal electrical activity, but the fluid between the heart and the pericardium may press in on the heart (cardiac

tamponade) and prevent effective pumping.

CHAPTER 22

The Heart as a Pump

Emile L. Boulpaep

The Cardiac Cycle

The sequence of mechanical and electrical events that repeats with every heartbeat is called the **cardiac cycle**. The **duration** of the cardiac cycle is the reciprocal of the heart rate:

$$\text{Duration (s/beat)} = \frac{60 \text{ (s/min)}}{\text{Heart rate (beats/min)}} \quad (22-1)$$

For example, for a heart rate of 75 beats/min, the cardiac cycle lasts 0.8 s or 800 ms.

The closing and opening of the cardiac valves define four phases of the cardiac cycle

The cardiac pump is of the two-stroke variety. Like a pump with a reciprocating piston, the heart alternates between a filling phase and an emptying phase. Under normal circumstances, the electrical pacemaker in the sinoatrial node (see [pp. 489–490](#)) determines the duration of the cardiac cycle, and the electrical properties of the cardiac conduction system and cardiac myocytes determine the relative duration of contraction and relaxation. As long as the heart rate remains unchanged, this pattern remains steady.

The cardiac **atria** are small chambers. The right atrium receives deoxygenated systemic venous return from the inferior and superior venae cavae. The left atrium receives oxygenated blood from the lungs through the pulmonary circulation. Both atria operate more as passive reservoirs than as mechanical pumps. However, they do contract, and this contraction does enhance ventricular filling and cardiac output to a small degree ([Box 22-1](#)).

Box 22-1

Importance (and Unimportance) of Atrial Contraction

The relative importance of atrial contraction to overall cardiac function is evident in patients who develop atrial fibrillation (see [Fig. 21-14H](#)), an arrhythmia associated with loss of this atrial “kick.” In atrial fibrillation, chaotic electrical activity, bombarding the atria with as many as 500 impulses per minute from all directions, prevents the concerted action of atrial cardiac muscle fibers that is necessary for coordinated atrial contraction. As a result, the atria fibrillate—they look like a wriggling bag of worms. In healthy persons with otherwise normal hearts, the loss of atrial contraction usually causes no symptoms at rest, or perhaps only a sensation of an irregular or rapid heartbeat (i.e., the result of atrial fibrillation). However, if the patient already has a compromised myocardium (e.g., from ischemic heart disease, prolonged hypertension, or mitral stenosis), or if the patient is debilitated by dysfunction of other organs (e.g., chronic emphysema), the loss of the atrial contraction may further reduce cardiac output just enough to send the patient into florid congestive heart failure (see [Box 22-4](#)) or even shock (i.e., arterial pressure so low that it compromises perfusion of peripheral tissues). The physician may treat a patient with an otherwise normal heart in a leisurely fashion, or perhaps not at all—keeping in

mind that patients with atrial fibrillation are at high risk for development of atrial thrombosis and thus possibly cerebral embolism and stroke. In patients with a compromised myocardium, emergency chemical or electrical cardioversion may be necessary.

The inlet valves of the ventricles are called the **AV (atrioventricular) valves**. They permit blood to flow in one direction only, from the atria to the ventricles. The valve located between the *right* atrium and the right ventricle is the **tricuspid valve** because it has three flaps, or cusps. The valve located between the *left* atrium and the left ventricle is the **mitral valve** because it has only two cusps, which resemble a bishop's miter.

The outlet valves of the ventricles are called **semilunar valves**. They also allow blood to flow in just a single direction, from each ventricle into a large outflow-tract vessel. Both the **pulmonary valve**, located between the right ventricle and pulmonary artery, and the **aortic valve**, located between the left ventricle and aorta, have three cusps.

Cardiac valves open passively when upstream pressure exceeds downstream pressure. They close passively when downstream pressure exceeds upstream pressure. The movement of the valve leaflets can be detected by echocardiography (see [p. 427](#)); their closure makes **heart sounds** that can be heard with a stethoscope. The stethoscope can also detect leaks in the valves that permit jets of blood to flow backward across the valvular orifice (i.e., regurgitation), as well as stenotic lesions that narrow the valve opening, forcing the blood to pass through a narrower space (i.e., stenosis). During certain parts of the cardiac cycle, blood passing through either **regurgitant** or **stenotic** lesions makes characteristic sounds that are called **murmurs** (see [Box 17-1](#)).

The cardiac cycle can be artificially divided into phases in any number of ways. However, from the point of view of the ventricles and the positions of their valves, we must consider a minimum of four distinct **phases**:

- *Inflow phase*. The inlet valve is open and the outlet valve is closed.
- *Isovolumetric contraction*. Both valves are closed, with no blood flow.
- *Outflow phase*. The outlet valve is open and the inlet valve is closed.
- *Isovolumetric relaxation*. Both valves are closed, with no blood flow.

[Table 22-1](#) summarizes these four phases and the key events of the cardiac cycle. Note that the same events occur on the right side of the heart as on the left side.

TABLE 22-1
Events in the Cardiac Cycle

VALVULAR EVENTS	CARDIAC CHAMBER EVENTS	PHASE	
Opening of AV valves (tricuspid and mitral)	Rapid ventricular filling	1	Diastole
	Decreased ventricular filling; diastasis	1	Diastole
	Atrial contraction (additional ventricular filling)	1	Diastole
Closing of AV valves (tricuspid and mitral)	Isovolumetric ventricular contraction (with all valves closed)	2	Systole
Opening of semilunar valves (pulmonary and aortic)	Rapid ventricular ejection (fast muscle shortening)	3	Systole
	Decreased ventricular ejection (slower muscle shortening)	3	Systole
Closing of semilunar valves (pulmonary and aortic)	Isovolumetric ventricular relaxation (with all valves closed)	4	Diastole
Opening of AV valves (tricuspid and mitral)			

It is common to separate these phases into two parts. **Systole** includes phases 2 and 3, when the ventricles are contracting, whereas **diastole** includes phases 4 and 1, when the ventricles are relaxing. At a heart rate of 75 beats/min (cycle duration = 800 ms), systole occupies ~300 ms, and diastole ~500 ms.

With increasing heart rate—and thus decreasing cycle length—diastole shortens relatively more than systole does.

For convenience, the events in [Table 22-1](#) start a short time after the beginning of diastole, with the opening of the AV valves and the start of ventricular filling (phase 1).

Changes in ventricular volume, pressure, and flow accompany the four phases of the cardiac cycle 🔥N22-1

[Figure 22-1](#) illustrates the changes in pressure and volume that occur during the cardiac cycle. The four vertical lines indicate the timing of the four *valvular events* that terminate each of the four phases defined previously:

- AV valve closure terminates phase 1.
- Semilunar valve opening terminates phase 2.
- Semilunar valve closing terminates phase 3.
- AV valve opening terminates phase 4.

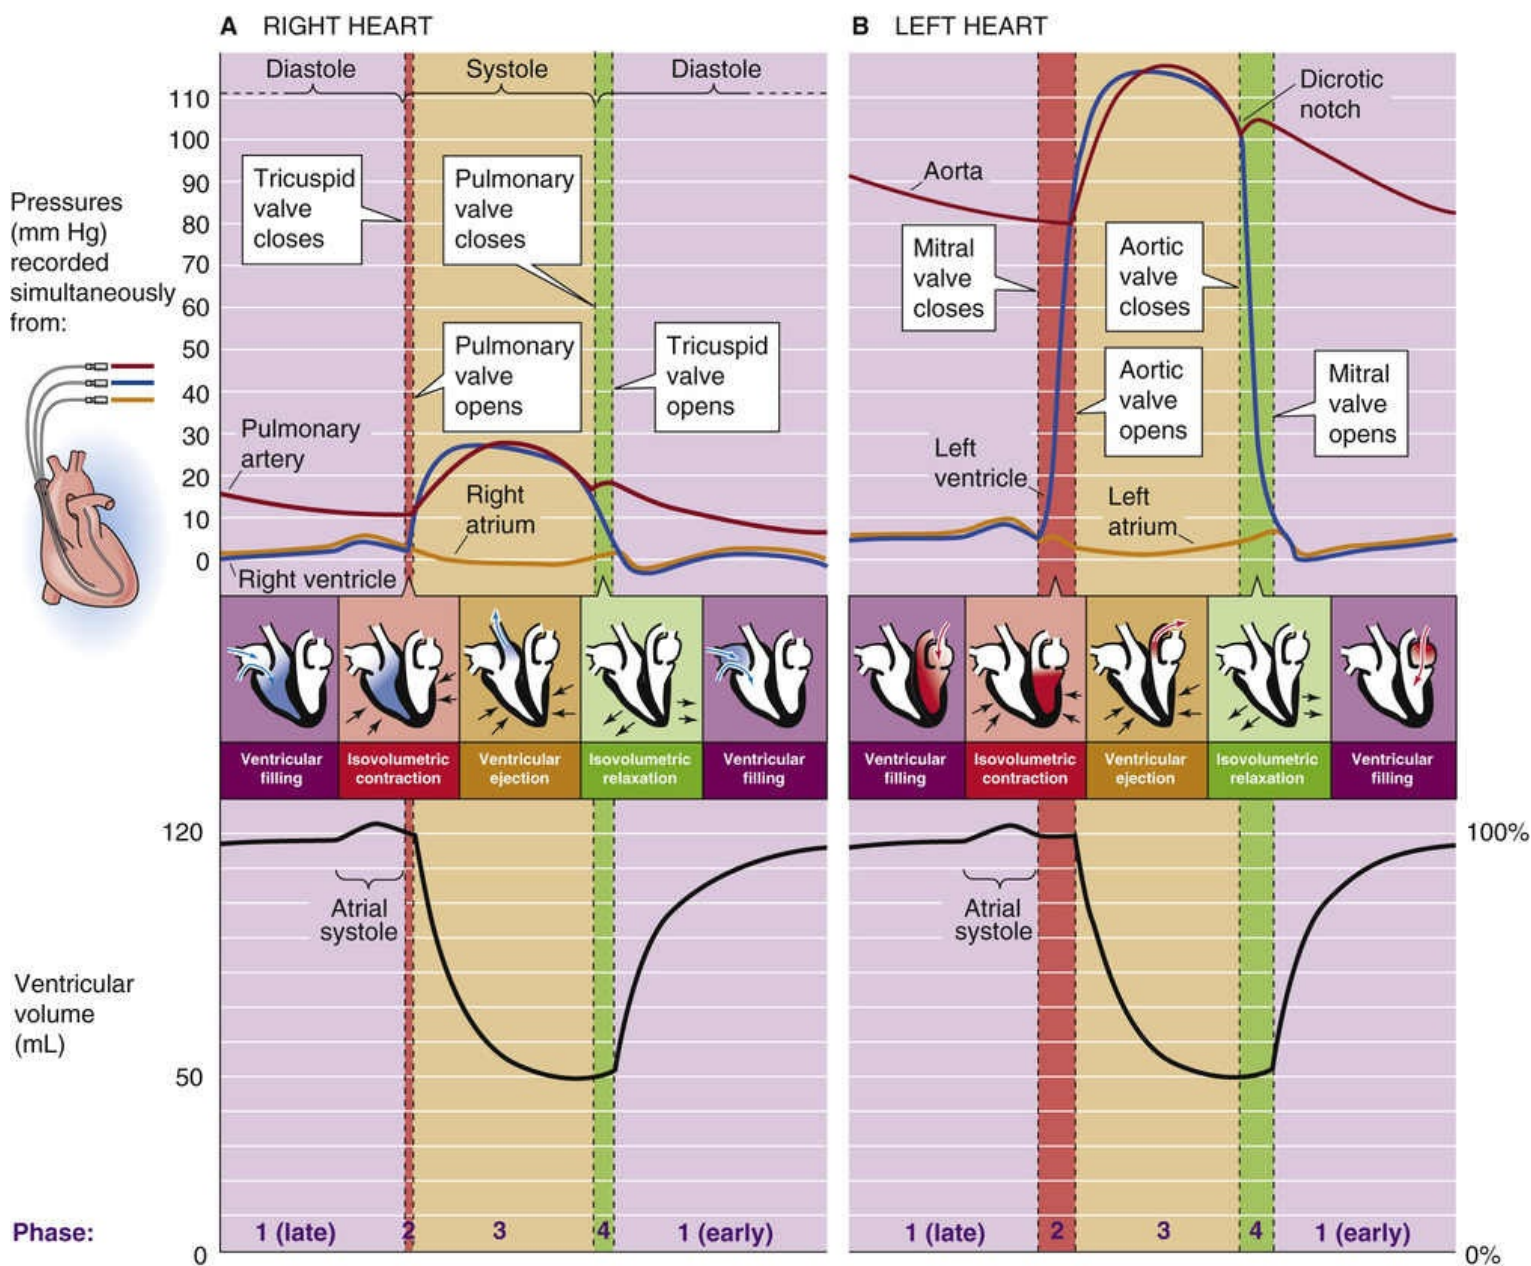

FIGURE 22-1 Pressures and ventricular volumes during the cardiac cycle. **A**, Right heart. **B**, Left heart. The inset shows the placement of catheters used for pressure measurements in the right heart.

The shapes of pressure tracings for the right heart (see Fig. 22-1A) and the left heart (see Fig. 22-1B) are quite similar except that the pressures on the right are a scaled-down version of those on the left. In both cases, the tracings begin in the *middle* of phase 1; that is, the period of decreased filling toward the end of diastole called **diastasis** (from the Greek *dia* [apart] + *histanai* [to stand]). Note that the volume changes in the left ventricle are exactly the same as those in the right ventricle because the cardiac outputs of the right and left sides of the heart are virtually identical (see p. 414). For purposes of illustration, we now focus on the records for the *left* heart (see Fig. 22-1B).

Diastasis Period (Middle of Phase 1)

During the diastasis, the mitral valve is open, but little blood flows from the left atrium to the left ventricle; ventricular volume slowly rises and approaches a plateau. The pressures in both the left atrium and the left ventricle rise slowly, driven by the pressure in the pulmonary veins, which is only slightly higher. The atrial pressure parallels—and is only slightly above—the ventricular pressure because the mitral valve is wide open, and the flow between the two chambers is minimal. The P wave of the

electrocardiogram (ECG; see [p. 493](#)), which corresponds to atrial excitation, occurs at the end of this phase.

Atrial Contraction (End of Phase 1)

Immediately following the P wave is the atrial contraction, which causes a variable amount of blood to enter the left ventricle. In a person at rest, the atrial contraction transfers into the left ventricle a volume of blood that represents <20% of the subsequent stroke volume and often only a few percent. During heavy exercise, this figure can rise to 40% (see [Box 22-1](#)). Atrial contraction causes a slight rise in intra-atrial pressure, and a comparable rise in ventricular pressure and volume. All during this period, the aortic pressure decreases as blood flows out to the periphery.

Isovolumetric Contraction (Phase 2)

When the ventricles begin to depolarize, as evidenced by the QRS complex on the ECG, systole commences. The ventricles contract, and very soon the pressure in the left ventricle exceeds that in the left atrium (first crossover of blue and orange pressure tracings in [Fig. 22-1B, top](#)). As a result, the *mitral valve closes*. The aortic valve has been closed this entire time. Thus, the left ventricle contracts with both mitral and aortic valves closed. Because the blood has no place to go, the result is an isovolumetric contraction that causes the pressure in the left ventricle to rise rapidly, eventually exceeding the pressure in the aorta (first crossover of blue and red tracings) and causing the aortic valve to open.

Ejection or Outflow (Phase 3)

As the *aortic valve opens*, the ejection phase begins. During the first part of phase 3—**rapid ejection**—ventricular pressure (blue tracing in [Fig. 22-1B, top](#)) continues to rise, closely followed by a rapid elevation of aortic pressure, which, at first, is slightly less (red tracing). Accompanying these rapid pressure increases is a precipitous reduction in ventricular volume (see [Fig. 22-1B, bottom](#)), as blood flows into the aorta. Aortic pressure continues to rise and eventually exceeds ventricular pressure (second crossover of blue and red tracings in [Fig. 22-1B, top](#)) just before both the aortic and ventricular pressures begin to fall. Despite the reversal of the pressure gradient across the aortic valve, the cusps of the aortic valve do not immediately snap shut because of the inertia of blood flow, [N22-2](#) which imparts considerable kinetic energy to the blood. During the latter part of phase 3—**decreased ejection**—the decrease in ventricular volume becomes less rapid, and both the ventricular and aortic pressures fall off. During the entire ejection phase, about 70 mL of blood flows into the aorta, leaving about 50 mL behind in the ventricle.

N22-2

Inertial Component of Flow in the Aorta

Contributed by Emile L. Boulpaep

As discussed in [N22-3](#), when pressure and flow fluctuate, the simple Ohm's law–like relationship $\Delta P = F \cdot R$ should be replaced by $\Delta P = F \cdot Z$, where Z is a complex **mechanical impedance**. Within the impedance term are components that describe compliant impedance, viscous (or resistive) impedance, and inertial impedance.

In Figure 22-1B (and also in the top panel of Fig. 22-2), the *pressure curves* for the left ventricle (blue

curve) and the aorta (red curve) cross over in the middle of the ejection phase. Yet, the aortic valve does not close at that instant, despite the apparent reversal of the pressure gradient. The *flow curve* in the aorta (black curve in the second panel of Fig. 22-2) is further proof that the aortic valve remains open: even after the apparent pressure gradient reverses just past the peak ejection, blood flow remains positive during the remainder of the ejection phase.

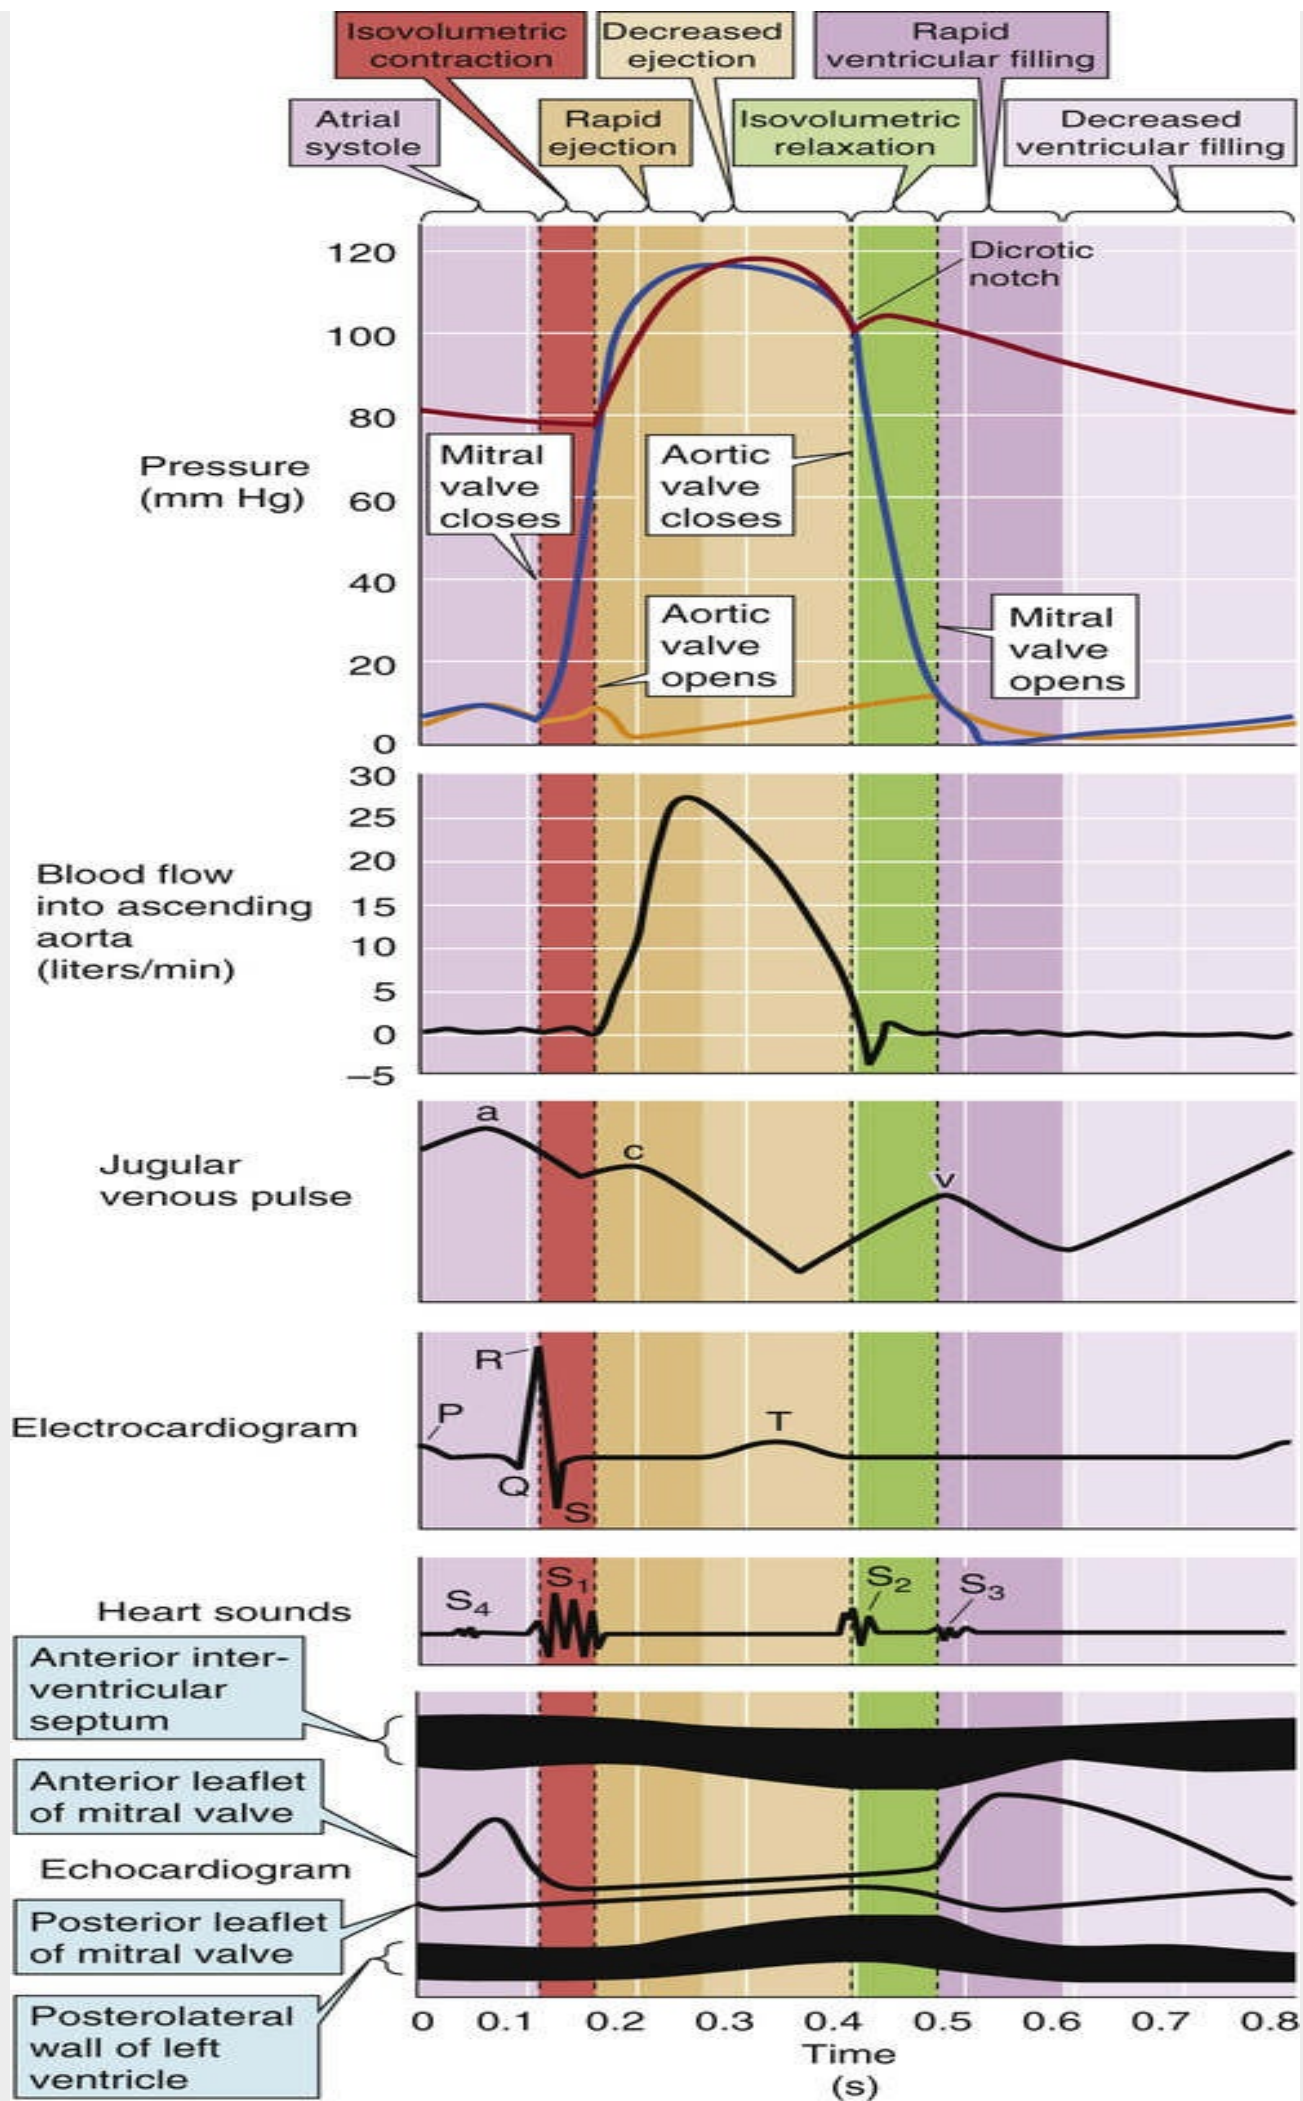

FIGURE 22-2 Mechanical, electrical, acoustic, and echocardiographic events in the cardiac cycle. *Top*, A repeat of Figure 22-1B, with three modifications: (1) the cardiac cycle begins with atrial contraction; (2) phase 1 of the cardiac cycle has three subparts: rapid ventricular filling, decreased ventricular filling, and atrial systole; (3) phase 3 has two subparts: rapid and decreased ventricular ejection.

Blood flow in the aorta is a good example of a case in which the flow dynamics is primarily **inertial** in character. During ejection, the aorta receives the entire stroke volume of the left ventricle at a high linear velocity. Thus, the kinetic energy ($\frac{1}{2} mv^2$) is large, because aortic flow carries a large mass of blood (m) at a high velocity (v). The *compliance term* (mostly radial compliance) within the complex impedance of the aorta is not so important because axial flow is much more important than radial flow. Finally, the *viscous-resistance term* within the complex impedance of the aorta is minimal because the radius of the aorta is large and resistance is inversely proportional to r^4 (see Equation 17-11). Thus, in the aorta, the inertial impedance becomes the major determinant of the overall impedance Z .

The dominance of the inertial impedance is illustrated by the finding that the aortic valve does not close despite a reversal of the pressure gradient between the left ventricle and the aortic arch as recorded by indwelling catheters with *side openings*. As shown in Figure 17-11, the “side pressure” measurement does not take into account the kinetic momentum (i.e., Bernoulli forces) along the axis of blood flow. If we had included the inertial component in our measurement of ΔP —by measuring pressure with catheters that face upstream, as shown by the uppermost catheter in Figure 17-11—we would observe no reversal of the pressure. Thus, there is no violation of the principle that $\Delta P = F \cdot Z$, which is to say that blood is still flowing down an energy gradient.

Isovolumetric Relaxation (Phase 4)

Late in the ejection phase, blood flow across the aortic valve falls to extremely low values, until it actually reverses direction (i.e., retrograde or negative flow). At this point, the *aortic valve closes*, defining the onset of diastole. As blood flow in the aorta again becomes briefly positive (i.e., forward), there is a small upward deflection in the aortic pressure trace. The result is the **dicrotic notch** (from the Greek *dikrotos* [double-beat]), or **incisura**, and the subsequent dicrotic wave, which interrupts the generally downward trend of aortic pressure. Because both the aortic and mitral valves are closed, and no blood can enter the left ventricle, this is the period of isovolumetric relaxation. Pressure falls rapidly in the left ventricle.

Rapid Ventricular Filling Period (Beginning of Phase 1)

When ventricular pressure falls below that in the left atrium (second crossover of blue and orange tracings in Fig. 22-1B), the *mitral valve opens*. Immediately following mitral valve opening, left ventricular volume begins to increase rapidly (see Fig. 22-1B, bottom). During this period of rapid ventricular filling, the left atrial and ventricular pressures evolve in parallel because the mitral valve is wide open. A period of relatively decreased filling follows, the period of diastasis with which we began our discussion. Thus, diastole includes both the rapid ventricular filling period and diastasis. As already noted, the length of diastole decreases with elevations in heart rate. This decrease comes first at the expense of the period of slower ventricular filling (i.e., diastasis).

During rapid ventricular filling, the aortic valve remains closed. Because blood continues to flow out to the periphery, owing to the recoil of the aorta's elastic wall (see Box 22-2), the aortic pressure falls. This fall continues during diastasis.

The ECG, phonocardiogram, and echocardiogram all follow the cyclic pattern of the cardiac cycle

Accompanying the basic cyclic pattern of cardiac pressure and volume changes are characteristic mechanical, electrical, acoustic, and echocardiographic changes. [Figure 22-2](#) illustrates these events for the left heart and the systemic circulation. Notice that the pressure records in the top panel of [Figure 22-2](#) start with the atrial contraction—that is, slightly later than in [Figure 22-1](#).

Aortic Blood Flow

Blood flow from the left ventricle to the ascending aorta (see [Fig. 22-2](#), second panel from top) rises most rapidly during the rapid ejection phase of the left ventricle. The peaking of aortic flow defines the beginning of the decreased-ejection phase.

Jugular Venous Pulse

The third panel of [Figure 22-2](#) includes the jugular venous pulse, for comparison with the timing of other events. We will discuss the jugular venous pulse below in the chapter.

Electrocardiogram

The ECG (see [Fig. 22-2](#), fourth panel from top, and [pp. 493–496](#)) begins with the middle of the P wave (atrial depolarization). The QRS complex (ventricular depolarization) is the prelude to the upswing in ventricular pressure. The T wave (ventricular repolarization) occurs in the decreased-ejection phase.

Phonocardiogram and Heart Sounds

The opening and closing of the valves are accompanied by **heart sounds** (see [Fig. 22-2](#), fifth panel from top), easily heard through a stethoscope or recorded with a digital stethoscope and stored as a phonocardiogram ([Table 22-2](#)). The dominant frequencies of heart sounds are lower (110 to 180 Hz) than those of heart murmurs (see [Box 17-1](#)), which result from turbulence (180 to 500 Hz). Each of the vertical dotted lines in [Figure 22-2](#) indicates the movement of two valves, one on the right side of the heart and one on the left. Thus, two valves can contribute to a single heart sound, although the two components can often be separated by the ear. The phonocardiogram in [Figure 22-2](#) shows the timing of the two major, or physiological, heart sounds (S_1 and S_2), as well as two other sounds (S_3 and S_4) that are occasionally heard.

TABLE 22-2

The Heart Sounds

SOUND	DESCRIPTION	ASSOCIATED EVENTS
S_1	First heart sound (sounds like “lub”) Two bursts, a mitral M_1 and a tricuspid T_1 component	Closure of mitral and tricuspid valves
S_2	Second heart sound (sounds like “dub”) An aortic A_2 and a pulmonary P_2 component	Closure of aortic and pulmonary valves
OS	Opening snap	Opening of a stenotic mitral valve
S_3	Third heart sound	Diastolic filling gallop or ventricular or protodiastolic gallop
S_4	Fourth heart sound	Atrial sound that creates an atrial or presystolic gallop

The physiological heart sounds S_1 and S_2 are heard following the closure of the cardiac valves: the

mitral and tricuspid valves for S_1 , and the aortic and pulmonary valves for S_2 . However, the actual apposition of the valve leaflets (i.e., “slamming the door”) does not produce the sound. Instead, vibrations resulting from sudden tension in the AV valves and the adjacent ventricular walls produce the **first heart sound, S_1** . Similarly, vibrations of the large vessel walls and columns of blood produce the **second heart sound, S_2** , following closure of the semilunar valves. These vibrations propagate through adjacent tissues to the chest wall, where one can normally hear the first and second heart sounds through a stethoscope. S_1 is usually stronger, longer, and of lower frequency than S_2 .

Although the four vertical lines that define the four phases of the cardiac cycle are very similar for the right and left sides of the hearts, they do not line up perfectly with one another, as can be seen by comparing [Figure 22-1A and B](#). For example, the aortic valve usually closes just before the pulmonary valve. This timing difference produces the **physiological splitting** of the A_2 (i.e., aortic) and P_2 (i.e., pulmonary) components of the second heart sound. As we shall see below (see [pp. 517–519](#)), inspiration accentuates the splitting of S_2 . Pathological changes that accentuate the asynchrony between the left and right sides of the hearts (e.g., right bundle branch block) may also lead to splitting of the *first* heart sound.

With stiffening of the mitral valve, seen in mitral stenosis, the opening of the mitral valve may produce an additional sound, an **opening snap (OS)**, in early diastole just after S_2 .

A physiological **third heart sound, S_3** , is present in some normal individuals, particularly children. S_3 occurs in early diastole when rapid filling of the ventricles results in recoil of ventricular walls that have a limited distensibility. An S_3 also can be heard in adults when the ventricle is so overfilled at the end of systole that the addition of 70 mL more blood during diastole brings the ventricle into a volume range in which ventricular compliance is very low. The result is an accentuated recoil, heard as an S_3 . An S_3 can originate from the left or the right side of the heart. A “gallop rhythm” is a grouping of three heart sounds that, together, sound like hoofs of a galloping horse. Thus, the addition of an S_3 to the physiological S_1 and S_2 creates a three-sound sequence, S_1 - S_2 - S_3 , that is termed a **protodiastolic gallop** or ventricular gallop.

When present, a **fourth heart sound, S_4** , coincides with atrial contraction. It is usually heard in pathological conditions in which an unusually strong atrial contraction occurs in combination with low compliance of the left ventricle. The addition of an S_4 produces another three-sound sequence, S_4 - S_1 - S_2 , which is also a gallop rhythm, a **presystolic gallop** or atrial gallop.

Echocardiogram

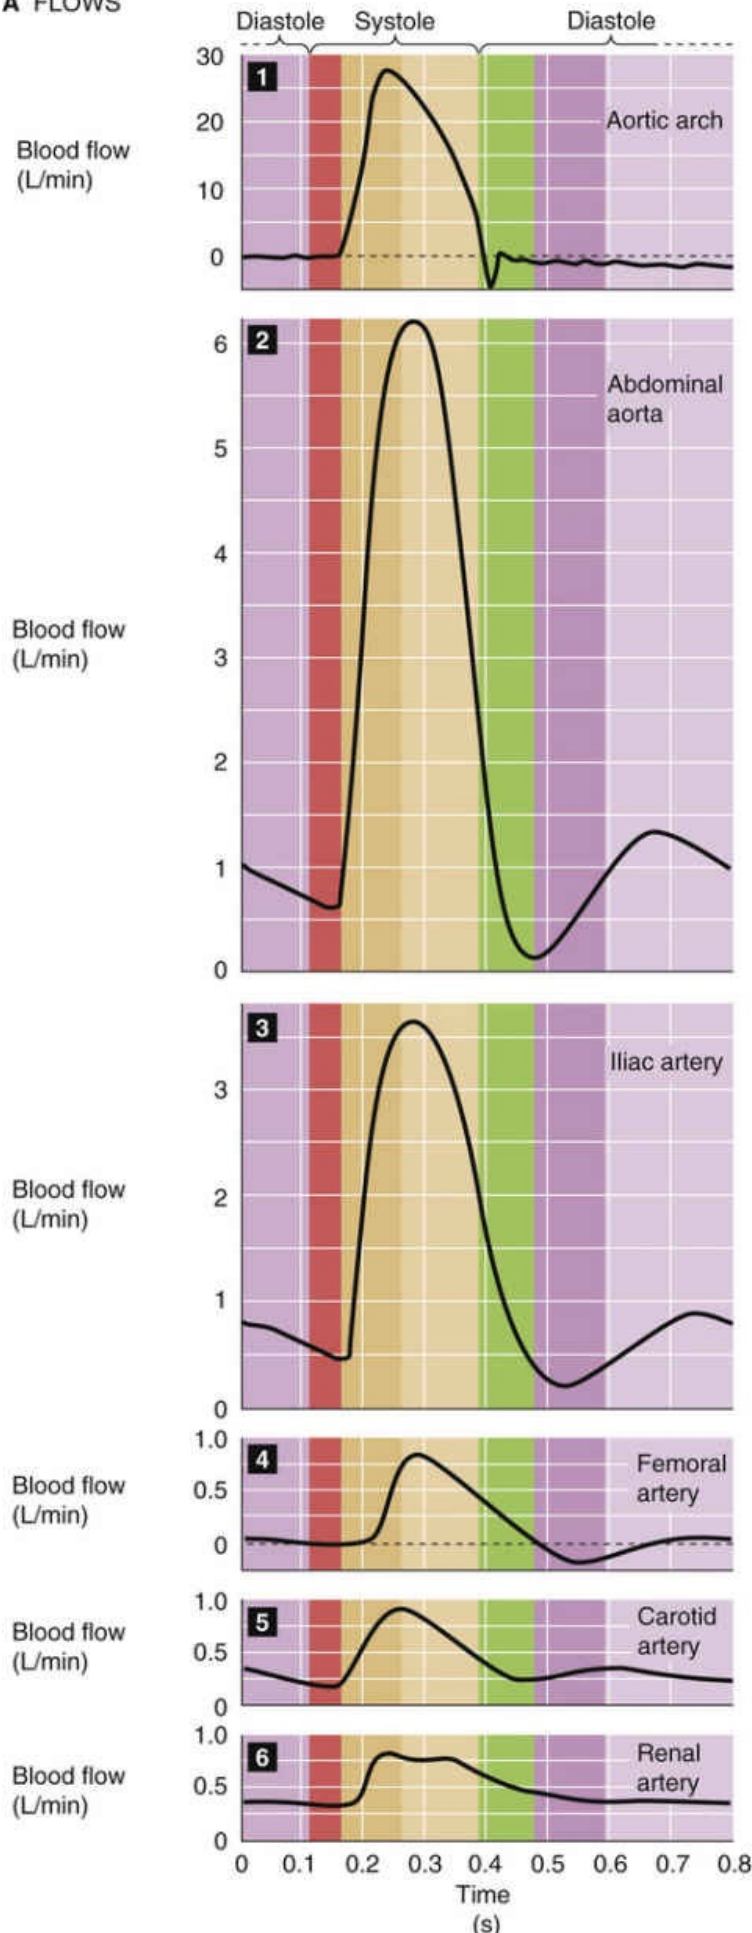

We discussed echocardiography on [page 427](#). The echocardiogram in the bottom panel of [Figure 22-2](#) shows that the separation between the anterior and posterior leaflets of the mitral valve increases during atrial contraction. The leaflets meet at the beginning of phase 2 and remain together until rapid ventricular filling occurs in the beginning of phase 1, when the separation between leaflets becomes maximal. During the decreased phase of ventricular filling, the leaflets once again move closer together, until the next atrial contraction.

The cardiac cycle causes flow waves in the aorta and peripheral vessels

With the closing and opening of the heart's exit valves (i.e., pulmonary and aortic valves), blood flow and blood velocity across these valves oscillate from near zero, when the valves are closed, to high values,

when the valves are open. *Blood flow* in the aortic arch actually oscillates between slightly negative and highly positive values ([Fig. 22-3A](#), panel 1). *Pressure* in the aortic arch typically oscillates between ~80 and ~120 mm Hg (see [Fig. 22-3B](#), panel 1), but varies greatly among individuals. Phasic changes in pressure and flow also occur in the peripheral arteries. Arterial pressure is usually measured in a large artery, such as the brachial artery (see [p. 421](#)). Because very little pressure drop occurs between the aorta and such a large, proximate artery, the measured **systolic** and **diastolic** arterial pressures, as well as the pulse pressure and mean arterial pressure (see [p. 418](#)), closely approximate the corresponding aortic pressures.

A FLOWS

B PRESSURES

FIGURE 22-3 Flow (A) and pressure (B) profiles in the aorta and smaller vessels.

If blood vessels were rigid tubes, so that the resistance (R) were constant, and if the driving pressure

(ΔP) were also constant throughout the cardiac cycle, we could describe blood flow (F) by a simple Ohm's law–like relationship, as we did in [Equation 17-1](#). However, because blood vessels are compliant (so that R varies with pressure; see [Fig. 19-7B](#)) and because both aortic pressure and flow vary during the cardiac cycle, we cannot describe real arteries in this way. In the field of hydraulics, oscillating flows and pressures have not only an **amplitude**, but also a **phase**. As a result, the ratio $\Delta P/F$ is no longer resistance—a simple, time-independent quantity—but a *complex* quantity called the **mechanical impedance** [N22-3](#) that depends on the classical “resistance” as well as the compliance and inertial properties of the vessels and blood.

N22-3

Mechanical Impedance of Blood Flow

Contributed by Emile Boulpaep

We began this chapter by drawing an analogy between the flow of blood and electrical current, as described by an Ohm's law of hydrodynamics: $\Delta P = F \times R$. We now know that there are other factors that influence pressure. In addition to the flow resistance R (electrical analogy = ohmic resistor), we must also consider the compliance C (electrical analogy = capacitance) as well as the inertance L (electrical analogy = inductance). A similar problem is faced in electricity when dealing with alternating (as opposed to direct) currents. In Ohm's law for alternating currents, $E = I \times Z$, where Z is a complex quantity called the impedance. Z depends on the electrical resistance R , the electrical capacitance C , and the electrical inductance L . Similarly, for blood flow, we can write $\Delta P = F \times Z$, where Z is also a complex quantity, called **mechanical impedance**, that includes the following:

1. **Compliant impedance** that opposes volume change (compliance of the vessel).
2. **Viscous (or resistive) impedance** that opposes flow (shearing forces in the liquid). This term is the R of Ohm's law of hydrodynamics: $\Delta P = F \times R$ (see [Equation 17-1](#)).
3. **Inertial impedance** that opposes a change of flow (kinetic energy of fluid and vessels).

Considering all these sources of pressure, we can state that the total pressure difference at any point in time, instead of being given by Ohm's law, is

$$P_{\text{total}} = P_{\text{gravity}} + P_{\text{compliance}} + P_{\text{viscous resistance}} + P_{\text{inertance}} \quad (\text{NE 22-1})$$

The P_{gravity} term in the above equation is discussed on pages 418–419 in the section titled “Gravity Causes a Hydrostatic Pressure Difference When There Is a Difference in Height.”

Because of these resistive, compliant, and inertial properties, the pressure and flow waves in vessels distal to the aorta are not quite the same as in the aorta. Instead, the farther the vessels are from the aorta, the more different the pressure and flow waves become.

Aortic Arch

During the rapid-ejection phase, peak *flow* through the aortic arch is remarkably high, ~ 30 L/min (dark beige band in Fig. 22-3A, panel 1). The peak linear velocity is ~ 100 cm/s, which makes it more likely that the blood will reach the critical Reynolds number value for turbulence (see p. 416). The rapid ejection of blood also causes a rapid rise of the *pressure* in the aorta to above that in the ventricle (see Fig. 22-3B, panel 1). Even though the pressure gradient across the valve reverses, the valve does not close, as is evidenced by the continuous flow of blood from the ventricle into the aorta. The reason that flow continues in the forward direction is the *inertial* component of the blood flow, which represents considerable kinetic energy. Eventually, blood in the aortic arch decelerates sufficiently that the flow becomes zero and eventually negative (producing reflux through the valve). As the aortic valve closes, it produces the dicrotic notch in the aortic pressure trace.

Thoracic-Abdominal Aorta and Large Arteries

Just distal to the aortic arch, a transformation of the flow and pressure curves begins to occur. The records in panels 2 through 4 in Figure 22-3A show the flow curves for the abdominal aorta and some of its large branches. Peak systolic flow becomes smaller as one moves from the aorta toward the periphery (i.e., iliac and femoral arteries), as would be predicted because of the branching of the vessels. However, in the abdominal aorta, a new phenomenon is seen. As the elastic aorta—which stored blood during systole—releases blood during diastole, a second peak of flow appears. Note that this *diastolic component* of flow is larger in the abdominal aorta than in the more distal iliac artery, and is almost absent in the femoral artery. Of particular importance is the sizable diastolic flow in the carotid and renal arteries (see Fig. 22-3A, panels 5 and 6). The basis for the diastolic component of flow is the subject of Box 22-2.

Box 22-2

Effect of Aortic Compliance on Blood Flow

There is a large diastolic component to total blood flow in the large arteries that lie close to the aorta, such as the carotid and renal arteries (see Fig. 22-3A, panels 5 and 6). This sizeable diastolic component is largely the result of the high **compliance** of the vessel walls and the **radial expansion** of the vessels that occurs during ventricular ejection. We can reach at least an intuitive understanding of the radial contribution to flow in the aorta and large arteries by examining the ability of the aorta to store and to give up energy during the acceleration and deceleration of flow.

Figure 22-4 compares two branches of a hydraulic system that are identical in radius and length. One branch (branch 1) is rigid and made of glass; the other (branch 2) is elastic and made of rubber. Both branches terminate in a spout with an outflow resistance that is analogous to the resistance of arterioles. We assume that the resistance of the spout is much greater than that of the glass or rubber tube, so that we can ignore the effect of small changes in the diameter of the rubber tube on overall resistance. If we apply a *steady pressure* to both branches, the flows through the two branches are continuous and identical (see Fig. 22-4A).

A STEADY INPUT PRESSURE (CONTINUOUS FLOW)

B SQUARE-PULSE PRESSURE (PULSATILE FLOW)

C "WINDKESSEL" MODEL OF AORTA

FIGURE 22-4 Effect of pulsatile pressure on flow through a compliant vessel. In **C**, the gold arrows indicate movements analogous to systole, and the violet arrows, movements analogous to diastole.

However, if we apply the *pressure in square pulses*, the flows in the two branches are quite different (see Fig. 22-4B). The flow through the glass tubing instantly rises to a maximum value with the onset of the pressure wave, and then instantly falls to zero when the driving pressure falls to zero. Thus, the plot of flow through the glass tube perfectly mirrors the plot of the applied square-wave pressure. The flow through the rubber tube has a very different profile. During the interval of peak pressure, the rubber vessel gradually dilates, storing a volume of fluid. Therefore, the flow rises slowly to its maximum value. During the interval of the cycle when the driving pressure falls to zero, the expanded rubber vessel delivers its stored volume downstream, which results in some forward flow despite the absence of any pressure head. The time-averaged outflow from the rubber tube exceeds that from the glass tube.

The aorta and large vessels behave like the rubber tube in Figure 22-4B. The oscillating pressure head in our model (i.e., between zero and a peak value) represents ventricular pressure. The maintenance of flow during interruption of the pressure head is equivalent to the continuing flow from the aorta during diastole.

Figure 22-4C shows an alternative mechanical model, that of a Windkessel (German for “wind chamber”), in which we replace the compliance of a distensible rubber tube with the compressible air within a chamber above the blood.

The two models illustrated in Figure 22-4B and C show how compliant blood vessels can convert discontinuous flow into a more continuous flow. The so-called Windkessel action of the arterial system considerably improves the efficiency of the pump (i.e., the heart) because the vessels are able to convert the phasic flow peaks of the pump into a more continuous flow.

The cardiac cycle also causes pressure waves in the aorta and peripheral vessels

The *pressure* curves in Figure 22-3B show that, with increasing distance from the heart (panels 1 to 4), the rising portion of the wave becomes steeper and the peak narrower. Because the peak gradually increases in height and the minimum pressure gradually decreases, the pulse pressure becomes greater. With increasing distance from the heart, an important secondary pressure oscillation appears during diastole (see Fig. 22-3B, fourth panel). Thus, although the pressure waves are distorted, they are not damped. Although it might seem counterintuitive that the peak arterial pressure should increase as we get farther from the heart (Is the blood flowing against a pressure gradient?), it turns out that the *mean* arterial pressure does fall very slightly with increasing distance from the heart.

Terminal Arteries and Arterioles

In the smallest arteries, the flows must be small. Here, the trend toward an increased peak pressure reverses. Instead, the pulse wave gets damped out for two reasons. First, because we are dealing with many parallel vessels with a large aggregate wall area, the aggregate compliance increases, damping the pressure wave. Second, because these smaller arteries have a smaller radius and thus a far greater resistance, the mean arterial pressure must fall in proportion to the much higher resistance. Thus, in contrast to the situation in the larger arteries, damping predominates over distortion.

Capillaries

By the time the blood reaches the capillaries, the damping is so severe that pulsations (i.e., pressure oscillations) do not normally occur—blood flow is continuous. The pulmonary capillaries are an exception; their upstream vessels are short, and they have low resistance and high compliance. The pulsation of systemic capillaries occurs only in cases of markedly increased pulse pressure, such as in patients with aortic regurgitation or hyperthyroidism, or in cases of generalized peripheral vasodilation.

Distortion of pressure waves is the result of their propagation along the arterial tree

Imagine that you are listening to a patient's heart with a stethoscope while simultaneously feeling the pulse of the radial artery near the wrist. For each heartbeat that you hear, you feel a radial pulse. You know that the peak pressure in the left ventricle occurs about midway between the first and second heart sounds, but the delay between the midpoint of the two heart sounds and the peak of the radial pulse is only ~ 0.1 s. Red blood cells (RBCs) take several seconds to flow from the heart to the wrist. Why, then, are you able to feel the pulse so soon after the heartbeat?

The answer is that the blood vessels conduct the palpable pulse as a **pressure wave**. The linear velocity of RBCs—carried in the blood by convection—ranges from ~ 1 m/s in the aorta to vanishingly small values in the capillaries (see p. 448). However, the pressure wave travels at a velocity of 5 to 6 m/s in the aorta, increasing to 10 to 15 m/s in the small arteries.

The following example illustrates the difference between the velocity of a pressure wave and that of convection. Imagine that two people are submerged in a river, floating downstream (convection). Now the person upstream makes a sound under water. The sound waves (an example of a pressure wave) travel to the person downstream with a velocity that is far greater than the velocity of the river.

We can illustrate how pressure waves propagate along arteries by replotting the arterial pressure profiles from Figure 22-3B and stacking them one on top of the other. The four pressure waves in Figure 22-5 actually represent data obtained simultaneously in a dog with four catheters, the first placed in the aortic arch and the last three, each placed precisely 10 cm downstream from the previous one. The downstream propagation of the wave through the larger arteries is accompanied by a serious *distortion* of the pressure profile: it gets narrower and taller as we move downstream.

FIGURE 22-5 Arterial pressure waves. These simultaneous pressure records are from a dog, with catheters placed at 0, 10, 20, and 30 cm from the aortic arch. As the wave moves down the vessel, the upstroke is delayed, but the peak is higher.

Effect of Frequency on Wave Velocity and Damping

The pressure wave **N22-4** moving from the aorta to the periphery is actually an ensemble of many individual waves, each with its own frequency. Higher-frequency waves travel faster and undergo more damping than low-frequency waves (Fig. 22-6A). Recombination of these waves at a more peripheral site thus produces a new wave with a shape that is a distorted version of the original aortic wave.

A DISTORTION IN A VESSEL WITH UNIFORM DISTENSIBILITY

B DISTORTION IN A VESSEL WITH DECREASING DOWNSTREAM DISTENSIBILITY

FIGURE 22-6 Propagation of pressure waves. In **A** and **B**, the flow is from left to right. The left pair of pressure waves is at the same early time, whereas the right pair of pressure waves is at the same late time. If on the right (i.e., end of the vessel) we sum waves of different frequencies at the same instant in time, then the composite wave is distorted (like the green femoral artery curve in Fig. 22-5).

N22-4

Distortion of Propagated Waves

Contributed by Emile Boulpaep

The peak of the arterial pressure profile gets taller and sharper as we move away from the heart (see Fig. 22-5). There are three major reasons for this:

- 1. The higher-frequency components of the wave travel faster.** The pressure wave in the arch of the aorta is far more complex than a simple sine or cosine wave. Nevertheless, we can think of the complex waveform in the aortic arch as being the algebraic sum of many individual sine and cosine waves, each with its own amplitude, frequency, and phase (i.e., how much the wave's peak is shifted left or right along the time axis). The precise mathematical method by which complex waveforms are broken down into simpler components is called Fourier analysis. It turns out that waves of higher frequency propagate with a greater velocity than waves of lower frequency. Thus, the farther the high- and low-frequency waves travel down the vessel, the more separated they become from one another (a process termed **dispersion**; see Fig. 22-6A). It also turns out that even if we examine a single sine wave—which, of course, has a single frequency—the position of the peak will shift backward as the wave travels down the vessel (this is called a **phase shift**). The magnitude of the phase shift increases with increasing frequency. Furthermore, the blood vessels produce more **damping** on the peaks of higher-frequency waves than on those of low-frequency waves (see Fig. 22-6A). When we sum these various effects on the sine-wave and cosine-wave components downstream, the reconstructed pressure wave has a different (i.e., distorted) shape compared with the original wave.
- 2. The vessels become stiffer toward the periphery, increasing wave velocity, especially for higher-frequency components.** Vessel walls become stiffer progressing down the vascular tree. The smaller peripheral vessels have a thicker wall relative to their luminal diameter. Waves propagate faster in stiff vessels than in compliant ones. Thus, pressure waves travel faster in smaller arteries. Increased stiffness speeds up high-frequency waves more than low-frequency ones (see Fig. 22-6B).
- 3. The pressure waves bounce off the end of the arterial tree and reflect back up the vessels.** The vascular circuit is not infinite, nor does the end of the vasculature have a device that completely absorbs a transmitted pressure wave. Therefore, some of the wave must reflect back up the artery and sum with the waves traveling in the forward direction. By themselves, reflected waves are not large enough to explain the large distortions in the arterial pressure profile. Moreover, if the wave distortions were due only to reflections, then the reflections at any one point in the vascular tree would have to be stable with time (i.e., the reflections would have to create a “standing wave”). However, the vascular tree is far too short to create standing waves of the appropriate frequencies. In addition, to create a standing wave, the heart would have to beat with an absolutely invariant rhythm, which, of course, is not the case. Thus, reflections make only a small contribution to the distortion.

Effect of Wall Stiffness on Wave Velocity

As the pressure wave  **N22-4** reaches vessels that have a stiffer wall (e.g., greater ratio of wall thickness to vessel diameter), the velocity of the wave increases (see [Fig. 22-6B](#)). Conversely, with a more compliant vessel, some of the energy of the pressure pulse goes into dilation of the vessel, so that the pressure wave spreads out and slows down. Because aging causes a decrease in vessel compliance (i.e., distensibility), the velocity of propagation actually increases.

Pressure waves in veins do not originate from arterial waves

We have seen above in this chapter that flow in *capillaries* is usually not pulsatile. Nevertheless, blood flow in systemic capillaries can exhibit slow oscillations unrelated to the cardiac cycle. The action of upstream vasomotor control elements in arterioles and precapillary sphincters can cause fluctuations. In addition, changes in tissue pressure (e.g., caused by muscle contraction) can compress capillaries and cause further fluctuations in capillary flow. Pulmonary capillaries are especially susceptible to changes in the surrounding alveolar pressure (see [pp. 687–689](#)).

Although systemic *veins* have pressure waves, these waves do not originate from arterial waves propagating through the capillary beds, which are nonpulsatile. Three mechanisms can contribute to the **venous pulse**: (1) retrograde action of the heartbeat during the cardiac cycle, (2) the respiratory cycle, and (3) the contraction of skeletal muscles.

Effect of the Cardiac Cycle

A large vein close to the heart, such as the **jugular vein**, has a complex pulse wave ([Fig. 22-7A](#)) synchronized to the cardiac cycle. The three maxima, or peaks, in the jugular pulse wave are labeled *a*, *c*, and *v*. The three minima, or dips, are labeled *av*, *x*, and *y*. These pressure transients reflect events in the cardiac cycle:

- The ***a* peak** is caused by the contraction of the right atrium.
- The ***av* minimum** is due to relaxation of the right atrium and closure of the tricuspid valve.
- The ***c* peak** reflects the pressure rise in the right ventricle early during systole and the resultant bulging of the tricuspid valve—which has just closed—into the right atrium.
- The ***x* minimum** occurs as the ventricle contracts and shortens during the ejection phase later in systole. The shortening heart—with tricuspid valve still closed—pulls on and therefore elongates the veins, lowering their pressure.
- The ***v* peak** is related to filling of the right atrium against a closed tricuspid valve, which causes right atrial pressure to rise. As the tricuspid valve opens, the *v* peak begins to wane.
- The ***y* minimum** reflects a fall in right atrial pressure during rapid ventricular filling, as blood leaves the right atrium through an open tricuspid valve and enters the right ventricle. The increase in venous pressure after the *y* minimum occurs as venous return continues in the face of reduced ventricular filling.

**A JUGULAR VENOUS PRESSURE CHANGES
CAUSED BY CARDIAC CYCLE**

**B JUGULAR VENOUS PRESSURE CHANGES
CAUSED BY RESPIRATORY CYCLE**

**C VENOUS PRESSURE CHANGES IN FOOT
CAUSED BY MUSCLE CONTRACTION**

FIGURE 22-7 Venous pressure changes. In **A**, the time scale is a single cardiac cycle. The relative heights of the peaks and valleys are variable. In **B**, the time scale surrounds one protracted inspiration (i.e., several heartbeats); the y-axis in the lower panel shows the *mean* jugular venous pressure. (**B**, Data from Brecher GA: Venous Return. New York, Grune & Stratton, 1956; **C**, data from Pollack AA, Wood EH: Venous pressure in the saphenous vein at the ankle in man during exercise and changes in posture. J Appl Physiol 1:649–662, 1949.)

Effect of the Respiratory Cycle

Poiseuille was the first to observe that the pressure in the jugular vein becomes negative during

inspiration (see [Fig. 22-7B](#)). During inspiration, the diaphragm descends, causing intrathoracic pressure (and therefore the pressure inside the thoracic vessels) to decrease and intra-abdominal pressure to increase (see [p. 607](#)). Consequently, the venous return from the head and upper extremities transiently increases, as low-pressure vessels literally suck blood into the thoracic cavity. Simultaneously, the venous flow decreases from the lower extremities because of the relatively high pressure of the abdominal veins during inspiration. Therefore, during inspiration, pressure in the jugular vein falls while pressure in the femoral vein rises.

Effect of Skeletal Muscle Contraction (“Muscle Pump”)

The contraction of skeletal muscle can also affect pressure and flow in veins. Large veins in the lower limbs are equipped with valves that prevent retrograde movement of blood (see [p. 419](#)). When a person is at rest and in the recumbent position, all venous valves are open and venous blood flow toward the heart is continuous. Standing causes the venous pressure in the foot to rise gradually to the hydrostatic pressure dictated by the vertical blood column from the foot to the heart (see [Fig. 22-7C](#)). If the person begins to walk, the combination of the pumping action of the leg muscles on the leg veins and the action of the venous valves as hydrostatic relay stations causes the venous pressure in the foot to decrease. Each step causes both a small oscillation and a small net decrease in foot vein pressure. Once foot vein pressure has bottomed out, each step simply causes a small pressure oscillation. Walking causes a net decrease in pressure in both the superficial and deep foot veins, as well as in the corresponding capillaries. When the exercise ceases, the venous pressure again rises.

Cardiac Dynamics

The heart is a system of two pumps linked in series. The muscular wall of the left ventricle is thicker and more powerful than that of the right. The interventricular septum welding the two pumps together is even thicker. The thick muscular walls of the ventricles are responsible for exerting the heart's pumping action.

The heart does not depend on a rhythm generator in the brain, like the central pattern generators (see [p. 390](#)) that drive other rhythmic behaviors such as respiration, locomotion, chewing, and shivering. Instead, pacemaker cells within the heart itself initiate cardiac excitation. When the heart is in a normal sinus rhythm, the pacemaker cells setting the rate are located in the sinoatrial (SA) node of the right atrium (see [p. 489](#)). The action potential then spreads through atrial myocytes and specialized tracts or bundles. The impulse cannot cross from the atria to the ventricles except through the AV node. The AV node inserts a time delay into the conduction that is essential to allow the ventricles to finish filling with blood before contraction and ejection occur. From the AV node, the impulse spreads through the bundle of His and then the right and the left bundle branches, the latter of which divides in an anterior and posterior fascicle. Finally, the system of Purkinje fibers excites the ventricular myocytes, where the impulse propagates from cell to cell through gap junctions.

The right ventricle contracts like a bellows, whereas the left ventricle contracts like a hand squeezing a tube of toothpaste

The two ventricles share a common envelope of spiral and circular muscle layers. The arrangement of the spiral bundles ensures that ventricular contraction virtually wrings the blood out of the heart, although incompletely. The apex contracts before some of the basal portions of the ventricle, a sequence that propels blood upward to the aortic and pulmonary valves.

The mechanical action of the **right ventricle** resembles that of a bellows used to fan a fire ([Fig. 22-8A](#)). Although the distance between the free wall and the septum is small, the free wall has such a large surface area that a small movement of the free wall toward the septum ejects a large volume.

A RIGHT VENTRICULAR CONTRACTION

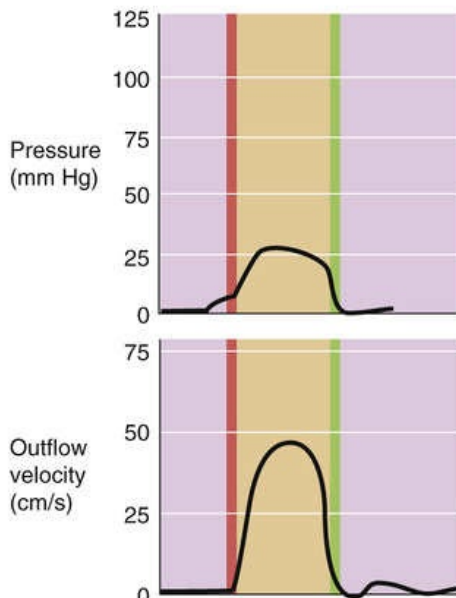

B LEFT VENTRICULAR CONTRACTION

C TIMING OF EVENTS IN CARDIAC CYCLE

D RIGHT VENTRICULAR PRESSURE AND FLOW

E LEFT VENTRICULAR PRESSURE AND FLOW

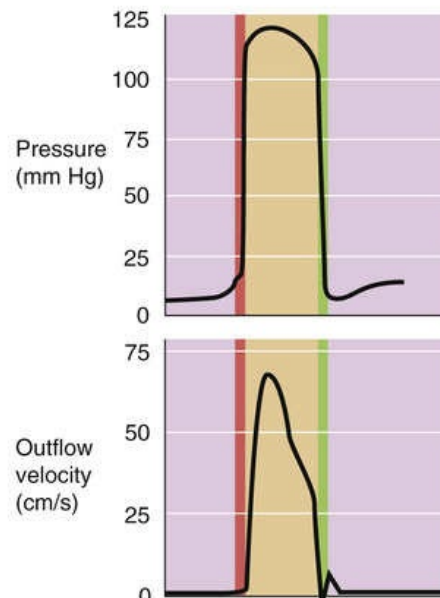

FIGURE 22-8 Comparison of the dynamics of the left and right ventricles.

The mechanism of emptying of the right ventricle involves three motions. First, the longitudinal axis of the right ventricle shortens when spiral muscles pull the tricuspid valve ring toward the apex. Second, the

free wall of the right ventricle moves toward the septum in a bellows-like motion. Third, the contraction of the deep circular fibers of the *left* ventricle forces the septum into a convex shape, so that the septum bulges into the right ventricle. This bulging of the septum stretches the free wall of the right ventricle over the septum. These three motions are well suited for ejection of a large volume, but not for development of a high pressure. The right ventricle ejects the same blood volume as the left ventricle does, but it does so at much lower intraventricular pressures.

The mechanical action of the **left ventricle** occurs by a dual motion (see [Fig. 22-8B](#)): First, constriction of the *circular muscle layers* reduces the diameter of the chamber, progressing from apex to base, akin to squeezing a tube of toothpaste. Second, contraction of the *spiral muscles* pulls the mitral valve ring toward the apex, thereby shortening the long axis. The first mechanism is the more powerful and is responsible for the high pressures developed by the left ventricle. The conical shape of the lumen gives the left ventricle a smaller surface-to-volume ratio than the right ventricle and contributes to the ability of the left ventricle to generate high pressures.

The contraction of the **atria** normally makes only a minor contribution to the filling of the two ventricles when the subject is at rest (see [Box 22-1](#)). However, the contraction of the atria is a useful safety factor in at least two circumstances. During tachycardia, when the diastolic interval—and thus the time for passive filling—is short, the atrial contraction can provide a much-needed boost. Atrial contraction is also useful in certain pathological conditions. For example, when a narrowed (i.e., stenotic) AV valve offers substantial resistance to the flow of blood from atrium to ventricle, the atrial pump can make an important contribution to ventricular filling.

The right atrium contracts before the left, but the left ventricle contracts before the right

When the cardiac cycle was introduced above in the chapter, we assumed that the events on the right and left sides of the heart happen simultaneously. However, as we have already noted in our discussion of the splitting of heart sounds, the timing of the two sides of the heart is slightly different (see [Fig. 22-8C](#)).

Atrial Contraction

Because the SA node is located in the right atrium, atrial contraction begins and ends earlier in the right atrium than in the left (see [Fig. 22-8C](#), “Contraction” panel).

Initiation of Ventricular Contraction

Ventricular contraction starts slightly earlier on the *left* side, and the mitral valve closes before the tricuspid valve. However, this timing difference in the closure of the AV valves (see [Fig. 22-8C](#), “Valve movements” panel) is so small that it is unusual to hear a split S_1 . On the other hand, the right ventricle has a briefer period of isovolumetric contraction because it does not need to build up as much pressure to open its semilunar (i.e., outflow) valve and to initiate ejection. Thus, the pulmonary valve opens slightly ahead of the aortic valve.

Ventricular Ejection

Ejection from the right ventricle lasts longer than that from the left. The semilunar valves do not close simultaneously. The aortic valve, with its higher downstream pressure, closes before the pulmonary valve. Therefore, the pulmonary valve—with its lower downstream pressure—opens first and closes last.

This timing difference in the closure of the semilunar valves explains the normal physiological splitting of S_2 (see Fig. 22-8C, “Sounds” panel). During inspiration, the relatively negative intrathoracic pressure enhances filling of the right heart, causing it to have a larger end-diastolic volume and therefore more blood to eject. The additional time required for right ventricular ejection postpones the closure of the pulmonary valve (P_2), broadening the physiological splitting of S_2 (see p. 511).

Ventricular Relaxation

Isovolumetric relaxation is briefer in the right heart than in the left. The pulmonary valve closes *after* the aortic valve, and the tricuspid valve opens *before* the mitral valve. Therefore, the right ventricle begins filling before the left.

Measurements of ventricular volumes, pressures, and flows allow clinicians to judge cardiac performance

Definitions of Cardiac Volumes

The cardiac output is the product of heart rate and stroke volume (see p. 414). The **stroke volume (SV)** is the difference between ventricular **end-diastolic volume (EDV)** and ventricular **end-systolic volume (ESV)**; that is, the difference between the maximal and minimal ventricular volumes. EDV is typically 120 mL, and ESV is 50 mL, so that

$$\begin{aligned} \text{SV} &= \text{EDV} - \text{ESV} \\ &= 120\text{mL} - 50\text{mL} \\ &= 70\text{mL} \end{aligned} \quad (22-2)$$

The **ejection fraction (EF)** is a dimensionless value, defined as the SV normalized to the EDV:

$$\text{EF} = \frac{\text{SV}}{\text{EDV}} \quad (22-3)$$

In our example, the EF is (70 mL)/(120 mL) or ~0.6. The value should exceed 55% in a healthy person. Whereas the ejection fractions of the left and right ventricles as a rule are equal, clinicians normally measure left ventricular ejection fraction (LVEF).

Measurements of Cardiac Volumes

Clinicians routinely measure the volumes of the cardiac chambers by means of angiography or echocardiography (see pp. 426–428). **One-dimensional (or M-mode) echocardiography** allows one to assess left ventricular performance in terms of linear dimensions and velocities by providing measurements of (1) velocity of the posterior left ventricular wall, (2) fractional shortening of the left ventricular circumference, and (3) rate of fractional circumferential shortening. **Two-dimensional**

echocardiography makes it possible to determine several ventricular volumes:

- Left ventricular end-diastolic volume (LVEDV)
- Left ventricular end-systolic volume (LVESV)
- Stroke volume ($SV = LVEDV - LVESV$)
- Left ventricular ejection fraction ($LVEF = SV/LVEDV$)

Measurement of Ventricular Pressures

For right-sided heart catheterizations, clinicians use a Swan-Ganz catheter, which consists of three parallel tubes of different lengths. The longest is an end-hole catheter with a balloon flotation device that directs the tip in the direction of the blood flow. The other two tubes are side-hole catheters that terminate at two points proximal to the tip. The physician advances the catheter percutaneously through a large systemic vein, into the right heart, and then into the pulmonary circulation, where the tip of the longest tube literally *wedges* in a small pulmonary artery. Because a continuous and presumably closed column of blood connects the probe's end and the left atrium, the **wedge pressure** is taken as an index of left atrial pressure. For left-sided heart catheterizations, clinicians insert a simple catheter percutaneously into an artery and then advance the catheter tip upstream to the left heart. [Table 22-3](#) lists some of the most important pressure values for the right and left sides of the heart.

TABLE 22-3
Comparison of Pressures in the Right and Left Circulations

PRESSURES (mm Hg)					
RIGHT ATRIUM			LEFT ATRIUM		
Mean		2	Mean		8
			a wave	13	
			c wave	12	
			v wave	15	
RIGHT VENTRICLE			LEFT VENTRICLE		
Peak systolic	30		Peak systolic	130	
End diastolic	6		End diastolic	10	
PULMONARY ARTERY			AORTA		
Mean		15	Mean		95
Peak systolic	25		Peak systolic	130	
End diastolic	8		End diastolic	80	
PULMONARY CAPILLARIES			SYSTEMIC CAPILLARIES		
Mean		10	Mean		25

Measurement of Flows

The cardiologist can calculate flow from changes in ventricular volume, as measured by echocardiography and the Doppler ultrasound technique (see [pp. 427–428](#)), both of which measure the flow of blood in the outflow tract (i.e., aorta). [Figure 22-8D and E](#) illustrate the profiles of outflow pressure and velocity for the two ventricles. Although the two ventricles expel on average the same *amount* of blood in a single cardiac cycle, the peak *velocity* is much higher in the left ventricle. In addition, the velocity rises far more rapidly in the left ventricle, which indicates greater acceleration of the blood during ejection. The *pressure* wave is about five times larger in the left ventricle than in the right, and the rate at which the pressure rises ($\Delta P/\Delta t$) is more rapid in the left ventricle.

The pressure-volume loop of a ventricle illustrates the ejection work of the ventricle

In [Figure 22-1](#), we saw separate plots of ventricular *pressure* against time and *volume* against time. If, at each point in time, we now plot pressure against volume, the result is a **pressure-volume loop**, as is shown in [Figure 22-9](#) for the left ventricle. This loop is a “phase plot” that describes the relationship between left ventricular pressure and left ventricular volume during the cardiac cycle. Notice that, although *time* does not explicitly appear in this plot, as we make one complete counterclockwise cycle around the loop, we sequentially plot pressure and volume at all time points of the cardiac cycle. However, the distance between two points on the loop is not proportional to elapsed time.

FIGURE 22-9 Pressure-volume loop of the left ventricle.

In examining this pressure-volume loop, we will arbitrarily start at point A in [Figure 22-9](#), and then consider each of the segments of the loop (e.g., AB, BC, and so on) before again returning to point A. Although we use the left ventricle as an example, a similar analysis applies to the right ventricle.

Segment AB

Point A in [Figure 22-9](#) represents the instant at which the *mitral valve opens*. At this point, left ventricular volume is at its minimal value of ~50 mL, and left ventricular pressure is at the fairly low value of ~7 mm Hg. As the mitral valve opens, the ventricle begins to fill passively, because atrial pressure is higher than ventricular pressure. During interval AB, ventricular pressure falls slightly to ~5 mm Hg

because the ventricular muscle is continuing to relax during diastole. Thus, despite the rapid entry of blood, ventricular pressure falls to its lowest value in the cardiac cycle.

Segment BC

During a second phase of ventricular filling, volume rises markedly from ~70 to ~120 mL, accompanied by a rather modest increase in pressure from ~5 to ~10 mm Hg. The modest rise in pressure, despite a doubling of ventricular volume ΔV , reflects the high compliance ($C = \Delta V / \Delta P$) of the ventricular wall during late diastole. The relationship between pressure and volume during segment BC is similar to that in blood vessels (see p. 454).

Segment CD

Point C in Figure 22-9 represents the *closure of the mitral valve*. At this point, ventricular filling has ended and **isovolumetric contraction**—represented by the vertical line CD—is about to begin. Thus, by the definition of *isovolumetric*, ventricular volume remains at 120 mL while left ventricular pressure rises to ~80 mm Hg, about equal to the aortic end-diastolic pressure.

Segment DE

Point D in Figure 22-9 represents the *opening of the aortic valve*. With the outlet to the aorta now open, the ventricular muscle can begin to shorten and to eject blood. During this period of rapid ejection, ventricular volume decreases from ~120 to ~75 mL. Notice that as contraction continues during interval DE, the ventricular pressure rises even farther, reaching a peak systolic value of ~130 mm Hg at point E.

Segment EF

Point E in Figure 22-9 represents the instant at which the ventricular muscle starts to relax. During this period of decreased ejection, ventricular pressure falls from ~130 to ~100 mm Hg. Nevertheless, blood continues to leave the ventricle, and ventricular volume falls from ~75 mL at point E to ~50 mL at point F. Point F represents end-systolic volume and pressure. Notice that the ventricle does not shrink to zero volume at the end of systole. In total, $120 - 50 = 70$ mL of blood has left the ventricle during systole (i.e., between points D and F). Therefore, the stroke volume is substantially less than the maximum ventricular volume (i.e., EDV). The ejection fraction in this example is ~60%, which is in the normal range. Ejection occurs against aortic pressures ranging between 80 and 130 mm Hg. Therefore, ejection is not “isotonic” (see pp. 237–238).

Segment FA

Point F in Figure 22-9 represents the *closing of the aortic valve*. At this point, ejection has ended and **isovolumetric relaxation** is about to begin. The ventricular volume remains at 50 mL, while left ventricular pressure falls from ~100 mm Hg at point F to ~7 mm Hg at point A. At the end of isovolumetric relaxation, the mitral valve opens and the cardiac cycle starts all over again with ventricular filling.

The six segments of the pressure-volume loop in Figure 22-9 correspond to different phases of the cardiac cycle:

- *Phase 1*, the inflow phase, includes segments AB and BC.
- *Phase 2*, isovolumetric contraction, includes segment CD.

- *Phase 3*, the outflow phase, includes segments DE and EF.
- *Phase 4*, isovolumetric relaxation, includes segment FA.

Segments CDEF represent systole, whereas segments FABC represent diastole.

The “pumping work” done by the heart accounts for a small fraction of the total energy the heart consumes

The heart does its useful work as a pump by imparting momentum to the blood and propelling it against the resistance of the periphery.

Work, in its simplest definition, is the product of the force applied to an object and the distance the object moves ($W = \text{force} \times \text{distance}$). In considering **pressure-volume work**, we must revise this definition. Imagine that we have a volume of blood in a syringe. If we apply a *constant* force to the plunger—that is, if we apply a *constant* pressure to the blood—the plunger moves a certain distance as we eject the blood through the needle, thereby reducing blood volume by an amount ΔV . How much work have we done? For pressure moving a fluid, the external work is

$$W = P \cdot \Delta V$$

(22-4)

If the aortic pressure were constant, the work done with each heartbeat would be simply the product of the aortic pressure (P) and the stroke volume ($\Delta V = SV = EDV - ESV$).

The pressure-volume relationships in [Figure 22-10](#) illustrate the pressure-volume work of the **left ventricle**. The surface below the *segment* ABC (i.e., filling phase) is the work done *by the blood* (previously contained in the venous reservoirs and atria at a low pressure) on the ventricle (see [Fig. 22-10A](#)). The surface below DEF (i.e., ejection phase) is the work done *by the heart* on the blood during the ejection (see [Fig. 22-10B](#)). The difference between the areas in [Figure 22-10A and B](#)—that is, the area within the single-cycle loop—is the *net* external work done by the heart (see [Fig. 22-10C](#)). 🍷N22-5

FIGURE 22-10 External work of the left ventricle.

N22-5

“Pumping Work” Done by the Heart

Contributed by Emile Boulpaep

In applying Equation 22-4,

$$W = P \cdot \Delta V$$

to the external work done by the heart, we assumed that the left ventricle pumps against a constant aortic pressure. In reality, of course, the aortic pressure is not constant. Thus, in Equation 22-4 we also should have included a $V \cdot \Delta P$ term to take into account the changing aortic pressure, so that Equation 22-4 becomes

$$W = P \cdot \Delta V + \Delta P \cdot V \quad (\text{NE 22-2})$$

Nevertheless, our calculation of work using the *area of the loop* in Figure 22-10C does take this extra term into account.

The pressure-volume diagram for the **right ventricle** has the same general shape. However, the area (i.e., *net* external work) is only about one fifth as large because the pressures are so much lower.

The area of the loop in Figure 22-10C—that is, the pressure-volume work ($P \cdot V$)—ignores the speed at which the ventricle pumps the blood (i.e., the acceleration that the heart imparts to the blood, or the time it takes to complete one cardiac cycle). Thus, the work per beat should also include the **kinetic**

energy ($\frac{1}{2} mv^2$) that the heart imparts to the ejected blood:

$$\underbrace{W}_{\text{Total external work}} = \underbrace{P \cdot V}_{\text{Pressure-volume work}} + \underbrace{\frac{1}{2} mv^2}_{\text{Kinetic energy}}$$

(22-5)

Of its total external work, the heart delivers only a relatively small fraction as kinetic energy. Moreover, the total external work is itself only a small portion of the total energy that the heart actually expends. Like other muscles, the heart not only shortens and performs *classical* work (e.g., isotonic contraction), but it also maintains active tension without shortening (i.e., isometric contraction; see pp. 237–238). During the isovolumetric contraction, the ventricle develops and maintains a high pressure without performing any total external work—just as we perform no useful work when we hold a weight without lifting it. However, in both isometric exercises, the muscle breaks down ATP as long as it maintains isometric tension; the energy ends up as heat. This type of energy cost in heart muscle is called **tension heat**, **N22-6** which is proportional to the product of the tension of the ventricular wall (T) and the length of time (Δt) that the ventricle maintains this tension (i.e., tension-time integral). In the case of the heart, the pressure against which the ventricle must pump is a major determinant of the wall tension.

N22-6

Tension Heat

Contributed by Emile Boulpaep

From the physical sciences, we know that we can define external mechanical **work** as the product of force and displacement. In the case of the heart, the external mechanical work is the product of the changes in pressure (i.e., force per unit area) and volume (i.e., displacement in three dimensions):

$$W = P \cdot \Delta V + \Delta P \cdot V \quad \text{(NE 22-3)}$$

This is the equation we introduced in **N22-5**. The first term is particularly important during isovolumetric contraction, and the second term is particularly important during the ejection phase. However, as we noted on page 521, the heart consumes more energy than we can account for by the external mechanical work in the above equation.

Imagine that the left ventricle had to maintain itself for some time at point D in Figure 22-9. Here there is neither a change in pressure nor a change in volume, so that the above equation would tell us that the heart is performing no external mechanical work. Maintaining this isometric tension is like extending an arm holding a weight without lifting it—we do no external mechanical work, yet we burn ATP—**tension heat**. Moreover, this tension heat is proportional not only to the mass of the weight but also to how long we hold it! In contrast, if we transferred the weight from our arm to a nail in the wall, that nail could hold that weight for an indefinite period without consuming any energy.

If the path DEF in Figure 22-9 (i.e., ejection) were perfectly horizontal (a volume decrease at constant

pressure), the external mechanical work would be $P \cdot \Delta V$ (i.e., the second term in the above equation). However, merely maintaining this constant pressure during the period of ejection requires energy—tension heat. Moreover, just as in our analogy with the extended arm holding the weight, the tension heat of the heart is proportional to the pressure (i.e., the tension) and the time the pressure is maintained, as described by the third term in Equation 22-6. Returning to Figure 22-9, we can increase the tension heat either by elevating the path DEF (i.e., raising the pressure) or increasing the time interval (Δt) between D and F (i.e., slowing the ejection of the same volume). In practice, the Δt for each ejection might increase with aortic stenosis, which increases the ejection time. Alternatively, cumulative Δt (i.e., the aggregate Δt over a minute's time) will increase with a high heart rate. Thus, performing the same external work at a high heart rate requires more total energy consumption than performing the same work at a low heart rate.

The total energy transformed in one cardiac cycle is the sum of the total external work done on the blood and the tension heat:

$$E = \underbrace{P \cdot V}_{\text{Pressure-volume work}} + \underbrace{\frac{1}{2}mv^2}_{\text{Kinetic energy}} + \underbrace{k \cdot T \cdot \Delta t}_{\text{Tension heat}}$$

Total external work

(22-6)

where k is a proportionality constant that converts $T \cdot \Delta t$ into units of energy. The tension heat is the *major* determinant of the total energy requirements of the heart. Total external work represents a relatively small fraction (3%) of the total energy needs of the heart at rest, rising to as much as 10% during exercise. The heat developed as part of the tension-time integral remains the major component of the total energy consumption, even during exercise.

The tension heat is not only far more costly for the heart than the pressure-volume work but is also of considerable practical interest for the patient with coronary artery disease who wishes to step up cardiac output during increased physical activity. The major burden for such an individual may be not so much the total external work expended in driving additional blood through the circulation (i.e., increasing the cardiac output), but rather an increase in *tension heat* ($k \cdot T \cdot \Delta t$). Thus, it is advantageous to the patient to have a low wall tension (T)—that is, a low blood pressure. It is also advantageous for the patient not to spend too much time (Δt) in systole. The heart spends a greater fraction of its time in systole when the heart rate is high. Thus, the cardiac patient is better off to increase cardiac output at low pressure and low heart rate (i.e., a low $T \cdot \Delta t$ product). The only option left is to increase stroke volume.

The ratio of the ventricle's total external work ($P \cdot V + \frac{1}{2}mv^2$) to the total energy cost (i.e., W/E) is the heart's **mechanical efficiency**. Note that the mechanical efficiency has nothing to do with how effective the ventricle is at expelling blood (i.e., ejection fraction).

From Contractile Filaments to a Regulated Pump

In [Chapter 9](#), we examined the general features of muscle contraction and compared the properties of skeletal, cardiac, and smooth muscle. In this chapter, we examine how some of the features of cardiac muscle underlie cardiac performance.

The entry of Ca^{2+} from the outside triggers Ca^{2+} -induced Ca^{2+} release from the sarcoplasmic reticulum

Excitation-contraction (EC) coupling in cardiac ventricular myocytes (see [pp. 242–243](#)) is similar to EC coupling in skeletal muscle (see [pp. 229–230](#)). One major difference is that, in the case of skeletal muscle, the initiating event is the arrival of an action potential at the neuromuscular junction, the release of acetylcholine, and the initiation of an end-plate potential. In the ventricular myocyte, action potentials in adjacent myocytes depolarize the target cell through gap junctions (see [p. 483](#)) and thereby generate an action potential.

As in a skeletal muscle fiber (see [pp. 229–230](#)), the depolarization of the plasma membrane in the ventricular myocyte invades T tubules that run radially to the long axis of the myocyte. Unlike skeletal muscle cells, cardiac myocytes also have *axial* T tubules that run parallel to the long axis of the cell and interconnect adjacent radial T tubules.

Another major difference in EC coupling between cardiac and skeletal muscle is the way that the L-type Ca^{2+} channels (Cav1.2, dihydropyridine receptors) in the T-tubule membrane activate the Ca^{2+} -release channels made up of four RYR2 molecules in the sarcoplasmic reticulum (SR) membrane. In skeletal muscle, the linkage is mechanical and does not require Ca^{2+} entry per se. If you place skeletal muscle in a Ca^{2+} -free solution, the muscle can continue contracting until its intracellular Ca^{2+} stores become depleted. In contrast, cardiac muscle quickly stops beating. Why?

In cardiac muscle, Ca^{2+} entry through the L-type Ca^{2+} channel Cav1.2 ([Fig. 22-11](#), red arrow No. 1) is essential for raising $[\text{Ca}^{2+}]_i$ in the vicinity of the RYR2 on the SR. A subset of Cav1.2 channels may be part of caveolae. This trigger Ca^{2+} activates an adjacent cluster of RYRs in concert, causing them to release Ca^{2+} locally into the cytoplasm by **Ca^{2+} -induced Ca^{2+} release (CICR)** (see [Fig. 22-11](#), red arrow No. 2). In the CICR coupling mechanism, the action of this Ca^{2+} is analogous to that of a neurotransmitter or chemical messenger that diffuses across a synapse to activate an agonist-gated channel, but in this case the synapse is the intracellular diffusion gap of ~ 15 nm between plasma-membrane Cav channels and RYR channels on the SR membrane. The CICR mechanism is a robust amplification system whereby the local influx of Ca^{2+} from small clusters of L-type Cav channels in the plasma membrane triggers the coordinated release of Ca^{2+} from the high-capacity Ca^{2+} stores of the SR. Such single CICR events can raise $[\text{Ca}^{2+}]_i$ to as high as $10\text{ }\mu\text{M}$ in microdomains of $\sim 1\text{ }\mu\text{m}$ in diameter. These localized increases in $[\text{Ca}^{2+}]_i$ appear as **calcium sparks** [N9-3](#) when they are monitored with a Ca^{2+} -sensitive dye by confocal microscopy. If many L-type Ca^{2+} channels open simultaneously in ventricular myocytes, the spatial and temporal summation of many elementary Ca^{2+} sparks leads to a global increase in $[\text{Ca}^{2+}]_i$. The time course of this global $[\text{Ca}^{2+}]_i$ increase in ventricular myocytes lasts longer than that of the action potential (compare blue and black curves in inset in [Fig. 22-11](#)) because the RYR Ca^{2+} -release channels remain open for a longer time than L-type Ca^{2+} channels.

FIGURE 22-11 Role of Ca²⁺ in cardiac contraction. The inset pertains to ventricular myocytes. V_m, membrane potential.

Atrial myocytes have a poorly developed T-tubule system. In atrial cells, depolarization-induced activation of L-type Cav channels on the plasma membrane triggers Ca²⁺ release from RYR channels in the peripheral SR (i.e., closest to the plasma membrane), eliciting subsurface Ca²⁺ sparks. These peripheral Ca²⁺ sparks then activate a wave of CICR that propagates inwardly throughout the central SR network of the atrial myocyte.

A global rise in [Ca²⁺]_i initiates contraction of cardiac myocytes

The basic structure of the thin and thick filaments in cardiac muscle is the same as in skeletal muscle (see Fig. 9-5). After [Ca²⁺]_i increases, Ca²⁺ binds to the cardiac isoform of troponin C (TNNC1; see Table 9-1), and the Ca²⁺-TNNC1 complex releases the inhibition of the cardiac isoform of troponin I (TNNI3) on actin. As a result, the tropomyosin (TPM1) filaments bound to cardiac troponin T (TNNT2) on the thin filament shift out of the way (see Fig. 9-6), allowing myosin to interact with active sites on the actin. ATP fuels the subsequent cross-bridge cycling (see Fig. 9-7). Because the heart can never rest, cardiac myocytes have a very high density of mitochondria and thus are capable of sustaining very high rates of

oxidative phosphorylation (i.e., ATP synthesis).

The cross-bridge cycling causes thick filaments to slide past thin filaments, generating tension. The time course of cardiac tension development is delayed relative to the time course of the global surge in $[Ca^{2+}]_i$ (compare red and blue curves in inset of Fig. 22-11).

When we discussed the mechanics of skeletal muscle in Chapter 9, we introduced the concept of a length-tension diagram (see Fig. 9-9C), which is a plot of muscle tension as a function of muscle length. The length parameter in such a plot can be either the length of the whole skeletal muscle or the length of a single sarcomere. For heart muscle, which wraps around the ventricle, the length parameter can be either the ventricular volume, which is analogous to whole-muscle length, or the sarcomere length. The sarcomere, stretching from one Z line to another, is the functional unit in both skeletal and cardiac muscle.

Phosphorylation of phospholamban and of troponin I speeds cardiac muscle relaxation

With the waning of the phase 2 plateau of the cardiac action potential (see Fig. 21-4B, top panel), the influx of Ca^{2+} through L-type Ca^{2+} channels decreases, which lessens the release of Ca^{2+} by the SR. By itself, halting of Ca^{2+} entry and release can only prevent a further increase in $[Ca^{2+}]_i$. The actual relaxation of the contractile proteins depends on four processes: (1) extrusion of Ca^{2+} into the extracellular fluid (ECF), (2) reuptake of Ca^{2+} from the cytosol by the SR, (3) uptake of Ca^{2+} from the cytosol into the mitochondria, and (4) dissociation of Ca^{2+} from troponin C. Processes 2 and 4 are highly regulated.

Extrusion of Ca^{2+} into the ECF

Even during the plateau of the action potential, the myocyte extrudes some Ca^{2+} . After the membrane potential returns to more negative values, Ca^{2+} extrusion (see Fig. 22-11, green arrow No. 1) gains the upper hand and $[Ca^{2+}]_i$ falls. In the steady state (i.e., during the course of several action potentials), the cell must extrude all the Ca^{2+} that enters the cytosol from the ECF through L-type Ca^{2+} channels. As in most other cells (see p. 126), this extrusion of Ca^{2+} into the ECF occurs by two pathways: (1) a sarcolemmal Na-Ca exchanger (NCX1), which operates at relatively high levels of $[Ca^{2+}]_i$; and (2) a sarcolemmal Ca pump (cardiac subtypes 1, 2, and 4 of plasma-membrane Ca ATPase, or PMCA), which may function at even low levels of $[Ca^{2+}]_i$. However, PMCA contributes only modestly to relaxation. Because PMCA is concentrated in caveolae, which contain receptors for various ligands, its role may be to modulate signal transduction.

Reuptake of Ca^{2+} by the SR

Even during the plateau of the action potential, some of the Ca^{2+} accumulating in the cytoplasm is sequestered into the SR (see Fig. 22-11, green arrow No. 2) by the cardiac subtype of the sarcoplasmic and endoplasmic reticulum Ca pump SERCA2a (see p. 118). **Phospholamban (PLN)**,  N22-7 an integral SR membrane protein with a single transmembrane segment, is an important regulator of SERCA2a. In SR membranes of cardiac, smooth, and slow-twitch skeletal muscle, unphosphorylated PLN can exist as a homopentamer that may function in the SR as an ion channel or as a regulator of Cl^- channels. The dissociation of the pentamer allows the hydrophilic cytoplasmic domain of PLN monomers to inhibit SERCA2a. However, phosphorylation of PLN by any of several kinases relieves PLN's inhibition of SERCA2a, allowing Ca^{2+} resequestration to accelerate. The net effect of phosphorylation is

an increase in the rate of cardiac muscle relaxation. PLN-knockout mice have uninhibited SERCA2a Ca pumps and thus an increased velocity of muscle relaxation.

N22-7

Phospholamban

Contributed by Emile Boulpaep

Phospholamban (PLN or PLB) is a 6-kDa integral membrane protein with 52 amino acids and a single transmembrane domain. The protein kinases that can phosphorylate PLN include PKA, sarcoplasmic reticulum calmodulin kinase (SRCaM kinase—a distinct Ca^{2+} -CaM-dependent protein kinase), and a cGMP-dependent kinase (see pp. 66–67).

As noted in the text, the phosphorylated PLN can exist as a homopentamer that may function in the SR as an ion channel. Structural biology studies of PLN indicate that, at its narrowest point, the pore radius is 1.8 Å.

Phosphorylation of PLN by protein kinase A (PKA) explains why β_1 -adrenergic agonists (e.g., epinephrine), which act through the PKA pathway (see p. 57), speed up the relaxation of cardiac muscle. Phosphoprotein phosphatase 1 (PP1) dephosphorylates PLN, thereby terminating Ca^{2+} reuptake.

Uptake of Ca^{2+} by Mitochondria

The mitochondria take up a minor fraction of the Ca^{2+} accumulating in the cytoplasm (see Fig. 22-11, green arrow No. 3). The inner mitochondrial membrane contains large-conductance, highly selective Ca^{2+} channels (MiCas) that are inwardly rectifying. At potentials of -160 mV, which are typical for energized mitochondria, the MiCa channels carry a substantial Ca^{2+} current. Unlike many other Ca^{2+} channels, MiCa does not inactivate as intramitochondrial $[\text{Ca}^{2+}]$ rises to micromolar concentrations.

Dissociation of Ca^{2+} from Troponin C

As $[\text{Ca}^{2+}]_i$ falls, Ca^{2+} dissociates from troponin C (see Fig. 22-11, green arrow No. 4; see p. 233), blocking actin-myosin interactions and causing relaxation. β_1 -adrenergic agonists accelerate relaxation by promoting phosphorylation of troponin I, which in turn enhances the dissociation of Ca^{2+} from troponin C.

The overlap of thick and thin filaments cannot explain the unusual shape of the cardiac length-tension diagram

We discussed passive and active length-tension diagrams for skeletal muscle in conjunction with Figure 9-9C and D. We obtain a *passive* length-tension diagram by holding a piece of resting skeletal or cardiac muscle at several predefined lengths and measuring the tension at each length (Fig. 22-12A, green and violet curves). We obtain the *active* length-tension diagram by stimulating the muscle at each predefined length (i.e., isometric conditions) and measuring the *increment* in tension from its resting or passive value (see Fig. 22-12A, turquoise and brown curves).

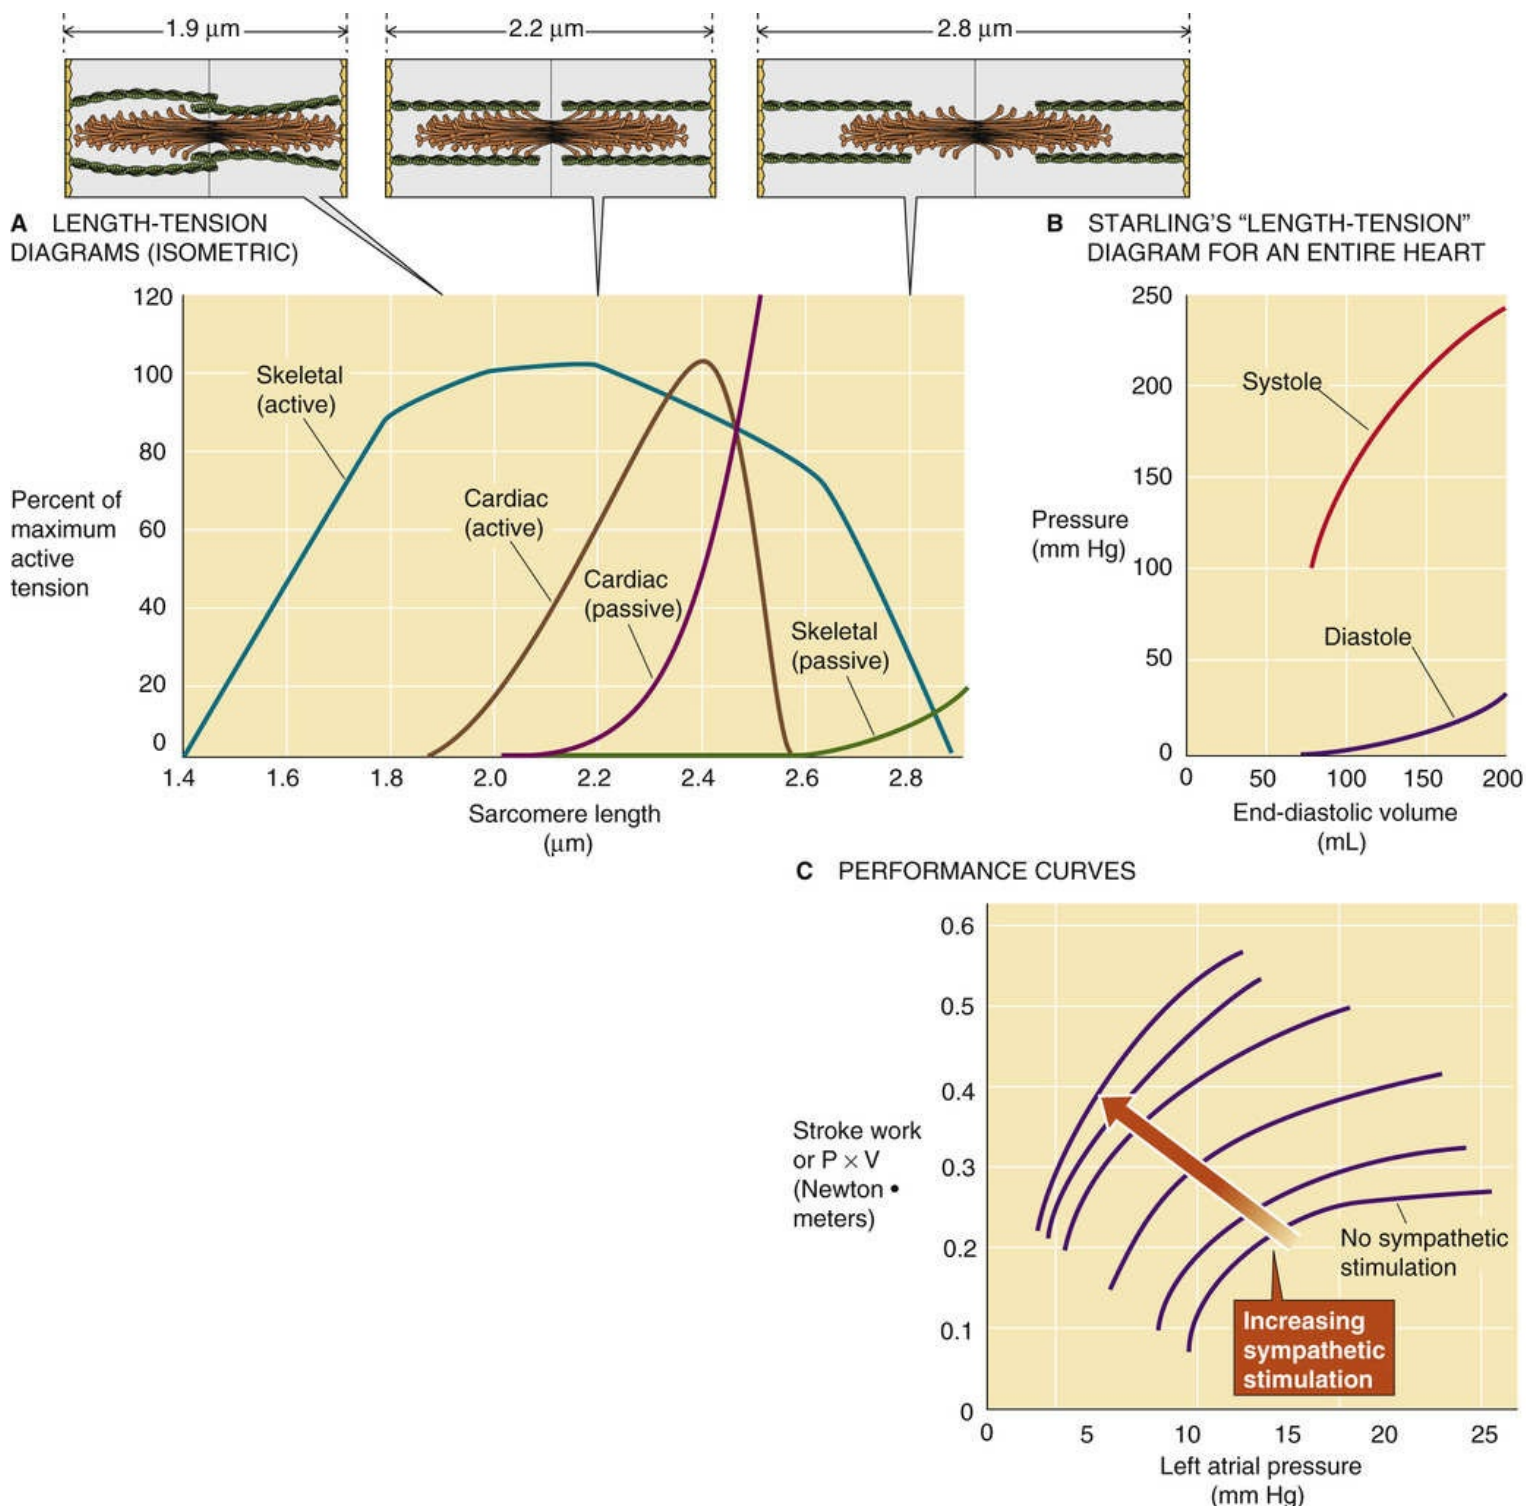

FIGURE 22-12 Length-tension diagram. Compared with **A**, in **B** EDV on the x-axis is used as an index of sarcomere length. (Because EDV was difficult to measure before the days of echocardiography, Starling actually used left atrial pressure as an index of the degree of filling.) Starling measured pressure on the y-axis as an index of tension. Thus, systolic pressure replaces active tension, and diastolic pressure replaces passive tension. In **C**, left atrial pressure on the x-axis is used as an index of sarcomere length, and stroke work (systolic pressure \times ejected volume) on the y-axis is used instead of tension.

The **passive length-tension diagrams** for skeletal and cardiac muscle are quite different. The passive tension of a skeletal muscle (see Fig. 22-12A, green curve) is practically nil until the length of the sarcomere exceeds 2.6 μm . Beyond this length, passive tension rises slowly. On the other hand, the passive tension of cardiac muscle (see Fig. 22-12A, violet curve) begins to rise at much lower sarcomere lengths and rises much more steeply. As a result, cardiac muscle will break if it is stretched beyond a sarcomere length of 2.6 μm , whereas it is possible to stretch skeletal muscle to a sarcomere length of 3.6 μm .

The reason for the higher passive tension is that the noncontractile (i.e., elastic) components of cardiac muscle are less distensible. The most important elastic component is the giant protein **titin** (see p. 234), which acts as a spring that provides the opposing force during stretch and the restoring force during shortening (see Fig. 9-4B).

The **active length-tension diagrams** also differ between skeletal and cardiac muscle. The active tension of skeletal muscle (see Fig. 22-12A, turquoise curve) is high and varies only modestly between sarcomere lengths of 1.8 and 2.6 μm . In Chapter 9, we attributed the shape of this curve to the degree of myofilament overlap (see pp. 238–240). In cardiac muscle (see Fig. 22-12A, brown curve), active tension has a relatively sharp peak when the muscle is prestretched to an initial sarcomere length of $\sim 2.4 \mu\text{m}$. As the prestretched sarcomere length increases from 1.8 to 2.4 μm , active tension rises steeply. We cannot account for this rise by an increase in the overlap of thick and thin filaments because the filament dimensions of cardiac and skeletal muscle are similar. Rather, the rise in tension at longer sarcomere lengths in cardiac muscle probably has two general causes: (1) Raising the sarcomere length above 1.8 μm increases the Ca^{2+} sensitivity of the myofilaments. One mechanism controlling the Ca^{2+} sensitivity may be interfilament spacing between thick and thin filaments, because fiber diameter varies inversely with fiber length. As we stretch the muscle to greater sarcomere lengths, the lateral filament lattice spacing is less than in an unstretched fiber so that the probability of cross-bridge interaction increases. Increased cross-bridge formation in turn increases the Ca^{2+} affinity of TNNC1, thereby recruiting more cross-bridges and therefore producing greater force. Another mechanism could be that, as the muscle elongates, increased strain on titin either alters lattice spacing or alters the packing of myosin molecules within the thick filament. (2) Raising the sarcomere length above 1.8 μm increases tension on stretch-activated Ca^{2+} channels, thereby increasing Ca^{2+} entry from the ECF and thus enhancing Ca^{2+} -induced Ca^{2+} release.

As cardiac sarcomere length increases above 2.4 μm , active tension declines precipitously, compared with the gradual fall in skeletal muscle. Once again, this fall-off does not reflect a problem in the overlap of thin and thick filaments. Instead, titin increases the passive *stiffness* of cardiac muscle and may also impede development of *active tension* at high sarcomere lengths.

Starling's law states that a greater fiber length (i.e., greater ventricular volume) causes the heart to deliver more mechanical energy

Long before the development of the sliding-filament hypothesis and our understanding that active tension should depend on sarcomere length, Ernest Starling in 1914 anticipated the results of Figure 22-12A using an isolated heart-lung preparation. **N22-10 Starling's law** states that “the mechanical energy set free on passage from the resting to the contracted state depends on the area of ‘chemically active surfaces,’ i.e., on the length of the fibres.” Therefore, the initial length of myocardial fibers determines the work done during the cardiac cycle. Figure 22-12B shows the results of experiments that Starling performed on the intact heart. Starling assumed that the initial *length* of the myocardial fibers is proportional to the end-diastolic volume. Further, he assumed that *tension* in the myocardial fibers is proportional to the systolic pressure. Therefore, starting from a volume-pressure diagram, Starling was able to reconstruct an equivalent length-tension diagram (Table 22-4).

TABLE 22-4

Equivalent Units for Converting Between a Three-Dimensional Heart and a Linear Muscle Fiber

ISOLATED MUSCLE = LINEAR		CARDIAC VENTRICLE = HOLLOW ORGAN	
PARAMETER	UNITS	PARAMETER	UNITS
Length	mm	Volume	mL
Extent of shortening	mm	Stroke volume	mL
Velocity of shortening	mm/s	Velocity of ejection	mL/s
Load	g	Pressure	mm Hg
or force	dyne		
or tension	dyne/cm ²		

This table shows the equivalence between dimensions when converting from the contraction of a hollow organ, such as a cardiac ventricle, to a linear model of a single muscle contraction.

N22-10

Starling’s Law

For the original description of Starling’s law, see the landmark paper: Patterson SW, Piper H, Starling EH: The regulation of the heart beat. J Physiol 48:465-513, 1914.

His diagram for *diastole* (see Fig. 22-12B, purple curve), which shows a rising pressure (tension) with increased EDV (fiber length), is very similar to the early part of the *passive* length-tension diagram for cardiac muscle (see Fig. 22-12A, violet curve). His diagram for *systole* (see Fig. 22-12B, red curve) is more or less equivalent to the ascending phase of the *active* length-tension diagram for cardiac muscle (see Fig. 22-12A, brown curve). Therefore, Starling's systole curve shows that the heart is able to generate more pressure (i.e., deliver more blood) when more is presented to it.

A **ventricular performance curve** (see Fig. 22-12C) is another representation of Starling's length-tension diagram, but it is one a clinician can obtain for a patient. A ventricular performance curve shows stroke work ($P \cdot \Delta V$, see Equation 22-4), which includes Starling's systolic pressure (itself an estimate of muscle tension) on the y-axis, plotted against left atrial pressure, which corresponds to Starling's end-diastolic volume (itself an estimate of muscle length), on the x-axis. What we learn from performance curves obtained for living subjects is that Starling's law *is not a fixed relationship*. For instance, the norepinephrine released during sympathetic stimulation—which increases myocardial contractility (as we will see below in this chapter)—steepens the performance curve and shifts it upward and to the left (see brown arrow in Fig. 22-12C). Similar shifts occur with other **positive inotropic** agents (e.g., cardiac glycosides), that is, drugs that increase myocardial contractility. Note also that ventricular performance curves show no descending component because sarcomere length does not increase beyond 2.2 to 2.4 μm in healthy hearts.

The velocity of cardiac muscle shortening falls when the contraction occurs against a greater opposing force (or pressure) or at a shorter muscle length (or lower volume)

The functional properties of cardiac muscle—how much tension it can develop, how rapidly it can contract—depend on many factors, but especially on two properties intrinsic to the cardiac myocyte.

1. *Initial sarcomere length.* For the beating heart, a convenient index of initial sarcomere length is *EDV*. Both initial sarcomere length and EDV are measures of the **preload** imposed on the cardiac muscle *just before* it ejects blood from the ventricle during systole. *Starling's law*, in which the independent variable is EDV, focuses on preload.
2. *Force that the contracting myocytes must overcome.* In the beating heart, a convenient index of opposing force is the *arterial pressure* that opposes the outflow of blood from the ventricle. Both opposing force and arterial pressure are measures of the **afterload** the ventricular muscle must overcome as it ejects blood during systole. Experiments on *isotonic contractions* focus on the afterload, factors that the ventricle can sense only *after* the contraction has begun.

Figure 22-13 shows how one might measure the *velocity of shortening* in a way that is relevant for a cardiac muscle facing both a preload and an afterload. In Figure 22-13A, the muscle starts off at rest, stretched between a fixed support (bottom of the muscle) and the left end of a lever (top of the muscle). A weight attached to the other end of the lever, but resting on a table, applies stretch to the muscle to the extent allowed by the screw, which adjusts the “stop” of the lever's left end. Thus, the combination of the weight and the screw determines initial sarcomere length (i.e., preload). At this time, the muscle cannot sense the full extent of the weight. The more we stretch the muscle by retracting the screw, the greater the preload. When we begin to stimulate the muscle, it develops a gradually increasing tension (see Fig. 22-13C, lower blue curve), but the length between the fixed point and the left end of the lever (see Fig. 22-13A) remains constant. That is, the muscle cannot shorten. Therefore, in the first phase of the experiment, the muscle exerts increasing *isometric tension*.

When the muscle has built up enough tension, it can now begin lifting the weight off the table (see Fig. 22-13B). This phase of the contraction is termed afterloaded shortening. The tension now remains at a fixed afterload value (flat portion of lower curve in Fig. 22-13C) but the muscle gradually shortens (rising portion of upper blue curve). Therefore, in the second phase of the experiment, the muscle exerts *isotonic contraction*. From the slope of the upper curve in Figure 22-13C, we can compute the velocity of shortening at a particular afterload.

This experiment roughly mimics the actions of ventricular muscle during systole. Initially, during its *isometric* contraction, our hypothetical muscle increases its tension at constant length, as during the *isovolumetric* contraction of the cardiac cycle shown in segment CD of Figure 22-9. The initial length corresponds to EDV, the preload. Later, the muscle shortens while overcoming a constant force (i.e., generating a constant tension), as during the ejection phase of the cardiac cycle shown in segment DEF of Figure 22-9. The tension corresponds to arterial pressure, the afterload.

What happens if we vary the afterload (i.e., change the weight)? As we already observed in our discussion of skeletal muscle, it is easier to lift a feather than a barbell. Thus, with a heavier weight, the muscle develops a lot of tension, but shortens slowly (see Fig. 22-13D, red tracings). Conversely, with a lighter weight, the muscle develops only a little bit of tension, but shortens rapidly (purple curves).

If we plot the velocities of shortening in Figure 22-13D as a function of the three different afterloads being lifted, we obtain the purple, blue, and red points on the load-velocity curve in Figure 22-13E. The velocity of muscle shortening corresponds to the outflow velocity of the ventricle (see Fig. 22-8D, E). Thus, at higher opposing arterial pressures the outflow velocity should decrease. The black curve in Figure 22-13E applies to a muscle that we stretched only slightly in the preload phase (i.e., low preload in Fig. 22-13A). The red curve in Figure 22-13E shows a similar load-velocity relationship for a muscle that we stretched greatly in the preload phase (i.e., high preload). In both cases, the velocity of shortening

increases as the tension (i.e., afterload) falls.

When the afterload is so large that no shortening ever occurs, that afterload is the **isometric tension**, shown as the point of zero velocity on the x-axis of [Figure 22-13E](#). As expected from Starling's law, the greater the initial stretch (i.e., preload), the greater the isometric tension. In fact, at *any* velocity (see [Fig. 22-13E](#), dashed horizontal line), the tension is greater in the muscle that was stretched more in the preload phase (red curve)—a restatement of Starling's law.

In summary, at a given preload (i.e., walking up the black curve in [Fig. 22-13E](#)), the velocity of shortening for cardiac muscle becomes greater with lower afterloads (i.e., opposing pressure). Conversely, at a given afterload—that is, comparing the black and red curves for any common x value (see [Fig. 22-13E](#), dashed vertical line)—the velocity of shortening for cardiac muscle becomes greater with a greater preload (i.e., sarcomere length).

Finally, the curves in [Figure 22-13E](#) do not represent a fixed set of relationships. Positive inotropic agents shift all curves up and to the right. Thus, a positive inotropic agent allows the heart to achieve a given velocity against a greater load, or to push a given load with a greater velocity.

Another way of representing how velocity of shortening depends on the initial muscle length (i.e., preload) is to monitor velocity of shortening during a single isotonic contraction. If we first apply a large preload to stretch a piece of muscle to an initial length of 9.0 mm (see [Fig. 22-13F](#)) and then stimulate it, the velocity instantly rises to a peak value of ~ 8.5 mm/s; it then gradually falls to zero as the muscle shortens to 7.5 mm. If we start by applying a smaller preload, thereby stretching the muscle to an initial length of 8.5 or 8.0 mm, the peak velocity falls. Thus, initial length determines not only the tension that cardiac muscle can generate, but also the speed with which the muscle can shorten.

Increases in heart rate enhance myocardial tension

Heart muscle tension has a special dependence on the frequency of contraction. If we stimulate isolated heart muscle only a few times per minute, the tension developed is much smaller than if we stimulate it at a physiological rate of 70 times per minute. The progressive rise of tension after an increase in rate—the positive **staircase phenomenon**—was first observed by Henry Bowditch in 1871. Underlying the staircase phenomenon is an increase in SR Ca^{2+} content and release. The larger SR Ca^{2+} content has three causes. First, during each action potential plateau, more Ca^{2+} enters the cell through Cav1.2 L-type Ca^{2+} channels, and the larger number of action potentials per minute provides a longer aggregate period of Ca^{2+} entry through these channels. Second, the depolarization during the plateau of an action potential causes the Na-Ca exchanger NCX1 to operate in the reverse mode, [N21-2](#) allowing Ca^{2+} to enter the cell. At higher heart rates, these depolarizations occur more frequently and are accompanied by an increase in $[\text{Na}^+]_i$, which accentuates the reversal of NCX1, both of which enhance Ca^{2+} uptake. Third, the increased heart rate stimulates SERCA2a, thereby sequestering in the SR the Ca^{2+} that entered the cell because of the first two mechanisms. The mechanism of this stimulation is that the rising $[\text{Ca}^{2+}]_i$, through calmodulin (CaM), activates CaM kinase II, which leads to phosphorylation of PLN; phosphorylation of PLN in turn enhances SERCA2a.

Contractility is an intrinsic measure of cardiac performance

Now that we know that the performance of the heart depends on such factors as degree of filling (i.e., preload), arterial pressure (i.e., afterload), and heart rate, it would be useful to have a measure of the heart's *intrinsic* contractile performance, independent of these *extrinsic* factors. **Contractility** is such a

measure.

Contractility is a somewhat vague but clinically useful term that distinguishes a better-performing heart from a poorly performing one. In a patient,  **N22-8** it is difficult to assess cardiac performance by use of the approaches illustrated in [Figures 22-12](#) and [22-13](#). One clinically useful measure of contractility is the ejection fraction (see p. 519). However, according to Starling's law, ejection depends on EDV (i.e., preload), which is *external* to the heart. Two somewhat better gauges of contractility are the **rate of pressure development** during ejection ($\Delta P/\Delta t$) and the **velocity of ejection**. Both correlate well with the velocity of shortening in [Figure 22-13E and F](#), and they are very sensitive guides to the effect of inotropic interventions.

N22-8

Assessment of Contractility in Patients

Contributed by Emile Boulpaep

For two reasons, it is not practical to assess cardiac performance in a patient by using the approaches outlined in Figures 22-12 and 22-13. First, with patients, we do not deal with isolated muscles in vitro. Second, the aforementioned figures require that we study the muscle under the artificial conditions of only **isometric** (i.e., preloaded) or only **isotonic** (i.e., afterloaded) contractions. During a full cardiac cycle, of course, these conditions alternate.

FIGURE 22-13 Effect of preload and afterload on velocity of shortening. In **A**, the developed tension is not yet sufficient to lift the weight (i.e., afterload). In **B**, the muscle, which has now developed sufficient tension to lift the weight, shortens against a constant afterload. In **C**, the slope of the blue curve ($\Delta L/\Delta t$) is the velocity of shortening. The velocities of shortening for three different afterloads (tensions) in **D** are plotted as the three colored points of the lower curve in **E**. In **F**, the x-axis has the longest lengths on the left, so that "time" runs from left to right (arrows). Note that the family of curves is enclosed by the envelope created by the curve for the greatest initial length.

A third assessment of contractility focuses on the physiological relationship between pressure and volume during the cardiac cycle. In the era of echocardiography, these volume data are now reasonably easy to obtain. We return to the ventricular **pressure-volume loop** that we introduced in [Figure 22-9](#) and

redraw it as the purple loop in [Figure 22-14A](#). In this example, the EDV is 120 mL. Point D' on the loop represents the relationship between pressure and volume at the end of the isovolumetric contraction, when the aortic valve opens. If we had prevented the aortic valve from opening, ventricular pressure would have continued to rise until the ventricle could generate no additional tension. In this case, the pressure would rise to point G', the theoretical maximum isovolumetric pressure. We could repeat the measurement at very different EDVs by decreasing or increasing the venous return. Point G represents the maximum isovolumetric pressure for an EDV below 120 mL (orange loop), and point G'' represents this pressure for an EDV above 120 mL (green loop). The gold dashed line through points G, G', and G'' in [Figure 22-14A](#) would describe the relationship between pressure and EDV under isometric conditions (i.e., aortic valve closed)—the equivalent of an isometric *Starling curve* (e.g., brown curve in [Fig. 22-12A](#)). The steeper this line, the greater the contractility.

A STANDARD CONTRACTILITY CONDITIONS

B INCREASED CONTRACTILITY

C INCREASED PRELOAD (FILLING)

D INCREASED AFTERLOAD (AORTIC PRESSURE)

FIGURE 22-14 Assessment of contractility by the use of a ventricular pressure-volume loop. The purple pressure-volume loop is the normal curve in [Figure 22-9](#). In **A**, at the same normal state of cardiac contractility, the red loop is generated by decreasing EDV, and the green loop is generated by increasing EDV. The slope of the line through the points at the end of systole (F, F', and F'') represents the ESPVR.

It is impossible to measure maximum isovolumetric pressures in a patient because it is hardly advisable to prevent the aortic valve from opening. However, we can use the **end-systolic pressure** at point F' on the normal pressure-volume loop with an EDV of 120 mL (purple loop in [Fig. 22-14A](#)). For an EDV below 120 mL (orange loop), the corner point would slide down and to the left (point F). Conversely, for an EDV above 120 mL (green loop), the corner point would slide upward and to the right (point F''). The corner points of many such pressure-volume loops fall along a line—the **end-systolic pressure-volume relation (ESPVR)** [N22-9](#)—that is very similar to that generated by the points G, G', and G''.

N22-9

Using the End-Systolic Pressure-Volume Relation in Lieu of an Isometric Starling Curve

Contributed by Emile Boulpaep

The ESPVR is a load-insensitive index of left ventricular contractility. This relation has been measured in small animal species using a conductance-catheter technique—whereby several electrodes along a catheter are used to compute the electrical conductance, which can be converted to absolute ventricular volume—and indwelling pressure gauges. Sato and colleagues (1998) tested the ESPVR under different contractility states: baseline condition, after sympathectomy, and after β blockade in rats. The general slope of the curve decreased with decreasing contractility; that is, modestly after sympathectomy and strongly after β blockade. The curve was not always perfectly straight. The ESPVR was slightly convex toward the pressure axis under baseline conditions, linear under sympathectomy conditions, and slightly concave toward the pressure axis under β -blockade conditions.

Effect of Changes in Contractility

The ESPVR is a clinically useful measure of contractility. Enhancing the contractility increases the slope of the ESPVR line, just as it increases the steepness of the ventricular performance curves (see brown arrow in Fig. 22-12C). For example, imagine that—with the same EDV and aortic pressure as in the control situation (purple area and gold ESPVR line in Fig. 22-14B)—we increase contractility. We represent increased contractility by steepening the ESPVR line (from gold to red dashed line in Fig. 22-14B). The result is that ejection continues from point D' to a new point F (red loop in Fig. 22-14B) until the left ventricular volume reaches a much lower value than normal. In other words, enhanced contractility increases *stroke volume*. Decreasing contractility would flatten the slope of the ESPVR and decrease stroke volume.

Effect of Changes in Preload (i.e., Initial Sarcomere Length)

A pressure-volume loop nicely illustrates the effect of increasing preload (i.e., increasing filling or EDV) without changing contractility. Starting from the control situation (see Fig. 22-14C, purple area), increase of the EDV shifts the isovolumetric segment to the right (segment CD on the red loop). Because the volume change along segment DEF is larger than for the control situation, stroke volume increases—as predicted by Starling's law.

Effect of Changes in Afterload

A pressure-volume loop also illustrates the effect of an increased afterload (i.e., increase in aortic pressure). Starting from the control situation (see Fig. 22-14D, purple area), an increase of aortic pressure shifts the upper right corner of the loop from point D' (purple loop) to D (red loop) because the ventricle cannot open the aortic valve until ventricular pressure reaches the higher aortic pressure. During the ejection phase—assuming that contractility (i.e., slope of the ESPVR) does not change—the ventricle necessarily ejects less blood until segment DEF intersects the ESPVR line. Therefore, an increase in afterload (at constant contractility) causes the loop to be taller and narrower, so that stroke volume and ejection fraction both decrease. However, if we were to increase contractility (i.e., increase the slope of the ESPVR), we could return the stroke volume to normal.

Positive inotropic agents increase myocardial contractility by raising $[Ca^{2+}]_i$

Modifiers of contractility can affect the dynamics of cardiac muscle contraction independent of preload or afterload. These factors have in common their ability to change $[Ca^{2+}]_i$. When these factors increase myocardial contractility, they are called positive inotropic agents. When they decrease myocardial contractility, they are called negative inotropic agents (Boxes 22-3 and 22-4).

Box 22-3

Cardiac Hypertrophy

Either volume overload or pressure overload can mechanically compromise the heart. A **volume**

overload is an excessive EDV (i.e., preload). For example, a large AV shunt would volume overload both the left and right sides of the heart. The increased EDV leads to an increase in stroke volume (see Fig. 22-14C), which elevates cardiac output. Systemic arterial pressure usually remains normal. A **pressure overload** is an excessive pressure in the ventricle's outflow tract (i.e., afterload). For the left heart, the problem would be an increase in systemic arterial pressure (i.e., hypertension). The increased aortic pressure leads to a decrease in stroke volume (see Fig. 22-14D). However, because of a compensatory increase in heart rate, cardiac output usually remains normal. When, over time, the adaptive process of hypertrophy becomes inadequate to cope with demand, the result is mechanical dysfunction and, ultimately, heart failure (see Box 22-4).

Because cells of the adult heart are terminally differentiated, stimuli that might be mitogenic in other cells cannot elicit cell division in the heart, but rather cause the cardiac myocytes to hypertrophy and increase muscle mass. Elite athletes develop **physiological hypertrophy**, in which the cardiac cells increase proportionally both in length and in width. Volume overload leads to **eccentric hypertrophy** characterized by increases in myocyte length out of proportion to width. Pressure overload causes **concentric hypertrophy** with a relatively greater increase in myocyte width.

A host of events may trigger hypertrophy, including various hypertrophic factors, increases in $[Ca^{2+}]_i$, and mechanical forces.

Hypertrophic Factors

Agents implicated in cardiac hypertrophy include the cardiac cytosolic protein **myotrophin (Myo/V1)** and the cytokine **cardiotrophin 1 (CT-1)**, as well as catecholamines, angiotensin II (ANG II), endothelin 1, insulin-like growth factor 2, transforming growth factor- β , and interleukin-1. Catecholamines and ANG II both activate the mitogen-activated protein kinase (MAPK) cascade (see pp. 68–69). Farther downstream in the signal-transduction pathway, the transcriptional response to hypertrophic stimuli includes the zinc-finger transcription factor, GATA-4 (see pp. 80–81), and perhaps also the transcription factors SRF and Sp1, as well as the TEF-1 family.

Calcium

Elevated $[Ca^{2+}]_i$ may be both a trigger for hypertrophy and part of signal-transduction pathways that lead to hypertrophy. $[Ca^{2+}]_i$ in heart cells is probably elevated initially during chronic volume or pressure overloads, just as $[Ca^{2+}]_i$ would be elevated in a normal heart that is working hard. Elevated $[Ca^{2+}]_i$ may activate calcineurin, a Ca^{2+} -dependent phosphatase (see p. 58). After being dephosphorylated by calcineurin, the transcription factor NFAT3 can enter the nucleus and bind to GATA4 (see above), which transcriptionally activates genes responsible for hypertrophy. Mice that express constitutively activated forms of calcineurin develop cardiac hypertrophy and heart failure.

Mechanical Factors

Mechanical stretch induces the expression of specific genes. The mechanical sensor that triggers cardiac hypertrophy may be **MLP (muscle LIM protein)**, part of the myocardial cytoskeleton. Stretch activates a phosphorylation cascade of protein kinases: Raf-1 kinase, extracellular signal-regulated kinase (ERK), and a separate subfamily of the MAPKs called SAPKs (for stretch-activated protein kinases). These various kinases regulate gene expression by activating the transcription factor AP-1 (see pp. 81–82).

The pathways we have just discussed lead to several changes in gene expression within cardiac myocytes during hypertrophy. In addition to synthesizing many housekeeping proteins, hypertrophic cardiac myocytes undergo other changes that are more specific for contraction. Some of the most striking

changes include *reduced* levels of the mRNA encoding three critical proteins in the membrane of the SR: (1) the Ca^{2+} -release channel, (2) PLN, and (3) SERCA2. In addition, cardiac hypertrophy is associated with increased levels of mRNA for the skeletal α -actin, which is normally expressed in fetal heart, but not in adult heart. Hypertrophic hearts also have increased expression of the angiogenic factor vascular endothelial growth factor (VEGF; see p. 481).

Although a hypertrophied myocardial cell may be able to do more work than a nonhypertrophied cell, it has a lower “contractility” when normalized to its cross-sectional area. Why should hypertrophied cardiac muscle not be as good as normal muscle? Possibilities include alterations in the transient increases in $[\text{Ca}^{2+}]_i$ during the cardiac action potential and alterations in the expression of the contractile filaments, particularly the myosin isoenzymes.

Box 22-4

Cellular Basis of Heart Failure

Heart failure is among the most common causes of hospitalization in developed countries for people aged 65 years or older and is a leading cause of death. People whose hearts cannot sustain an adequate cardiac output become breathless (because blood backs up from the left side of the heart into the lungs) and have swollen feet and ankles (because blood backs up from the right side of the heart and promotes net filtration in systemic capillaries; see Box 20-1). On the cellular level, decreased contractility in heart failure could be a result of cardiac hypertrophy (see Box 22-3), reflecting alterations in the transient increases of $[\text{Ca}^{2+}]_i$, the expression of the contractile filaments, or both.

Changes in $[\text{Ca}^{2+}]_i$ physiology could reflect altered properties of the Cav1.2 L-type Ca^{2+} channel in the plasma membrane or the Ca^{2+} -release channel RYR2 in the SR membrane. In an animal model of hypertension-induced cardiac hypertrophy that leads to heart failure, the Cav1.2 channels exhibit an impaired ability to activate RYR2 through Ca^{2+} -induced Ca^{2+} release. A distortion of the microarchitecture in hypertrophic cells, and thus a distortion of the spacing between Cav1.2 channels and RYR2, could be responsible for impaired coupling. Each of the four RYR2 molecules in the Ca^{2+} -release channel associates with a molecule of **calstabin 2** (also known as the FK506-binding protein, FKBP12.6) that, together with other proteins, forms a macromolecular complex regulating the Ca^{2+} -release channel. Depletion of calstabin 2 in heart failure results in leaky RYR2 channels that continually release Ca^{2+} into the cytosol. High $[\text{Ca}^{2+}]_i$ makes the heart prone to delayed afterdepolarizations (see p. 506), ventricular arrhythmias, and sudden death.  **N21-16**

Changes in the expression of contractile proteins can reduce contractility. Two isoforms of myosin heavy chain, α MHC and β MHC, are present in the heart (see Table 9-1). The speed of muscle shortening increases with the relative expression of α MHC. In human heart failure, the amount of α MHC mRNA, relative to total MHC mRNA, falls from ~35% to ~2%.

An interesting animal model of heart failure is the knockout mouse that lacks the gene encoding MLP, the muscle LIM protein (see pp. 530–531). MLP-deficient mice have the same disrupted cytoskeletal architecture seen in failing hearts. In addition, these mice have a dilated cardiomyopathy. Although humans with failing hearts are generally not deficient in MLP, the evidence from these knockout mice suggests that the MLP system could play a role in certain forms of cardiomyopathy.

Positive Inotropic Agents

Factors that increase myocardial contractility increase $[Ca^{2+}]_i$, either by opening Ca^{2+} channels, inhibiting Na-Ca exchange, or inhibiting the Ca pump—all at the plasma membrane.

1. *Adrenergic agonists*. Catecholamines (e.g., epinephrine, norepinephrine) act on β_1 adrenoceptors to activate the α subunit of G_s -type heterotrimeric G proteins. The activated α_s subunits produce effects by two pathways. First, α_s raises intracellular levels of cAMP and stimulates PKA (see [p. 57](#)), which can then act by the mechanisms summarized in [Table 23-2](#) to increase contractility and speed relaxation. Second, α_s can directly open L-type Ca^{2+} channels in the plasma membrane, which leads to an increased Ca^{2+} influx during action potentials, increased $[Ca^{2+}]_i$, and enhanced contractility.
2. *Cardiac glycosides*. Digitalis derivatives inhibit the Na-K pump on the plasma membrane (see [p. 117](#)) and therefore raise $[Na^+]_i$. We would expect the increased $[Na^+]_i$ to slow down the Na-Ca exchanger NCX1, to raise steady-state $[Ca^{2+}]_i$, and to enhance contractility. Recent evidence suggests that cardiac glycosides may also increase $[Ca^{2+}]_i$ by a novel pathway—increasing the Ca^{2+} permeability of Na^+ channels in the plasma membrane.
3. *High extracellular $[Ca^{2+}]$* . Acting in two ways, elevated $[Ca^{2+}]_o$ increases $[Ca^{2+}]_i$ and thereby enhances contractility. First, it decreases the exchange of external Na^+ for internal Ca^{2+} . Second, more Ca^{2+} enters the myocardial cell through L-type Ca^{2+} channels during the action potential.
4. *Low extracellular $[Na^+]$* . Reducing the Na^+ gradient decreases Ca^{2+} extrusion through NCX1, raising $[Ca^{2+}]_i$ and enhancing contractility.
5. *Increased heart rate*. As we noted in introducing the staircase phenomenon (see [p. 528](#)), an increased heart rate increases SR stores of Ca^{2+} and also increases Ca^{2+} influx during the action potential.

Negative Inotropic Agents

Factors that decrease myocardial contractility all decrease $[Ca^{2+}]_i$.

1. *Ca^{2+} -channel blockers*. Inhibitors of L-type Ca^{2+} channels (see [pp. 189–192](#))—such as verapamil, diltiazem, and nifedipine—reduce Ca^{2+} entry during the plateau of the cardiac action potential. By reducing $[Ca^{2+}]_i$, they decrease contractility.
2. *Low extracellular $[Ca^{2+}]$* . Depressed $[Ca^{2+}]_o$ lowers $[Ca^{2+}]_i$, both by increasing Ca^{2+} extrusion through NCX1 and by reducing Ca^{2+} entry through L-type Ca^{2+} channels during the plateau of the cardiac action potential.
3. *High extracellular $[Na^+]$* . Elevated $[Na^+]_o$ increases Ca^{2+} extrusion through NCX1, thereby decreasing $[Ca^{2+}]_i$.

Regulation of Arterial Pressure and Cardiac Output

Emile L. Boulpaep

When faced with a patient who appears seriously ill, clinicians focus their immediate attention on the patient's vital signs: temperature, respiratory rate, pulse, and blood pressure. These parameters are aptly named vital because they reflect the most fundamental aspects of health and even survival; a significant abnormality in any of these components indicates that emergent care is required.

In this chapter, we focus on blood pressure, a critical hemodynamic factor and one that is easily measured. An adequate blood pressure is necessary for proper organ perfusion. Too low, and we say that the patient is in shock. Too high, and we say that the patient is hypertensive; an acute and profound elevation of the blood pressure can be just as dangerous as a sudden plummeting of blood pressure. Here, we examine both the short- and long-term mechanisms that the body uses to regulate arterial blood pressure.

Because the arterial blood pressure depends to a large degree on the cardiac output, we also examine the regulation of this critical parameter. Finally, because cardiac output also depends on the venous return of blood to the heart, we discuss the matching between input (i.e., venous return) and cardiac output.

Short-Term Regulation of Arterial Pressure

Systemic mean arterial blood pressure is the principal variable that the cardiovascular system controls

Imagine that we must distribute city water to 1000 houses. We could decide in advance that each house uses 500 L/day and then pump this amount to each house at a constant rate. In other words, we would deliver ~20 L/hr, regardless of actual water usage. The cardiovascular equivalent of such a system would be a circulation in which the cardiac output and the delivery of blood to each tissue remain constant.

Alternatively, we could connect all the houses to a single large water tower that provides a constant pressure head. Because the height of the water level in the tower is fairly stable, all faucets in all houses see the same pressure at all times. This system offers several advantages. First, each house can regulate its water usage by opening faucets according to need. Second, heavy water usage in one house with all faucets open does not affect the pressure head in the other houses with only one faucet open. Third, the pressure head in the water tower guarantees that each house will receive sufficiently high pressure to send water to any upper floors. This water tower system is analogous to our own circulatory system, which provides the same flexibility for distribution of blood flow by, first and foremost, *controlling the systemic mean arterial blood pressure*.

The priority given to arterial pressure control is necessary because of the anatomy of the circulatory system. A network of branched arteries delivers to each organ a mean arterial pressure that approximates the mean aortic pressure. Thus, all organs, whether close to or distant from the heart, receive the same mean arterial pressure. Each organ, in turn, controls local blood flow by increasing or decreasing local arteriolar resistance. In [Chapter 20](#), we described these local control mechanisms in a general way, and in [Chapter 24](#), we will discuss specific vascular beds.

The system that we just introduced works because a change in blood flow in one vascular bed does not affect blood flow in other beds—as long as the heart can maintain the mean arterial pressure. However, the circulatory system must keep mean arterial pressure not only *constant* but also *high enough* for glomerular filtration to occur in the kidneys or to overcome high tissue pressures in organs such as the eye.

Since [Chapter 17](#), we have regarded the heart as the generator of a constant driving pressure. The principles of the feedback loops that the body uses to control the circulation are similar to those involved in the regulation of many other physiological systems. The short-term regulation of arterial pressure—on a time scale of seconds to minutes—occurs via neural pathways and targets the heart, vessels, and adrenal medulla. This short-term regulation is the topic of the present discussion. The long-term regulation of arterial pressure—on a time scale of hours or days—occurs via pathways that target the blood vessels, as well as the kidneys, in their control of extracellular fluid (ECF) volume. This long-term regulation is the topic of the final portion of the chapter.

Neural reflexes mediate the short-term regulation of mean arterial blood pressure

The neural reflex systems that regulate mean arterial pressure operate as a series of negative-feedback loops. All such loops are composed of the following elements:

1. **A detector.** A sensor or receptor quantitates the controlled variable and transduces it into an electrical signal that is a measure of the controlled variable.
2. **Afferent neural pathways.** These convey the message away from the detector, to the central nervous system (CNS).
3. **A coordinating center.** A control center in the CNS compares the signal detected in the periphery to a set-point, generates an error signal, processes the information, and generates a message that encodes the appropriate response.
4. **Efferent neural pathways.** These convey the message from the coordinating center to the periphery.
5. **Effectors.** These elements execute the appropriate response and alter the controlled variable, thereby correcting its deviation from the set-point.

A dual system of sensors and neural reflexes controls mean arterial pressure. The primary sensors are baroreceptors, which are actually stretch receptors or mechanoreceptors that detect distention of the vascular walls. The secondary sensors are chemoreceptors that detect changes in blood P_{O_2} , P_{CO_2} , and pH. The control centers are located within the CNS, mostly in the medulla, but sites within the cerebral cortex and hypothalamus also exert control. The effectors include the pacemaker and muscle cells in the heart, the vascular smooth-muscle cells (VSMCs) in arteries and veins, and the adrenal medulla.

We all know from common experience that the CNS influences the circulation. Emotional stress can cause blushing of the skin or an increase in heart rate. Pain—or the stress of your first day in a gross anatomy laboratory—can elicit fainting because of a profound, generalized vasodilation and a decrease in heart rate (i.e., bradycardia).

Early physiologists, such as Claude Bernard, observed that stimulation of peripheral sympathetic nerves causes vasoconstriction and that interruption of the spinal cord in the lower cervical region drastically reduces blood pressure (i.e., produces hypotension). However, the first idea that a *reflex* might be involved in regulating the cardiovascular system came from experiments in which stimulating a particular sensory (i.e., afferent) nerve caused a change in heart rate and blood pressure. In 1866, Élie de Cyon and Carl Ludwig [N23-1](#) studied the depressor nerve, a branch of the vagus nerve. After they transected this nerve, they found that stimulation of the central (i.e., cranial) end of the cut nerve slows down the heart and produces hypotension. Ewald Hering showed that stimulation of the central end of another cut nerve—the sinus nerve (nerve of Hering), which innervates the carotid sinus—also causes bradycardia and hypotension. These two experiments strongly suggested that the depressor and sinus nerves carry sensory information to the brain and that the brain in some fashion uses this information to control cardiovascular function.

Élie de Cyon and Carl F. Ludwig

Contributed by Walter Boron

Élie de Cyon

Born into a Jewish community in Telsch, Lithuania (then a part of the Russian Empire), not far from the

German border, **Ila Faddevitch Tsion** (1842–1910)—also known as Élie de Cyon (French) or Elias Cyon (English)—was a tragic figure. He studied medicine in Warsaw and Kiev before moving to Berlin, where he received his doctorate in medicine and surgery. After de Cyon joined the Medical-Surgical Academy in St. Petersburg and earned a second doctorate (in medicine) in 1865, the Ministry of Education in Russia sent him to Paris to study physiology, presumably with Claude Bernard. Afterward, de Cyon moved to Leipzig to work with Carl Ludwig. There, he developed the **isolated, perfused, working frog heart** and with Ludwig discovered the **baroreflex**. In 1866, de Cyon described the inhibitory effect of the vagus nerve on cardiac muscle. The branch of the vagus that innervates the heart is known as the **nerve of Ludwig-Cyon**. With his brother M. de Cyon, E. de Cyon in 1867 discovered the nerve that stimulates the heart. E. de Cyon observed, but did not document, the response of the heart to increased filling pressure, thereby anticipating by a few years the Frank-Starling mechanism.

In 1867, E. de Cyon again journeyed to St. Petersburg and was professor of physiology at St. Petersburg University from 1868 to 1872. During this time, he was a mentor of and had a major influence on I.P. Pavlov (1849–1936 N42-4), who mastered surgical techniques and began his studies of circulation and digestion with de Cyon. In 1874—against the will of the faculty—de Cyon was appointed professor and chair of physiology at the Medical-Surgical Academy of St. Petersburg. However, majority nihilist students demanded de Cyon's removal, chaos erupted, troops were called in, and the academy was closed. de Cyon requested and received a transfer to Leipzig but was dismissed from Russian service in 1875. He received an invitation from Claude Bernard to move to France, where de Cyon performed his research and obtained his third doctorate. However, after Bernard's death in 1878, de Cyon fell out of favor, left science, and became involved in a wide range of activities, including newspaper work and an effort to unite French and Russian interests against Germany. He moved in high social circles and died in Paris in 1919, never having returned to Russia.

Carl F. Ludwig

Carl F. Ludwig (1816–1895) was born in Witzenhausen, Germany, and obtained his doctorate in medicine in Marburg in 1839. In 1865 he became the inaugural professor of physiology at Leipzig, a position that he held until his death. Along with a few contemporaries—Helmholtz, Brücke, and Du Bois-Reymond—Ludwig rejected the view that special biological laws applied to animals, and instead he championed the view that the laws of physics and chemistry applied also to animals—a philosophy necessary for the further development of physiology as a science. Ludwig invented the **kymograph** for recording changes in blood pressure—the first graphical output in the field of physiology. His research touched many areas of physiology, his institute became a center of physiological research, and he trained a large number of investigators from across Europe. The papers from his institute usually bear only the name of his pupils!

High-pressure baroreceptors at the carotid sinus and aortic arch are stretch receptors that sense changes in arterial pressure

Corneille Heymans was the first to demonstrate that pressure receptors—called baroreceptors—are located in arteries and are part of a neural feedback mechanism that regulates mean arterial pressure. He found that injection of epinephrine—also known as adrenaline—into a dog raises blood pressure and, later, lowers heart rate. Heymans hypothesized that increased blood pressure stimulates arterial sensors, which send a neural signal to the brain, and that the brain in turn transmits a neural signal to the heart, resulting in bradycardia.

To demonstrate that the posited feedback loop did not depend on the blood-borne traffic of chemicals between the periphery and the CNS, Heymans cross-perfused two dogs so that only nerves connected the head of the dog to the rest of the animal's body. The dog's head received its blood flow from a second animal. (Today, one would use a heart-lung machine to perfuse the head of the first dog.) Heymans found that the vagus nerve carried both the upward and the downward traffic for the reflex arc and that agents carried in the blood played no role. He used a similar approach to demonstrate the role of the peripheral chemoreceptors in the control of respiration (see [pp. 710–713](#)). For his work on the neural control of respiration, Heymans received the Nobel Prize in Physiology or Medicine in 1938. 🏆[N23-2](#)

The entire control process, known as the **baroreceptor control of arterial pressure** ([Fig. 23-1](#)), consists of baroreceptors (i.e., the detectors), afferent neuronal pathways, control centers in the medulla, efferent neuronal pathways, and the heart and blood vessels (i.e., the effectors). The negative-feedback loop is designed so that *increased mean arterial pressure causes vasodilation and bradycardia*, whereas *decreased mean arterial pressure causes vasoconstriction and tachycardia* (i.e., increased

heart rate).

FIGURE 23-1 Baroreceptor control of arterial pressure. In this example, we assume that an increase in mean arterial pressure (*violet box*) is the primary insult.

The sensor component consists of a set of mechanoreceptors located at strategic *high-pressure sites* within the cardiovascular system. As discussed below, the cardiovascular system also has *low-pressure* sensors that detect changes in venous pressure. The two most important high-pressure loci are the carotid sinus and the aortic arch. Stretching of the vessel walls at either of these sites causes vasodilation and bradycardia. The **carotid sinus** (Fig. 23-2A) is a very distensible portion of the wall of the internal carotid artery located just above the branching of the common carotid artery into the external and internal carotid arteries. The arterial wall at the carotid sinus contains thin lamellae of elastic fibers but very little collagen or smooth muscle. The **aortic arch** (see Fig. 23-2B) is also a highly compliant portion of the arterial tree that distends during each left ventricular ejection.

A INNERVATION OF CAROTID SINUS AND BODY

B INNERVATION OF AORTIC ARCH AND BODIES

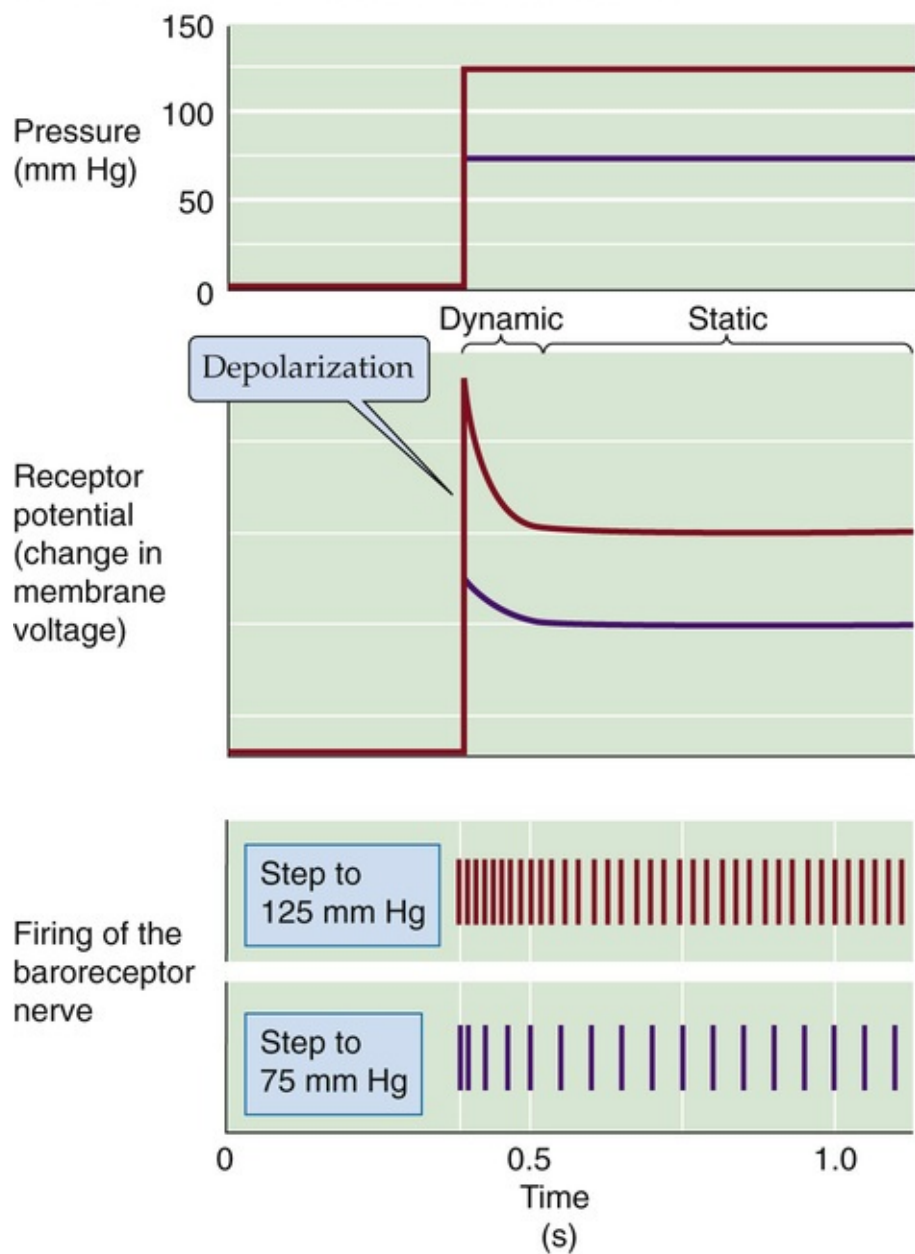

FIGURE 23-2 Afferent pathways of the high-pressure baroreceptors. In **B**, the chemoreceptors (i.e., aortic bodies) are located on the underside of the aortic arch as well as—on the right side of the body—at the bifurcation of the right brachiocephalic artery. On the left side of the body, aortic bodies, if present, are in a notch between the left common carotid artery and the left subclavian artery.

The baroreceptors in both the carotid sinus and the aortic arch are the branched and varicose (or coiled) terminals of myelinated and unmyelinated sensory nerve fibers, which are intermeshed within the elastic layers. The terminals express several nonselective cation channels in the TRP family: TRPC1, TRPC3, TRPC4, and TRPC5. TRPC channels may play a role both as primary electromechanical transducers and as modulators of transduction. An increase in the transmural pressure difference enlarges the vessel and thereby deforms the receptors. Baroreceptors are not really pressure sensitive but *stretch sensitive*. Indeed, TRPC1 is stretch sensitive. Direct stretching of the receptor results in increased firing of the baroreceptor's sensory nerve. The difference between stretch sensitivity and pressure sensitivity becomes apparent when one prevents the expansion of the vessel by surrounding the arterial wall with a plaster cast. When this is done, increase of the transmural pressure fails to increase the firing rate of the baroreceptor nerve. Removal of the cast restores the response. Other tissues surrounding the receptors act as a sort of mechanical filter, although much less so than the plaster cast.

As shown by the red records in the upper two panels of [Figure 23-3A](#), a step increase in transmural pressure (i.e., stretch) produces an inward current that depolarizes the receptor, generating a **receptor potential** (see [pp. 353–354](#)). The pressure increase actually causes a biphasic response in the receptor voltage. Following a large initial depolarization (the *dynamic* component) is a more modest but steady depolarization (the *static* component). This receptor potential, unlike a regenerative action potential, is a graded response whose amplitude is proportional to the degree of stretch (compare red and purple records).

A RESPONSE TO INCREASED PRESSURE

B PRESSURE-ACTIVITY RELATIONSHIPS

FIGURE 23-3 Afferent pathways of the high-pressure baroreceptors. In **A**, the records refer to hypothetical experiments on a baroreceptor in which one suddenly raises blood pressure to 75 mm Hg

These sensory neurons are *bipolar neurons* (see [p. 259](#)) whose cell bodies are located in ganglia near the brainstem. The central ends of these neurons project to the medulla. The cell bodies of the aortic baroreceptor neurons, which are located in the nodose ganglion (a sensory ganglion of the vagus nerve), express several TRPC channels. **N23-3** Although these nonselective cation channels are stretch sensitive and blocked by Gd^{3+} , they probably set only the *sensitivity* of the baroreceptor response. **N23-3**

N23-3

Receptor Potential of Baroreceptors

Contributed by Emile Boulpaep

As noted in the text, increased intraluminal pressure (actually an increase tension in the vessel wall) triggers an inward current that generates a depolarization (i.e., receptor potential). The inward current that underlies the receptor potential is not sensitive to blockers of voltage-gated Na^+ , K^+ , or Ca^{2+} channels, but is blocked by Gd^{3+} . The channels inhibited by the Gd^{3+} may be the mechanoelectrical transducers in baroreceptor nerve endings. TRPC1, TRPC3, TRPC4, TRPC5, TRPC6, and TRPC7 channels are present in the plasma membrane of the cell bodies of the aortic baroreceptor neurons in the nodose ganglion. Although these channels are stretch sensitive, the cell body presumably is not subject to stretch. On the other hand, TRPC1 and TRPC3 are present in the fine nerve endings of myelinated A-type fibers that are tonically active in the normal range of arterial blood pressures. Thus, these channels could be responsible for sensory transduction. An alternate view is that such TRPC channels may set the *sensitivity* of the baroreceptor.

On the other hand, several types of K^+ channels modulate the *sensitivity* of the baroreceptor nerve endings to stretch. By patch-clamping the cell bodies of the aortic arch baroreceptor neurons, investigators have found that these K^+ currents include Ca^{2+} -activated K^+ currents (K_{Ca} channels; see p. 196) and A currents (K_v channels sensitive to 4-aminopyridine; see pp. 193–196). The various types of K^+ channels found at the cell bodies may also be functional at the peripheral sensory endings. Agents that block these K^+ channels cause a sustained depolarization of the baroreceptor endings, decreasing the pressure sensitivity of the baroreceptors, presumably by inactivating other voltage-gated channels.

Increased arterial pressure raises the firing rate of afferent baroreceptor nerves

If, in the absence of a pressure step, we depolarize the baroreceptor nerve ending, the result is an increase in the frequency of action potentials in the sensory nerve. Therefore, it is not surprising that graded

increases in pressure produce graded depolarizations, resulting in graded increases in the spike frequency (see Fig. 23-3A, lower two panels). Graded *decreases* in pressure gradually diminish receptor activity until the firing falls to vanishingly low frequencies at pressures around 40 to 60 mm Hg. Therefore, the baroreceptor encodes the mechanical response as a frequency-modulated signal.

A step increase in pressure generates a large initial depolarization, accompanied by a transient high-frequency discharge. The smaller steady depolarization is accompanied by a steady but lower spike frequency. Because baroreceptors have both a dynamic and a static response, they are sensitive to both the *waveform* and the *amplitude* of a pressure oscillation. Therefore, bursts of action potentials occurring in phase with the cardiac cycle encode information on the pulse pressure (i.e., difference between the peak systolic and lowest diastolic pressures). The **static** pressure-activity curve in Figure 23-3B—obtained on single units of the sinus nerve—shows that the spike frequency rises sigmoidally with increases in *steady* blood pressure. The **pulsatile** pressure-activity curve in Figure 23-3B shows that when the pressure is *oscillating*, the mean discharge frequency at low mean pressures is higher than when pressure is steady.

Not all arterial receptors have the same properties. As we gradually increase intravascular pressure, different single units in the isolated carotid sinus begin to fire at different static pressures. Thus, the overall baroreceptor response to a pressure increase includes both an increased firing rate of active units and the **recruitment** of more units, until a saturation level is reached at ~200 mm Hg. The carotid sinus in some individuals is unusually sensitive. When wearing a tight collar, such a person may faint just from turning the head because compression or stretching of the carotid sinus orders the medulla to lower blood pressure.

The responses of the receptors in the carotid sinus and the aortic arch are different. In a given individual, a change in the carotid sinus pressure has a greater effect on the systemic arterial pressure than does a change in the aortic pressure. Compared with the carotid sinus receptor, the **aortic arch receptor**

- has a higher threshold for activating the static response (~110 mm Hg versus ~50 mm Hg);
- has a higher threshold, likewise, for the dynamic response;
- continues responding to pressure increases at pressures at which the carotid baroreceptor has already saturated;
- is less sensitive to the rate of pressure change; and
- responds less effectively to a decrease in pressure than to an increase in pressure (over the same pressure range).

Once a change in the arterial pressure has produced a change in the firing rate of the sensory nerve, the signal travels to the medulla. The afferent pathway for the carotid sinus reflex is the **sinus nerve**, which then joins the **glossopharyngeal** trunk (cranial nerve [CN] IX; see Fig. 23-2A). The cell bodies of the carotid baroreceptors are located in the petrosal (or inferior) ganglion of the glossopharyngeal nerve (Fig. 23-4A). The afferent pathways for the aortic arch reflex are sensory fibers in the **depressor branch** of the **vagus nerve** (CN X; see Fig. 23-2B). After joining the superior laryngeal nerves, the sensory fibers run cranially to their cell bodies in the nodose (or inferior) ganglion of the vagus (see Fig. 23-4A).

A LATERAL VIEW OF BRAINSTEM

B AFFERENT AND EFFERENT PATHWAYS

FIGURE 23-4 Medullary control centers for the cardiovascular system. **A**, Relevant nuclei and cranial nerves are colorized and labeled in dark type. **B**, Hypothetical section through the medulla, showing projections of structures that do not necessarily coexist in a single cross section. Glu, etc., glutamate and other neurotransmitters (i.e., norepinephrine and peptides); NE, norepinephrine.

The medulla coordinates afferent baroreceptor signals

The entire complex of medullary nuclei involved in cardiovascular regulation is called the medullary cardiovascular center. Within this center, broad subdivisions can be distinguished, such as a vasomotor area and a cardioinhibitory area. The medullary cardiovascular center receives all important information from the baroreceptors and is the major coordinating center for cardiovascular homeostasis.  **N23-4**

N23-4

Identifying the Medullary Cardiovascular Control Center

Contributed by Emile Boulpaep

Investigators have established the overall importance of the medullary cardiovascular center in cardiovascular control using a variety of technical approaches:

- 1. Successive transections of the brain and spinal cord.** Transecting the brainstem at the level of the pons does not affect the maintenance of normal blood pressure. However, transecting the medulla below the level of the facial colliculus (see Fig. 23-4A) causes blood pressure to fall. Lower sections produce even deeper drops in pressure, all the way to ~40 mm Hg. The lowest pressures occur after transection at the level of the first cervical segment (i.e., spinal shock).
- 2. Stimulation of the bulbopontine region.** Stimulating random cells in the medulla or pons can produce either pressor (i.e., increased blood pressure) or depressor responses. In general, the pressor areas extend more rostrally and more laterally than the depressor areas.
- 3. Recording from single neurons.** Some neurons in medullary nuclei or other medullary areas exhibit electrical activity that is synchronous with the pulse. However, it is difficult to trace the activity of a specific neuron to a specific sensory input (e.g., a specific carotid baroreceptor) or to the control of a specific effector (e.g., the smooth muscle of a particular blood vessel). These recordings have not revealed any somatotopic organization (see pp. 400–401).
- 4. Labeling of pathways.** Following the microinjection of radiolabeled amino acids into neurons of the NTS, the *anterograde* transport of the label allows tracking of the efferent pathway by autoradiography. Conversely, by exposing the cut central end of the carotid sinus nerve to horseradish peroxidase, it is possible—by exploiting the *retrograde* transport of the marker—to trace the course of the fibers to the NTS.

Most afferent fibers from the two high-pressure baroreceptors project to the **nucleus tractus solitarii** (NTS, from the Latin *tractus solitarii* [of the solitary tract]; see [p. 348](#)), one of which is located on each side of the dorsal medulla (see [Fig. 23-4A and B](#)). The neurotransmitter released by the baroreceptor afferents onto the NTS neurons is glutamate, which binds to the GluA2 subunits of AMPA (α -amino-3-

hydroxy-5-methyl-4-isoxazole propionic acid) receptors (see pp. 323–324 and Fig. 13-15C and D). Some neurons in the NTS (and also in the dorsal motor nucleus of the vagus; see below) have P2X purinoceptors that are activated by extracellular ATP.

Inhibitory interneurons project from the NTS onto the **vasomotor area** in the ventrolateral medulla (see Fig. 23-4B). This vasomotor area includes the A1 and C1 areas in the rostral ventrolateral medulla, **N23-5** as well as the inferior olivary complex and other nuclei. Stimulation of the neurons in the **C1 area** produces a vasoconstrictor response. Unless inhibited by output from the NTS interneurons, neurons within the C1 area produce a tonic output that promotes vasoconstriction. Therefore, an increase in pressure stimulates baroreceptor firing, which, in turn, causes NTS interneurons to inhibit C1 neurons, resulting in *vasodilation*. This C1 pathway largely accounts for the *vascular* component of the baroreceptor reflex. The bursting pattern of C1 neurons is locked to the cardiac cycle.

N23-5

The Vasomotor Area

Contributed by Emile Boulpaep

The **vasomotor area** includes the A1 and C1 areas in the rostral ventrolateral medulla, as well as the inferior olivary complex and other nuclei (i.e., the nucleus gigantocellularis lateralis, lateral reticular nucleus, and medullary raphe).

The **C1 area** also includes some adrenergic neurons, identified by the presence of the enzyme phenylethanolamine-*N*-methyltransferase (see Fig. 13-8C), which converts norepinephrine to epinephrine. Multiple brainstem neurons synapse with C1-area neurons and release ACh, gamma-aminobutyric acid, enkephalin, and substance P. As we will see on page 544, the antihypertensive agent clonidine acts by binding to imidazole receptors on C1-area neurons.

Some of the baroreceptor afferent fibers project directly to the vasomotor area without interaction with the NTS.

Excitatory interneurons project from the NTS onto a **cardioinhibitory area**, which includes the **nucleus ambiguus** and the **dorsal motor nucleus of the vagus** (see p. 339). Neurons in the dorsal motor nucleus of the vagus largely account for the *cardiac* component of the baroreceptor reflex (i.e., bradycardia). Some *inhibitory* interneurons probably project from the NTS onto a **cardioacceleratory** area, also located in the dorsal medulla. Stimulation of neurons in this area causes heart rate and cardiac contractility to increase.

The efferent pathways of the baroreceptor response include both sympathetic and parasympathetic divisions of the autonomic nervous system

After the medullary cardiovascular center has processed the information from the afferent baroreceptor pathways and integrated it with data coming from other pathways, this center must send signals back to the periphery via efferent (i.e., motor) pathways. The baroreceptor response has two major efferent pathways: the sympathetic and parasympathetic divisions of the autonomic nervous system.

Sympathetic Efferents

As discussed above, increased baroreceptor activity instructs the NTS to *inhibit* the C1 (i.e., vasomotor) and cardioacceleratory areas of the medulla. Functionally diverse bulbospinal neurons in both areas send axons down the spinal cord to synapse on and to stimulate preganglionic sympathetic neurons in the intermediolateral column of the spinal cord. Thus, we can think of these bulbospinal neurons as being presympathetic or pre-preganglionic. The synapse can be adrenergic (in the case of the C1 neurons), peptidergic (e.g., neuropeptide Y), or glutamatergic. The glutamatergic synapses are the most important for the vasomotor response; the released glutamate acts on both NMDA (*N*-methyl-D-aspartate) and non-NMDA receptors on the preganglionic sympathetic neurons.

The cell bodies of the preganglionic sympathetic neurons are located in the intermediolateral gray matter of the spinal cord, between levels T1 and L3 (see Fig. 14-4). After considerable convergence and divergence, most of the axons from these preganglionic neurons synapse with postganglionic sympathetic neurons located within ganglia of the paravertebral sympathetic chain as well as within prevertebral ganglia (see Fig. 14-2). The neurotransmitter between the preganglionic and postganglionic sympathetic neurons is acetylcholine (ACh), which acts at N₂ nicotinic acetylcholine receptors (nAChRs; p. 339). Because of the convergence and divergence, sympathetic output does not distribute according to dermatomes (see p. 339). Postganglionic sympathetic fibers control a wide range of functions (see Fig. 14-4). Those that control blood pressure run with the large blood vessels and innervate both *muscular arteries and arterioles and veins*.

Increased sympathetic activity produces vasoconstriction. Indeed, the baroreceptor reflex produces *vasodilation* because it *inhibits* the tonic stimulatory output of the vasomotor C1 neurons. Because the bulbospinal neurons synapse with preganglionic sympathetic neurons between T1 and L3, severing of the spinal cord above T1 causes a severe fall in blood pressure. Sectioning of the cord below L3 produces no fall in blood pressure.

Another important target of postganglionic neurons with a cardiovascular mission is the heart. Output from the middle cervical and stellate ganglia, along with that from several upper thoracic ganglia (see Fig. 14-4), ramifies and after extensive convergence and divergence forms the cardiac nerves. Thus, severing of the spinal cord above T1 would block the input to the preganglionic sympathetic fibers to the heart. In addition, some preganglionic fibers do not synapse in sympathetic ganglia at all but directly innervate the chromaffin cells of the *adrenal medulla* via the splanchnic nerve. These cells release epinephrine, which acts on the heart and blood vessels (see below).

Parasympathetic Efferents

As noted above, increased baroreceptor activity instructs the NTS to stimulate neurons in the nucleus ambiguus and the dorsal motor nucleus of the vagus (cardioinhibitory area). The target neurons in these two nuclei are preganglionic parasympathetic fibers of the vagus nerve (CN X) that project to the heart. These efferent vagal fibers follow the common carotid arteries, ultimately synapsing in small ganglia in the walls of the atria. There, they release ACh onto the N₂-type nAChRs of the postganglionic parasympathetic neurons. The short postganglionic fibers then innervate the *sinoatrial (SA) node, the atria, and the ventricles*, where they act primarily to slow conduction through the heart (see below).

The principal effectors in the neural control of arterial pressure are the heart, the arteries, the veins, and the adrenal

medulla

The cardiovascular system uses several effector organs to control systemic arterial pressure: the heart, arteries, veins, and adrenal medulla (Fig. 23-5).

FIGURE 23-5 Autonomic control of cardiovascular end organs.

Sympathetic Input to the Heart (Cardiac Nerves)

The sympathetic division of the autonomic nervous system influences the heart through the cardiac nerves,

which form a plexus near the heart (see Fig. 23-2). The postganglionic fibers, which release **norepinephrine**, innervate the SA node, atria, and ventricles. Their effect is to increase both heart rate and contractility (Table 23-1). Because it dominates the innervation of the SA node (which is in the right atrium), sympathetic input from the *right* cardiac nerve has more effect on the *heart rate* than does input from the left cardiac nerve. On the other hand, sympathetic input from the *left* cardiac nerve has more effect on *contractility*. In general, the cardiac nerves do not exert a strong tonic cardioacceleratory influence on the heart. At rest, their firing rate is less than that of the vagus nerve.

TABLE 23-1
Effects of Sympathetic and Parasympathetic Pathways on the Cardiovascular System

EFFECTOR RESPONSE	ANATOMIC PATHWAY	NEUROTRANSMITTER	RECEPTOR	G PROTEIN	ENZYME OR PROTEIN	2nd Messenger
Tachycardia	Sympathetic	NE	β_1 on cardiac pacemaker	G_{α_s}	\uparrow AC	\uparrow [cAMP] _i
Bradycardia	Parasympathetic	ACh	M_2 on cardiac pacemaker	Direct action of dimeric G_{GIRK}	GIRK1 K ⁺ channels	ΔV_m
Increase cardiac contractility	Sympathetic	NE	β_1 on cardiac myocyte	G_{α_s} Direct action of G_{α_s} on Cav1.2	\uparrow AC	\uparrow [cAMP] _i
Decrease cardiac contractility	Parasympathetic	ACh	M_2 on cardiac myocyte	G_{α_i}	\downarrow AC	\downarrow [cAMP] _i
			Presynaptic M_2 receptor on noradrenergic neuron	G_{α_i}	\downarrow AC	\downarrow [cAMP] _i in neuron
			M_3 receptor on cardiac myocyte	G_{α_q}	\uparrow PLC \rightarrow \uparrow [Ca ²⁺] _i \rightarrow \uparrow NOS \rightarrow \uparrow GC	\uparrow [cGMP] _i \rightarrow \downarrow Cav1.2
Vasoconstriction in most blood vessels (e.g., skin)	Sympathetic	NE	α_1 on VSMC	G_{α_q}	\uparrow PLC	\uparrow [Ca ²⁺] _i
Vasoconstriction in some blood vessels	Sympathetic	NE	α_2 on VSMC	$G_{\alpha_{i/o}}$	\downarrow AC	\downarrow [cAMP] _i
Vasodilation in most blood vessels (e.g., muscle)	Adrenal medulla	Epi	β_2 on VSMC	G_{α_s}	\uparrow AC	\uparrow [cAMP] _i
Vasodilation in erectile blood vessels	Parasympathetic	ACh	Presynaptic M_2 receptor on noradrenergic neurons	G_{α_i}	\downarrow AC	\downarrow [cAMP] _i in neuron
		ACh	M_3 on endothelial cell	G_{α_q}	\uparrow PLC \rightarrow \uparrow [Ca ²⁺] _i \rightarrow \uparrow NOS	NO diffuses to VSMC
		NO	NO receptor (i.e., GC) inside VSMC	—	\uparrow GC	\uparrow [cGMP] _i
		VIP	VIP receptor on VSMC	G_{α_s}	\uparrow AC	\uparrow [cAMP] _i
Vasodilation in blood vessels of salivary gland	Parasympathetic	ACh	M_3 receptor on gland cell	G_{α_q}	\uparrow Kallikrein	\uparrow Kinins
Vasodilation in blood vessels of muscle in fight-or-flight response	Sympathetic	ACh	Presynaptic M_2 receptor on noradrenergic neurons	G_{α_i}	\downarrow AC	\downarrow [cAMP] _i in neuron
		NANC	Receptor on VSMC			

AC, adenylyl cyclase; Epi, epinephrine; GC, guanylyl cyclase; NANC, nonadrenergic, noncholinergic; NE, norepinephrine; PLC, phospholipase C; VIP, vasoactive intestinal peptide; V_m, membrane potential.

Parasympathetic Input to the Heart (Vagus Nerve)

The vagus normally exerts an intense tonic, parasympathetic activity on the heart through **ACh** released by the postganglionic fibers. Severing of the vagus nerve or administration of atropine (which blocks the action of ACh) increases heart rate. Indeed, experiments on the effects of the vagus on the heart led to the discovery of the first neurohumoral transmitter identified, ACh (see p. 205). Vagal stimulation decreases heart rate by its effect on pacemaker activity (see p. 492). Just as the actions of the right and left cardiac nerves are somewhat different, the right vagus is a more effective inhibitor of the SA node than the left. The left vagus is a more effective inhibitor of conduction through the atrioventricular (AV) node. Vagal stimulation, to some extent, also reduces cardiac contractility.

Sympathetic Input to Blood Vessels (Vasoconstrictor Response)

The vasoconstrictor sympathetic fibers are disseminated widely throughout the blood vessels of the body. These fibers are most abundant in the kidney and the skin, relatively sparse in the coronary and cerebral vessels, and absent in the placenta. They release norepinephrine, which binds to adrenoceptors on the membrane of VSMCs. In most vascular beds, *vasodilation* is the result of a decrease in the tonic discharge of the vasoconstrictor sympathetic nerves.

Parasympathetic Input to Blood Vessels (Vasodilator Response)

Parasympathetic *vasodilator* fibers are far less common than sympathetic *vasoconstrictor* fibers. The parasympathetic vasodilator fibers supply the salivary and some gastrointestinal glands and are also crucial for vasodilation of erectile tissue in the external genitalia (see pp. 1105–1106 and 1127). Postganglionic parasympathetic fibers release ACh, which, as we shall see, *indirectly* causes vasodilation. In addition, these fibers produce vasodilation by releasing nitric oxide (NO) and vasoactive intestinal peptide (see pp. 346–347).

Sympathetic Input to Blood Vessels in Skeletal Muscle (Vasodilator Response)

In addition to the more widespread sympathetic vasoconstrictor fibers, skeletal muscle in nonprimates has a special system of sympathetic fibers that produce *vasodilation* (see pp. 342–343).  **N23-6** These special fibers innervate the large precapillary vessels in skeletal muscle. The origin of the sympathetic vasodilator pathway is very different from that of the vasoconstrictor pathway, which receives its instructions—ultimately—from the vasomotor area of the medulla. Instead, the sympathetic vasodilator fibers receive their instructions—ultimately—from neurons in the cerebral cortex, which synapse on other neurons in the hypothalamus or in the mesencephalon. The fibers from these second neurons (analogous to the bulbospinal neurons discussed above) transit through the medulla without interruption and reach the spinal cord. There, these fibers synapse on preganglionic sympathetic neurons in the intermediolateral column, just as do other descending neurons. The vasodilatory preganglionic fibers synapse in the sympathetic ganglia on postganglionic neurons that terminate on VSMCs surrounding skeletal muscle blood vessels. These postganglionic vasodilatory fibers release ACh and perhaps other transmitters.

N23-6

Cholinergic Sympathetic Neurons

Contributed by Emile Boulpaep, Walter Boron

From a macroscopic anatomical point of view, there is no doubt that the cholinergic sympathetic nerve endings of **sudomotor nerves** (i.e., the nerves that cause sweat secretion) and some vasomotor nerves are distal to the sympathetic ganglia. In this sense, these fibers are clearly “*postganglionic*.” Indeed, these rare cholinergic sympathetic fibers run together from the sympathetic ganglion to the target organ together with the majority adrenergic fibers.

From a physiological point of view, all of the sympathetic neurons that reach the adrenal medulla (see p. 343) are “preganglionic.” That is, these fibers derive from neuron cell bodies that lie in the intermediolateral cell column of the spinal cord. Their axons then transit through the paravertebral ganglia of the sympathetic trunk (see the left side of Fig. 14-4) without synapsing, and then follow along

the splanchnic nerves. Most of these axons then go directly to the adrenal medulla, where they synapse on their targets, the *chromaffin cells*. However, some axons transit through the **celiac ganglion**—again without synapsing—before reaching their target chromaffin cells in the adrenal medulla. Thus, all sympathetic fibers that synapse on chromaffin cells are physiologically “*preganglionic*”: a single neuron carries information from the spinal cord to the target cell. However, the sympathetic neurons that traverse the celiac ganglion before reaching the adrenal medulla could—from a macroscopic anatomical point of view—be regarded as *postganglionic*.

Authors in the 1960s and 1970s suggested that cholinergic sympathetic fibers that innervate the sweat glands (see pp. 342 and 571) and some of the vascular smooth muscle in skeletal muscle (see p. 539) derive from neuronal cell bodies in the spinal cord. This situation would be analogous to that of the cholinergic sympathetic innervation of the adrenal medulla. If this were true, then one could regard these cholinergic sympathetic sudomotor/vasomotor fibers—physiologically—as being “preganglionic.” However, more recent experiments suggest that these cholinergic sympathetic fibers can arise from neuron cell bodies located in sympathetic ganglia and that these neurons develop from neural crest cells (see p. 539). Using antibodies directed against the **vesicular ACh transporter** (VAChT, which transports ACh from the cytoplasm of the nerve terminal into the synaptic vesicles), Schäfer and colleagues demonstrated that VAChT-positive “principal ganglionic cells” (i.e., postganglionic neurons) are present in *paravertebral sympathetic ganglia* at all levels of the thoracolumbar paravertebral chain. These observations are consistent with the idea that sudomotor nerve fibers and some vasomotor nerve fibers (e.g., skeletal microvasculature) are **cholinergic postganglionic sympathetic neurons**. These authors also demonstrated VAChT-positive principal ganglionic cells in two other sympathetic ganglia: the stellate and superior cervical ganglia.

Schäfer and colleagues also studied the developmental biology of postganglionic sympathetic neurons. They found that a small minority of sympathetic neurons have a cholinergic phenotype even during early embryonic development—before the neurons innervate sweat glands.

Thus, a true postganglionic sympathetic neuron—postganglionic in both the gross anatomical and the physiological sense of the word—can be cholinergic. In other words, a preganglionic sympathetic “first” neuron, with its cell body in the intermediolateral column, may synapse in a sympathetic ganglion with a postganglionic sympathetic “second” neuron that releases ACh at its nerve terminals. Thus, it is no longer necessary to assume that cholinergic sympathetic sudomotor/vasomotor neurons are, in fact, preganglionic fibers that traversed the sympathetic ganglion without synapsing.

Therefore, blood vessels within skeletal muscle receive both sympathetic adrenergic and sympathetic cholinergic innervation. The cholinergic system, acting directly via muscarinic receptors (see pp. 341–342), relaxes VSMCs and causes rapid vasodilation. This vasodilation in skeletal muscle occurs in the fight-or-flight response as well as perhaps during the anticipatory response in exercise (see pp. 349–

350). In both cases, mobilization of the sympathetic vasodilator system is accompanied by extensive activation of the sympathetic division, including cardiac effects (i.e., increased heart rate and contractility) and generalized vasoconstriction of all vascular beds *except those in skeletal muscle*. (Little vasoconstriction occurs in cerebral and coronary beds, which have sparse sympathetic vasoconstrictor innervation.)

Adrenal Medulla

We have already mentioned that some preganglionic sympathetic fibers in the sympathetic splanchnic nerves also innervate the chromaffin cells in the adrenal medulla. Therefore, the adrenal medulla is the equivalent of a sympathetic ganglion. The synaptic terminals of the preganglionic fibers release ACh, which acts on **nAChRs** of the **chromaffin cells** of the adrenal medulla (see p. 1030). Chromaffin cells are thus modified postganglionic neurons that release their transmitters—**epinephrine** and, to a far lesser degree, norepinephrine—into the bloodstream rather than onto a specific end organ. Thus, the adrenal medulla participates as a global effector that through its release of epinephrine causes generalized effects on the circulation. As we will see in the next section, the epinephrine released by the adrenal medulla acts on both the heart and the blood vessels and thereby contributes to the control of the systemic arterial pressure.

The unique combination of agonists and receptors determines the end response in cardiac and vascular effector cells

Adrenergic Receptors in the Heart

The *sympathetic* output to the heart affects both heart rate and contractility. Norepinephrine, released by the postganglionic sympathetic neurons, acts on postsynaptic β_1 -adrenergic receptors of pacemaker cells in the SA node as well as on similar receptors of myocardial cells in the atria and ventricles. The β_1 adrenoceptor, via the G protein G_s , acts via the cAMP–protein kinase A pathway (see p. 57) to phosphorylate multiple effector molecules in both pacemaker cells and cardiac myocytes (see Table 23-1).

In **pacemaker cells**, **N23-7** β_1 agonists stimulate (1) I_f , the diastolic Na^+ current through HCN channels, and (2) I_{Ca} , a Ca^{2+} current through T-type and L-type Ca^{2+} channels. The net effect of these two changes is an increased rate of diastolic depolarization (i.e., phase 4 of the action potential; see Fig. 21-4A) and a negative shift in the threshold for the action potential (see pp. 492–493). Because diastole shortens, the *heart rate* increases.

N23-7

Action Potential of the Sinoatrial Node

Contributed by W. Jonathan Lederer

Figure 21-4A illustrates the phases of the SA node action potential and the underlying currents.

During phase 0 of the action potential, I_{Ca} *activates* regeneratively (see red record in bottom panel of Fig. 21-4A, specifically the rapid downstroke), producing a rapid upstroke of V_m . Underlying I_{Ca} are both T-type and L-type Ca^{2+} channels.

At the transition between phases 0 and 3, I_{Ca} then begins to *inactivate*, a feature that begins the repolarization process. Note that phases 1 and 2 are not seen in the SA node because the inactivation of I_{Ca} combines with the slow activation of I_K to bring about the phase 3 repolarization of the action potential.

As V_m approaches the maximum diastolic potential at the beginning of phase 4, three slow changes in membrane current take place that underlie phase 4 pacemaker activity:

1. I_K deactivates slowly with time (over hundreds of milliseconds), producing a decreasing outward current (see green record in middle panel of Fig. 21-4A, specifically the slow decline of outward current during phase 4).
2. I_{Ca} contributes inward (i.e., depolarizing) current in the following way. Even though V_m has become more negative at the end of phase 3, V_m is still positive enough to keep I_{Ca} *partially activated* (albeit to only a small extent) from the previous action potential. Additionally, at the end of phase 3, V_m is still negative enough to cause I_{Ca} to *recover slowly from inactivation* (remember that recovery from inactivation and activation of I_{Ca} are independent processes). Thus, as I_{Ca} recovers from inactivation over hundreds of milliseconds, there is a small, increasingly inward I_{Ca} that tends to depolarize the SA nodal cells during phase 4 (see red record in lower panel of Fig. 21-4A, specifically the slow downstroke of inward current during phase 4).
3. I_f slowly activates as V_m becomes sufficiently negative at the end of phase 3. The result is a slowly growing, inward (i.e., depolarizing) current (see blue record in middle panel of Fig. 21-4A, specifically the rather rapid downstroke of inward current during phase 4).

Thus, during phase 4, the sum of a *decreasing outward* current (I_K) and two *increasing inward* currents (I_{Ca} and I_f) produces the slow pacemaker depolarization associated with the SA node.

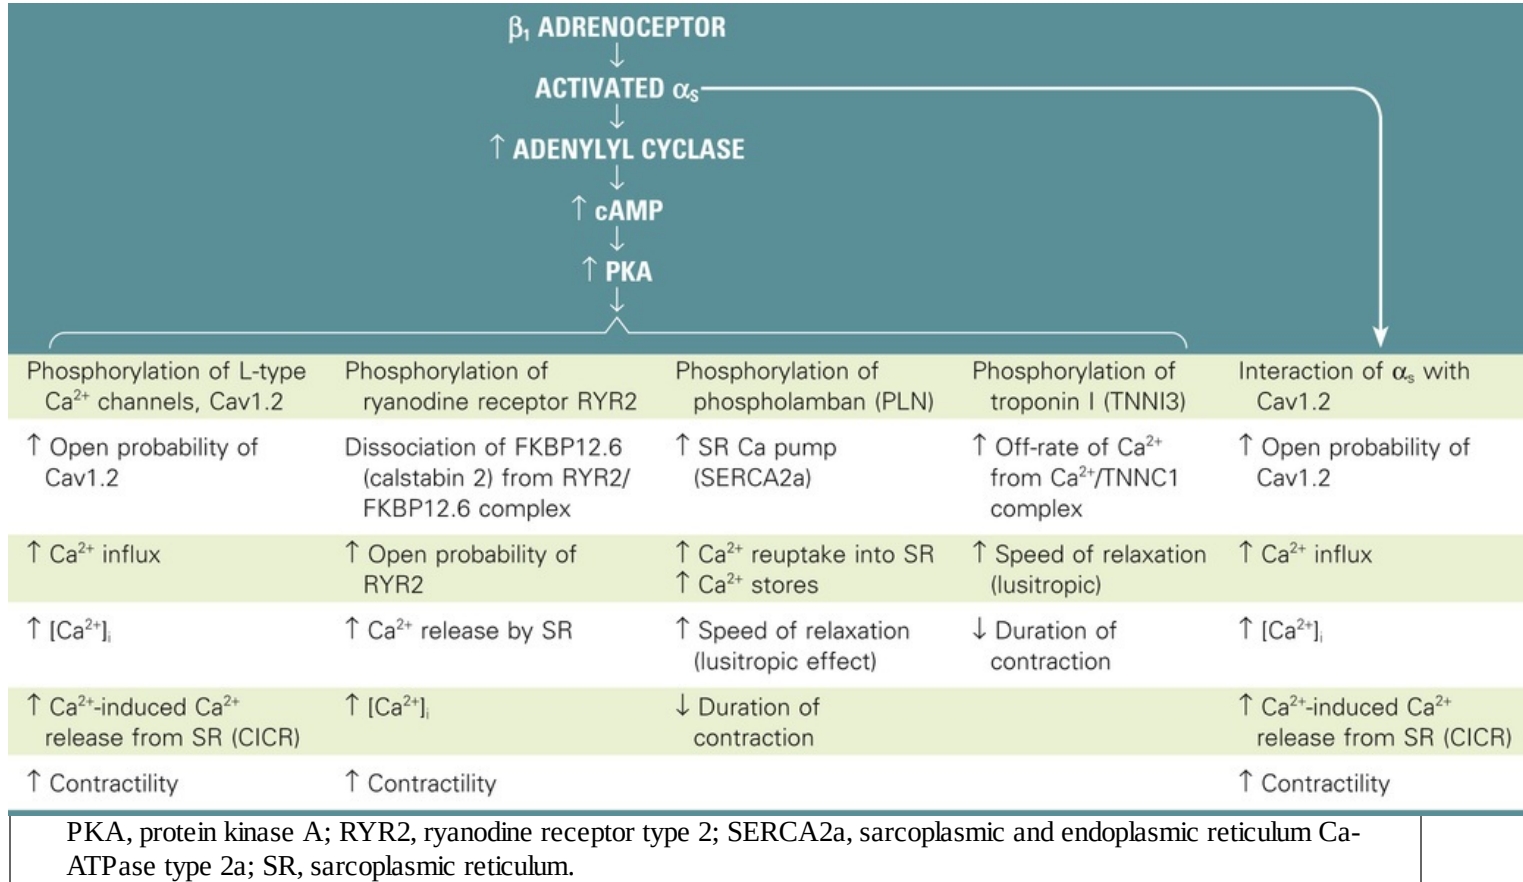

As V_m rises from about -65 mV toward the threshold of about -55 mV during the pacemaker depolarization, I_{Ca} becomes increasingly activated and eventually becomes regenerative, producing the rapid upstroke of the action potential ... which takes us back to the beginning of this discussion. Note that the turning off of I_f tends to oppose the rapid upstroke of V_m during phase 0. However, the activation of I_{Ca} overwhelms the turning off of I_f .

In **myocardial cells**, β_1 agonists exert several parallel **positive inotropic** effects via protein kinase A (Table 23-2). In addition, the activated α_s subunit of the G protein can directly activate L-type Ca^{2+} channels. The net effects of these pathways are contractions that are both stronger (see p. 493) and briefer (see pp. 522–524).

TABLE 23-2

Effects of Activating the β_1 -Adrenergic Receptor in Ventricular Muscle*

*See Chapter 22 for a discussion of calstabin 2 (Box 22-4), Cav1.2 (p. 522 and Box 22-4), PLN (pp. 523–524 and Box 22-3), RYR2 (p. 522 and Box 22-4), SERCA2 (p. 523 and Box 22-3), TNNC1 (p. 522), and TNNI3 (p. 522)

Cholinergic Receptors in the Heart

Parasympathetic output to the heart affects heart rate and, to a much lesser extent, contractility. ACh released by postsynaptic parasympathetic neurons binds to M_2 muscarinic (i.e., G protein-coupled) receptors on pacemaker cells of the SA node and on ventricular myocytes (see [Table 23-1](#)).

In **pacemaker cells**, ACh acts by three mechanisms. (1) ACh triggers a membrane-delimited signaling pathway mediated not by the G-protein α subunits but rather by the $\beta\gamma$ heterodimers (see [p. 56](#)). The newly released $\beta\gamma$ subunits directly open inward-rectifier K^+ channels (GIRK1 or Kir3.1) in pacemaker cells (see [pp. 197–198](#)). The resulting elevation of the K^+ conductance makes the maximum diastolic potential more negative during phase 4 of the action potential. (2) ACh also decreases I_f , thereby reducing the rate of diastolic depolarization. (3) ACh decreases I_{Ca} , thereby both reducing the rate of diastolic depolarization and making the threshold more positive (see [p. 492](#)). The net effect is a reduction in heart rate.

In **myocardial cells**, ACh has a **minor negative inotropic effect**, which could occur by two mechanisms: (1) Activation of the M_2 receptor, via $G\alpha_i$, inhibits adenylyl cyclase, reducing $[\text{cAMP}]_i$ and thereby counteracting the effects of adrenergic stimulation. (2) Activation of the M_3 receptor, via $G\alpha_q$, stimulates phospholipase C, raising $[\text{Ca}^{2+}]_i$ and thus stimulating nitric oxide synthase (NOS; [pp. 66–67](#)). The newly formed NO stimulates guanylyl cyclase and increases $[\text{cGMP}]_i$, which somehow inhibits L-type Ca^{2+} channels and decreases Ca^{2+} influx.

Adrenergic Receptors in Blood Vessels

The sympathetic division of the autonomic nervous system can modulate the tone of vascular smooth

muscle in arteries, arterioles, and veins via two distinct routes—postganglionic sympathetic neurons and the adrenal medulla. Whether the net effect of sympathetic stimulation in a particular vessel is vasoconstriction (increased VSMC tone) or vasodilation (decreased VSMC tone) depends on four factors: (1) which agonist is released, (2) which adrenoceptors that agonist binds to, (3) whether receptor occupancy tends to cause vasoconstriction or vasodilation, and (4) which receptor subtypes happen to be present on a particular VSMC.

Which agonist is released is the most straightforward of the factors. Postganglionic sympathetic neurons release norepinephrine, and the adrenal medulla releases primarily epinephrine.

Which receptors the agonist binds to is more complex. Norepinephrine and epinephrine do not have exclusive affinity for a single type of adrenoceptor. The original α and β designations followed from the observation that norepinephrine appeared to have its greatest activity on α receptors, and epinephrine, on β receptors. However, although norepinephrine binds with a greater affinity to α receptors than to β receptors, it also can activate β receptors. Similarly, although epinephrine binds with a greater affinity to β receptors than to α receptors, it can also activate α receptors. Of course, synthetic agonists may be more specific and potent than either norepinephrine or epinephrine (e.g., the α agonist phenylephrine and β agonist isoproterenol). A finer pharmacological and molecular dissection reveals that both α and β receptors have subgroups (e.g., β_1 and β_2), and even the subgroups have subgroups (see pp. 342–343). Each of these many adrenoceptor types has a unique pharmacology. Thus, the β_1 receptor has about the same affinity for epinephrine and norepinephrine, but the β_2 receptor has a higher affinity for epinephrine than for norepinephrine.

Whether receptor occupancy tends to cause vasoconstriction or vasodilation is straightforward (see Table 23-1). The *vasoconstriction* elicited by catecholamines is an α effect, in particular, an α_1 effect. Thus, norepinephrine released from nerve terminals acts on the α_1 adrenoceptor, which is coupled to the G protein G_q . The resulting activation of phospholipase C (see pp. 53–56) and formation of inositol 1,4,5-trisphosphate (IP_3) lead to a rise in $[Ca^{2+}]_i$ and smooth-muscle contraction (see Table 20-7). In contrast, *vasodilation*, elicited by epinephrine released from the adrenal medulla, is a β_2 effect. Occupancy of the β_2 adrenoceptor triggers the cAMP–protein kinase A pathway, leading to phosphorylation of myosin light-chain kinase (MLCK; p. 247); this reduces the sensitivity of MLCK to the Ca^{2+} -calmodulin complex, resulting by default in smooth-muscle relaxation (see Table 20-7).

Which receptor subtypes happen to be present on a particular VSMC is a complex issue. Many blood vessels are populated with a mixture of α -receptor or β -receptor subtypes, each stimulated to varying degrees by norepinephrine and epinephrine. Therefore, the response of the cell depends on the relative dominance of the subtype of receptor present on the cell surface. Fortunately, the only two subtypes in blood vessels that matter clinically are α_1 and β_2 .

The ultimate outcome in the target tissue (vasoconstriction versus vasodilation) depends on both the heterogeneous mixture of agonists (norepinephrine versus epinephrine) applied and the heterogeneous mixture of VSMC receptors (α_1 and β_2) present in tissues. As an example, consider blood vessels in the skin and heart. Because cutaneous blood vessels have *only* α_1 receptors, they can only vasoconstrict, regardless of whether the agonist is norepinephrine or epinephrine. On the other hand, epinephrine causes coronary blood vessels to dilate because they have a greater number of β_2 receptors than α_1 receptors.

Cholinergic Receptors in or near Blood Vessels

The addition of ACh to an isolated VSMC causes contraction. Thus, in an artificial situation in which the

nerve terminals release only ACh and in which no other tissues are present, ACh would lead to vasoconstriction. In real life, however, ACh dilates blood vessels by binding to muscarinic receptors on neighboring cells and generating *other* messengers that indirectly cause vasodilation (see [Tables 23-1 and 20-7](#)). For example, in **skeletal muscle**, ACh may bind to M_2 receptors on the presynaptic membranes of postganglionic sympathetic neurons, decreasing $[cAMP]_i$ and inhibiting the release of norepinephrine. Thus, inhibition of vasoconstriction produces vasodilation.

In **erectile tissue**, ACh not only binds to presynaptic M_2 receptors as before, but also binds to M_3 receptors on vascular *endothelial cells* and, via the phospholipase C pathway, releases IP_3 and raises $[Ca^{2+}]_i$ (see [Fig. 14-11](#)). The Ca^{2+} stimulates NOS to produce NO (see [pp. 66–67](#)), which diffuses from the endothelial cell to the VSMC. Inside the VSMC, the NO activates soluble guanylyl cyclase, resulting in the production of cGMP and activation of protein kinase G. The subsequent phosphorylation of MLCK causes relaxation (see [p. 477](#)).

In **salivary glands**, [N23-8](#) postganglionic parasympathetic neurons release ACh, which may stimulate gland cells to secrete kallikrein, an enzyme that cleaves kininogens to vasodilating kinins (e.g., bradykinin). A similar paracrine sequence of events may occur in the **sweat glands** of nonapical skin, where postganglionic sympathetic fibers release ACh, indirectly leading to local vasodilation (see [p. 571](#)).

Vasodilation in Salivary and Sweat Glands

Contributed by Emile Boulpaep

1. **Salivary glands.** For a discussion of the physiology of vasodilator kinins see pages 553–554.
2. **Sweat glands.** See page 571 for a discussion of the mechanisms whereby cholinergic sympathetic neurons cause vasodilation in nonapical skin.

Nonadrenergic, Noncholinergic Receptors in Blood Vessels

Postganglionic parasympathetic nerve terminals may cause vasodilation by co-releasing neurotransmitters other than ACh (see [Table 23-1](#)), such as NO, neuropeptide Y, vasoactive intestinal peptide, and calcitonin gene-related peptide. NO of neuronal origin acts in the same way as endothelium-derived NO. Neuropeptide Y acts by lowering $[cAMP]_i$; vasoactive intestinal peptide and presumably calcitonin gene-related peptide act by raising $[cAMP]_i$ (see [Table 20-8](#)).

The medullary cardiovascular center tonically maintains blood pressure and is under the control of higher brain centers

The medullary cardiovascular center normally exerts its tonic activity on the sympathetic preganglionic neurons, whose cell bodies lie in the thoracolumbar segments of the spinal cord. However, a variety of somatic and visceral afferents also make connections with this efferent pathway in the spinal cord, and

such afferents are responsible for several reflexes that occur at the spinal level. The sympathetic preganglionic neurons are normally so dependent on medullary input that they are not very sensitive to local afferents. Rather, these somatic and visceral afferents exert their major effect by ascending to the medulla and synapsing in the NTS. Nevertheless, some spinal (i.e., segmental) cardiovascular reflexes do exist. For example, the skin blanches in response to both pain and inflammation. These spinal reflexes become most powerful after a spinal transverse lesion.

Neurons of the C1 area of the medulla (see [Fig. 23-4](#)) are responsible for maintaining a normal mean arterial pressure. In general, C1 neurons are tonically active and excite sympathetic preganglionic neurons to produce vasoconstriction (see [p. 537](#)). The presence of tonically active neurons in the C1 area raises the possibility that these neurons play a role in some forms of hypertension. Interestingly, clonidine, an antihypertensive agent, acts by binding to imidazole receptors on C1 area neurons.

Besides the afferents from the baroreceptors, the medullary cardiovascular center receives afferents from respiratory centers and from higher CNS centers, such as the hypothalamus and cerebral cortex (see [Fig. 23-5](#)). The **hypothalamus** integrates many cardiovascular responses. Indeed, one can use a microelectrode to stimulate particular sites in the hypothalamus to reproduce a variety of physiological responses. The dorsomedial hypothalamic nucleus in the hypothalamus acts on the rostral ventrolateral medulla (see [p. 537](#)) to mediate vasomotor and cardiac responses (e.g., during exercise and acute stress). The **cerebral cortex** influences the hypothalamic integration areas along both excitatory and inhibitory pathways. Thus, a strong emotion can lead to precipitous hypotension with syncope (i.e., fainting). Conditioned reflexes can also elicit cardiovascular responses. For example, it is possible, by reward conditioning, to train an animal to increase or to decrease its heart rate.

Secondary neural regulation of arterial blood pressure depends on chemoreceptors

Although baroreceptors are the primary sensors for blood pressure control, a second set of receptors, the peripheral chemoreceptors, also play a role. Whereas input from baroreceptors exerts a *negative* drive on the medullary *vasomotor center*, causing vasodilation, the peripheral chemoreceptors exert a *positive* drive on the vasomotor center, causing vasoconstriction ([Fig. 23-6A](#)). As far as the heart is concerned, inputs from *both* the baroreceptors and the peripheral chemoreceptors exert a positive drive on the *cardioinhibitory center*; that is, they both decrease heart rate (compare [Figs. 23-1](#) and [23-6A](#)).

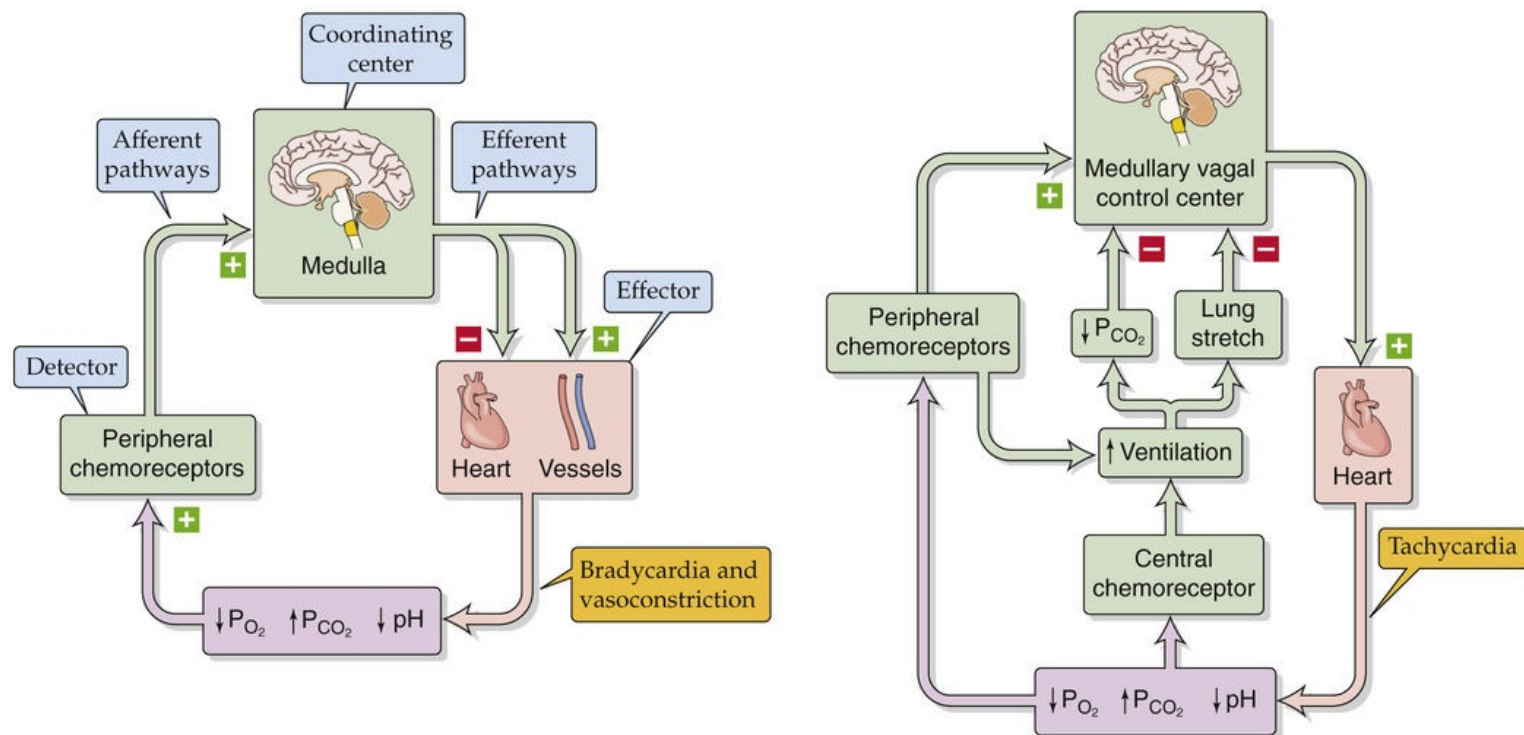

FIGURE 23-6 Chemoreceptor control of the cardiovascular system. In this example, we assume that a decrease in P_{O_2} , an increase in P_{CO_2} , or a decrease in pH is the primary insult (violet box). In **A**, the bradycardia occurs only when ventilation is fixed or prevented (e.g., breath-holding). In **B**, the effects of breathing overcome the intrinsic cardiovascular response, producing tachycardia.

The medullary *respiratory* centers—which include the areas that integrate the input from the peripheral chemoreceptors—strongly influence medullary *cardiovascular* centers. A fall in arterial P_{O_2} , a rise in P_{CO_2} , or a fall in pH stimulates the peripheral chemoreceptors to increase the firing frequency of the afferent nerves to the medulla. In the absence of conflicting input, which we discuss next, the intrinsic response of the medulla to this peripheral chemoreceptor input is to direct efferent pathways to cause *vasoconstriction* and *bradycardia* (see Fig. 23-6A). Opposite changes in the P_{O_2} , P_{CO_2} , and pH have the opposite effects.

The **peripheral chemoreceptors**—whose primary role is to regulate ventilation (see pp. 710–713)—lie close to the baroreceptors. Just as there are two types of high-pressure baroreceptors (i.e., carotid sinus and aortic arch), there are also two types of peripheral chemoreceptors: the carotid bodies and the aortic bodies (compare the location of the baroreceptor and chemoreceptor systems in Fig. 23-2A, B).

Carotid Bodies

The carotid body—or glomus caroticum—is located between the external and internal carotid arteries. Although the human carotid body is small (i.e., $\sim 1 \text{ mm}^3$), it has an extraordinarily high blood flow per unit mass and a minuscule arteriovenous difference for P_{O_2} , P_{CO_2} , and pH—putting it in an excellent position to monitor the composition of the *arterial blood*. The chemosensitive cell in the carotid body is the **glomus cell**, **N23-9** which synapses with nerve fibers that join the glossopharyngeal nerve (CN IX). A fall in arterial P_{O_2} , a rise in arterial P_{CO_2} , or a fall in the pH increases the spike frequency in the sensory fibers of the afferent sinus nerve.

Peripheral Chemoreceptors

Contributed by George Richerson, Emile Boulpaep, Walter Boron

Recent progress on the physiology of glomus cells has largely been a result of the ability to study glomus cells in culture and in the isolated carotid body in vitro.

Regarding the model in Figure 32-11, some controversy—which may reflect species differences—exists about which K^+ channel is the target of hypoxia. Some evidence favors the charybdotoxin-sensitive Ca^{2+} -activated K^+ channel. Other data point to a Ca^{2+} -insensitive voltage-gated K^+ channel and a voltage-insensitive “resting” K^+ channel.

Although one report (Williams et al, 2004) suggested that hemoxygenase-2 (HO-2) is a universal O_2 sensor, the results of a later study (Ortega-Sáenz et al, 2006) showed that mice deficient in HO-2 have a normal ability to sense a decrease in $[O_2]$.

Aortic Bodies

The aortic bodies are situated immediately under the concavity of the aortic arch and in the angle between the *right* subclavian and carotid arteries. Aortic bodies may also be present at the angle between the *left* subclavian and common carotid arteries. The aortic glomus cells synapse with nerve fibers that are afferent pathways in the vagus nerve (CN X).

Afferent Fiber Input to the Medulla

The most important signal affecting the glomus cells is a low P_{O_2} , which triggers an increase in the firing rate of the sensory fibers. We will discuss ways in which this signal triggers neuronal firing on [page 712](#). Like the afferent fibers from the baroreceptors, the afferent fibers from both the carotid body (CN IX) and the aortic bodies (CN X) project to the NTS in the medulla. Indeed, the responses to input from the peripheral chemoreceptors overlap with those to input from the baroreceptors.

Physiological Role of the Peripheral Chemoreceptors in Cardiovascular Control

The fluctuations in P_{O_2} that normally occur in humans are not large enough to affect the blood pressure or heart rate. For the cardiovascular system, the peripheral chemoreceptors play a role only during severe hypoxia (e.g., hemorrhagic hypotension). As already noted, the *intrinsic* cardiovascular effects of hypoxia on the peripheral chemoreceptors include vasoconstriction and bradycardia (see [Fig. 23-6A](#)). However, it is not easy to demonstrate this primary reflex bradycardia; indeed, it is observed only during forced

apnea. Under real-life conditions, *hypoxia causes tachycardia*. Why? Hypoxia—via the peripheral chemoreceptors—normally stimulates the medullary respiratory centers, which in turn stimulate ventilation (see [Fig. 23-6B](#)). As discussed below, the high P_{CO_2} that may accompany hypoxia stimulates the central chemoreceptors, and this independently stimulates ventilation. This increased ventilation has two effects. First, it stretches the lungs, which in turn stimulates pulmonary stretch receptors. Afferent impulses from these pulmonary stretch receptors ultimately inhibit the cardioinhibitory center, causing reflex tachycardia. Second, as discussed on [pages 679–680](#), increased alveolar ventilation caused by hypoxia lowers systemic P_{CO_2} , raising the pH of the brain ECF and inhibiting the cardioinhibitory center. Again, the net effect is tachycardia. Thus, the physiological response to hypoxia is tachycardia.

Central Chemoreceptors

In addition to peripheral chemoreceptors, *central* chemoreceptors are present in the medulla (see [p. 713](#)). However, in contrast to the peripheral chemoreceptors, which primarily sense a low P_{O_2} , the central chemoreceptors mainly sense a low brain pH, which generally reflects a high arterial P_{CO_2} .

As already noted (see [Fig. 23-4B](#)), tonic baroreceptor input to the NTS in the medulla stimulates inhibitory interneurons that project onto the vasomotor area. This pathway exerts a considerable restraining influence on sympathetic output, which would otherwise cause vasoconstriction. Thus, cutting of these baroreceptor afferents causes vasoconstriction. The central chemoreceptor also influences the vasomotor area. Indeed, a high arterial P_{CO_2} (i.e., low brain pH), which stimulates the central chemoreceptor, disinhibits the vasomotor area—just as cutting of baroreceptor afferents disinhibits the vasomotor area. The result is also the same: an increase in the sympathetic output and vasoconstriction.

In summary, a low P_{O_2} acting on the peripheral chemoreceptor and a high P_{CO_2} acting on the central chemoreceptor act in concert to enhance vasoconstriction.

Regulation of Cardiac Output

Other things being unchanged, an increased cardiac output raises mean arterial pressure. Therefore, it is not surprising that, as we have just seen, the heart is an important effector organ in the feedback loops that regulate mean arterial pressure. Cardiac output is the product of the heart rate and stroke volume (see [Equation 17-6](#)), and both factors are under the dual control of (1) regulatory mechanisms intrinsic to the heart, and (2) neural and hormonal pathways that are extrinsic to the heart.

Mechanisms intrinsic to the heart modulate both heart rate and stroke volume

Intrinsic Control of Heart Rate

As the length of diastole increases, the heart rate necessarily decreases. The diastolic interval is determined by the nature of the action potential fired off by the SA node. Such factors as the maximum diastolic potential, the slope of the diastolic depolarization (phase 4), and the threshold potential all influence the period between one SA node action potential and the next (see [Fig. 21-6](#)). Intrinsic modifiers of the SA node pacemaker, such as $[K^+]_o$ and $[Ca^{2+}]_o$, greatly influence the ionic currents responsible for SA node pacemaker activity but are not part of any cardiovascular feedback loops.

Intrinsic Control of Stroke Volume

Stroke volume is the difference between end-diastolic volume and end-systolic volume (see [Equation 22-2](#)). Various processes intrinsic to the heart affect both of these variables.

The **end-diastolic volume (EDV)** depends on the following:

1. **Filling pressure.** Ventricular filling pressure depends to a large degree on *atrial* filling pressure. When increased venous return causes atrial filling pressure to rise, EDV rises as well.
2. **Filling time.** The *longer* the filling time, the greater the EDV. As heart rate rises, diastole shortens to a greater extent than does systole, thereby decreasing EDV.
3. **Ventricular compliance** (reciprocal of the slope of the diastole curve in [Fig. 22-12B](#)). As ventricular compliance increases, a given filling pressure will produce a greater increase in ventricular volume, thus resulting in a greater EDV.

The **end-systolic volume (ESV)** depends on the following:

1. **Preload** (i.e., end-diastolic volume). According to Starling's law of the heart, increase of the EDV increases the stretch on the cardiac muscle and the force of the contraction (see the systole curve in [Fig. 22-12B](#)), and thus the stroke volume. Only at a very large EDV does contraction begin to weaken as the muscle fibers are too stretched to generate maximal power (see [Fig. 22-12A](#)).
2. **Afterload** (force against which the ventricle ejects its contents). The afterload of the left ventricle is the mean systemic arterial pressure; the afterload of the right ventricle is the mean pulmonary arterial

pressure. Increased afterload impedes the heart's ability to empty and thereby increases ESV.

3. Heart rate. An increased heart rate leads to greater Ca^{2+} entry into myocardial cells, thereby increasing contractility and reducing ESV (see [p. 530](#)).

4. Contractility. Positive inotropic agents act by increasing $[\text{Ca}^{2+}]_i$ within the myocardial cells (see [p. 530](#)), thereby enhancing the force of contraction and decreasing ESV.

Note that a particular variable may affect both EDV and ESV. For example, an increased heart rate decreases EDV and decreases ESV. Therefore, its effect on stroke volume—the *difference* between these two volumes—may be difficult to predict.

Mechanisms extrinsic to the heart also modulate heart rate and stroke volume

We have already seen that the sympathetic and parasympathetic pathways are the efferent limbs of the feedback loops that control mean arterial pressure (see [Fig. 23-5](#)). These efferent limbs also control cardiac output via heart rate and stroke volume. Because we have already described the anatomy, neurotransmitters, and transduction mechanisms involved in these pathways, we focus here on how these pathways specifically affect the heart rate and stroke volume.

Baroreceptor Regulation

Baroreceptor responses affect both heart rate and stroke volume, the *product* of which is *cardiac output*. However, baroreceptors do not monitor cardiac output per se but rather arterial pressure. Thus, the baroreceptor response does *not* correct spontaneous alterations in cardiac output unless they happen to change mean arterial pressure. For example, when an increase in the cardiac output matches a commensurate decrease in the peripheral resistance, leaving the mean arterial pressure unchanged, the baroreceptors do not respond. On the other hand, even if cardiac output is unchanged, it will be the target of the baroreceptor response if other factors (e.g., changes in peripheral resistance) alter arterial pressure.

Chemoreceptor Regulation

In [Figure 23-6B](#), we saw that the integrated response to hypoxia and respiratory acidosis is *tachycardia*. This tachycardia response turns out to be a very helpful feedback mechanism for maintaining cardiac output. For example, a reduced cardiac output lowers arterial P_{O_2} , raises P_{CO_2} , and lowers pH. These changes stimulate the peripheral chemoreceptors, indirectly producing tachycardia and thereby increasing cardiac output. Thus, the chemoreceptor response corrects changes in blood chemistry that are likely to result from reduced cardiac output. Once again, the detector (i.e., the peripheral chemoreceptor) does not sense changes in the cardiac output per se but rather in the metabolic consequences of altered cardiac output. Changes in cardiac output go unnoticed by the chemoreceptors if they do not affect arterial P_{O_2} , P_{CO_2} , or pH.

It is fortunate that a high P_{CO_2} increases the heart rate (see [Fig. 23-6B](#)) because a high P_{CO_2} has a direct effect on the heart, *decreasing* myocardial contractility. High P_{CO_2} leads to intracellular acidosis of the

myocardial cells (see pp. 645–646). The low pH_i shifts the $[Ca^{2+}]_i$ -tension curve of cardiac muscle to higher $[Ca^{2+}]_i$ values, which reflects a lower sensitivity of the cardiac form of troponin C (TNNC1) to $[Ca^{2+}]_i$. Thus, in the absence of reflex tachycardia, high P_{CO_2} would decrease myocardial force and thereby lower cardiac output.

Low-pressure baroreceptors in the atria respond to increased “fullness” of the vascular system, triggering tachycardia, renal vasodilation, and diuresis

The baroreceptors located at *high*-pressure sites (i.e., the carotid sinus and aortic arch) are not the only stretch receptors involved in feedback regulation of the circulation. Low-pressure baroreceptors—bare ends of myelinated nerve fibers—are located at strategic *low*-pressure sites, including the pulmonary artery, the junction of the atria with their corresponding veins, the atria themselves, and the ventricles (Fig. 23-7A). Distention of these receptors depends largely on venous return to the heart. Therefore, these mechanoreceptors detect the “fullness” of the circulation and are part of a larger system of volume sensors that control the effective circulating volume of blood (see p. 838). These low-pressure receptors also help control cardiac output. By regulating both effective circulating volume and cardiac output, these receptors also *indirectly* regulate mean arterial blood pressure.

FIGURE 23-7 Low-pressure receptors. In **B**, A-type receptors (*orange*) are located mainly in the body of the right atrium; B-type receptors (*green*) are located mainly in the superior and inferior vena cava. ECG, electrocardiogram.

Atrial Receptors

The most extensively studied low-pressure receptors are the atrial receptors. These are located at the ends of afferent axons—either A or B fibers—that join the vagus nerve (CN X). The A fibers fire in synchrony with atrial systole and therefore monitor heart rate (see [Fig. 23-7B](#)). The B fibers fire in a burst during ventricular systole (see [Fig. 23-7B](#)) and gradually increase their firing rate as the atria fill, reaching maximum firing frequency at the peak of the v wave of the atrial (i.e., jugular) pulse (see [Fig. 22-7A](#)). Thus, the B fibers monitor the rising atrial volume. Because the **central venous pressure (CVP)**—the pressure inside large systemic veins leading to the right heart—is the main determinant of right atrial filling, the B fibers also detect changes in CVP. By inference, the atrial B-type stretch receptors primarily monitor effective circulating volume and venous return.

The afferent pathways for the low-pressure receptors are similar to those for high-pressure baroreceptors and peripheral chemoreceptors traveling along the vagus nerve and projecting to the NTS (see [p. 537](#)) and other nuclei of the medullary cardiovascular center. To some extent, the efferent pathways and effector organs (i.e., heart and blood vessels) also are similar. However, whereas increased stretch of the high-pressure receptors *lowers* heart rate, increased stretch of the atrial B-type receptors *raises* heart rate (the **Bainbridge reflex**, which we discuss in the next section). Moreover, whereas increased stretch of the high-pressure receptors causes *generalized* vasodilation, increased stretch of the atrial B-type receptors decreases sympathetic vasoconstrictor output *only to the kidney*. The net effect of increased atrial stretch (i.e., tachycardia and renal vasodilation) is an increase in renal blood flow and—as seen on [page 768](#)—an increase in urine output (i.e., diuresis). Decreased atrial stretch has little effect on heart rate but increases sympathetic output to the kidney. Therefore, as far as their direct cardiovascular effects are concerned, the high-pressure baroreceptors respond to stretch (i.e., increased blood pressure) by attempting to decrease blood pressure. The low-pressure baroreceptors respond to stretch (i.e., increased fullness) by attempting to eliminate fluid.

The afferent fibers of the atrial receptors that project to the NTS also synapse there with neurons that project to magnocellular neurons in the paraventricular nucleus of the hypothalamus (see [Fig. 40-8](#)). These hypothalamic neurons synthesize **arginine vasopressin (AVP)**—also known as antidiuretic hormone (see [pp. 817–819](#))—and then transport it down their axons to the posterior pituitary for release into the blood (see [pp. 979–981](#)). Increased atrial stretch lowers AVP secretion, which produces a water diuresis and thus decreases total body water (see [pp. 846–849](#)).

In addition to stimulating bare nerve endings, atrial stretch causes a *non-neural* response by stretching the atrial myocytes themselves. When stretched, atrial myocytes release **atrial natriuretic peptide (ANP)** or factor (ANF). **N3-18** ANP is a powerful vasodilator. It also causes diuresis (see [p. 843](#)) and thus enhances the renal excretion of Na^+ (i.e., it causes natriuresis). In these ways, it lowers effective circulating volume blood pressure.

Thus, enhanced atrial filling with consequent stretching of the atrial mechanoreceptors promotes diuresis by at least three efferent mechanisms, the first two of which are neurally mediated: (1) Tachycardia in combination with a reduced sympathetic vasoconstrictor output to the kidney increases renal blood flow. (2) Atrial baroreceptors cause decreased secretion of AVP. (3) The stretch of the atrial myocytes themselves enhances the release of ANP.

Ventricular Receptors

Stretching of the ventricular *low-pressure* stretch receptors causes bradycardia and vasodilation, responses similar to those associated with stretching of the arterial *high-pressure* receptors. However, these ventricular receptors do not contribute appreciably to homeostasis of the cardiac output.

Cardiac output is roughly proportional to effective circulating blood volume

The Bainbridge reflex is the name given to the tachycardia caused by an increase in venous return. An increase in blood volume leads to increased firing of low-pressure B fibers (see [Fig. 23-7B](#)) during atrial filling. The efferent limb of this Bainbridge reflex is limited to instructions carried by both parasympathetic and sympathetic pathways to the SA node, which determines heart rate. Effects on cardiac contractility and stroke volume are insignificant. Because the Bainbridge reflex saturates, the increase in heart rate is greatest at low baseline heart rates.

The Bainbridge reflex acts as a counterbalance to the baroreceptor reflex in the control of **heart rate**. The orange curve on the right upper quadrant of [Figure 23-8](#) illustrates the Bainbridge reflex: increase of the effective circulating volume (i.e., increase of venous return and stimulation of *low-pressure* receptors) increases heart rate. On the other hand, we have already noted that decreased atrial stretch has little effect on heart rate by the Bainbridge reflex. The orange curve in the left upper quadrant of [Figure 23-8](#) illustrates the intervention of the *high-pressure* baroreceptors. That is, a decrease in blood volume does not cause heart rate to fall but rather causes it to rise. Indeed, a significant reduction in blood volume leads to a fall in mean arterial pressure, reduced baroreceptor firing, and—via the cardioinhibitory and cardioacceleratory areas in the medulla (see [Fig. 23-4B](#))—stimulation of the SA node. Therefore, on examination of the full orange curve in [Figure 23-8](#), we see that changes in blood volume or venous return have a biphasic effect on heart rate. By different mechanisms, volume loading and volume depletion *both* cause a graded increase in heart rate. In general, during volume loading, the Bainbridge reflex prevails, whereas during volume depletion, the high-pressure baroreceptor reflex dominates. *Heart rate is at its minimum when effective circulating volume is normal.*

FIGURE 23-8 Effect of blood volume on cardiac output. The investigators changed effective circulating volume (x-axis) by altering blood volume.

Like heart rate (see Fig. 23-8, orange curve), **stroke volume** also shows a peculiar, biphasic dependence on effective circulating volume (blue curve) that is the result of two competing effects. In the case of stroke volume, the competitors are Starling's law and the baroreceptor reflex. According to Starling's law, as venous blood volume increases, enhanced ventricular filling increases EDV, thereby improving cardiac performance and thus stroke volume (see pp. 524–526). The Starling relationship reflects the *intrinsic* properties of the heart muscle. However, in a real person, the baroreceptor reflex has a major influence on the dependence of stroke volume on blood volume. At low blood volumes, the baroreceptor reflex produces high sympathetic output, increasing contractility and steepening the Starling relationship (blue curve in the left lower quadrant of Fig. 23-8). At high blood volumes, the Starling relationship normally tends to be less steep. Moreover, the baroreceptor reflex reduces sympathetic

output, thereby decreasing contractility and further flattening the blue curve in the right half of [Figure 23-8](#).

In contrast to the biphasic response of heart rate and stroke volume to changes in effective circulating volume, **cardiac output** rises monotonically (see [Fig. 23-8](#), red curve). The reason for this smooth increase is that cardiac output is the product of heart rate *and* stroke volume. Starting from very low blood volumes (see the extreme left of [Fig. 23-8](#)), increase in the blood volume causes a gradual rise in stroke volume (blue curve), offset by a fall in heart rate (orange curve), resulting in an overall rise of cardiac output (red curve) until blood volume and stroke volume reach normal levels. Further increases in blood volume have no effect on stroke volume (blue curve) but increase heart rate (orange curve), further increasing cardiac output (red curve). Consequently, the dependence of cardiac output on effective circulating volume [N23-10](#) is the result of the complex interplay among three responses: (1) the Bainbridge reflex, (2) the baroreceptor reflex, and (3) Starling's law.

N23-10

Monotonic Dependence of Cardiac Output on Effective Circulating Volume

Contributed by Emile Boulpaep

The following is a summary and restatement of the discussion that began on pages 547–548.

Starting from a volume-contracted state (change in effective circulating volume = -30 mL/kg in [Fig. 23-8](#)), a gradual increase in effective circulating volume causes the cardiac output to increase monotonically (see [Fig. 23-8](#), lower left portion of red curve) because the rising stroke volume (Starling's law, steepened by baroreceptor response, as indicated by the lower left portion of the blue curve) more than counterbalances the falling heart rate (baroreceptor reflex, as indicated by the falling phase of the orange curve).

Continuing now from a normal volume state (change in effective circulating volume = 0 mL/kg in [Fig. 23-8](#)), an additional increase in effective circulating volume causes a further monotonic increase in cardiac output because a rising heart rate (the Bainbridge reflex, as indicated by the rising phase of the orange curve) combines with the flat stroke-volume curve (the Starling relationship—normally flattening at high degrees of stretch—is further flattened by the baroreceptor reflex).

Matching of Venous Return and Cardiac Output

Venous return is the blood flow returning to the heart. Most often, the term is used to mean the *systemic* venous return, that is, return of blood to the right heart. Because the input of the right heart must equal its output in the steady state, and because the cardiac outputs of the right and left sides of the heart are almost exactly the same, the input to the right heart must equal the output of the left heart. Thus, the systemic venous return must match the systemic cardiac output.

Increases in cardiac output cause right atrial pressure to fall

The right atrial pressure (RAP) determines the extent of ventricular filling and indeed was the first of the three determinants of EDV discussed above in the chapter. In turn, RAP depends on the venous return of blood to the heart. Imagine that we replace the heart and lungs with a simple pump—with adjustable flow—that delivers blood into the aorta and simultaneously takes it back up from the right atrium ([Fig. 23-9A](#)). Using this simple pump, we can study the factors that govern venous return from the peripheral systemic circulation to the right heart by varying flow (the *independent* variable) while recording RAP (the *dependent* variable).

A MODEL OF SYSTEMIC CIRCULATION**B VASCULAR FUNCTION CURVE WITH REVERSED AXES****C VASCULAR FUNCTION CURVE**

FIGURE 23-9 Vascular function. In **A**, a heart-lung machine replaces the right heart, the pulmonary circulation, and the left heart. We can set the pump flow to predetermined values and examine how cardiac output determines CVP and RAP. C_V and C_A are vascular compliances. **B** shows the dependent variable (RAP) on the y-axis, whereas **C** shows RAP on the x-axis.

We start our experiment with the pump generating a normal cardiac output of 5 L/min; the RAP is 2 mm Hg. This situation is represented by point A in [Figure 23-9B](#), which is a plot of RAP versus venous return (i.e., our pump rate). When we reverse the axes, the plot is known as a **vascular function curve**. Note that we express venous return (i.e., cardiac *input*) in the same units as cardiac *output*. We now turn off the pump, a situation analogous to cardiac arrest. For several seconds, blood continues to flow from the arteries and capillaries into the veins because the arterial pressure continues to exceed the venous pressure. Remember that the aortic pressure does not fall to zero during diastole because of the potential energy stored in the elastic recoil of the arterial walls (see [Box 22-2](#)). Similarly, after a cardiac arrest, this potential energy continues to push blood to the venous side until all pressures are equal throughout the vascular tree, and flow stops everywhere.

When blood flow finally ceases after a cardiac arrest, the pressures in the arteries, capillaries, veins, and right atrium are uniform. This pressure is called the **mean systemic filling pressure (MSFP)** and is ~7 mm Hg (point B in [Fig. 23-9B](#)). Why is the MSFP not zero? When you fill an elastic container (e.g., a balloon) with fluid, the pressure inside depends on how much fluid you put in as well as the compliance of the container (see [Equation 19-5](#)). In the case of the cardiovascular system, MSFP depends on the blood volume and the overall compliance of the entire vascular system. Now that blood flow has ceased, there is obviously no longer any force (i.e., no ΔP) driving the blood from the veins into the pump. Therefore, RAP equals MSFP.

Now, starting with the system at a standstill (point B in [Fig. 23-9B](#)), we increase pump rate to some level, measure the steady-state RAP, and repeat this procedure several times at different pump rates. As the pump rate increases, RAP falls (see [Fig. 23-9B](#)) because the inflow to the pump draws blood out of the right atrium, the site closest to the inlet of the pump. Because the upstream CVP exceeds RAP, blood flows from the large veins into the right atrium. At a pump rate of 5 L/min, the RAP falls to about +2 mm Hg, its original value. At even higher pump rates, RAP eventually falls to negative values.

Cardiovascular physiologists usually work with the vascular function curve with the axes reversed from those shown in [Figure 23-9B](#), treating RAP as the independent variable and plotting it on the x-axis (see [Fig. 23-9C](#)). As RAP becomes less positive, it provides a greater driving pressure (i.e., greater $\Delta P = CVP - RAP$) for the return of blood from the periphery to the right atrium, as it must for cardiac output to increase. Thus, the cardiac output steadily rises as RAP falls. However, as RAP becomes increasingly negative, the transmural pressure of the large veins becomes negative, so that the large veins feeding blood to the right atrium collapse. No further increment in venous return can occur, even though the driving pressure, ΔP , is increasing. Therefore, the vascular function curve plateaus at negative values of RAP, around -1 mm Hg (see [Fig. 23-9C](#)).

Two different theories [N23-11](#) attempt to explain the shape of the vascular function curve in [Figure 23-9C](#). One explanation for the curve's steepness emphasizes the high compliance of the venous capacitance vessels; the other focuses on their small viscous resistance. In reality, both compliance and resistance are responsible for the steepness of the vascular function curve.

How Does Cardiac Output Determine Right Atrial Pressure?

Contributed by Emile Boulpaep

Imagine that we replace the right heart, the pulmonary circulation, and the left heart with a single pump (see Fig. 23-9A), similar to the heart-lung machine used for cardiopulmonary bypass during open heart surgery. In explaining the shape of the vascular-function curve in Figure 23-9C, we can stress either that large veins have a high compliance or that they have a low resistance.

Model of High Venous Compliance

In the high-venous-compliance model, we ignore the small axial pressure gradient along the lumen of the venous reservoir that is a result of the small viscous resistance between the large veins and right atrium. Instead, we assume that the CVP is the same as the RAP and that we can lump the compliance of all large-capacitance veins into a single compliance (C_V). The model in Figure 23-9A has two reservoirs—an aortic and a venous reservoir—separated by the peripheral resistance of the microcirculation. As we noted in our discussion of the “Windkessel” function of the aorta (see Fig. 22-4C), the compliance of the aorta (C_A) is far less than that of the large veins (C_V). During normal pumping of the heart, the aortic pressure (P_A) is much higher than the CVP (P_V). Let us consider what happens immediately after a cardiac arrest. At that moment, P_A still exceeds P_V , and blood continues to flow from the aortic reservoir to the venous reservoir until P_A and P_V both become equal to MSFP. How much blood volume shifts from the aortic to the venous reservoir depends on the relative compliances of the two reservoirs. For the aorta,

$$C_A = \frac{\Delta V_A}{\Delta P_A} \quad (\text{NE 23-1})$$

and for the veins,

$$C_V = \frac{\Delta V_V}{\Delta P_V} \quad (\text{NE 23-2})$$

C_V is ~20 times larger than C_A . In the equilibrium state, all the blood lost by the aorta ends up in the veins (i.e., $\Delta V_V = -\Delta V_A$). Therefore, because C_V is ~20 times larger than C_A , and because the magnitudes of the volume changes are identical, the fall in the aortic pressure (ΔP_A) must be ~20-fold greater than the rise in venous pressure (ΔP_V). Thus, at equilibrium, when all the pressures are the same, we must end up at a pressure (MSFP = ~7 mm Hg) that is much closer to the physiological CVP (CVP = ~2 mm Hg) than the original mean aortic pressure ($P_A = \sim 95$ mm Hg).

When the heart starts to pump again, it depletes the volume in the highly distensible venous reservoir, so that P_V progressively falls to the original steady-state value of 2 mm Hg. At this point, cardiac output and venous return are once again matched.

Model of Low Venous-Resistance

In the low-venous-resistance model, we ignore the capacitance of the veins, and instead focus on the resistance between the large veins and right atrium. The hydrodynamic equivalent of Ohm's law says that the driving pressure equals flow times resistance:

$$\Delta P = F \times R \quad (\text{NE 23-3})$$

Because the venous return equals F , it should depend on the axial pressure gradient (ΔP) between the CVP upstream and the RAP downstream. According to this model, RAP is the force that opposes flow into the atria. Venous return should also depend on the resistance to blood flow between the large systemic (i.e., “central”) veins that serve as the blood reservoir, on the one hand, and the right atrium, on the other. This resistance to venous return (RVR) resides mostly in these large-capacitance veins. From Ohm's law, the venous return depends on the CVP, RAP, and RVR:

$$\text{Cardiac input} = \text{Venous return} = \frac{\Delta P}{R} = \frac{\text{CVP} - \text{RAP}}{\text{RVR}} \quad (\text{NE 23-4})$$

RVR is usually considered to be the reciprocal of the slope of the linear portion of the vascular function curve in Figure 23-9C. However, this line is not really a plot of Ohm's law. Ohm's law should be a plot of the venous return versus the driving pressure (ΔP), as suggested by Equation NE 23-4. Instead, in Figure 23-9C, we plot the venous return versus RAP, which is not quite the same as ΔP . Changes in RAP in Figure 23-9C represent ΔP only if the “upstream pressure” (i.e., CVP) remains constant, which can only be true over a limited range of flows. The CVP remains constant only as long as sufficient blood is present on the venous side of the circulation. If flow increases too much, not enough blood can enter the veins, CVP falls, and the change in RAP is no longer equal to the change in the driving pressure ΔP . Despite this caveat, cardiovascular physiologists often take the reciprocal of the linear portion of Figure 23-9C as RVR.

According to this model, the negative intravascular pressures at high venous return (i.e., at high cardiac output) cause the large intrathoracic veins to collapse, which effectively increases the RVR to infinity. Hence, the curve plateaus.

Conclusions

Although both the high-capacitance and low-resistance models provide an intuitive understanding of the vascular function curve in Figure 23-9C, both compliance and viscous resistive properties of the venous system affect the relationship between pressure and flow.

Changes in blood volume shift the vascular function curve to different RAPs, whereas changes in arteriolar tone alter the slope of the curve

Because the vascular function curve depends on how full the capacitance vessels are, *changing the blood*

volume affects the vascular function curve. An increase in blood volume (e.g., a transfusion) shifts the curve to the right. In the example in [Figure 23-10A](#), the intercept with the x-axis (i.e., MSFP) moves from 7 to 9 mm Hg, as would be expected if more blood were put into a distensible container, whether it is a balloon or the circulatory system. A decrease in blood volume (e.g., hemorrhage) shifts the curve and the x-intercept to the left. Thus, MSFP increases with transfusion and decreases with hemorrhage. However, changes in blood volume do *not* affect the *slope* of the linear portion of the vascular function curve as long as there is no change in either vessel compliance or resistance.

FIGURE 23-10 Effect of changes in blood volume and vasomotor tone on the vascular function curve.

The purple curves are the same as the vascular function curve in [Figure 23-9C](#). In **B**, dilation of the arterioles increases CVP and thus raises the driving force (CVP – RAP) for venous return. Constriction of arterioles has the opposite effects.

Change in the venomotor tone, by constriction or dilation of *only the veins*, is equivalent to change in the blood volume. Returning to our balloon analogy, even if we hold the amount of blood constant, we can increase pressure inside the balloon by increasing the tension in the wall. Because most of the blood volume is in the veins, a pure increase in venomotor tone would be equivalent to a blood transfusion (see [Fig. 23-10A](#)). Conversely, a pure decrease in venomotor tone would reduce the tension in the wall of the container, shifting the curve to the left, just as in a hemorrhage.

Change in the tone of the arterioles has a very different effect on the vascular function curve. Because the arterioles contain only a minor fraction of the blood volume, changes in the arteriolar tone have little effect on MSFP and thus on the x-intercept. However, changes in the arteriolar tone can have a marked effect on the CVP, which, along with the RAP, determines the driving force for the venous return. Arteriolar constriction flattens the vascular function curve; arteriolar dilation has the opposite effect (see [Fig. 23-10B](#)). We can understand this effect by examining the vertical line through the three curves at an RAP of 2 mm Hg. For the middle or normal curve, the difference between a CVP of, say, 5 mm Hg and an RAP of 2 mm Hg ($\Delta P = \text{CVP} - \text{RAP} = 3 \text{ mm Hg}$) produces a venous return of 5 L/min. Arteriolar constriction might lower the CVP from 5 to 4 mm Hg, thereby reducing ΔP from 3 to 2 mm Hg. Because the driving pressure (ΔP) drops to $\frac{2}{3}$ of normal, venous return also falls to $\frac{2}{3}$ of normal. Thus, arteriolar

constriction flattens the vascular function curve. Similarly, arteriolar dilation might raise CVP from 5 to 6 mm Hg, so that the ΔP increases from 3 to 4 mm Hg, producing a venous return that is $\frac{4}{3}$ of normal. Thus, arteriolar dilation steepens the vascular function curve.

In the preceding analysis, we assumed “pure” changes in blood volume or vessel tone. In real life, things can be more complicated. For example, hemorrhage is typically followed by arteriolar constriction for maintenance of the systemic arterial pressure. Thus, real situations may both shift the x-intercept and change the slope of the vascular function curve.

Because vascular function and cardiac function depend on each other, cardiac output and venous return match at exactly one value of RAP

Just as there is a vascular function curve, there is also a cardiac function curve that in effect is Starling's law. The classical Starling's law relationship (see [Fig. 22-12B](#)), which is valid for both ventricles, is a plot of developed pressure versus EDV. However, we already expressed Starling's law as a cardiac performance curve in [Figure 22-12C](#), plotting stroke work on the y-axis and atrial pressure on the x-axis. Because stroke work—at a fixed arterial pressure and heart rate—is proportional to cardiac output, we can replace stroke work with *cardiac output* on the y-axis of the cardiac performance curve. The result is the red cardiac function curve in [Figure 23-11A](#). Note that the cardiac function curve is a plot of cardiac output versus RAP, and it has the same *units* as the vascular function curve. We can plot the two relationships on the same graph (see [Fig. 23-11A](#)). However, the y-axis for the cardiac function curve is *cardiac output*, whereas the y-axis for the vascular function curve is *venous return*. Of course, cardiac output and venous return (i.e., cardiac input) must be the same in the steady state.

A MATCHING OF A SINGLE CARDIAC FUNCTION CURVE WITH A SINGLE VASCULAR FUNCTION CURVE

B SHIFT OF VASCULAR FUNCTION CURVE

C SHIFT OF CARDIAC FUNCTION CURVE

FIGURE 23-11 Matching of cardiac output with venous return. The purple curves are the same as the vascular function curve in [Figure 23-9C](#). The red cardiac function curves represent Starling's law. In **A**, point A is the single RAP at which venous return and cardiac output match. A transient increase in RAP from 2 to 4 mm Hg causes an initial mismatch between cardiac output (point B) and venous return (point B'), which eventually resolves (B'C'A and BCA). In **B**, permanently increasing blood volume (transfusion) shifts the vascular function curve to the right (as in [Fig. 23-10A](#)), so that a match between the cardiac output and venous return now occurs at a higher RAP (point B). In **C**, permanently increasing cardiac contractility shifts the cardiac function curve upward, so that a match between the cardiac output and the venous return now occurs at a lower RAP (point B).

We can now ask, Do the cardiac output and venous return depend on RAP? Does RAP depend on the cardiac output and venous return? The answer to both questions is an emphatic yes! They all depend on each other. There is no absolute dependent or independent variable in this closed circuit because, in the

steady state, venous return and cardiac output must be equal. Venous return (from the vascular function curve) and cardiac output (from the cardiac function curve) can be equal only at the single point where the two curves intersect (point A in [Fig. 23-11A](#)). Only transient and small deviations in these two curves are possible unless either or both of the function curves change in shape.

Imagine what would happen if RAP transiently increased from 2 to 4 mm Hg (see [Fig. 23-11A](#)). Starling's law states that the increased ventricular filling initially increases cardiac output from starting point A (5 L/min) to point B (7.3 L/min). Simultaneously, the increase in RAP causes a decrease in the driving pressure ΔP for venous return, that is, the difference $CVP - RAP$. Thus, the increase in RAP would initially reduce the venous return from point A (5 L/min) to point B' (3 L/min). This imbalance between cardiac output and venous return cannot last very long. The transiently elevated cardiac output will have two effects. First, by sucking the right atrium dry, it will tend to lower RAP. Second, by pumping blood out of the heart and toward the veins, it will raise CVP. As a result, the difference $CVP - RAP$ increases, and venous return moves from point B' to C'. Because RAP is lower at point C' than at B', the cardiac output must also be less at point C than at point B. The imbalance between C and C' (6.5 versus 4 L/min) is now less than that between B and B' (7.3 versus 3 L/min). In this way, venous return gradually increases, cardiac output gradually decreases, and RAP gradually decreases until once again they all come into balance at point A. Thus, the cardiovascular system has an intrinsic mechanism for counteracting small, transient imbalances between cardiac input and output.

The only way to produce a *permanent change* in cardiac output, venous return, and RAP is to change at least one of the two function curves. The vascular function curve may be any one of a large family of such curves (see [Fig. 23-10A, B](#)), depending on the precise blood volume, venomotor tone, and arteriolar tone. Thus, a transfusion of blood shifts the vascular function curve to the right, establishing a new steady-state operating point at a higher RAP (point A \rightarrow point B in [Fig. 23-11B](#)). Similarly, vasodilation would rotate the vascular function curve to a steeper slope, also establishing a new steady-state operating point at a higher RAP.

The cardiac function curve also may be any one of a large family (see [Fig. 22-12C](#)), depending on afterload, heart rate, and, above all, the heart's contractile state. Therefore, increasing contractility by adding a cardiac glycoside such as digitalis (see [p. 530](#)) shifts the cardiac function curve upward and to the left, establishing another steady-state operating point (point A \rightarrow point B in [Fig. 23-11C](#)). Both physiological and pathological conditions can reset the vascular and cardiac function curves, resulting in a wide range of operating points for the match between venous return and cardiac output.

Intermediate- and Long-Term Control of the Circulation

In addition to the rapidly acting neural mechanisms that control the total peripheral resistance and cardiac output, humoral controls contribute to the homeostasis of the circulation. In most instances, these control systems operate on a time scale of hours or days, far more slowly than the neurotransmitter-mediated reflex control by the CNS.

Two classes of humoral controls influence the circulation:

1. Vasoactive substances released in the blood, or in the proximity of vascular smooth muscle, modulate the vasomotor tone of arteries and veins, affecting blood pressure and the distribution of blood flow.
2. Nonvasoactive substances, which act on targets other than the cardiovascular system, control the effective circulating volume by modulating ECF volume. By determining the filling of the blood vessels, these nonvasoactive agents also modulate the mean arterial pressure and cardiac output.

Endocrine and paracrine vasoactive compounds control the circulatory system on an intermediate- to long-term basis

Vasoactive substances, both endocrine and paracrine, cause blood vessels to contract or to relax ([Table 23-3](#)). In many instances, paracrine control dominates over endocrine control. The chemical messengers controlling the blood vessels can be amines, peptides, or proteins; derivatives of arachidonic acid; or gases such as NO.

TABLE 23-3
Vasoactive Compounds

VASOCONSTRICTORS	VASODILATORS
Epinephrine (via α_1 receptors)	Epinephrine (via β_2 receptors)
Serotonin	Histamine
ANG II	ANP
AVP	Bradykinins
ET	PGE ₂ , PGI ₂
	NO

Biogenic Amines

Monoamines may be either vasoconstrictors (epinephrine and serotonin) or vasodilators (histamine).

1. **Epinephrine.** The source of this hormone is the adrenal medulla (see [pp. 1030–1033](#)). Epinephrine binds to **α_1 receptors** on VSMCs with less affinity than norepinephrine, causing *vasoconstriction* (see [Table 20-7](#)), and with high affinity to **β_2 receptors** on VSMCs, causing *vasodilation* (see [Table 20-7](#)). Because β_2 receptors are largely confined to the blood vessels of skeletal muscle, the heart, the liver, and the adrenal medulla itself, epinephrine is not a systemic vasodilator. Epinephrine also binds to β_1 receptors in the heart, thereby *increasing the heart rate and contractility* (see [p. 542](#)). For the

cardiovascular system, the effects of catecholamines originating from the adrenal medulla are usually minor compared with those of the norepinephrine released from the sympathetic nerve endings.

2. Serotonin. Also known as 5-hydroxytryptamine (5-HT; see [Fig. 13-8B](#)), this monoamine is synthesized by serotonergic nerves, enterochromaffin cells, and adrenal chromaffin cells. 5-HT is also present in platelets and mast cells. Serotonin binds to **5-HT_{2A} and 5-HT_{2B} receptors** on VSMCs, causing *vasoconstriction* (see [Table 20-8](#)). Circulating serotonin is generally not involved in normal systemic control of the circulation but rather in local control. Serotonin is particularly important in vessel damage, where it contributes to hemostasis (see [p. 439](#)).

3. Histamine. Like serotonin, histamine (see [Fig. 13-8B](#)) may also be present in nerve terminals. In addition, mast cells release histamine in response to tissue injury and inflammation. Histamine binds to **H₂ receptors** on VSMCs, causing *vasodilation* (see [Table 20-8](#)). Although histamine causes vascular smooth muscle to relax, it causes visceral smooth muscle (e.g., bronchial smooth muscle in asthma) to contract.

Peptides

Vasoactive peptides may be either vasoconstrictors or vasodilators (see [Table 23-3](#)).

1. Angiotensin II (ANG II). Part of the renin-angiotensin-aldosterone cascade (see [pp. 841–842](#)), ANG II, as its name implies, is a powerful *vasoconstrictor*. The liver secretes angiotensinogen into the blood. The enzyme renin, released into the blood by the kidney, then converts angiotensinogen to the decapeptide ANG I. Finally, angiotensin-converting enzyme (ACE), which is present primarily on endothelial cells, particularly those of the lung, cleaves ANG I to the octapeptide ANG II. Aminopeptidases further cleave it to the heptapeptide ANG III, which is somewhat less vasoactive than ANG II. [N23-12](#)

N23-12

Metabolism of the Angiotensins

Contributed by Emile Boulpaep, Walter Boron

The liver synthesizes and releases into the blood the α_2 -globulin **angiotensinogen (Agt)**, which is a plasma glycoprotein that consists of 452 amino acids. Its molecular weight ranges from 52 to 60 kDa, depending on the degree of glycosylation. Angiotensinogen belongs to the **serpin** (serine protease inhibitor) superfamily of proteins, which also includes antithrombin III (see [p. 446](#) as well as [Tables 18-4](#) and [18-5](#)). The liver contains only small stores of angiotensinogen, which it constitutively secretes. Production by the liver is greatly increased during the acute-phase response (see [Box 18-1](#)).

Angiotensinogen is synthesized in several tissues other than liver. In addition to the 52- to 60-kDa form of angiotensinogen, a high-molecular-weight (HMW) angiotensinogen complex of 450 to 500 kDa is also present in plasma. Polymorphisms within the angiotensinogen gene may contribute to normal variations in arterial blood pressure and a tendency to develop hypertension.

The juxtaglomerular cells of the kidney—also called granular cells (see [p. 727](#))—are specialized smooth-muscle cells of the afferent arteriole that synthesize and release both the glycoprotein **renin** (molecular weight 37 to 40 kDa)—pronounced *ree-nin*—and its inactive precursor **prorenin**, which is the major circulating form. Prorenin-activating enzymes on endothelial cells convert this prorenin to

renin. The kidney is the major source of circulating prorenin/renin, and the liver is responsible for removing renin from the circulation. The half-life of renin in plasma is 10 to 20 minutes. Renin is an aspartyl proteinase that cleaves a leucine-valine bond near the amino (N) terminus of angiotensinogen to release a decapeptide called **angiotensin I** (ANG I), which is not biologically active. By an alternative pathway, nonrenin proteases can also produce ANG I. The full sequence of ANG I is **Asp-Arg-Val-Tyr-Ile-His-Pro-Phe-His-Leu**:

Angiotensin-converting enzyme (ACE; molecular weight ~200 kDa) is produced by and attached to endothelial cells. ACE is a dipeptidyl carboxypeptidase (a zinc peptidase) that cleaves ANG I by removing the carboxy-terminal (C-terminal) dipeptide histidine-leucine and producing the octapeptide **angiotensin II** (ANG II). The ACE cleavage site is a phenylalanine-histidine bond. The sequence of ANG II is **Asp-Arg-Val-Tyr-Ile-His-Pro-Phe**:

ANG II has a half-life in blood of 1 to 3 minutes, indicating that a large fraction is removed in a single pass through the circulation. ANG II acts on G protein-coupled receptors known as **AT₁** and **AT₂**. In addition, two other receptors are less well characterized: **AT₃** and **AT₄**. ANG IV (see below) can bind to **AT₄** receptors.

By an alternative pathway, non-ACE proteases can also convert ANG I to ANG II. Conversely, note that ANG I is not a specific substrate for ACE, which can cleave other peptides, including bradykinin (see pp. 553–554), enkephalins, and substance P.

Aminopeptidase A (also called angiotensinase A, or glutamyl aminopeptidase) further cleaves the aspartate-arginine bond on ANG II to produce the heptapeptide **angiotensin III** (ANG III, also called ANG-(2-8)), which has the sequence **Arg-Val-Tyr-Ile-His-Pro-Phe**. Ang III, like ANG II, can also bind to AT receptors.

Aminopeptidase B (also called angiotensinase B, or arginyl aminopeptidase) finally cleaves an arginine-valine bond on ANG III to produce the hexapeptide **angiotensin IV** (ANG IV, also called ANG-(3-8)). The sequence of ANG IV is **Val-Tyr-Ile-His-Pro-Phe**. This metabolite is inactive.

Finally, another ANG metabolite has received attention in recent years. **ANG-(1-7)** consists only of the first seven amino acids of ANG I*: **Asp-Arg-Val-Tyr-Ile-His-Pro**. This heptapeptide can arise from ANG I by at least three routes:

Note that, by the above nomenclature, ANG I is ANG-(1-10), and ANG II is ANG-(1-8). The first and third pathways involve a new enzyme called **ACE2**. The second is catalyzed by any in a family of enzymes called **neutral endopeptidases (NEPs)**. ANG-(1-7) can bind to a G protein–coupled receptor called the **Mas receptor** and—when acting on the cardiovascular system—can elicit effects opposite those of ANG II.

* ANG-(1-7) is not to be confused with another heptapeptide metabolite of ANG II, namely, **ANG III**—also known as ANG-(2-8). ANG III has actions similar to those of ANG II, but is weaker (see p. 553).

In VSMCs, ANG II binds to G protein–coupled **AT_{1A} receptors**, activating phospholipase C, raising $[\text{Ca}^{2+}]_i$, and leading to *vasoconstriction* (see [Table 20-8](#)). However, ANG II is *normally* not present in plasma concentrations high enough to produce systemic vasoconstriction. In contrast, ANG II plays a major role in cardiovascular control during blood loss (see [p. 585](#)), exercise, and similar circumstances that reduce renal blood flow. Reduced perfusion pressure in the kidney causes the release of renin (see [p. 841](#)). Plasma ANG II levels rise, leading to an intense vasoconstriction in the splanchnic and renal circulations. The resulting reduced renal blood flow leads to even more renin release and higher ANG II levels, a dangerous positive-feedback system that can lead to acute renal failure. A widely studied model of hypertension that demonstrates the importance of this mechanism is the Goldblatt model for hypertension ([Box 23-1](#)).

Box 23-1

Hypertension

Hypertension is found in ~20% of the adult population. It can damage endothelial cells, producing a number of proliferative responses, including arteriosclerosis. In the long term, hypertension can lead to coronary artery disease, myocardial infarction, heart failure, stroke, and renal failure. In the great

majority of cases, hypertension is the result of dysfunction of the mechanisms used by the circulation for the long-term rather than short-term control of arterial pressure. In fact, chronically hypertensive patients may have diminished sensitivity of their arterial baroreceptors.

Most people with an elevated blood pressure have “primary hypertension,” in which it is not possible to identify a single, specific cause. Renal artery stenosis, which compromises renal blood flow, is the most common cause of secondary hypertension. An experimental equivalent of renal artery stenosis is the “one-clip two-kidney” model of hypertension first described by Goldblatt (see Box 40-2). This model does not explain most cases of hypertension, but it does give us our best description of the pathophysiological mechanism involved in at least some patients with elevated blood pressure. The most common cause of renal artery stenosis is the narrowing of the renal artery by atherosclerotic plaque. Fibromuscular disease of the renal arterial wall can also be responsible, usually in young women, as can any space-occupying lesion (e.g., metastatic cancer or benign cysts). If the stenosis is removed by angioplasty or surgery, and if preliminary test results show that the stenosis is the likely cause of the elevation in blood pressure, then a significant percentage of such patients will experience resolution of their hypertension.

The cumulative obstruction of smaller arteries and arterioles may also produce hypertension, as is often seen in diseases of the renal parenchyma or any end-stage renal disease. Conversely, constriction of larger vessels proximal to the kidneys can also cause hypertension, as is the case with coarctation of the aorta, a congenital malformation that constricts flow through the aorta to the lower parts of the body. Another cause of secondary hypertension is chronic volume overload. Volume overload can be acquired, such as in primary aldosteronism (caused by either a benign adenoma or bilateral hyperplasia) and pheochromocytoma (a tumor of the adrenal medulla that releases excessive amounts of catecholamines into the circulation). Volume overload can be genetic, as in rare mendelian forms of hypertension such as Liddle disease  **N23-14** and pseudohypoaldosteronism type 2.

N23-14

Liddle Disease

Contributed by Emile Boulpaep, Walter Boron

Liddle disease is caused by a gain-of-function mutation in the β or γ subunit of the **epithelial Na⁺ channel ENaC**. For example, the critical regions in the β subunit are critical for endocytosis or proteasomal degradation of the channel. Thus, mutations result in an overabundance of ENaC at the apical membrane, resulting in excessive Na⁺ reabsorption, an increase in effective circulating volume, and hypertension. The disease is readily diagnosed by determining whether the hypertension is reversed by the drug amiloride, which antagonizes ENaC. Indeed, amiloride is an effective therapy for Liddle disease.

For a description of ENaC, see Table 6-2, family No. 14.

ANG II has a range of other effects—besides direct vasoactive effects—that indirectly increase mean arterial pressure: (1) ANG II increases cardiac contractility. (2) It reduces renal plasma flow, thereby enhancing Na^+ reabsorption in the kidney. (3) As discussed in the next section, ANG II and ANG III also stimulate the adrenal cortex to release aldosterone. (4) In the CNS, ANG II stimulates thirst and leads to the release of another vasoconstrictor, AVP. (5) ANG II facilitates the release of norepinephrine by postganglionic sympathetic nerve terminals. (6) Finally, ANG II also acts as a cardiac growth factor (see [Box 22-3](#)).

2. Arginine vasopressin (AVP). The posterior pituitary releases AVP, also known as antidiuretic hormone. AVP binds to **V_{1A} receptors** on VSMCs, causing *vasoconstriction* (see [Table 20-8](#)), but only at concentrations higher than those that are strongly antidiuretic (see [pp. 817–819](#)). Hemorrhagic shock causes enhanced AVP release and a vasoconstriction that contributes to a transient restoration of arterial pressure (see [pp. 584–585](#)).

3. Endothelins (ETs). Endothelial cells produce ETs (see [pp. 461–463](#)) that bind to **ET_A receptors** on VSMCs, causing *vasoconstriction* (see [Table 20-8](#)). Although, on a molar basis, ETs are the most powerful vasoconstrictors, it is not clear whether these paracrine agents play a dominant role in overall blood pressure homeostasis.

4. Atrial natriuretic peptide (ANP or ANF). Released from atrial myocytes in response to stretch (see [p. 547](#)), this 28–amino-acid peptide binds to **ANP receptor A (NPR1)** on VSMCs, which is membrane-bound guanylyl cyclase, causing *vasodilation* (see [Table 20-8](#)). Although ANP lowers blood pressure, its role in the overall regulation of mean arterial pressure is doubtful. Because ANP also has powerful diuretic and natriuretic actions, it ultimately reduces plasma volume and therefore blood pressure.  [N23-13](#)

N23-13

Crosstalk Between Atrial Natriuretic Peptide and Endothelin

Contributed by Emile Boulpaep

Atrial Natriuretic Peptide (ANP) is also involved in an intriguing feedback loop involving endothelin. ANP stimulates endothelin formation by endothelial cells, but endothelin is itself a secretagogue for the atrial myocytes, causing them to release ANP. Thus, a vasodilator (ANP) promotes the release of a

vasoconstrictor (ET), which in turn promotes the release of the original vasodilator.

5. **Kinins.** At least three different kinins exist: (1) the nonapeptide **bradykinin**, which is formed in plasma; (2) the decapeptide **lysyl-bradykinin**, which is liberated from tissues; and (3) **methionyl-lysyl-bradykinin**, which is present in the urine. These kinins are produced by the breakdown of **kininogens**, catalyzed by **kallikreins**—enzymes that are present in plasma and in tissues such as the salivary glands, pancreas, sweat glands, intestine, and kidney. Kallikreins form in the blood from the following cascade: Plasmin acts on clotting factor XII, releasing fragments with proteolytic activity. These factor XII fragments convert an inactive precursor, prekallikrein, to kallikreins. The kinins formed by the action of these kallikreins are eliminated by the **kininases** (kininase I and II). Kininase II is the same as ACE. Thus, the same enzyme (ACE) that generates a vasoconstrictor (ANG II) also disposes of vasodilators (bradykinin). Bradykinin binds to **B₂ receptors** on endothelial cells, causing release of NO and prostaglandins and thereby *vasodilation* (see [Table 20-8](#)). Like histamine, the kinins *relax* vascular smooth muscle but *contract* visceral smooth muscle.

Prostaglandins

Many tissues synthesize prostaglandins, derivatives of arachidonic acid (see [pp. 61–62](#)). Prostacyclin (prostaglandin I₂ [PGI₂]) binds to prostanoid **IP receptors** on VSMCs, causing strong *vasodilation* (see [Table 20-8](#)). PGE₂ binds to prostanoid **EP₂** and **EP₄ receptors** on VSMCs, also causing *vasodilation* (see [Table 20-8](#)). It is doubtful that prostaglandins play a role in systemic vascular control. In veins and also in some arteries, arachidonic acid or Ca²⁺ ionophores cause endothelium-dependent contractions. Because cyclooxygenase inhibitors prevent this vasoconstrictor response, venous endothelial cells probably metabolize arachidonic acid into a vasoconstrictive cyclooxygenase product, presumably thromboxane A₂.

Nitric Oxide

Nitric oxide synthase (NOS) produces NO from arginine in endothelial cells (see [p. 480](#)). NO activates the **soluble guanylyl cyclase** in VSMCs, causing *vasodilation* (see [Table 20-8](#)). Although NO is a powerful paracrine *vasodilator*, it is not clear that it plays an important role in overall blood pressure homeostasis.

Pathways for the renal control of ECF volume are the primary long-term regulators of mean arterial pressure

The *volume of the* ECF includes both the blood plasma and the interstitial fluid. The small solutes in the plasma and interstitial fluid exchange freely across the capillary wall, so that the entire ECF constitutes a single osmotic compartment. Because the plasma volume is a more or less constant fraction (~20%) of the ECF volume, changes in the ECF volume produce proportional changes in plasma volume. Thus, assuming that the compliance of the vasculature is constant (see [Equation 19-5](#)), such an increase in plasma volume will lead to an increase in transmural blood pressure.

We saw in [Chapter 20](#) that the *Starling forces* across a capillary (i.e., the hydrostatic and colloid osmotic pressure differences) determine the traffic of fluid between the plasma and the interstitial fluid (see [p. 471](#)). Thus, alterations in the Starling forces acting across the capillary wall can affect the plasma

volume and therefore blood pressure.

Because of the importance of the ECF volume and Starling forces in determining the plasma volume, one might expect that the body would have specific sensors for ECF volume, interstitial fluid volume, and blood volume. However, the parameter that the body controls in the intermediate- and long-term regulation of the mean arterial pressure is none of these but rather a more vague parameter termed the **effective circulating volume**. The effective circulating volume is not an anatomical volume but the *functional* blood volume that reflects the extent of tissue perfusion, as sensed by the fullness or pressure in the vessels. The control mechanisms that defend effective circulating volume include the two classes of stretch receptors described in this chapter. First, the high-pressure receptors in the carotid sinus and aorta (see pp. 534–536) do double duty. In the short term, these baroreceptors regulate blood pressure by their direct cardiovascular effects, as was already discussed. In the longer term, they regulate effective circulating volume. Second, the low-pressure receptors—located in the pulmonary artery, the junction of the atria with their corresponding veins, the atria themselves, and the ventricles (see pp. 546–547)—regulate effective circulating volume by direct and indirect effects on the cardiovascular system. In addition to these already familiar receptors involved in neural control of the circulation, other sensors monitor effective circulating volume (see Table 40-2): the baroreceptors in the renal artery, the stretch receptors in the liver, and the atrial myocytes themselves as well as—to some extent—osmoreceptors in the CNS.

As we will see in Chapter 40, these sensors of effective circulating volume send signals to the dominant effector organ—the kidney—to change the rate of Na^+ excretion in the urine. These signals to the kidney follow four parallel effector pathways (see p. 834): (1) the renin–ANG II–aldosterone axis, (2) the autonomic nervous system, (3) the posterior pituitary that releases AVP, and (4) the atrial myocytes that release ANP. Of these four parallel pathways, the most important is the **renin-angiotensin-aldosterone** system. By regulating total body Na^+ content, the kidney determines ECF volume. Therefore, the kidney ultimately governs the blood volume and is thus the principal agent in the long-term control of mean arterial pressure.

CHAPTER 24

Special Circulations

Steven S. Segal

In the preceding chapters, we considered blood flow to peripheral capillary beds as if the “periphery” were a single entity. In this chapter, we break that entity down into some of its component parts. Because each organ in the body has its own unique set of requirements, special circulations within each organ have evolved with their own particular features and regulatory mechanisms. Especially for times of great stress to the body, each organ possesses circulatory adaptations that allow it to make the changes appropriate for causing minimal harm to the overall organism. Here, we focus on the circulations of the brain, heart, skeletal muscle, abdominal viscera, and skin. Elsewhere we discuss other special circulations in the context of particular organs—the lungs (see [pp. 683–689](#)), the kidneys (see [pp. 745–750](#)), the placenta (see [pp. 1136–1139](#)), and the fetal circulation (see [pp. 1157–1158](#)).

The blood flow to individual organs must vary to meet the needs of the particular organ, as well as of the whole body

The blood flow to each tissue must meet the nutritional needs of that tissue's parenchymal cells, while at the same time allowing those cells to play their role in the homeostasis of the whole individual. The way in which the circulatory system distributes blood flow must be flexible so that changing demands can be met. In the process of meeting these demands, the body makes compromises. Consider the circulatory changes that accompany exercise. Blood flow to active skeletal muscle increases tremendously through both an increase in and a redistribution of cardiac output. Blood flow to the coronary circulation must also rise to meet the demands of exercise. Furthermore, in order to dispose of the heat generated during exercise, the vessels in the skin dilate, thereby promoting heat transfer to the environment. As cardiac output is increasingly directed to active muscle and skin, circulation to the splanchnic and renal circulations decreases, while blood flow to the brain is preserved.

This chapter focuses on the perfusion of select *systemic* vascular beds, but keep in mind that the lungs receive the entire cardiac output and therefore must also be able to accommodate any changes in total blood flow.

Neural, myogenic, metabolic, and endothelial mechanisms control regional blood flow

Several mechanisms govern vascular resistance and thus the distribution of blood circulating throughout the body. The interplay among neural, myogenic, metabolic, and endothelial mechanisms establishes a resting level of vasomotor tone. The extent to which a particular vascular bed depends on a particular blood-flow-control mechanism varies from organ to organ. We have discussed the following four mechanisms in the preceding chapters, and briefly review them here.

Neural Mechanisms

The resistance vessels of nearly every organ are invested with fibers of the autonomic nervous system (ANS), particularly those of the sympathetic division (see [pp. 542–543](#)). In addition to playing a critical role in controlling blood pressure and cardiac output, the ANS modulates local blood flow to meet the needs of particular tissues.

Myogenic Mechanisms

Many vessels, particularly the muscular arteries and arterioles that govern vascular resistance, are inherently responsive to changes in transmural pressure. Increased pressure and the accompanying stretch of vascular smooth-muscle cells (VSMCs) elicit vasoconstriction (see [pp. 477–478](#)), whereas decreased pressure elicits vasodilation. This myogenic response plays an important role in the autoregulation (see [p. 481](#)) that occurs in the vessels of the brain, heart, skeletal muscle, and kidneys.

Metabolic Mechanisms

Throughout the body, the vessels that govern blood flow are sensitive to the local metabolic needs of parenchymal cells. [Table 20-9](#) lists several changes that act synergistically to increase local blood flow. For example, a decrease in P_{O_2} or pH promotes relaxation of VSMCs, thereby causing vasodilation. In response to activity, excitable cells raise extracellular K^+ concentration ($[K^+]_o$), which also causes vasodilation. Tissues with high energy demands—such as the brain, heart, and skeletal muscle during exercise—rely heavily on such local control mechanisms.

Endothelial Mechanisms

Endothelial cells release a variety of vasoactive substances (see [Table 20-10](#)). For example, the shear stress exerted by the movement of blood through the vessel lumen stimulates the release of nitric oxide (NO), which relaxes VSMCs and prevents leukocyte adhesion. Endothelial cells and VSMCs also use gap junctions for electrical and chemical signaling between themselves, thereby coordinating their activity during blood flow control.

In addition to the previous mechanisms, which are part of a sophisticated feedback control system, other factors—which are not regulatory in nature—can affect the local circulation. These other factors are all mechanical forces that are external to the blood vessels and that tend to either to collapse or to open them. For example, in the heart (see [p. 517](#)) and skeletal muscle (see [p. 517](#)), muscle contraction transiently halts blood flow by compressing blood vessels within the tissue.

The Brain

Anastomoses at the circle of Willis and among the branches of distributing arteries protect the blood supply to the brain, which is ~15% of resting cardiac output

The brain accounts for only ~2% of the body's weight, yet it receives ~15% of the resting cardiac output. Of all the organs in the body, the brain is the least tolerant of ischemia. It depends entirely on oxidative sources of energy production. Each day, the human brain oxidizes ~100 g of glucose,  **N24-1** which is roughly equivalent to the amount stored as glycogen in the liver. Interruption of cerebral blood flow for just a few seconds causes unconsciousness. If ischemia persists for even a few minutes, irreversible cellular damage is likely.

N24-1

Brain Metabolism

Contributed by Emile Boulpaep, Walter Boron

As noted in Chapter 11 (see pp. 275 and 288), the brain has rather limited glycogen stores (~10% of the amount stored in the liver), and virtually all of these stores are in the astrocytes, which have mechanisms for transferring the energy to the neurons. As noted in the text on page 557, the glucose consumption by the brain alone is capable of exhausting the liver's entire store of glycogen in only 1 day. When food is not eaten for >24 hours, the brain must either rely on glucose derived from gluconeogenesis (largely from the breakdown of muscle protein) or utilize an alternative fuel. For example, as levels of ketone bodies rise in the bloodstream during fasting, the enzymes required for their oxidation are induced in brain cells, thereby enabling an alternative substrate for energy production and conserving lean body mass.

The text addresses related issues in three locations: (1) on page 557, (2) on page 287 (see Fig. 11-10), and (3) in Chapter 58 on metabolism.

Arteries

Blood reaches the brain through four *source arteries*—the two internal carotid arteries and the two vertebral arteries (Fig. 24-1). The vertebral arteries join to form the basilar artery, which then splits to form the two posterior cerebral arteries, which in turn are part of the **circle of Willis** at the base of the brain. The internal carotid arteries are the major source of blood to the circle. Three bilateral pairs of *distributing arteries* (anterior, middle, and posterior cerebral arteries) arise from the circle of Willis to envelop the cerebral hemispheres. Smaller branches from the vertebral and basilar arteries distribute blood to the brainstem and cerebellum. The distributing arteries give rise to pial arteries that course over the surface of the brain, forming anastomoses, and then branch again into arterioles that penetrate the tissue at right angles to the brain surface. These penetrating arterioles branch centripetally to give rise to capillaries. The anastomoses on the cortical surface provide the collateral circulation that is so important should a distributing artery or one of its branches become occluded. Each of the four source arteries tends to supply the brain region closest to where the source artery joins the circle of Willis. If a stenosis develops in one source artery, other source arteries to the circle of Willis can provide alternative flow.

Nevertheless, if flow through a carotid artery becomes severely restricted (e.g., with atherosclerotic plaque), ischemia may occur in the ipsilateral hemisphere, with impairment of function.

A MAJOR ARTERIAL SUPPLY AND CIRCLE OF WILLIS

B DISTRIBUTING ARTERIES

FIGURE 24-1 Vascular anatomy of the brain. The illustration in **B**, with the temporal lobe pulled away, depicts the major branches of the left middle cerebral artery, one of the distributing arteries. Pial arteries course over the surface of the brain and give rise to penetrating arterioles that supply the microcirculation within the brain.

Veins

The veins of the brain are wide, thin-walled structures that are nearly devoid of VSMCs and have no valves. In general, the veins drain the brain radially, in a centrifugal direction. The intracerebral veins converge into a superficial pial plexus lying under the arteries. The plexus drains into collecting veins, which course over the distributing arteries and empty into the **dural sinuses** (see [Fig. 11-1B](#)). The exception to this radial pattern is the deep white matter of the cerebral hemispheres and basal ganglia; these regions drain centrally into veins that course along the walls of the lateral ventricles to form a deep venous system, which also empties into the dural sinuses. Nearly all of the venous blood from the brain leaves the cranium by way of the **internal jugular vein**. 🧠[N24-2](#)

N24-2

Emissary Veins

Contributed by Steve Segal

The emissary veins traverse the skull, carrying blood from the sinuses (e.g., superior sagittal sinus), which are surrounded by the dura mater inside the skull, to branches of the superficial temporal veins that are external to the skull. The emissary veins are typically responsible for little venous drainage from the brain.

Capillaries

One of the most characteristic features of the brain vasculature is the **blood-brain barrier** (see [pp. 284–287](#)), which prevents the solutes in the lumen of the capillaries from having direct access to the brain extracellular fluid (BECF). For this reason, many drugs that act on other organs or vascular beds have no effect on the brain. Polar and water-soluble compounds cross the blood-brain barrier slowly, and the ability of proteins to cross the barrier is extremely limited. Only water, O₂, and CO₂ (or other gases) can readily diffuse across the cerebral capillaries. Glucose crosses more slowly via facilitated diffusion. No substance is *entirely* excluded from the brain; the critical variable is the rate of transfer. The blood-brain barrier protects the brain from abrupt changes in the composition of arterial blood. In a similar manner, a blood-testis barrier protects the germinal epithelia in males. The blood-brain barrier may become damaged in regions of the brain that are injured, infected, or occupied by tumors. Such damage can be helpful in identifying the location of tumors because tracers that are excluded from healthy central nervous system (CNS) tissue can enter the tumor. In specialized areas of the brain—the **circumventricular organs** (see [pp. 284–285](#))—the capillaries are fenestrated and have permeability characteristics similar to those of capillaries in the intestinal circulation.

Lymphatics

The brain lacks lymphatic vessels.

Vascular Volume

The skull encloses all of the cerebral vasculature, along with the brain and the cerebrospinal fluid compartments. Because the rigid cranium has a fixed total volume, vasodilation and an increase in vascular volume in one region of the brain must be met by reciprocal volume changes elsewhere within the cranium. Precise control of the cerebral blood volume is essential for preventing elevation of the intracranial pressure. With cerebral edema or hemorrhage, or with the growth of a brain tumor, neurological dysfunction can result from the restriction of blood flow due to vascular compression. An analogous situation can occur in the eyes of patients with glaucoma (see pp. 360–361). Pressure buildup within the eye compresses the optic nerve and retinal artery, and blindness can result from the damage caused by diminished blood flow to the retinal cells.

Neural, metabolic, and myogenic mechanisms control blood flow to the brain

Cerebral blood flow averages 50 mL/min for each 100 g of brain tissue and, because of autoregulation, is relatively constant. Nevertheless, regional changes in blood distribution occur in response to changing patterns of neuronal activity (Fig. 24-2).

FIGURE 24-2 Changes in regional blood flow in the brain. The investigators used the washout of ^{133}Xe (see p. 426), measured with detectors placed over the side of the patient's head, as an index of regional blood flow in the dominant cerebral hemisphere. The turquoise “hot spots” represent regions where blood flow is >20% above mean blood flow for the entire brain. At rest, blood flow is greatest in the frontal and premotor regions. The patterns of blood flow change in characteristic ways with the seven other forms of cerebral activity shown. (Data from Ingvar DH: Functional landscapes of the dominant hemisphere. *Brain Res* 107:181–197, 1976.)

Neural Control

Sympathetic nerve fibers supplying the brain vasculature originate from postganglionic neurons in the superior cervical ganglia and travel with the internal carotid and vertebral arteries into the skull,

branching with the arterial supply. The sympathetic nerve terminals release norepinephrine, which causes contraction of VSMCs. *Parasympathetic* innervation of the cerebral vessels arises from branches of the facial nerve; these nerve fibers elicit a modest vasodilation when activated. The cerebral vessels are also supplied with sensory nerves, whose cell bodies are located in the trigeminal ganglia and whose sensory processes contain substance P and calcitonin gene-related peptide, both of which are vasodilatory neurotransmitters. Local perturbations (e.g., changes in pressure or chemistry) may stimulate the sensory nerve endings to release these vasodilators, an example of an axon reflex (see p. 571). 🟡N24-3

N24-3

Axon Reflex

Contributed by George Richerson

Axon reflexes are thought to occur when a nerve ending is depolarized by local factors (e.g., irritation, pressure, seizures, altered pH, high $[K^+]_o$, or other chemical signals), triggering an action potential that travels anterograde along the axon to a branch point, where the action potential propagates back down another branch. Thus, an axon reflex is a local reflex arc that involves only the distal/peripheral part of a motor or sensory neuron.

In the case of a motor neuron, the stimulus would trigger an action potential that would move retrograde up the fiber to the branch point and then orthograde down to a terminal that would release its normal complement of neurotransmitters. Of course, when responding to its normal “central” stimuli, this motor neuron would function in the usual orthograde fashion.

In the case of a sensory fiber, the stimulus would travel orthograde along the axon to a branch point and then travel retrograde to other nerve endings. If these endings have release machinery, they could activate an effector. Varicosities on sensory fibers may contain substance P (SP) and calcitonin-gene-related peptide (CGRP), which the processes release in response to a local stimulus. Both SP and CGRP are vasodilatory neurotransmitters.

Another example of an afferent fiber that can release a neurotransmitter is the cranial nerve IX sensory neurons that innervate the glomus cells of the carotid body. As pointed out on pages 710–712, this is an example of a bidirectional synapse. The glomus cells can trigger an action potential in the sensory neuron, and the sensory neuron can apparently release neurotransmitters that may modulate the glomus cell.

Axon reflexes can also occur in neurons of the CNS—for example, from one part of the cortex to another.

Despite this innervation, neural control of the cerebral vasculature is relatively weak. Instead, it is the local metabolic requirements of the brain cells that primarily govern vasomotor activity in the brain.

Metabolic Control

Neural activity leads to ATP breakdown and to the local production and release of adenosine, a potent vasodilator. A local increase in brain metabolism also lowers P_{O_2} while raising P_{CO_2} and lowering pH in the nearby BECF. These changes trigger vasodilation and thus a compensatory increase in blood flow. Cerebral VSMCs relax mainly in response to low *extracellular* pH; these cells are insensitive to increased P_{CO_2} per se, and decreased intracellular pH actually causes a weak vasoconstriction.

How does brain blood flow respond to systemic changes in pH? Lowering of *arterial* pH at a constant P_{CO_2} (metabolic acidosis; see p. 635) has little effect on cerebral blood flow because arterial H^+ cannot easily penetrate the blood-brain barrier and therefore does not readily reach cerebral VSMCs. On the other hand, lowering of arterial pH by an increase in P_{CO_2} (respiratory acidosis; see p. 633) rapidly leads to a fall in the pH around VSMCs because CO_2 readily crosses the blood-brain barrier. This fall in pH of the BECF evokes pronounced dilation of the cerebral vasculature, with an increase in blood flow that occurs within seconds. The rise in arterial P_{CO_2} caused by inhalation of 7% CO_2 can cause cerebral blood flow to double. Conversely, the fall in arterial P_{CO_2} caused by hyperventilation raises the pH of the BECF, producing cerebral vasoconstriction, decreased blood flow, and dizziness. Clinically, hyperventilation is used to lower cerebral blood flow in the emergency treatment of acute cerebral edema and glaucoma.

A fall in the blood and tissue P_{O_2} —from hypoxemia or impaired cardiac output—may also contribute to cerebral vasodilation, although the effects are less dramatic than those produced by arterial hypercapnia. The vasodilatory effects of hypoxia may be direct or may be mediated by release of adenosine, K^+ , or NO into the BECF. 🟡N24-4

N24-4

Vasodilatory Effect of Hypoxia in the Brain

Contributed by Steve Segal, Emile Boulpaep, Walter Boron

A fall in the blood and tissue P_{O_2} —from hypoxemia or impaired blood flow to the brain—may also contribute to vasodilation in the brain, although the effects are less dramatic than those produced by arterial hypercapnia. Several mediators may underlie the effect of hypoxia:

1. **Adenosine.** Levels of adenosine increase with hypoxia, reflecting the breakdown of ATP. Virtually any condition that increases brain O_2 consumption will result in adenosine production and release within seconds. Because adenosine is a potent vasodilator (see Tables 20-8 and 20-9), increased adenosine levels tend to enhance blood flow and correct the hypoxia.
2. **High $[\text{K}^+]$.** Hypoxia, seizures, and electrical stimulation all elevate $[\text{K}^+]$ in the BECF. Increased $[\text{K}^+]_o$ leads to vasodilation (see Table 20-9; 🟡N24-6), which in turn tends to wash away the excess K^+ . Thus, elevated $[\text{K}^+]_o$ may be involved only in the early portion of a hyperemic response.
3. **NO.** Both brain vascular endothelial cells and neurons contain nitric oxide synthase (see pp. 66–67 and 480) and thus can generate the highly permeable NO, which readily dilates the brain's resistance vessels.
4. **Direct effects of low P_{O_2} .** A mechanism receiving increasing attention is the effect of O_2 on the K^+ conductance of the VSMC membrane: a fall in P_{O_2} increases K^+ conductance, promoting VSMC relaxation.

Myogenic Control

Cerebral resistance vessels are inherently responsive to changes in their transmural pressure. Increases in

pressure lead to vasoconstriction, whereas decreases in pressure produce vasodilation.

The neurovascular unit matches blood flow to local brain activity

Neurons, glia, and cerebral blood vessels function as an integrated unit to distribute cerebral blood flow according to local activity within the brain (see Fig. 24-2). This “neurovascular coupling” involves several signaling pathways that complement the metabolic control discussed above. Some neurotransmitters and neuromodulators are vasoactive (e.g., acetylcholine, catecholamines, and neuropeptides) and can control blood vessels in the region of synaptic activity. The endfeet of astrocytes (see Fig. 11-6A) come into direct contact with the smooth muscle penetrating arterioles and the endothelial cells of capillaries. The release of neurotransmitters (e.g., glutamate and gamma-aminobutyric acid [GABA]) from neurons initiates $[Ca^{2+}]_i$ waves in astrocytes as well as in dendrites of adjacent neurons. These $[Ca^{2+}]_i$ waves stimulate the release of powerful vasodilators, including NO and metabolites of arachidonic acid. Thus, synaptic activity generates vasoactive mediators in neurons and astrocytes that can produce vasodilation. Concurrent activation of local interneurons with vascular projections helps to focus the vasomotor response. The vasodilator signal conducts through gap junctions from cell to cell along the endothelium and smooth-muscle cells of penetrating arterioles, retrograde to the pial arteries, which are a major part of vascular resistance. This reduction in proximal resistance directs increased blood flow to the region of increased neural activity.

Autoregulation maintains a fairly constant cerebral blood flow across a broad range of perfusion pressures

The perfusion pressure to the brain is the difference between the systemic arterial pressure (mean pressure, ~95 mm Hg) and intracranial venous pressure, which is nearly equal to the intracranial pressure (<10 mm Hg). A decrease in cerebral blood flow could thus result from a fall in arterial pressure or a rise in intracranial (or venous) pressure. However, the local control of cerebral blood flow maintains a nearly constant blood flow through perfusion pressures ranging from ~70 to 150 mm Hg. This constancy of blood flow—**autoregulation** (see p. 481)—maintains a continuous supply of O_2 and nutrients. In patients with hypertension, the cerebral blood flow remains normal because cerebral vascular resistance increases. Conversely, vascular resistance falls with hypotension. This autoregulation of blood flow has both myogenic and metabolic components.

Increases in intracranial pressure compress the brain vasculature and tend to reduce blood flow despite autoregulatory vasodilation. In such cases, the brain regulates its blood flow by inducing reflexive changes in *systemic arterial pressure*. This principle is exemplified by the **Cushing reflex**, an increase in arterial pressure that occurs in response to an increase in intracranial pressure. It appears that intracranial compression causes a local ischemia that stimulates vasomotor centers in the medulla. Increased sympathetic nerve activity in the systemic circulation then triggers a rise in total peripheral resistance. The Cushing reflex may occur acutely with the swelling that follows a head injury or more gradually with growth of a brain tumor. Over a considerable pressure range, the Cushing reflex ensures that the perfusion pressure can offset the effects of vascular compression and thereby maintain the constancy of cerebral blood flow.

The Heart

The coronary circulation receives 5% of the resting cardiac output from the left heart and mostly returns it to the right heart

The heart receives ~5% of the resting cardiac output, although it represents <0.5% of total body weight. The heart normally uses oxidative phosphorylation to generate the ATP required to pump blood. However, of all the O₂ that the heart consumes, no more than 40% reflects the oxidation of carbohydrate. More than 60% of myocardial O₂ consumption in the fasting state is due to the oxidation of fatty acids. The myocardium readily oxidizes ketone bodies (see [p. 1185](#)), which can provide considerable energy during starvation or during diabetic ketoacidosis. When the O₂ supply is adequate, the heart takes up and oxidizes both lactate and pyruvate, as do red (i.e., oxidative) skeletal muscle fibers, although the arterial concentration of pyruvate is usually low. When the energetic demand for ATP exceeds the supply of O₂, the heart can no longer take up lactate, but instead releases lactate by breaking down its own glycogen stores. In this manner, the heart can continue to function for a short time when it is deprived of O₂. If hypoxia develops in the myocardium, nociceptive fibers trigger the sensation of referred pain, known as **angina pectoris**. More severe or prolonged insults damage the myocardial tissue, which eventually becomes necrotic—**myocardial infarction**.

The entire blood supply to the myocardium derives from the right and left coronary arteries, which originate at the root of the aorta behind the cusps of the aortic valves ([Fig. 24-3](#)). Although the anatomy is subject to individual variation, the **right coronary artery** generally supplies the right ventricle and atrium, and the left coronary artery supplies the left ventricle and atrium. The **left coronary artery** divides near its origin into two principal branches: The **left circumflex artery** sends branches to the left atrium and ventricle, and the **left anterior descending artery** descends to the apex of the heart and branches to supply the interventricular septum and a portion of the right as well as the left ventricle. These arteries course over the heart, branching into segments that penetrate into the tissue and dividing into capillary networks. Capillary density in histological sections of the human heart exceeds 3000 per square millimeter (skeletal muscle has only ~400 per square millimeter). The small diameter of cardiac muscle fibers (<20 μm), less than half that of skeletal muscle (~50 μm), facilitates O₂ diffusion into the cardiac myocytes, which have a high energetic demand.

A VIEW FROM FRONT**B VIEW FROM DIAPHRAGM (POSTEROINFERIOR)****FIGURE 24-3** Heart and coronary circulation. AV, atrioventricular; SA, sinoatrial.

Once blood passes through the capillaries, it collects in venules, which drain outward from the myocardium to converge into the epicardial veins. These veins empty into the right atrium via the **coronary sinus**. Other vascular channels drain directly into the cardiac chambers. These include the **thebesian veins**, which drain capillary beds within the ventricular wall. Because the deoxygenated blood carried by the thebesian veins exits predominantly into the ventricles, this blood flow bypasses the pulmonary circulation. Numerous *collateral* vessels among branches of the arterial vessels and throughout the venous system act as anastomoses; these provide alternative routes for blood flow should a primary vessel become occluded.

Extravascular compression impairs coronary blood flow during systole

In other systemic vascular beds, blood flow roughly parallels the pressure profile in the aorta, rising in systole and falling in diastole (see Fig. 22-3). However, in the coronary circulation, flow is somewhat paradoxical: Although the heart is the source of its own perfusion pressure, myocardial contraction effectively compresses the heart's own vascular supply. Therefore, the profile of blood flow through the coronary arteries depends on both the perfusion pressure in the aorta (Fig. 24-4, top panel) and the extravascular compression resulting from the contracting ventricles, particularly the left ventricle.

FIGURE 24-4 Coronary blood flow cycle. Bands at the beginning of systole and diastole reflect isovolumetric contraction and relaxation, respectively.

Blood flow in the *left coronary artery* may actually reverse transiently in early systole (see Fig. 24-4, middle panel) because the force of the left ventricle's isovolumetric contraction compresses the left coronary vessels and the aortic pressure has not yet begun to rise (i.e., aortic valve is still closed). As aortic pressure increases later during systole, coronary blood flow increases, but never reaches peak values. However, early during diastole, when the relaxed ventricles no longer compress the left coronary vessels and aortic pressure is still high, left coronary flow rises rapidly to extremely high levels. All told, ~80% of total left coronary blood flow occurs during diastole.

In contrast, the profile of flow through the *right coronary artery* (see Fig. 24-4, lower panel) is very similar to the pressure profile of its feed vessel, the aorta. Here, systole contributes a greater proportion of the total flow, and systolic reversal does not occur. The reason for this difference is the lower wall tension developed by the right heart, which pumps against the low resistance of the pulmonary circulation and does not occlude the right coronary vessels during contraction.

The impact of systolic contraction on the perfusion of the left coronary vessels is highlighted by the effect of ventricular fibrillation (see Fig. 21-14J). At the onset of this lethal arrhythmia, left coronary perfusion transiently *increases*, reflecting the loss of mechanical compression of the vasculature.

Changes in heart rate, because they affect the duration of diastole more than that of systole, also affect coronary flow. During tachycardia, the fraction of the cardiac cycle spent in diastole decreases, minimizing the time available for maximal left coronary perfusion. If the heart is healthy, the coronary vessels can adequately dilate in response to the metabolic signals generated by increased cardiac work,

which offsets the negative effects of the shorter diastole. On the other hand, a high heart rate can be dangerous when severe coronary artery disease restricts blood flow.  [N24-5](#)

N24-5

Adverse Effects of Tachycardia on Left Coronary Perfusion

Contributed by Steve Segal, Emile Boulpaep

As shown in Figure 24-4, most of the blood flow to the left coronary artery occurs during diastole. During bradycardia, a greater proportion of time is spent in diastole. Although this effect promotes left coronary blood flow, the total requirement for blood flow falls. During tachycardia, the diastolic interval shortens relatively more than the systolic interval. Thus, if we were to sum up all the diastolic intervals that occur over the course of a minute, we would see that less total time is available for left coronary perfusion during diastole—even though the metabolic requirements of the left ventricle are much higher during tachycardia.

Coronary blood flow not only varies in *time* during the cardiac cycle, it also varies with *depth* in the wall of the heart. Blood flows to cardiac myocytes through arteries that penetrate from the epicardium toward the endocardium. During systole, the intramuscular pressure is greatest near the endocardium and least near the epicardium. All things being equal, the perfusion of the endocardium would therefore be less than that of the epicardium. However, total blood flows to the endocardial and epicardial halves are approximately equal because the endocardium has a lower intrinsic vascular resistance, and thus a greater blood flow during *diastole*. When the diastolic pressure at the root of the aorta is pathologically low (e.g., with aortic regurgitation) or coronary arterial resistance is high (e.g., with coronary artery occlusion), endocardial blood flow falls below the epicardial flow. Thus, the inner wall of the left ventricle often experiences the greatest damage with atherosclerotic heart disease.

Myocardial blood flow parallels myocardial metabolism

A striking feature of the coronary circulation is the nearly linear correspondence between myocardial O_2 consumption and myocardial blood flow. This relationship persists in isolated heart preparations, emphasizing that metabolic signals are the principal determinants of O_2 delivery to the myocardium. In a resting individual, each 100 g of heart tissue receives 60 to 70 mL/min of blood flow. Normally, the heart extracts 70% to 80% of the O_2 content of arterial blood (normally ~ 20 mL/dL blood), so that the venous O_2 content is extremely low (~ 5 mL/dL). Therefore, the myocardium cannot respond to increased metabolic demands by extracting much more O_2 than it already does when the individual is at rest. The heart can meet large increases in O_2 demand only by increasing coronary blood flow, which can exceed 250 mL/min per 100 g with exercise.

Because blood pressure normally varies within fairly narrow limits, the only way to substantially increase blood flow through the coronary circulation during exercise is by vasodilation. The heart relies primarily on metabolic mechanisms to increase the caliber of its coronary vessels. **Adenosine** has received particular emphasis in this regard. An increased metabolic activity of the heart, an insufficient coronary blood flow, or a fall in myocardial P_{O_2} results in adenosine release. Adenosine then diffuses to the VSMCs, activating purinergic receptors to induce vasodilation by lowering $[Ca^{2+}]_i$ (see [Table 20-8](#)).

Thus, inadequate perfusion to a region of the myocardium would elevate interstitial adenosine levels, causing vasodilation and restoration of flow to the affected region.

When cardiac work increases, contracting myocytes release K^+ , resulting in a transient rise in $[K^+]_o$ that may contribute to the initial increase in coronary perfusion (see [Table 20-9](#)). However, it is unlikely that K^+ mediates sustained elevations in blood flow. When the O_2 demand of cardiac myocytes exceeds O_2 supply, a rise in the P_{CO_2} and a fall in the P_{O_2} may also lower coronary vascular resistance and thereby increase local O_2 delivery.

Coronary blood flow is relatively stable between perfusion pressures of ~ 70 mm Hg and >150 mm Hg. Thus, like that of the brain, the blood flow to the heart exhibits autoregulation. In addition to the myogenic response, fluctuations in adenosine and P_{O_2} contribute to coronary autoregulation.

Although sympathetic stimulation directly constricts coronary vessels, accompanying metabolic effects predominate, producing an overall vasodilation

Sympathetic nerves course throughout the heart, following the arterial supply. Stimulation of these nerves causes the heart to beat more frequently and more forcefully. β_1 adrenoceptors on the cardiac myocytes mediate these chronotropic and inotropic responses. As discussed in the preceding section, the increased metabolic work of the myocardium leads to coronary vasodilation via metabolic pathways. However, during pharmacological inhibition of the β_1 receptors, which prevents the increase in metabolism, sympathetic nerve stimulation causes a coronary *vasoconstriction*. This response is the direct effect of sympathetic nerve activity on α adrenoceptors on the VSMCs of the coronary resistance vessels. Thus, blocking of β_1 receptors “unmasks” adrenergic vasoconstriction. However, under normal circumstances (i.e., no β blockade), the tendency of the *metabolic* pathways to vasodilate far overwhelms the tendency of the *sympathetic* pathways to vasoconstrict.

Activation of the **vagus nerve** has only a mild vasodilatory effect on the coronary resistance vessels. This muted response is not due to insensitivity of the resistance vessels to acetylcholine, which elicits a pronounced vasodilation when it is administered directly. Rather, the release of acetylcholine from the vagus nerve is restricted to the vicinity of the sinoatrial node. Thus, the vagus nerve has a much greater effect on heart rate than on coronary resistance.

Collateral vessel growth can provide blood flow to ischemic regions

When a coronary artery or one of its primary branches becomes abruptly occluded, ischemia can produce necrosis (i.e., a myocardial infarct) in the region deprived of blood flow. However, if a coronary artery narrows *gradually* over time, collateral blood vessels may develop and ameliorate the reduced delivery of O_2 and nutrients to the compromised area, preventing or at least diminishing tissue damage. Collateral vessels originate from existing vessel branches that undergo remodeling with the proliferation of endothelial and smooth-muscle cells. Stimuli for collateral development include angiogenic molecules (see [pp. 481–482](#)) released from the ischemic tissue and changes in mechanical stress in the walls of vessels supplying the affected region.

Vasodilator drugs may compromise myocardial flow through “coronary steal”

A variety of drugs can promote vasodilation of the coronary arteries. These are typically prescribed for patients with angina pectoris, the chest pain associated with inadequate blood flow to the heart (see [p. 564](#)). If the buildup of atherosclerotic plaque—which underlies angina pectoris—occurs in the large epicardial arteries, the increased resistance lowers the pressure in the downstream microvessels. Under such conditions, the physician should be cautious in using pharmacological agents to dilate the coronary vessels: In an ischemic area of the myocardium downstream from a stenosis, metabolic stimuli may have already maximally dilated the arterioles. Administration of a vasodilator can then increase the diameter of blood vessels only in *nonischemic* vascular beds that are parallel to the ischemic ones, which thereby decreases the pressure at the branch point, upstream from the stenosis. The result is **coronary steal**. When vasodilator therapy relieves angina, the favorable result is more likely attributable to the vasodilation of the *noncoronary* systemic vessels, which reduces peripheral resistance, thereby reducing the afterload during systole and thus the work of the heart.

The Skeletal Muscle

Perhaps the most impressive characteristic of the blood flow to skeletal muscle is its extreme range. Muscle blood flow at rest is 5 to 10 mL/min for each 100 g of tissue. With maximal aerobic exercise, it may increase 50-fold, reaching 250 mL/min or more for each 100 g of active muscle. The linear correspondence among work rate, O_2 consumption, and muscle blood flow implies a “coupling” between muscle fiber activity and O_2 delivery to capillaries. We discuss muscle blood flow during exercise beginning on [page 1214](#). Here we discuss the key features of the organization of the skeletal muscle vasculature and the integration of its blood flow control mechanisms.

A microvascular unit is the capillary bed supplied by a single terminal arteriole

The vascular supply to skeletal muscle begins externally to the tissue in the **feed arteries**. These muscular vessels are the last branches of the arterial supply, located just before entry into the tissue. As much as 30% to 50% of the total resistance to blood flow of skeletal muscle resides in these feed arteries. Therefore, an important site of blood flow control is located *proximally* to the microvessels within the tissue that are in direct contact with skeletal muscle fibers.

The arteriolar network originates from the site at which a feed artery enters the muscle. Within the muscle, arterioles branch through several orders ([Fig. 24-5A](#)) until reaching the **terminal arterioles** (see [Fig. 24-5B](#)), which are the last branches to contain smooth muscle and, therefore, the last branches still able to control blood flow. Thus, the terminal arteriole is the functional equivalent of the precapillary sphincter (see [p. 461](#)). The group of capillaries supplied by a terminal arteriole represents one **microvascular unit**, which is the smallest functional unit of blood flow control in skeletal muscle. Each unit consists of 15 to 20 capillaries that run parallel to the muscle fibers in each direction, for a distance of ≤ 1 mm, ending in a **collecting venule**.

A SKELETAL MUSCLE CIRCULATION

FIGURE 24-5 Microvascular units in skeletal muscle. **A**, A feed artery branches into primary arterioles, which, after two more orders of branching, give rise to transverse arterioles; the latter, in turn, give rise to terminal arterioles. **B**, The terminal arteriole supplies a “microvascular unit” (<1 mm in length).

Owing to the profound differences in length between capillaries (≤ 1 mm) and muscle fibers (centimeters), many microvascular units are required to span the distance of each muscle fiber. When a muscle fiber contracts, blood flow must increase throughout all of the microvascular units that supply that fiber to provide O_2 and to remove metabolites ([Box 24-1](#)).

Box 24-1

Treating Coronary Artery Disease

For many patients with gradual narrowing of the coronary arteries by atherosclerotic plaque, the first sign of disease may be the development of **angina pectoris**. Pain results when the metabolic demands of a region of myocardium exceed the ability of the compromised blood supply to satisfy those needs. Attacks of angina are often accompanied by characteristic changes on the electrocardiogram. If the diagnosis is in doubt—the chest pain of angina can sometimes be mimicked by gastroesophageal reflux,

hyperventilation, costochondritis, and other clinical entities—an exercise test may stress the heart sufficiently to bring on the pain, to induce electrocardiographic changes, or to alter coronary blood flow as monitored by thallium scanning (see p. 426). Some patients with significant coronary artery narrowing never experience angina and are said to have silent *ischemia*. In these patients, only an astute clinician may detect the coronary disease.

Many patients with a stable anginal pattern respond well to medication. *Nitrates* induce vasodilation by releasing NO (see p. 67). The nitrates dilate peripheral veins, reducing venous return and thus the preload to the heart (see p. 526); they also dilate the arteries and arterioles, reducing blood pressure and therefore the afterload. Finally, nitrates may increase coronary collateral flow to the involved region of myocardium (however, see discussion of coronary steal on p. 562). *Beta blockers* prevent the sympathetic nervous system from stimulating myocardial β_1 receptors, thereby reducing both heart rate and contractility. *Calcium channel blockers* lessen the contractility of the heart muscle and the vascular smooth muscle. These interventions all reduce the metabolic demands of the heart.

In patients for whom medication cannot control the angina, or who develop a pattern of unstable angina with an increasing frequency and severity of anginal attacks, mechanical revascularization may be required. For a long time, the only option was coronary artery bypass grafting, but nowadays **percutaneous transluminal coronary angioplasty** may often be successful. A cardiologist can perform this procedure at the same time as a diagnostic coronary artery catheterization. The physician advances a balloon-tipped catheter through a peripheral artery into the left ventricle and then loops the catheter back out the left ventricle to have a favorable angle for entering the coronary vessels from the aorta. Inflation of the balloon at the site of the obstruction flattens the plaque into the wall of the vessel and restores blood flow. The obstruction often recurs due to proliferation of VSMCs. Refinements in the technique, the placement of stents at the treated site, and the use of aggressive anticoagulation therapy have all contributed to the technique's growing success. Variants of this technique, in which lasers are used to remove the obstruction, are promising new approaches.

Given the continued prevalence of coronary artery disease, a great deal of research has been aimed at developing alternatives to medication and mechanical revascularization. Among the most promising of these is the use of angiogenesis promoters to stimulate the growth of new blood vessels for collateral blood flow (see pp. 481–482).

Metabolites released by active muscle trigger vasodilation and an increase in blood flow

When skeletal muscle is at rest, its vascular resistance is high, blood flow is low, and the venous O_2 content is only a few milliliters per deciliter lower than the arterial O_2 content. As exercise begins, the terminal arterioles (those closest to the capillaries) dilate first. This vasodilation increases blood flow through capillaries that are already flowing with blood and opens up previously unperfused capillaries, thus increasing the number of perfused capillaries and thereby decreasing the effective intercapillary distance (see Fig. 20-4B, C). Even before total blood flow increases very much, the greater demand of active muscle fibers for O_2 produces a large increase in the O_2 extraction ratio (see p. 464). As metabolic demand continues to increase, additional O_2 delivery is required.

The vasculature meets increased metabolic demand by progressively dilating the more proximal arteriolar branches and feed arteries. Thus, vasodilation “ascends” the resistance network as metabolic demand increases. A coordinated vasodilation throughout the resistance network is essential when

segments having substantial resistance are organized in series with each other. Dilation of the downstream arterioles, without dilation of the proximal arterioles and feed arteries, would result in only a limited ability to increase muscle blood flow because of the high resistance of upstream vessels. Thus, when feed arteries dilate in concert with arterioles, the increase in muscle blood flow is profound.

The primary stimulus triggering vasodilation is the release of vasodilator substances (e.g., adenosine, CO₂, K⁺) from active muscle fibers in proportion to the energy expenditure. These metabolites diffuse locally and—acting either directly on VSMCs or indirectly on adjacent endothelial cells—relax the VSMCs of resistance vessels, thereby increasing blood flow in proportion to local demand. Although a variety of substances released by muscle fibers can contribute to the hyperemia, no single stimulus yet explains the integrated response of blood flow control to muscle contraction. Furthermore, the hyperemic response to increased muscle activity begins within a second or two of the onset of exercise. In contrast, it would take several seconds for these substances to be produced by the skeletal muscle fibers, to reach the interstitium, and to diffuse to the arteriolar VSMCs in sufficient concentration to elicit vasodilation.

The initiation of muscle fiber contraction leads to a release of K⁺ that may hyperpolarize **N24-6** the VSMCs and endothelial cells of nearby arterioles (see [Table 20-9](#)). Once triggered, this electrical signal spreads from cell to cell through gap junctions along the endothelium and into VSMCs, conducting upstream to the larger vessels and causing them to dilate in concert. This mechanism of conducted vasodilation, together with the action of the muscle pump (see [p. 565](#)), contributes to the rapid onset of hyperemia. Increases in levels of other metabolites (e.g., adenosine and CO₂ levels) or decreases in P_{O₂} contribute to and sustain vasodilation and maintain the hyperemic response.

N24-6

Vasodilation Caused by Increases in [K⁺]_o

Contributed by Emile Boulpaep

Why does the transient increase in [K⁺]_o cause a transient paradoxical hyperpolarization, rather than the depolarization that one might expect from the Nernst equation (see Equation 6-5)?

First of all, the effect is transient because the increase in [K⁺]_o is short-lived—the ensuing vasodilation will wash away the excess extracellular K⁺.

Second, the rise in [K⁺]_o causes V_m (membrane potential) to become more negative (a hyperpolarization) even though E_K (the equilibrium potential for K⁺) becomes more positive (see Equation 6-5). The reason is that the K⁺ conductance of VSMCs depends largely on inwardly rectifying K⁺ channels (Kir channels; see Fig. 7-20). A peculiar property of Kir channels is that an increase in [K⁺]_o not only causes E_K to shift to more positive values, but also increases the slope conductance (i.e., the slope of the current-voltage relationship at E_K). VSMCs normally do not live at E_K, but at more positive voltages (−30 to −40 mV), reflecting the contributions from other conductances (e.g., Na⁺) with more positive equilibrium potentials. In the text, we introduced Equation 6-12 (shown here as Equation NE 24-1):

$$V_m = \frac{G_K}{G_m} E_K + \frac{G_{Na}}{G_m} E_{Na} + \frac{G_{Ca}}{G_m} E_{Ca} + \frac{G_{Cl}}{G_m} E_{Cl} \dots \tag{NE 24-1}$$

Here, G_K , G_{Na} , G_{Ca} , G_{Cl} , etc. represent membrane conductances for each ion, whereas G_m represents the total membrane conductance. Thus, G_K/G_m represents the fractional conductance for K^+ . Therefore, the equation tells us that V_m not only depends on the various equilibrium potentials, but also on their respective fractional conductances. Thus, if an increase in $[K^+]_o$ simultaneously causes (1) a slight decrease in the absolute value of E_K and (2) a larger increase G_K , the absolute value of the product $(G_K/G_m)E_K$ will be larger. Because $(G_K/G_m)E_K$ is a negative number, the net effect is that the computed value of V_m is more negative (i.e., a hyperpolarization).

In principle, a second phenomenon can contribute to the hyperpolarization. The increase in $[K^+]_o$ will enhance the activity of the electrogenic Na-K pump, resulting an increase in the pump's outward current, and therefore a hyperpolarization.

Sympathetic innervation increases the intrinsic tone of resistance vessels

Sympathetic nerve fibers invest the entire resistance network of skeletal muscle, from feed arteries to terminal arterioles. The release of norepinephrine by these nerve terminals activates α -adrenoceptors on VSMCs, leading to vasoconstriction beyond that produced by transmural pressure and myogenic tone. On the other hand, the shear stress of blood flowing past the endothelial cells produces vasodilators, such as NO. The interactions among these vasoconstrictor and vasodilatory mechanisms maintain the intrinsic basal tone of the VSMCs. Venules also constrict in response to sympathetic nerve stimulation but are not directly innervated, and instead respond to norepinephrine that diffuses from the nearby arterioles.

With nearly one third of total body mass composed of skeletal muscle, the sympathetic control of vasomotor tone to skeletal muscle is an integral component of the regulation of both systemic arterial pressure (via total peripheral resistance) and cardiac filling (via venous capacitance and return). This principle is particularly relevant during maximal aerobic exercise (see [pp. 1213–1215](#)), when the majority of cardiac output flows to the active skeletal muscles.

The basal firing rate of the sympathetic nerves to skeletal muscle is 1 to 2 Hz, which contributes only modestly to the resting vasomotor tone. However, with the onset of exercise, or when high-pressure baroreceptors detect a fall in blood pressure (see [pp. 534–536](#)), sympathetic firing to skeletal muscle resistance vessels may increase to 8 to 16 Hz. This degree of sympathetic nerve activity can close the lumens of arterioles in resting skeletal muscle. However, during exercise arterioles remain dilated under the influence of vasodilator metabolites released from surrounding muscle fibers. Because feed arteries are external to the muscle, enhanced sympathetic tone can limit total flow into the muscle and thereby help to maintain arterial pressure.

During exercise, total blood flow through skeletal muscle increases to as much as 80% of cardiac output. This redistribution of systemic blood flow occurs for two reasons. First, the increase in sympathetic nerve activity constricts the splanchnic circulation (see below), renal circulation (see [p. 752](#)), and the vessels of *inactive* skeletal muscle. Indeed, only the brain and heart are spared from vasoconstriction. Second, the metabolites released by active skeletal muscle overcome the constriction of arterioles that sympathetic activity would otherwise produce. In addition, substances released during muscle fiber contraction (e.g., NO and adenosine) may inhibit norepinephrine release from sympathetic nerve fibers surrounding the arterioles.

The vasodilatory effects of the metabolites notwithstanding, sympathetic vasoconstrictor activity can limit muscle blood flow, particularly when another large mass of muscle is active simultaneously and

requires a substantial portion of cardiac output. Thus, during “whole-body” exercise, each muscle group may receive only a fraction of the blood flow it would otherwise get if it were the *only* active group in the body. It is at the level of the feed arteries—which are external to the muscle and thus physically removed from the direct influence of the vasoactive products of muscular activity—that sympathetic vasoconstriction puts an upper limit on blood flow during intense aerobic exercise. At the same time, dilation of arterioles *within* the active muscle maximizes O₂ extraction by promoting capillary perfusion.

Rhythmic contraction promotes blood flow through the “muscle pump”

During exercise, skeletal muscle undergoes rhythmic changes in length and tension, giving rise to mechanical forces within the tissue analogous to those of the beating heart. The contraction of muscle forces venous blood out of the muscle and impedes arterial inflow (Fig. 24-6). Because valves in the veins prevent backflow of blood, each muscle contraction squeezes and empties the veins, driving blood toward the heart (see p. 516). During the subsequent relaxation, the reduction in venous pressure increases the arteriovenous driving force for capillary perfusion. As is true for coronary blood flow, skeletal muscle blood flow is maximal between contractions. This pumping action of skeletal muscle on the vasculature imparts substantial kinetic energy to the blood, thereby reducing the work of the heart. Remarkably, the skeletal muscle pump may generate up to half of the total energy required to circulate blood, an essential contribution for achieving the high blood flows experienced during maximal aerobic exercise. In contrast, drugs that dilate blood vessels of inactive muscle (i.e., muscle lacking a muscle pump) increase blood flow to a lesser extent than do rhythmic contractions.

FIGURE 24-6 Muscle pump.

The Splanchnic Organs

The splanchnic circulation includes the blood flow through the stomach, small intestine, large intestine, pancreas, spleen, and liver ([Fig. 24-7A](#)). The majority of flow to the liver occurs through the portal vein, which carries the venous blood draining from all of these organs except the liver itself.

A MAJOR VESSELS

B MESENTERIC ARTERIES

C BLOOD SUPPLY TO LAYERS OF INTESTINAL WALL

D MICROVASCULATURE OF THE VILLUS

The vascular supply to the gut is highly interconnected

The **celiac artery** is the primary blood supply to the stomach, pancreas, and spleen. The **superior and inferior mesenteric arteries** supply the large and small intestines, as well as parts of the stomach and pancreas. The superior mesenteric artery is the largest of all the splanchnic branches from the aorta, carrying >10% of the cardiac output. The extensive interconnections between the arcading arterial branches (see Fig. 24-7B) provide multiple collateral pathways through which blood can reach each portion of the intestines. This arrangement lessens the risk that the intestines may become ischemic should one of the arteries become occluded.

The microvascular network in the small intestine (see Fig. 24-7C) is representative of that throughout the gastrointestinal tract. After penetrating the wall of the intestine, small arteries course through the various muscle layers and reach the submucosa, where they branch into arterioles. Some arterioles remain in the submucosa to form a submucosal vascular plexus. Others project toward the intestinal lumen and into the mucosa, including the villi. Still others project away from the mucosa and course along the bundles of smooth muscle. Venules emerging from the villi and mucosal and muscularis layers converge into veins. These exit the intestinal wall, paralleling the arterial supply.

The arrangement of microvessels within a villus is like a fountain (see Fig. 24-7C). The incoming arteriole courses up the center of the villus, branching into many capillaries along the way to the tip of the villus. Capillaries converge into venules and carry blood back to the base of the villus. Capillaries also interconnect the arteriole and the venule all along the villus. These microvessels of villi are highly permeable to solutes of low molecular weight, thereby facilitating the absorption of nutrients.

The arrangement just described can create a **countercurrent exchange** system that enables permeable solutes to move from the arteriole to the venule without having to traverse the entire length of the villus, particularly when blood flow to the villi is *low*. With prolonged transit times, blood-borne O₂ can diffuse from the arteriole to the venule before reaching the tip of the villus, which makes it susceptible to anoxic damage. In contrast, when blood flow through the villi is high (particularly after a meal), the tips of the villi are well oxygenated (as in Fig. 24-7D), and the effects of countercurrent exchange are reduced.

Because the capillaries in the villi are fenestrated (i.e., they have large pores) and have a large surface area, they are well suited for absorbing nutrients from the intestinal lumen. The venous blood carries away the majority of **water-soluble nutrients** absorbed from the gut, eventually delivering them to the portal vein. **Lipophilic nutrients** absorbed from the intestinal lumen enter the central lacteal of the villus (see Fig. 24-7D), which merges with the intestinal lymphatics. The lymph then delivers these substances into the bloodstream via the thoracic duct.

Blood flow to the gastrointestinal tract increases up to eight-fold after a meal (postprandial hyperemia)

Throughout the gastrointestinal tract, blood flow in each layer of the gut wall closely correlates with the local metabolism (which reflects digestive and absorptive activity). Intestinal blood flow at rest, in the fasting state, is typically 30 mL/min for each 100 g of tissue. However, flow can reach 250 mL/min for each 100 g during peak hyperemia after a meal. The increase in blood flow with the ingestion and digestion of a meal reflects a complex interplay of several factors.

First, the CNS initiates an “anticipatory” response that increases splanchnic blood flow with the mere thought of food—corresponding to the “cephalic phase” of gastric (see [p. 871](#)) and pancreatic secretion (see [p. 890](#)).

Second, mucosal metabolic activity during digestion and absorption primarily depends on the rate of active transport of substances across the epithelium. These activities consume O₂ and produce **vasodilator metabolites** (e.g., adenosine and CO₂) that increase blood flow locally.

Third, the absorption of nutrients generates hyperosmolality in both the blood and the lymphatic vessels of the villus. Hyperosmolality itself stimulates an increase in blood flow.

Fourth, during digestion, the gastrointestinal tract releases several hormones, some of which are vasoactive. Of these, **cholecystokinin** and **neurotensin** (see [Table 41-1](#)) may reach high enough concentrations in the local circulation to promote intestinal blood flow.  **N24-7** The intestinal epithelium also releases various kinins (e.g., bradykinin and kallidin), which are powerful vasodilators. The magnitude of the postprandial hyperemia further depends on the nature of the luminal content. Bile acids and partially digested fats are particularly effective in promoting hyperemia by acting on chemoreceptors in the intestinal mucosa.

N24-7

Vasoactive Enteric Hormones

Contributed by Steve Segal

As noted in the text, the **cholecystokinin** and **neurotensin** released by the gastrointestinal (GI) tract may reach high enough concentrations in the local circulation to promote intestinal blood flow. However, these substances do not affect blood flow in other vascular beds because these hormones are too dilute, because other vascular beds lack appropriate receptors, or possibly because the hormones are destroyed as they pass through the liver. The intestinal mucosa releases additional peptide hormones (e.g., vasoactive intestinal peptide, gastrin, and secretin), but their effect on blood flow under physiological conditions is questionable.

In addition to the vasoactive hormones released by the GI tract, the carbohydrates and amino acids absorbed by the small intestine increase local osmolality, which in turn leads to an increase in blood flow. It has been suggested that amino acids may cause vasodilation independent of the osmolality effect.

The circulatory system does not distribute the increased splanchnic blood flow equally to all digestive organs, nor does it distribute the flow equally throughout the wall of even one segment of bowel. During and after a meal, as digestion and absorption proceed, blood flow increases sequentially along the gastrointestinal tract, first in the stomach and then in progressively more distal segments of the intestine. In all segments, blood flow through the muscularis layers primarily provides nutrition for the smooth-muscle cells. However, flow through the villi and submucosal vessels supports the absorption of foodstuffs as well as the secretion of electrolytes, fluids, and enzymes. After a meal, splanchnic blood flow remains elevated for 2 to 4 hours, primarily reflecting the vasodilation in the *mucosal* layer.

As in the heart and skeletal muscle, muscle contraction in the intestine (i.e., peristalsis) decreases blood flow, probably as a result of the compression applied by the muscularis in conjunction with the distending pressure of the luminal contents.

Sympathetic activity directly constricts splanchnic blood vessels, whereas parasympathetic activity indirectly dilates them

The gastrointestinal tract is endowed with its own division of the ANS, the **enteric nervous system (ENS)**; see pp. 339–340 and 855–856). At one level, the ENS is its own independent nervous system, with sensory neurons, the capacity to integrate and to process sensory data, and motor neurons. One of the components of the ENS, the myenteric (or Auerbach's) plexus, releases vasoactive neurotransmitters. However, this plexus probably achieves its major influence on blood flow by controlling the peristaltic activity of the intestinal smooth muscle.

The enteric division sends sensory information upstream to the peripheral ganglia and to the CNS. The ENS also receives important input from the sympathetic and parasympathetic divisions of the ANS. Postganglionic **sympathetic neurons** originate in the celiac, superior mesenteric, and inferior mesenteric ganglia and send nerve fibers that travel along the corresponding major arteries to all splanchnic organs. Except for the capillaries, all splanchnic blood vessels receive sympathetic innervation. The predominant neural influence is *sympathetic vasoconstriction*, mediated by norepinephrine acting on α adrenoceptors on VSMCs. The vasoconstriction occurs to a similar extent in both the muscularis and mucosal layers, without redistribution of flow between the layers. Vasoconstriction elicited by sympathetic nerve activity can reduce blood flow to <10 mL/min per 100 g of tissue (i.e., $\sim \frac{1}{3}$ of resting values).

Parasympathetic preganglionic fibers travel to the intestine via vagal or pelvic nerves, which contact postganglionic parasympathetic neurons in the intestinal wall. The effect of parasympathetic activity on blood flow is indirect. Parasympathetic activity stimulates intestinal motility and glandular secretion, which in turn increases intestinal metabolism, thereby enhancing blood flow to the gut.

Changes in the splanchnic circulation regulate total peripheral resistance and the distribution of blood volume

The splanchnic circulation serves both as a site of adjustable resistance and as a major reservoir of blood. During exercise, when blood flow increases to active skeletal muscle, sympathetic constriction of the splanchnic resistance vessels decreases the proportion of cardiac output directed to the viscera. Therefore, abdominal cramping can result from attempts to exercise too soon after eating, when the gastrointestinal tract still demands blood flow to support its digestive and absorptive activities.  **N24-8**

Myth of No Eating before Swimming

Contributed by Emile Boulpaep, Walter Boron

For information on eating before swimming, visit the following websites:

1. <http://www.dukemedicine.org/blog/myth-or-fact-should-you-wait-swim-after-eating> (accessed September 2015).
2. <http://www.medicinenet.com/script/main/art.asp?articlekey=47368> (accessed December 2014).

3. <http://www.todayifoundout.com/index.php/2011/01/swimming-within-an-hour-after-eating-is-not-dangerous/> (accessed December 2014).

The splanchnic circulation contains ~15% of the total blood volume, with the majority contained in the liver. During increases in sympathetic tone, splanchnic arteriolar constriction reduces perfusion, resulting in the passive collapse of the splanchnic veins. Blood contained in these veins moves into the inferior vena cava, thus increasing the circulating blood volume. With a greater increase in sympathetic activity, as would occur with intense exercise or severe hemorrhage, active venoconstriction mobilizes even more venous blood, thereby helping to maintain arterial pressure while promoting blood flow to active muscles. 🟡N24-9

N24-9

The Spleen as a Blood Reservoir

Contributed by Steve Segal

In aerobic animals such as dogs and horses, and in diving animals such as seals, the spleen serves as an important reservoir of blood; it contains up to 10% of the total blood volume with a hematocrit that is about 10% higher than that in the systemic circulation. Sympathetic stimulation in these animals causes the capsule of the spleen to contract, ejecting this hemoconcentrated blood into the systemic circulation. In humans and cats, the spleen is principally a reticuloendothelial organ, having little role as a blood reservoir.

Exercise and hemorrhage can substantially reduce splanchnic blood flow

A reduction in blood flow leads to the production of vasodilator metabolites (e.g., adenosine and CO_2), which stimulate arteriolar dilation and increase O_2 delivery. Nevertheless, during maximal exercise or severe hemorrhage, blood flow through the gut may fall to <25% of its resting value. Fortunately, temporary reductions in splanchnic flow can occur without serious O_2 deprivation; at rest, the viscera normally extract only ~20% of the O_2 carried in the blood, so that extraction can increase several-fold. However, extended periods of compromised splanchnic blood flow can irreversibly damage the intestinal parenchyma.

After a severe hemorrhage and sustained splanchnic vasoconstriction, the ischemic mucosal epithelia slough off, even after repletion of the blood volume and restoration of blood flow. Sloughing occurs particularly at the tips of the villi, where the epithelial cells are susceptible to ischemia because of countercurrent flow (see p. 567). As these cells slough, pancreatic enzymes generate toxic “activators” that enter the circulation and produce multiple organ failure, which can lead to an irreversible decline in cardiovascular function. In an experimental setting, one can avoid damage to the heart by collecting the blood draining from the gut during the first several minutes of reperfusion and thereby preventing access of these blood-borne substances to the heart. Another major consequence of damage to the epithelium is **endotoxic shock**, which results from disruption of the barrier that normally prevents bacteria and toxins from escaping the intestinal lumen and entering the systemic circulation and peritoneal cavity.

The liver receives its blood flow from both the systemic and the portal circulation

The liver receives nearly one fourth of resting cardiac output. Of this blood flow, ~25% is arterial blood that arrives via the hepatic artery. The remaining 75% of the hepatic blood flow comes from the portal vein, which drains the stomach, intestines, pancreas, and spleen (see [Fig. 24-7A](#)). Because the portal venous blood has already given up much of its O_2 to the gut, the hepatic artery is left to supply ~75% of the O_2 used by the liver.

We discuss the anatomy of the hepatic circulation in more detail on [page 946](#). Small branches of the portal vein give rise to terminal portal venules, and branches of the hepatic artery give rise to hepatic arterioles. These two independent sources of blood flow enter the liver lobule at its periphery. Blood flows from these terminal vessels into the sinusoids, which form the capillary network of the liver. The sinusoids converge at the center of the lobule to form terminal hepatic venules (i.e., central veins), which drain into progressively larger branches of the hepatic veins and finally into the inferior vena cava. Within the sinusoids, rapid exchange occurs between the blood and the hepatocytes because the vascular endothelial cells have large fenestrations and gaps. Thus, the liver sinusoids are more permeable to protein than are capillaries elsewhere in the body. As blood from the gastrointestinal tract passes the Kupffer cells of the liver (see [p. 946](#)), they remove bacteria and particulate matter, thereby preventing the access of potentially harmful material to the general circulation.

The mean blood pressure in the portal vein is normally 10 to 12 mm Hg. In contrast, the pressure in the hepatic artery averages 90 mm Hg. These two systems, with very different pressures, feed into the sinusoids (8 to 9 mm Hg). The sinusoids drain into the hepatic veins (~5 mm Hg), and these in turn drain into the vena cava (2 to 5 mm Hg). These remarkable values lead us to three conclusions. First, there must be a very high “precapillary” resistance between the hepatic artery (90 mm Hg) and the sinusoids (8 to 9 mm Hg), causing the arterial pressure to step down to sinusoidal values. If the sinusoidal pressure were as high as in typical capillaries (e.g., 25 mm Hg), blood would flow from the hepatic artery to the sinusoids and then backward into the portal vein. Second, because the pressure in the portal vein (10 to 12 mm Hg) is only slightly higher than that in the sinusoids (8 to 9 mm Hg), the precapillary resistance of the portal inflow (75% of the total blood flow entering the liver) must be very low. Third, because the pressure in the sinusoids is only slightly higher than that in the hepatic vein, the resistance of the sinusoids must also be extremely low.

As a result of the unique hemodynamics of the liver, changes in pressure within the hepatic vein have profound effects on fluid exchange across the wall of sinusoids. For example, in right-sided congestive heart failure, an elevated vena cava pressure can result in transudation of fluid from the liver into the peritoneal cavity, a condition known as **ascites**.

A change in the blood flow through one of the inputs to the liver (e.g., portal vein) leads to a reciprocal change in flow through the other input (i.e., hepatic artery). For example, if the inflow through the hepatic artery decreases, the pressure inside the sinusoids falls slightly, leading to an increase in flow from the portal vein into the sinusoids. When the inflow through the portal vein decreases, metabolic factors (e.g., decreases in metabolites carried by the portal blood) trigger an increase in flow from the hepatic arteriolar system. The hepatic arterial supply displays autoregulation (see [p. 481](#)), which is absent in the portal venous system. However, these adjustments do not fully stabilize total hepatic blood flow. With changes in O_2 delivery, the liver compensates with corresponding changes in O_2 extraction ratio. Hence, the liver tends to maintain constant O_2 consumption ([Box 24-2](#)).

Portal Hypertension

The cirrhotic liver is hard, shrunken, scarred, and laced with thick bands of fibrotic tissue. The most common cause of this in the United States is chronic alcoholism, but worldwide, hepatitis B and hepatitis C are also leading causes. Less commonly, inherited diseases, such as hemochromatosis (iron overload) and Wilson disease (altered copper metabolism), can be responsible, as can diseases of unclear etiology, such as biliary cirrhosis and sclerosing cholangitis.

When damage to the liver becomes severe, the clinical consequences of cirrhosis can become life-threatening. The 5-year survival rate is the same as that for primary lung cancer—less than 10%. The three major complications of cirrhosis are metabolic abnormalities, portal hypertension, and hepatic encephalopathy.

Metabolic Abnormalities

The liver's inability to maintain its normal synthetic activities (see pp. 964–971) results in a range of metabolic problems. Both albumin and cholesterol levels fall, and the prothrombin time rises, indicating failure of the liver to manufacture proteins in the coagulation cascade. The decreased plasma volume leads to renal hypoperfusion and renal failure—*hepatorenal syndrome*.

Portal Hypertension

The scarring that accompanies cirrhosis causes increased resistance to blood flow through the liver. When the portal venous pressure rises, the signs and symptoms of portal hypertension can appear. The increased portal venous pressure leads to increased pressure in the splanchnic capillaries. The Starling forces (see pp. 471–472) thus promote the filtration and extravasation of fluid. The result is abdominal edema (i.e., fluid accumulation in the interstitium), which can progress to frank **ascites**. As the portal pressure rises further, a portion of the portal blood begins to flow through and dilate the portal anastomoses with systemic veins. These anastomoses are present in the lower esophagus, around the umbilicus, at the rectum, and in the retroperitoneum.

Dilation of the vessels in the lower esophagus can lead to the development of *esophageal varices*. These veins, and similar veins in the stomach, can burst and cause life-threatening hemorrhage. When varices are associated with persistent or recurrent bleeding, the physician can inject sclerosing agents directly into the varices, a procedure called sclerotherapy. However, even after sclerotherapy, recurrent bleeding is not uncommon, and complications include perforation, stricture formation, infection, and aspiration. It is possible to prevent rupture of the varices in some patients by placing an intrahepatic portosystemic shunt. One introduces a catheter through the jugular vein and into the liver, and then a stent is placed between a branch of the hepatic vein and a branch of the portal vein, allowing portal blood to bypass the liver and flow directly into the vena cava.

In some cases of portal hypertension, surgical intervention is necessary. Portacaval shunts (i.e., those linking the portal vein and inferior vena cava) can stop rebleeding and reduce portal hypertension, but hepatic encephalopathy (see next) can occur and overall mortality is not improved. The distal splenorenal shunt is now the more popular choice of treatment. It is effective in preventing rebleeding, and because it diverts only a portion of the blood flow away from the liver (i.e., just the blood exiting the spleen; see Fig. 24-7A), it is associated with a much lower incidence of encephalopathy.

Hepatic Encephalopathy

Even as hepatic scarring increases vascular resistance through the liver, hepatic perfusion continues for a while. However, as we have just seen, eventually some of the portal blood flow shunts around the damaged liver into systemic veins, through pre-existing anastomoses. Because the liver is critical for removal and inactivation of naturally occurring toxic metabolites (see pp. 955–956), as well as pharmacological agents, toxins that bypass the liver directly enter the systemic veins and can build up in the plasma. If these toxins (e.g., NH_3 ; see Fig. 39-6) cross the blood-brain barrier, they can cause acute delirium.

The Skin

The skin is the largest organ of the body

The skin is the major barrier between the internal milieu of the body and the environment of the outside world. The skin is normally overperfused in relation to its nutritional requirements. Thus, local metabolic control of skin blood flow is of little functional importance. However, changes in blood flow to the skin also play a central role in the body's temperature regulation (see [pp. 1200–1201](#)).

In terms of blood flow, we can divide the skin into “apical” skin ([Fig. 24-8A](#))—which is present on the nose, lips, ears, hands, and feet—and “nonapical” skin (see [Fig. 24-8B](#)). In skin, capillaries reach only as superficially as the dermis; the epidermis does not have a blood supply. The venules that are part of a plexus of vessels near the dermal-epidermal border (i.e., the most superficial vessels) may contain an appreciable volume of blood, thereby imparting a pinkish hue to individuals with light-colored skin. When cutaneous blood flow decreases, this volume of blood also decreases, lessening the reddish component of skin color (i.e., pallor). Local nutritional flow through the precapillary sphincters and capillaries is under the control of local vasodilator metabolites and sensory stimuli (e.g., temperature, touch, pain). For example, the vascular beds can respond to local thermal changes, largely independently of sympathetic nerve activity: the blood vessels dilate when the skin is directly heated and constrict when it is cooled.

A APICAL SKIN**B NONAPICAL SKIN**

FIGURE 24-8 Blood flow to the skin. **A**, In apical skin, glomus bodies (a-v anastomoses) can reach a density of ~ 500 per cm^2 in the nail beds. **B**, The nonapical skin lacks glomus bodies. Postganglionic sympathetic fibers release norepinephrine (NE), causing the usual vasoconstriction. Preganglionic sympathetic fibers release acetylcholine (ACh) and cause vasodilation, perhaps mediated by formation of bradykinin.

The blood flow to the skin not only is affected by local metabolites and local warming and cooling but also is under sympathetic neural control. Increases in body core temperature increase blood flow to the skin, leading to a loss of heat. Decreases in core temperature result in the opposite effect of conserving heat. Unlike in other vascular beds, this neural control is far more important than local metabolic control in the overall regulation of skin blood flow.

Specialized arteriovenous anastomoses in apical skin help control heat loss

Apical Skin

The apical skin at the extremities of the body has a very high surface-to-volume ratio that favors heat loss. Circulation to these apical regions has an unusual feature—*arteriovenous (a-v) anastomoses* called **glomus bodies**. (These glomus bodies are unrelated to the glomus cells of the peripheral chemoreceptors.) Glomus bodies of the skin are tiny nodules found in many parts of the body, including the ears, the pads of the fingers and toes, and the nail beds. As the afferent arteriole enters the connective tissue capsule of the glomus body, it becomes a vessel with a small lumen and a thick, muscular wall comprising multiple layers of myoepithelioid cells. These vessels—which have a rich sympathetic

innervation—connect with short, thin-walled veins that eventually drain into larger skin veins. The a-v anastomoses, which are involved in heat exchange, are in parallel with the capillaries of the skin, which are involved in nutrient exchange (see [Fig. 24-8A](#)).

The anastomotic vessels are under neural control, rather than the control of local metabolites, and play a critical role in temperature regulation. In these apical regions, blood flow is under the control of sympathetic fibers that release norepinephrine and thereby constrict the arterioles, anastomotic vessels, and venules. Therefore, the increase in sympathetic tone that occurs in response to decreases in core temperature elicits vasoconstriction in the a-v anastomoses, a fall in blood flow, and a reduction in heat loss. Maximal sympathetic stimulation can completely obliterate the lumen of an anastomotic vessel, thus greatly reducing total blood flow to the skin. On the other hand, when the core temperature rises, the withdrawal of sympathetic tone leads to passive vasodilation; there is no active vasodilation. Indeed, blocking of the sympathetic input to a hand in a neutral thermal environment can increase blood flow 4-fold above basal levels—as much as heat stress can produce. Thus, sympathetic tone to the vasculature of apical skin is substantial at rest, particularly in cool environments, thereby minimizing heat loss.

Nonapical Skin

The body uses a very different approach for regulating blood flow in nonapical skin. One important difference is that this vasculature almost completely lacks a-v anastomoses. A second important difference is that there are two types of sympathetic neurons innervating the vessels of the skin. Some release *norepinephrine* and some release *acetylcholine*.

Vasoconstriction occurs in response to the release of norepinephrine. In contrast to the situation in *apical* skin, blockade of sympathetic innervation to *nonapical* skin in a thermoneutral environment produces little change in skin blood flow, demonstrating that little vasoconstrictor activity is present at rest.

Vasodilation in nonapical skin occurs in response to sympathetic neurons that release acetylcholine (see [p. 543](#)). Indeed, blockade of sympathetic innervation to the nonapical skin in a warm environment produces vasoconstriction and a decrease in skin blood flow, demonstrating neurally directed vasodilation before the blockade. The precise mechanism of this vasodilation is obscure. One proposal is that the acetylcholine stimulates eccrine sweat glands, causing the secretion of sweat as well as enzymes that lead to the local formation of vasoactive molecules. For instance, sweat gland cells release kallikrein, a protease that converts kininogens to kinins, one of which is bradykinin (see [p. 543](#)). These kinins may act in a paracrine fashion on nearby blood vessels to relax VSMCs and thereby increase local perfusion. Cholinergic sympathetic neurons may cause vasodilation by means of a second pathway involving the co-release of vasodilatory neurotransmitters (e.g., calcitonin gene-related peptide, vasoactive intestinal peptide) that act directly on VSMCs, independently of sweat gland activity. Evidence for the second pathway is that the vasodilation cannot be blocked by atropine and is therefore independent from the actions of acetylcholine.

Mechanical stimuli elicit local vascular responses in the skin

White Reaction

If the skin is stroked mildly with a sharp instrument, a blanched line appears in the trailing path of the instrument. The immediate response is attributable to passive expulsion of the blood by the external mechanical force. During the next 15 to 60 seconds, the **white reaction** that ensues is caused by

contraction of microvascular VSMCs and pericytes in response to mechanical stimulation. This active response has the effect of emptying the capillary loops, the collecting venules, and the subpapillary venous plexus of blood in a sharply delineated manner.

“Triple Response”

If a pointed instrument is drawn across the skin more forcefully, a series of reactions ensues that is collectively known as the **triple response**. Within several seconds, a band of increased redness appears due to a local dilation and increased perfusion of capillaries and venules within the perturbed area. This **red reaction** is independent of innervation and may persist for one to several minutes. The presumed cause is the local release of a vasodilator substance (e.g., histamine) from cells that were disturbed by the mechanical response.

If the stimulus is sufficiently strong or repeated, the reddening of the skin is no longer restricted to the line that was stroked but spreads to the surrounding region. This **flare reaction** appears several seconds after the localized redness and reflects the dilation of arterioles. The mechanism of the flare reaction is a local nervous response known as the **axon reflex**,  **N24-3** which depends on the branching of a single nerve fiber (see [Fig. 15-29](#)). A stimulus applied to one branch (containing the sensory receptor) gives rise to an action potential that travels centrally to the point of fiber branching. From this branch point, the afferent signal travels both orthodromically to the spinal cord and antidromically along the collateral branch. As a result, this collateral branch releases the vasodilating neurotransmitters. Sectioning of the nerve fiber central to the site of the collateral branch eliminates the awareness of the stimulus but does not eliminate the flare reaction until the nerve fiber degenerates.

When the stimulus is even more intense, as caused by the lash of a whip, the skin along the line of injury develops localized swelling known as a **wheal**. This local edema results from an increase in capillary permeability (e.g., in response to histamine) as filtration exceeds absorption. The wheal is preceded by and ultimately replaces the red reaction, appearing within a few minutes from the time of injury, and it is often surrounded by the flare reaction.

CHAPTER 25

Integrated Control of the Cardiovascular System

Emile L. Boulpaep

In the preceding chapters, we examined cardiovascular regulation at several different levels. Powerful *systemic* mechanisms operate over both the short term and the long term to control mean arterial pressure and cardiac output. Operating independently of these are *local* mechanisms of control that regulate blood flow at the microcirculatory level. In addition, individual organs have their own unique tools for managing specific circulatory requirements. In this chapter, we put it all together and learn how the cardiovascular system integrates the complex systemic, local, and individualized regulatory mechanisms in response to the demands of everyday life.

Interaction among the Different Cardiovascular Control Systems

The control of the cardiovascular system involves “linear,” “branched,” and “connected” interactions

In the previous chapters, we often presented physiological responses in a linear sequence or on a **linear chart**. For instance, we might represent the carotid-baroreceptor feedback loop (see [p. 534](#)) as a linear sequence of events ([Fig. 25-1A](#)). However, cardiovascular parameters and associated physiological responses are often related by multiple factors, requiring a more complex diagram called a **branching tree** (or an algorithmic tree). For example, in our discussion of the control of cardiac output (see [pp. 545–548](#)), we started with the knowledge that cardiac output depends on two parameters—stroke volume and heart rate. Therefore, with our very first step, we come to a fork in the road—an example of a branching tree (see [Fig. 25-1B](#)). At the next level, we encounter a pair of forks because stroke volume and heart rate both depend on two parameters. Finally, at the third level, we see that each of the determinants of stroke volume and heart rate depends on multiple factors (i.e., multiple forks).

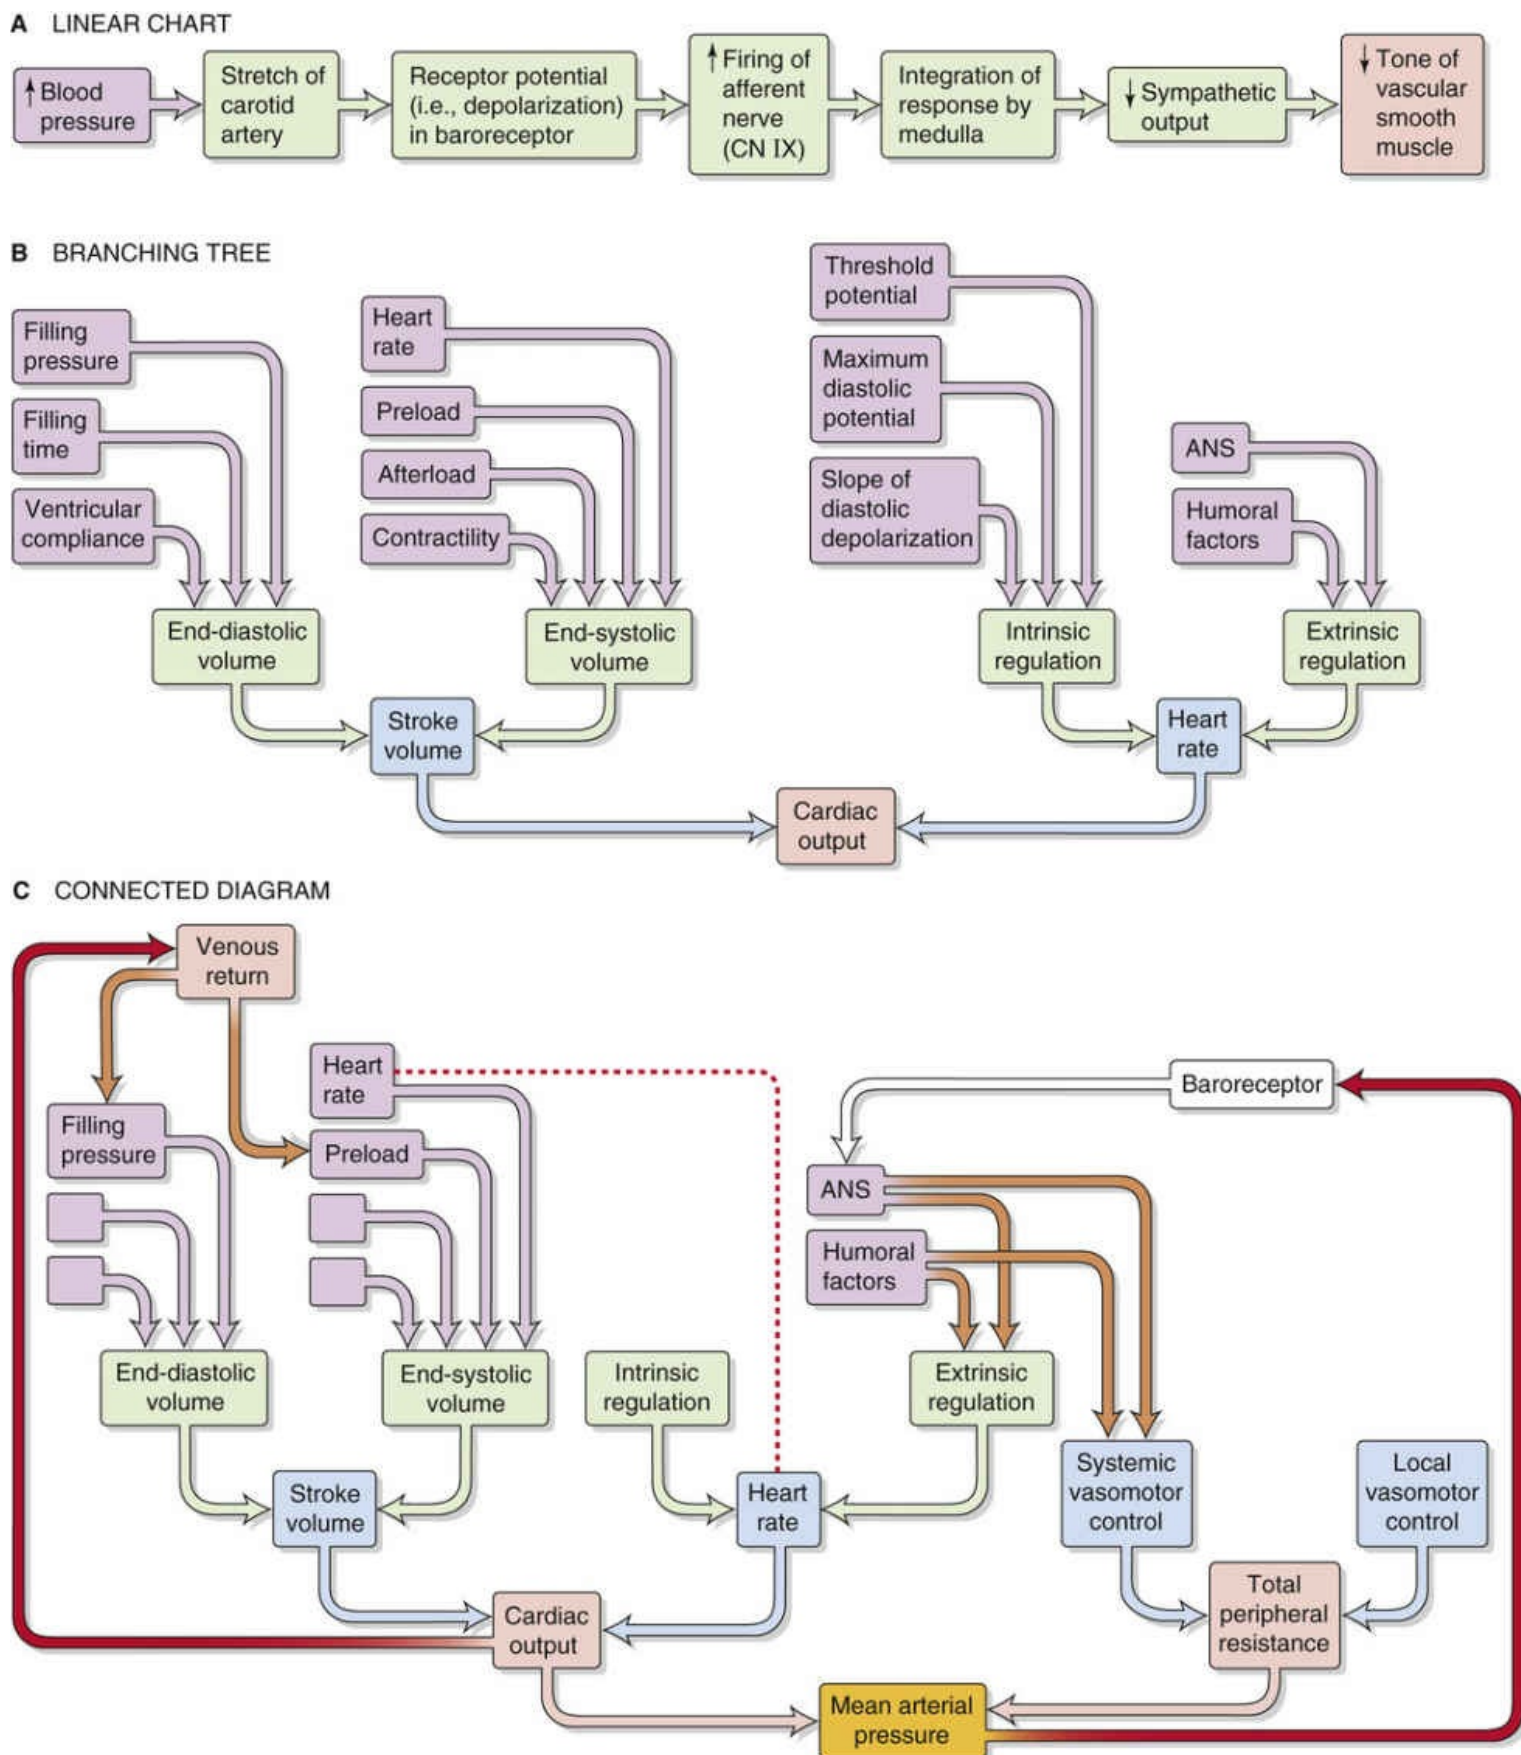

FIGURE 25-1 Patterns of cardiovascular control. **A**, The baroreceptor reflex is depicted as if increased blood pressure affected a single stretch receptor, which ultimately would influence a single effector (i.e., vascular smooth muscle). **B**, Cardiac output depends on multiple parameters, which in turn depend on multiple parameters, and so on. However, we ignore potential interactions among parameters. **C**, A branching tree represents the control of mean arterial pressure. The left limb repeats **B**. Superimposed on this simple tree are three more complex interactions: (1) feedback loops (red arrows), (2) two occurrences of the same parameter (connected by the red dashed line), and (3) examples of parameters exerting effects on two different branches of the tree (brown arrows). CN, cranial nerve.

The control of some cardiovascular parameters is even more complex, requiring that we graft branches from smaller trees. For example, we know from Ohm's law that *mean arterial pressure* depends on both *cardiac output* (and all the elements in its branching tree in Fig. 25-1B) and *total peripheral resistance*, which requires a branching tree of its own (see Fig. 25-1C). Moreover, sometimes an element in one part of the “forest” interacts with another element that is far away. A physiological system with such complex interactions is best represented by a **connected diagram**, which may include feedback loops (see Fig. 25-1C, red arrows), parameters that appear more than once in the tree (connected by a red dashed line), or factors that modulate parameters in two different branches of the tree (connected by brown arrows). Although not shown in Figure 25-1C, several feedback loops may impinge on a single element, and some loops are more dominant than others. The complex interactions among parameters make it difficult to distinguish factors of overriding importance from those of lesser weight. Moreover, when one disturbs a single parameter in a complex physiological system, the initial state of other parameters determines the end state of the system. In previous chapters, we have chosen situations that artificially isolate one portion of the cardiovascular system (e.g., heart, microcirculation) to explain in a simple way the homeostatic control mechanisms that govern that subsystem. However, conditions isolating subsystems rarely apply to a real person.

How can we evaluate which parameters are crucial? As an example, consider one subsystem, the heart. Let us assume that we can rigorously analyze all determinants of cardiac function—such as Starling's law, force-velocity relationships, effect of heart rate on contractility, and so forth. These analyses take the form of mathematical expressions, which we can combine by **systems analysis** to create a model that describes the behavior of the entire heart—at least theoretically. How can we test whether our model is reasonable? We can compare the physiological response of the heart in vivo with the response predicted by a computer simulation of the model. Using this approach, we may be able to establish whether we have used the correct feedback loops, whether we have assigned proper values to various elements, and whether we have assigned the proper weight to each interaction. In this way, we can use any agreement between the experimental data and the performance of the model as evidence—but not proof—that the concepts contained in the model are reasonable.

Regulation of the entire cardiovascular system depends on the integrated action of multiple subsystem controls as well as noncardiovascular controls

In performing a systems analysis of the entire cardiovascular system, we must consider the interrelationships among the various subsystems summarized in the central yellow block of Figure 25-2. Not surprisingly, we cannot fully understand how a particular disturbance affects the overall circulation unless we consider all subsystems in an integrated fashion. For instance, consider the effects of administering norepinephrine, which has a high affinity for α_1 adrenoceptors, less for β_1 adrenoceptors, and far less for β_2 adrenoceptors. These receptors are present, in varying degrees, in both the blood vessels and the heart. A *branching tree* would predict the following. Because α_1 adrenoceptors (high affinity) are present in most vascular beds, we expect widespread vasoconstriction. Because β_2 adrenoceptors (low affinity) are present in only a few vascular beds, we predict little vasodilation. Because β_1 adrenoceptors (intermediate affinity) are present in pacemaker and myocardial cells of the heart, we would anticipate an increase in both heart rate and contractility and therefore an increase in cardiac output.

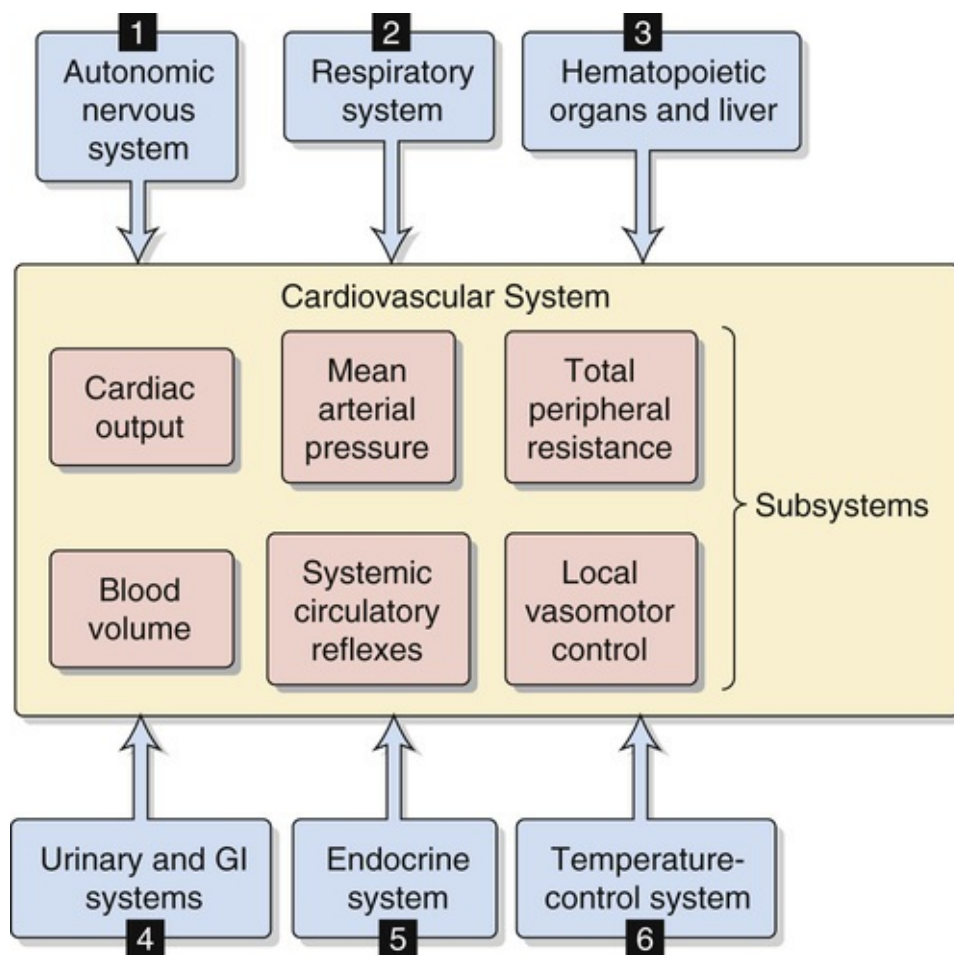

FIGURE 25-2 Interaction among cardiovascular subsystems and noncirculatory systems. GI, gastrointestinal.

Although our analysis predicts that the *heart rate* should increase, in most cases the dominant effect of intravenous norepinephrine injection is to slow down the heart. The explanation, which relies on a *connected diagram*, is that increased peripheral resistance (caused by stimulation of α_1 receptors) and increased cardiac output (caused by stimulation of β_1 receptors) combine to cause a substantial rise in mean arterial pressure. The baroreceptor reflex (see red arrow on right in Fig. 25-1C) then intervenes to instruct the heart to slow down (see p. 534). However, bradycardia may not occur if many vascular beds were dilated before the administration of norepinephrine; in this case, the rise in blood pressure would be modest. Bradycardia might also not occur if the baroreceptor reflex were less sensitive, as would be the case in a chronically hypertensive patient (see Box 23-1). Thus, the effect of intravenous administration of norepinephrine on heart rate depends on the pre-existing state of various subsystems.

In trying to understand the integrated response of the cardiovascular system to an insult, we must include in our analysis not only all the subsystems of the cardiovascular system but also the pertinent control systems outside the circulation (see blue boxes in Fig. 25-2):

1. Autonomic nervous system (ANS). Part of the ANS is intimately involved in cardiovascular control (e.g., high-pressure baroreceptor response). On the other hand, a generalized activation of the ANS, such as occurs with the fight-or-flight response (see p. 347) also affects the circulation.

2. Respiratory system. We have already seen that ventilatory activity converts the intrinsic bradycardia response to tachycardia during stimulation of the peripheral chemoreceptors (see p. 545). In addition, the action of the respiratory muscles during inspiration causes intrathoracic pressure to become more negative (see p. 607), thereby increasing venous return. A third example is that the evaporative loss of

water during breathing reduces total body water and, ultimately, blood volume.

3. Hematopoietic organs and liver. These systems control blood composition in terms of cell constituents and plasma proteins. The hematocrit and large proteins (e.g., fibrinogen) are major determinants of blood viscosity (see [pp. 437–439](#)) and therefore of blood flow. Because the plasma proteins also determine colloid osmotic pressure (see [p. 470](#)), they are a major component of the Starling forces (see [pp. 467–468](#)), which determine the distribution of extracellular fluid (ECF) between the interstitium and the blood plasma.

4. Gastrointestinal and urinary systems. Because the gastrointestinal tract and kidneys are the principal organs determining input and output of electrolytes and water, they are mainly responsible for controlling the volume and electrolyte composition of ECF. ECF volume plays a central role in the long-term control of blood pressure (see [p. 838](#)).

5. Endocrine system. Part of the endocrine system is intimately involved in cardiovascular control (e.g., epinephrine release by the adrenal medulla). Other hormones influence the cardiovascular system either because they are vasoactive agents (see [pp. 551–554](#)) or because they regulate fluid volume and electrolyte composition by acting on the kidney and gastrointestinal system.

6. Temperature control system. The cardiovascular system is a major effector organ for thermoregulation, carrying blood from the body core to the skin, where heat loss then occurs (see [pp. 1200–1201](#)). In part, this heat loss occurs as sweat glands secrete fluid that then evaporates. However, the loss of ECF volume reduces the effective circulating volume (see [pp. 554–555](#)).

Inclusion of control elements outside the circulation (see [Fig. 25-2](#)) in our connected diagram of the cardiovascular system (see [Fig. 25-1C](#)) would expand the computer model to include hundreds of independent and dependent variables. Rather than trying to grasp such an exhaustive model, we work here through the integrated cardiovascular responses to four important circulatory “stresses”: (1) orthostasis (i.e., standing up), (2) emotional stress, (3) exercise, and (4) hemorrhage.

Response to Erect Posture

Because of gravity, standing up (orthostasis) tends to shift blood from the head and heart to veins in the legs

About two thirds of the total blood volume resides in the systemic veins (see pp. 448–450). When a recumbent subject assumes an upright position, the blood shifts from the central blood volume reservoirs and other veins to large veins in the dependent limbs. In discussing Figure 17-8B, we assumed that the cardiovascular system somehow made the adjustments necessary to keep right atrial pressure (RAP) constant at about +2 mm Hg. Indeed, unless compensatory mechanisms intervene, blood redistribution will lower not only arterial blood pressure but also venous return and thus cardiac output.

To illustrate the effect of blood redistribution on venous return, we will represent the entire circulatory system by a horizontal, distensible cylinder 180 cm in length (the height of our person) and 3 cm in radius (Fig. 25-3A). This cylinder holds ~5000 mL of blood (the normal blood volume). We know that immediately after a cardiac arrest, the entire vascular system will have a mean systemic filling pressure (MSFP) of ~7 mm Hg (see p. 549). The MSFP is the pressure in the circulation that would remain in the absence of any pumping or any gravity effects. Thus, if a subject is recumbent and has no heartbeat, and if the cardiovascular system is filled with a normal blood volume of 5000 mL (V_o), the overall compliance of the system will produce a uniform pressure of ~7 mm Hg. If we were to transfuse an additional 100 mL (ΔV) of blood into our cylinder, the MSFP would rise by ~1 mm Hg (ΔP). We can conclude that the compliance, expressed as a normalized distensibility (see p. 454), is

$$\begin{aligned}\text{Relative distensibility} &= \frac{(\Delta V/V_o)}{\Delta P} & (25-1) \\ &= \frac{(100 \text{ mL}/5000 \text{ mL})}{1 \text{ mm Hg}} \\ &= 0.02 \frac{\text{mL}}{\text{mL} \times \text{mm Hg}} \\ &= 0.02/(\text{mm Hg})\end{aligned}$$

Thus, for every 2% increase in blood volume, the MSFP of the cylinder increases by 1 mm Hg.

A HORIZONTAL CYLINDER**B VERTICAL CYLINDER WITH HIGH COMPLIANCE**

Normalized distensibility is relatively high, 0.02/(mm Hg).

C VERTICAL CYLINDER WITH REDUCED COMPLIANCE

Normalized distensibility is relatively low, 0.01/(mm Hg).

FIGURE 25-3 Model of the orthostatic redistribution of blood. **A**, A horizontal tube (3-cm radius, 180 cm long) contains the entire blood volume (5 L). With no blood flow, pressure inside the tube is uniform and corresponds to a mean systemic filling pressure of 7 mm Hg. **B**, With the cylinder upright (orthostasis), pressure gradually increases toward the bottom, causing increasingly greater distention of this compliant tube. Because blood volume has shifted to the bottom, the upper level of the blood column is 30 cm below the level of the heart, preventing venous return. **C**, Reducing compliance of the tube by half also causes distention to fall by half. With the reduced shift of blood volume, the upper level of the blood column now just reaches the heart.

What will happen to our cylinder if we now turn it upright? This position is called orthostasis (from the Greek *orthos* [upright] + *histanai* [to stand]). Because we have a vertical column of blood 180 cm tall, we must now consider gravity (see Fig. 25-3B). The highest pressures will be at the bottom of the cylinder. (Fig. 17-8 shows that orthostasis causes venous pressure at the ankle to rise from 5 to

100 mm Hg.) Therefore, our cylinder will distend maximally at the bottom, and this distention represents a shift in blood volume. The bottom of the cylinder (corresponding to the “dependent areas” of a person) gains volume, whereas the top (i.e., corresponding to the cranial portion of a person) loses blood volume. In fact, there would be no blood at all at the top of the cylinder.

By just how much would the column of blood fall in our upright, 180-cm-tall cylinder? If the overall vascular volume distensibility were 0.02/(mm Hg), then the actual height of the blood column inside the cylinder would be only about 100 cm.  **N25-1** If the heart were 50 cm below the top of the cylinder, then the top of the column would now be ~30 cm below the level of the heart. Therefore, there would be no blood to return to the heart. Moreover, the RAP would be negative (–30 cm H₂O, or about –22 mm Hg). Because the heart cannot create a vacuum this large at its input by “sucking” blood—in fact, the heart must be filled by a positive RAP—cardiac output would fall to zero.

N25-1

Calculation of Distention in an Upright Cylinder

Contributed by Emile Boulpaep

Equation 19-4 and the identical Equation 25-1 both describe how the “relative” or “normalized” distensibility depends on the relative change in volume ($\Delta V/V_o$) and the pressure difference (ΔP):

$$\text{Relative distensibility} = \frac{(\Delta V/V_o)}{\Delta P} \quad (\text{NE 25-1})$$

We can now solve for the relative change in volume:

$$\frac{\Delta V}{V_o} = \text{Relative distensibility} \cdot \Delta P \quad (\text{NE 25-2})$$

For a very thin disk of fluid (height h) in the upright vessel, the change in volume (ΔV) is due solely to a change in vessel radius. In other words, because $V = h\pi r^2$, $\Delta V = h\pi(\Delta r)^2$. Thus, we can rewrite Equation NE 25-2 as

$$\frac{(\Delta r)^2}{(r_o)^2} = \text{Relative distensibility} \cdot \Delta P \quad (\text{NE 25-3})$$

In order to compute the shape of the upright vessel in Figure 25-3, the only other thing we need to know is how ΔP varies with height in the upright vessel. For a hydrostatic column, the pressure increases linearly as we descend to greater depths, as described by Equation 17-4. We reproduce this equation here:

$$P = \rho \cdot g \cdot h$$

(NE 25-4)

Here, ρ is the density of the liquid, g is the gravitational constant, and h is the height of the column. We could use this equation to compute the pressure in dynes per square centimeter or pascals. However, physiologists tend to express pressures in centimeters of H_2O or millimeters of mercury. For example, in Figure 25-3B, the pressure at the bottom of the 100-cm column is equivalent to 100 cm H_2O , which is also (knowing the density of mercury) 73.5 mm Hg.

Now we can compute the relative distention at the bottom of the upright cylinder, which is under a pressure of 73.5 mm Hg. Rearranging Equation NE 25-3 and solving for Δr (the change in radius), we have

$$\begin{aligned} (\Delta r)^2 &= \text{Relative distensibility} \cdot \Delta P \cdot (r_o)^2 \\ (\Delta r)^2 &= (0.02/\text{mm Hg}) \cdot (73.5 \text{ mm Hg}) \cdot (3 \text{ cm})^2 \\ \Delta r &= 3.6 \text{ cm} \end{aligned} \tag{NE 25-5}$$

Because the initial radius (r_o) of the horizontal cylinder in Figure 25-3A was everywhere 3 cm, the distended radius at the bottom of the upright column has increased by 3.6 cm for a total radius of 6.6 cm—in other words, the radius has more than doubled, and the volume has more than quadrupled (i.e., increased by a factor of 4.8).

If the relative distensibility were less (e.g., 0.01/mm Hg in Fig. 25-3C), then the Δr would also be less at the bottom of the upright cylinder. On the other hand, because the Δr is less at each height, the column of water would have to be higher to accommodate the volume. Thus, the pressure at the bottom of the column would be greater (i.e., 130 cm H_2O or 95.6 mm Hg in the example of Fig. 25-3C). As in Equation NE 25-5, we can compute the relative distention at the bottom of the upright cylinder, which this time is under a pressure of 95.6 mm Hg:

$$\begin{aligned} (\Delta r)^2 &= (0.01/\text{mm Hg}) \cdot (95.6 \text{ mm Hg}) \cdot (3 \text{ cm})^2 \\ \Delta r &= 2.9 \text{ cm} \end{aligned} \tag{NE 25-6}$$

In other words, uniformly reducing the relative distensibility by a factor of 2 still results in a near doubling of the radius and a near quadrupling of the volume (i.e., increased by a factor of 3.8).

The ANS mediates an “orthostatic response” that raises heart rate and peripheral vascular resistance and thus tends to restore mean arterial pressure

If our model predicts that orthostasis should cause RAP to fall to -22 mm Hg, how is it that the body manages to maintain RAP at about +2 mm Hg in the upright position? The answer is that pooling of blood in the dependent vessels is much less pronounced during orthostasis than would be predicted by Figure 25-3B, where ~2.3 L disappeared from the top of the cylinder. The actual amount of pooling in both legs

of a real person is only ~500 mL. **N25-2** Four major factors help reduce pooling and maintain RAP.

N25-2

Hypothetical Volume of Pooled Blood during Orthostasis

Contributed by Emile Boulpaep

In the example shown in Figure 25-3B, the column of blood would reach a height of 100 cm. Because the horizontal cylinder in Figure 25-3A had a length of 180 cm, turning the vessel upright reduced the length of the column by 80 cm. How much volume moved into the lower part of the distensible, upright vessel? The answer is the volume at the top of the white region in Figure 25-3B, which is the product of the 80-cm length and cross-sectional area:

$$\begin{aligned}\text{Hypothetical pooled volume} &= (80 \text{ cm}) \cdot \pi(3 \text{ cm})^2 \\ &= 2262 \text{ cm}^3 = \sim 2.3 \text{ L}\end{aligned}\quad (\text{NE 25-7})$$

Nonuniform Initial Distribution of Blood

In our cylinder example, the blood was initially distributed evenly throughout the length of the cylinder. In a recumbent human, however, most of the blood in large veins is located in the central blood volume (see p. 449), that is, the vessels near the heart. If a large fraction of the blood had started off in the head, the orthostatic shift of blood would have been more dramatic, as in Figure 25-3B. The majority of the 500 mL of blood that pools in the legs during orthostasis comes from the intrathoracic vascular compartments. What is the sequence of events by which blood volume redistributes during orthostasis? As one stands, the output from the heart for a number of beats exceeds the venous return into the thoracic pool. This excess blood ends up filling the vessels in the dependent regions of the body. The result is a net transfer of blood—by way of the heart—from the intrathoracic vascular compartments to the dependent vessels.

Nonuniform Distensibility of the Vessels

In Figure 25-3B, we assumed a relative distensibility of 0.02/(mm Hg). If we had instead used a value of 0.01/(mm Hg)—that is, if the vessels were *less* distensible—standing would cause a less dramatic shift of blood to the dependent vessels, ~1.4 L (see Fig. 25-3C) instead of ~2.3 L (see Fig. 25-3B). **N25-1** As a result, the height of the blood column would fall from 180 to only 130 cm (see Fig. 25-3C) in the upright position, rather than to 100 cm (see Fig. 25-3B). Assuming a lower distensibility for the leg veins is reasonable because small vessels are far stiffer than larger ones, such as the aorta and vena cava. With the lower relative distensibility of 0.01/(mm Hg), the column of blood would just reach the heart. Indeed, when a subject stands quietly, the zero effective pressure level—the height in the body where vascular pressure equals atmospheric pressure—is about at the level of the right atrium. Obviously, if the circulatory system reduces its distensibility even further through the regulated contraction of vascular smooth muscle (discussed below), the height of the column of blood will increase and improve venous return.

Muscle Pumps

An important compensation for blood pooling during orthostasis comes from skeletal muscle contraction. When a person stands, the muscles of the legs and abdomen tighten. The presence of valves in the veins, as well as intermittent muscular movement, contributes to the flow of blood upward along the veins (see [Fig. 22-7C](#) and [Fig. 24-6](#)). Vessels of the abdominal region remain nearly unaffected by orthostasis because the abdominal viscera are contained in a water-filled jacket that is maintained by the tone of the abdominal muscles.

Autonomic Reflexes

Because of decreased venous return, cardiac output tends to fall by ~20% soon after one assumes an erect position. However, the fall in cardiac output would be even greater in the absence of autonomic reflexes. The decreased venous return leads to a fall in RAP, which in turn leads to a decrease in stroke volume and thus arterial pressure. High-pressure baroreceptors (see [pp. 534–535](#)) sense this decrease in arterial pressure, **N25-3** which leads to an increased sympathetic output that raises vascular tone throughout the body and increases heart rate and contractility. Together, the constriction of arterioles (which raises total peripheral resistance) and the increased heart rate restore the systemic mean arterial pressure, despite a small decrease in stroke volume. In the dependent regions of the body, the sympathetic response also increases the tone of the veins, thereby decreasing their diameter and their capacity (compare [Fig. 25-3B and C](#)).

N25-3

Baroreceptor Responses in Orthostasis

Contributed by Emile Boulpaep

As noted in the text (see p. 576), orthostasis leads to the following sequence of events: Decreased venous return → fall in RAP → decrease in stroke volume → decreased arterial pressure → response of high-pressure baroreceptors (see [pp. 536–537](#)) → increased sympathetic output → generalized vasoconstriction and increased heart rate/contractility. Because RAP falls early in this sequence, you might wonder what role the atrial low-pressure baroreceptors play in the response. Reduced atrial stretch has little effect on heart rate (see [pp. 547–547](#)) and causes an increase in sympathetic output only to the kidney (i.e., causing renal vasoconstriction). Therefore, the low-pressure baroreceptors make only a minor contribution to the overall orthostatic response (i.e., generalized vasoconstriction and increased heart rate/contractility).

In summary, of the four factors that contribute to the stability of RAP during orthostasis, two are anatomical (i.e., nonuniformities of initial blood volume distribution and distensibility) and two are physiological (i.e., muscle pumps and autonomic reflexes). The two physiological mechanisms are both important. Indeed, after a lumbar sympathectomy, patients tend to faint when standing. However, after some months, they are able to compensate, perhaps by using the muscle pumps more effectively or by enhancing the sympathetic response of the heart.

The extent of the **orthostatic response**—how much the heart rate or peripheral vascular resistance increases under the control of the ANS—depends on a variety of factors ([Table 25-1](#)), which involve nearly the entire cardiovascular system. Because these factors may differ from person to person or may differ within any one individual according to the circumstances, the orthostatic response is highly

variable. We now discuss two examples of this variability.

TABLE 25-1

Factors Influencing the Degree of Orthostatic Response*

- Total blood volume
- Distribution of blood volume
- Size of vessels in dependent regions of the body
- Vascular distensibility
- Mean systemic filling pressure (pressure in the absence of cardiac output)
- Level at which zero effective pressure is normally located in a particular individual
- Degree of tilt
- Skeletal muscle tone; strength and rate of intermittent contraction of skeletal muscles
- Vascular sufficiency
- Abdominal muscle tone
- Temperature
- Response of low-pressure receptors
- Response of high-pressure baroreceptors
- Activity of the sympathetic system
- Initial heart rate
- Initial myocardial contractility
- Sensitivity of vascular smooth muscle to sympathetic stimulation

*That is, by how much standing up increases heart rate and peripheral vascular resistance.

Postural Hypotension

In very sensitive subjects lying on a tilt table, a sudden orthostatic tilt can cause such a large fall in arterial pressure that the individual becomes dizzy or even faints. **Fainting** is caused by a transient fall in arterial pressure that causes cerebral perfusion to become inadequate.

Temperature Effects

In a *cool environment*, in which the arterioles in the lower extremities are constricted, the initial dip in arterial pressure can be small, despite the decrease in stroke volume. The explanation is that the high arteriolar resistance delays the transfer of blood from the thoracic pool to the legs. As a result, the sympathetic response to the small drop in mean arterial pressure may already be in effect before further pooling can occur. In a *warm environment*, where the arterioles in the skin are more dilated, orthostasis leads to faster transfer of blood from the thoracic pool to the legs  **N25-4** so that—before the sympathetic response can develop—the initial decreases in stroke volume, mean arterial pressure, and pulse pressure can be large. Thus, soldiers standing quietly at attention in hot weather are more likely to faint than are soldiers marching in a cold environment because of differences in muscle pump activity and vasoconstriction.

Effects of Temperature on Venous Pooling

Contributed by Emile Boulpaep

As discussed on page 565, the contraction of skeletal muscle in the legs (the “muscle pump”—see Fig. 24-6) drives blood from the large veins in the lower limbs toward the heart. Conversely, each time these skeletal muscles relax, the vascular bed in the legs refills from the arterial side. Obviously, the arteriolar inflow resistance influences the rate at which the veins in the leg refill subsequent to the action of the muscle pump. When the lower limbs are at a high temperature, the arterioles dilate, lowering the inflow resistance and increasing the inflow of blood to the dependent vessels. Therefore, venous pooling worsens at high temperature, which explains why soldiers tend to faint under these conditions.

Responses to Acute Emotional Stress

The fight-or-flight reaction is a sympathetic response that is centrally controlled in the cortex and hypothalamus

Emotional responses vary greatly among people. A severe emotional reaction can resemble the **fight-or-flight response** in animals (see [p. 345](#)). This defense reaction causes a generalized increase in skeletal muscle tone and increased sensory attention.

Fight-or-flight behavior is an extreme example of an integrated acute stress response that originates entirely within the central nervous system (CNS), without involvement of peripheral sensors or reflexes. The response is due to the activation of sensory centers in the **cortex** ([Fig. 25-4](#)), which activate a part of the limbic system called the **amygdala** (see [p. 349](#)). The amygdala in turn activates the **locus coeruleus** (see [p. 312](#)), which is in the pons, as well as hypothalamic nuclei. Noradrenergic neurons in the locus coeruleus project to nearly every part of the CNS (see [Fig. 13-7A](#)), including the **hypothalamic paraventricular nucleus (PVN)**, which produces both an endocrine and an ANS response. The *endocrine response* of the PVN involves (1) release of arginine vasopressin (AVP) by magnocellular neurons in the PVN (see [Fig. 40-8](#)), thereby reducing urine output (see [pp. 817–818](#)); and (2) release of corticotropin-releasing hormone (CRH; see [p. 1023](#)) by parvocellular neurons in the PVN, activating the hypothalamic-pituitary-adrenal axis and thereby releasing cortisol, which is important for the metabolic response to stress. The *ANS response* of the PVN involves projections to (1) autonomic nuclei in the brainstem (dorsal motor nucleus of the vagus, rostral ventrolateral medulla, and nucleus tractus solitarii [NTS]) that are part of the **medullary cardiovascular center** (see [p. 537](#)), and (2) direct projections to the **spinal intermediolateral column** (see [Fig. 25-4](#)).

The overall fight-or-flight response involves the following:

- 1. Skeletal muscle blood flow.** In animals—but perhaps not in humans—activation of postganglionic sympathetic cholinergic neurons (see [p. 342–343](#)) *directly* causes a rapid increase in blood flow to skeletal muscle (see [p. 539](#)). In humans as well as in other mammals, flow also increases *secondarily* more slowly and less dramatically because the adrenal medulla releases epinephrine, which acts on β_2 adrenoceptors on skeletal muscle blood vessels. The result is dilation and an increase in blood flow. In a full-blown fight-or-flight reaction, muscle exercise generates metabolites that further increase skeletal muscle blood flow (see [pp. 563–564](#)). Of course, humans may not exercise skeletal muscle in responding to internal stress (e.g., anxiety or panic).
- 2. Cutaneous blood flow.** The **sympathetic** response causes little change in blood flow to skin unless it stimulates sweating. The neural pathway involves sympathetic cholinergic neurons (see [pp. 342–343](#)), which release acetylcholine and perhaps vasodilatory neurotransmitters (e.g., calcitonin gene–related peptide, vasoactive intestinal peptide). The acetylcholine causes the secretion of sweat and possibly also the local formation of kinins (see [pp. 553–554](#)). These kinins increase capillary permeability and presumably also dilate arterioles but constrict venules (i.e., increasing the midcapillary pressure). The result would be an increased filtration of fluid from the skin capillaries into the interstitium, causing dermal swelling.
- 3. Adrenal medulla.** Preganglionic sympathetic neurons stimulate the chromaffin cells to release epinephrine, which causes vasodilation in muscle (through β_2 adrenoceptors) and vasoconstriction in the kidney and splanchnic beds (through α_1 adrenoceptors).
- 4. Renal and splanchnic blood flow.** In virtually all vascular beds, increased sympathetic output causes vasoconstriction and thereby decreases blood flow. The systemic release of epinephrine also vasoconstricts these vascular beds rich in α_1 adrenoceptors.
- 5. Veins.** Most veins constrict in response to sympathetic output.
- 6. The heart.** Increased sympathetic output and decreased vagal output cause a rise in heart rate and contractility, so that cardiac output increases.
- 7. Blood volume.** High plasma levels of AVP reduce urine output and maintain blood volume.
- 8. Mean arterial pressure.** Depending on the balance of vasodilation and vasoconstriction, the overall result of vascular resistance changes may be either a decrease or an increase in total peripheral resistance. Nevertheless, because cardiac output increases, the net result of an increased cardiac output and a resistance change is an increase in arterial pressure.

The common faint reflects mainly a parasympathetic response caused by sudden emotional stress

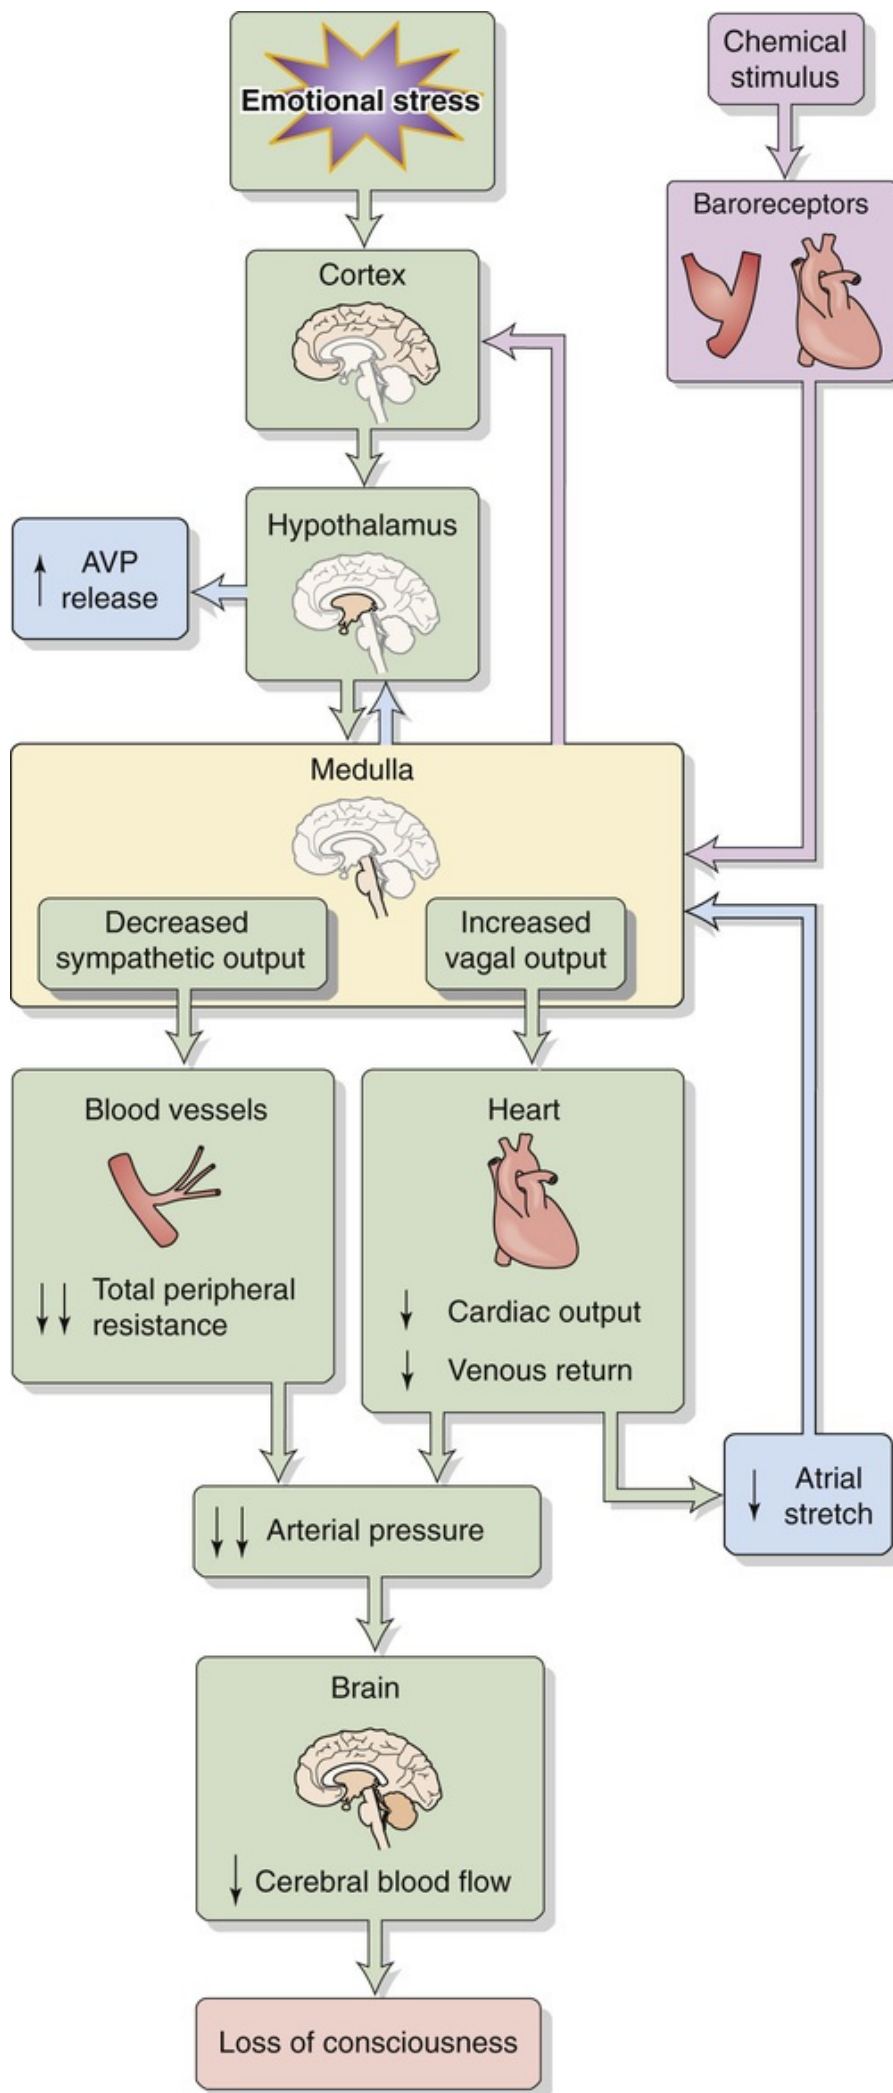

About one fifth of humans experience one or more episodes of fainting during adolescence. This type of

fainting is known as vasodepressor syncope or **vasovagal syncope (VVS)**. About 40% of syncope cases seen in outpatient settings are vasovagal in nature. VVS can occur in response to a sudden emotional stress, phlebotomy, the sight of blood, or acute pain. Fainting usually starts when the individual is standing or sitting, rarely when the individual is recumbent. The loss of consciousness is due to a transient fall in perfusion pressure to the brain. The “playing dead” reaction in animals is the equivalent of VVS in humans.

VVS originates with activation of specific areas in the cerebral cortex. Indeed, stimulation of areas in the anterior cingulate gyrus can trigger a faint. Although the exact trigger is not known, VVS has been attributed to activation of the **Bezold-Jarisch reflex**. This reflex—originally described as the cardiorespiratory response to the intravenous injection of Veratrum alkaloids—causes bradycardia, hypotension, and apnea. In experimental animals, stimulation of arterial baroreceptors (see [p. 534](#)) or ventricular baroreceptors (see [p. 547](#)) by any of a host of chemicals—Veratrum alkaloids, nicotine, capsaicin, histamine, serotonin, and snake and insect venoms—can also trigger the Bezold-Jarisch reflex. In patients, coronary injection of contrast material or of thrombolytic agents can cause VVS, presumably by stimulating ventricular receptors. It is possible that these chemical stimuli activate the same stretch-sensitive TRPC channels of arterial baroreceptors (see [pp. 534–535](#)) that are usually activated by high blood pressure. In humans, triggers clearly distinct from those known to initiate a Bezold-Jarisch reflex can also elicit VVS. Whatever the actual trigger, vagal afferents carry signals to higher CNS centers, which act through autonomic nuclei in the medulla to cause a massive stimulation of the parasympathetic system and abolition of sympathetic tone.

VVS involves changes in several parameters ([Fig. 25-5](#)):

- 1. Total peripheral resistance.** A massive vasodilation results from the removal of sympathetic tone from the resistance vessels of the skeletal muscle, splanchnic, renal, and cerebral circulations. The resulting fall in blood pressure fails to activate a normal baroreceptor response.
- 2. Cardiac output.** Intense vagal output to the heart causes bradycardia and decreased stroke volume, resulting in a marked decrease in cardiac output. Because atropine, a muscarinic receptor blocker, does not reliably prevent syncope, decreased sympathetic tone to the heart may also play a role in causing bradycardia.
- 3. Arterial pressure.** The combination of a sudden decrease in both total peripheral resistance and cardiac output causes a profound fall in mean arterial pressure.
- 4. Cerebral blood flow.** The fall in mean arterial pressure causes global cerebral ischemia. If the decreased cerebral blood flow persists for only a few seconds, the result is dizziness or faintness. If it lasts for ~10 seconds, the subject loses consciousness. The stress underlying the common faint also may provoke hyperventilation, which lowers arterial P_{CO_2} (see [p. 680](#)). The resulting constriction of cerebral blood vessels (see [p. 559](#)) further impairs cerebral blood flow, which increases the likelihood of a faint.
- 5. Other manifestations of altered ANS activity.** Pallor of the skin and sweating (beads of perspiration) are signs that often appear before the loss of consciousness. Intense vagal stimulation of the gastrointestinal tract may cause epigastric pain that is interpreted as nausea. Mydriasis (pupillary dilation) as well as visual blurring can also result from parasympathetic stimulation.  **N25-5**

N25-5

Ocular Symptoms and Signs Associated with Fainting

Contributed by Emile Boulpaep

On pages 579–580, the text points out that fainting may be associated with mydriasis (dilation of the pupil) and blurred vision. In addition, fainting may also be associated with dimmed vision.

The **mydriasis** that may occur during the loss of consciousness is *not* the direct consequence of the strong parasympathetic stimulation that underlies the fainting episode. Stimulation of the autonomic (parasympathetic) portion of cranial nerve III (see pp. 338–339, Fig. 14-4) would lead to *contraction* of the sphincter muscle in the iris, and therefore would lead to **miosis** (pupillary constriction). How then does mydriasis arise? It is likely that the brain ischemia that leads to the altered mental status of the faint also causes a palsy of the preganglionic fibers that originate in the oculomotor (Edinger-Westphal) nucleus (see Fig. 14-5), resulting in a relaxation of the iris's sphincter muscle and therefore mydriasis. Note that the dilator muscle of the iris is innervated by postganglionic *sympathetic* fibers emanating from the superior cervical ganglion. Evidently, the brain hypoperfusion that triggers the faint has a lesser effect on the sympathetic system that causes dilation of the pupil.

Blurred vision before or after the loss of consciousness may be a direct consequence of strong parasympathetic stimulation. The ciliary zonule fibers are elastic elements that tend to stretch the lens of the eye in a radial direction and thus to flatten the lens. The ciliary muscle that encircles the lens is composed of smooth-muscle fibers that are arranged both radially and circularly. The main effect of contraction of the ciliary muscle is to relax the radial tension exerted by elastic zonule fibers, thereby allowing the lens to become more curved. A higher curvature of the front surface of the lens increases its focal power (see Equation 15-1). It is possible that very strong parasympathetic stimulation could cause blurring by the following sequence of events: Preganglionic fibers in the oculomotor (Edinger-Westphal) nucleus synapse in the ciliary ganglion on postganglionic parasympathetic fibers that innervate the smooth-muscle fibers of the ciliary muscle. Parasympathetic activation of this system would cause the lens to accommodate for objects very close to the eye. Therefore, the patient would experience blurred vision for any object further removed from the eye.

Dimming of vision may be part of the prodrome of fainting, presumably due to a loss of adequate retinal perfusion.

Fainting is more likely to occur in a warm room (see pp. 576–577), after a volume loss (e.g., dehydration or hemorrhage), or after standing up or other maneuvers that tend to lower mean arterial pressure. You might think that these stresses would trigger baroreceptor responses that increase cardiac output and vascular resistance, thereby making fainting less likely. However, the same integrated pattern of brain activity that orchestrates VVS also appears to suppress the expected baroreceptor reflexes that would otherwise counteract the syncope. 🟡N25-6

N25-6

Suppression of the Classical Baroreceptor Response in

Vagovagal Syncope

Contributed by Emile Boulpaep

In rare cases, certain chemicals can cause vasovagal syncope.

One hypothesis is that certain chemicals that stimulate TRPC channels of baroreceptors can activate the baroreceptors maximally, as if blood pressure had risen markedly. According to this view, vasovagal syncope is the appropriate response: decreased cardiac output and decreased peripheral resistance. Even though blood pressure falls, vessels collapse, and stretch on the walls of the blood vessels wanes, the baroreceptors would still behave as if they were maximally stimulated.

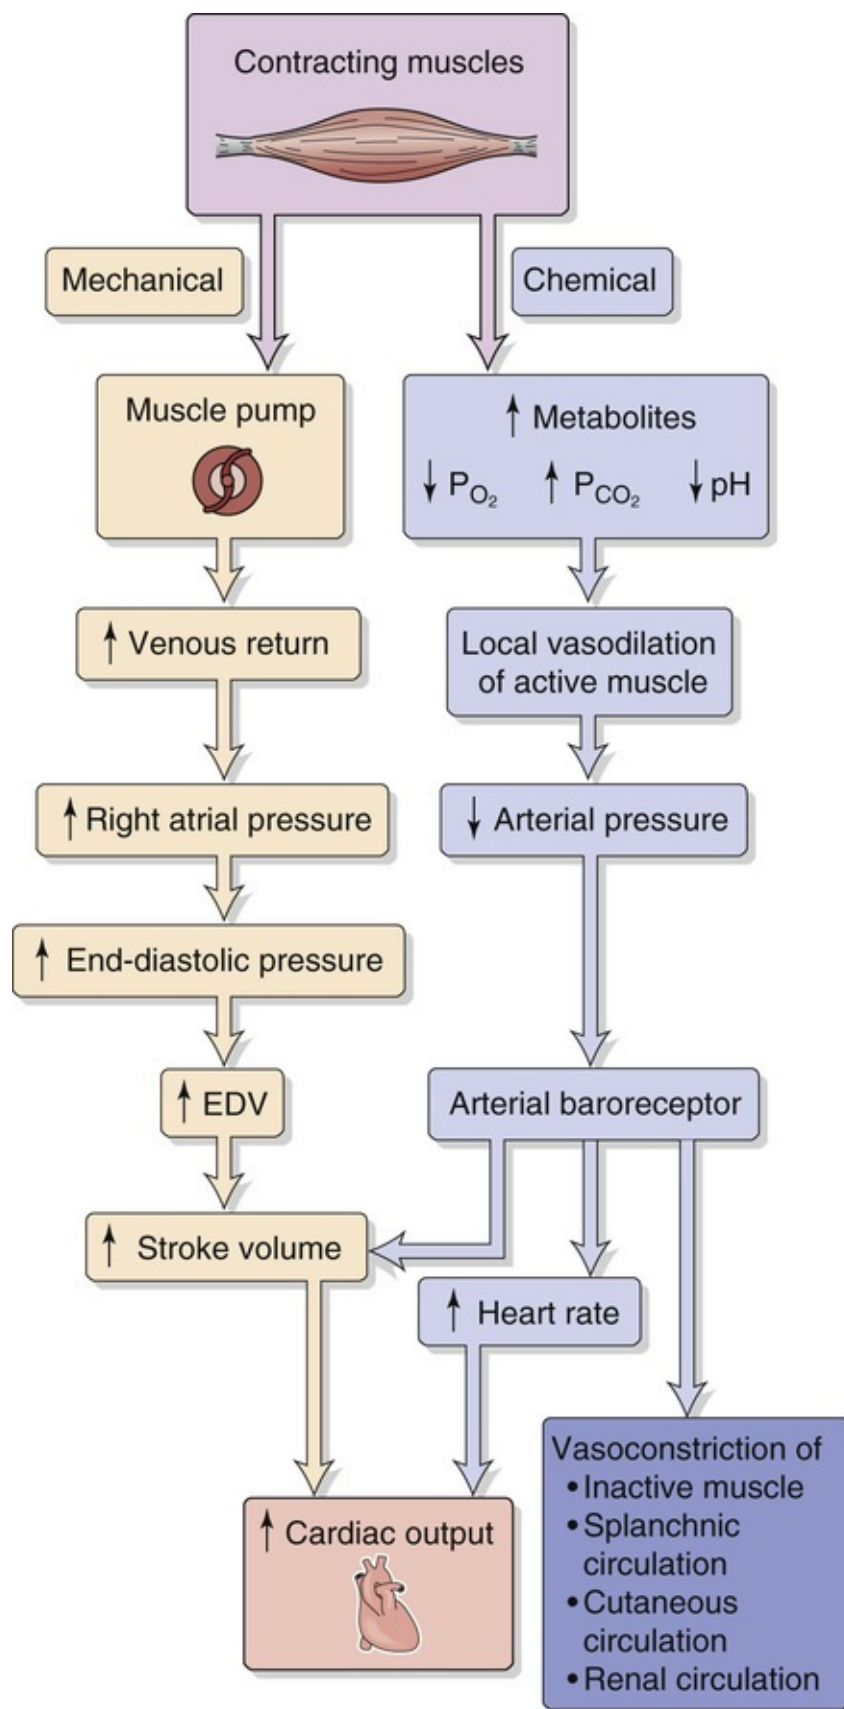

After regaining consciousness, the patient often notices oliguria (reduced urine output), caused by high plasma levels of AVP (also known as antidiuretic hormone; see [pp. 817–819](#)). Elevated levels of AVP can result in part from the reduced atrial stretch that occurs during periods of decreased venous return (see [pp. 546–547](#)). The pallor and nausea that persist after fainting may also result from the high levels of circulating AVP.

Response to Exercise

Adaptation to exercise probably places the greatest demands on circulatory function. The main feature of the cardiovascular response to exercise is an increased cardiac output, up to four or five times the resting cardiac output. The increase in cardiac output during exercise is more the result of increased heart rate (~ 3 times the control value) than of increased stroke volume (~ 1.5 times control). The cardiovascular response to exercise has both early and late components and originates from higher centers in the CNS (early), from mechanical and chemical changes triggered by contracting skeletal muscle (delayed), and from various reflexes (delayed).

Early physiologists suggested that muscle contraction leads to mechanical and chemical changes that trigger an increase in cardiac output

Contracting skeletal muscle produces cardiovascular changes that mimic many of those that occur during exercise. In fact, early physiologists believed that these skeletal muscle effects triggered *all* of the cardiovascular changes associated with exercise. We now know that these skeletal muscle effects are important only for the *delayed* cardiovascular responses in exercise. Muscle contraction directly affects the cardiovascular system in two ways ([Fig. 25-6](#))—through a mechanical response that increases venous return and through a chemical response that dilates blood vessels in active muscle.

Mechanical Response: Increased Venous Return

The pumping action of contracting skeletal muscle improves venous return (see pp. 516 and 565). As a result, RAP, ventricular end-diastolic pressure, and end-diastolic volume should all increase. According

to the Starling mechanism (see pp. 524–526), the result should be an increase in stroke volume.

Chemical Response: Local Vasodilation in Active Muscle

Enhanced skeletal muscle metabolism produces multiple changes in the chemistry of the interstitial fluid. The P_{O_2} and pH fall, whereas other metabolites (CO_2 , lactic acid, K^+ , and adenosine) accumulate. Moreover, the accumulation of metabolites causes interstitial osmolarity to increase. After a small delay that follows the onset of muscle contraction, the developing chemical changes cause the arterioles to dilate (see pp. 477–478 and 563–564), which may lead to an initial fall in arterial pressure. However, this fall is transient because of the intervening baroreceptor response (see p. 534), which increases heart rate and stroke volume, both of which enhance cardiac output. At the same time, the baroreceptor reflex vasoconstricts inactive muscle regions as well as the splanchnic, renal, and cutaneous circulations.

Cardiovascular physiologists believed for a long time that the mechanical and chemical limbs in Figure 25-6, both of which originate in active muscle, are responsible for the increased cardiac output during exercise. However, Figure 25-6 is not only incomplete, some of its predictions are incorrect or do not occur in the predicted order. As far as the *mechanical effect* on venous return is concerned, the model predicts a rise in ventricular end-diastolic pressure and thus end-diastolic volume. As far as the *chemical effect* is concerned, the model predicts that it should take time for chemical changes in active skeletal muscle to produce local vasodilation. Therefore, there ought to be a time lag between the initiation of exercise and the fall in mean arterial pressure that triggers the baroreceptor response (e.g., increased heart rate).

In the 1950s, Rushmer tested these predictions on trained unanesthetized dogs. Recording the *mechanical limb* of Figure 25-6, he found that at the onset of exercise, left ventricular end-diastolic pressure does *not* rise and that left ventricular end-diastolic volume diminishes rather than increases. These findings cast doubt on the primary role of the Starling mechanism in raising stroke volume during exercise. Recording the *chemical limb* of Figure 25-6, Rushmer found *no* transient fall in mean arterial pressure, thus casting doubt on the importance of the baroreceptor reflex. Furthermore, he saw *no* delay between the onset of exercise and the increase of heart rate, thus calling into question the idea that the chemically induced vasodilation is at the root of the tachycardia.

The explanation for the discrepancies between the predicted and actual findings is the presence of a central command that rapidly activates the sympathetic division of the ANS.

Central command organizes an integrated cardiovascular response to exercise

During exercise, a **central command** controls the parallel activation of both the motor cortex (see pp. 402–403) and cardiovascular centers. The central command involves such brain areas as the **medial prefrontal cortex** (involved in the mental state of thinking and planning exercise) as well as the insula and anterior cingulate gyrus, which are **cortical parts of the limbic system** (see p. 349). Indeed, the medial prefrontal cortex receives multiple limbic inputs. Moreover, both cortical centers modulate stress-related sympathetic outflow, including the sympathetic outflow related to exercise.  N25-7 Rushmer and his colleagues explored various sites in the diencephalon (see p. 270) of dogs to determine if stimulation of any of them might mimic the integrated sympathetic response to exercise. In the 1950s, Rushmer found that stimulation of the H_2 fields of Forel in the ventral thalamus or neurons in the periventricular gray matter of the hypothalamus reproduced all the details of the cardiac response to exercise, even though the

muscles of the dog were completely quiescent. The central command centers project to the lateral hypothalamus, rostral ventrolateral medulla, and NTS to make autonomic adaptations appropriate for exercise ([Fig. 25-7](#)):

FIGURE 25-7 Integrated cardiovascular response to exercise. The hypothalamus orchestrates an *early* response, which includes vasodilation of active muscle (the mechanism of which is controversial in humans), vasoconstriction of certain inactive tissues, and increased cardiac output. In addition to those responses shown in Figure 25-6, the *delayed* responses (*highlighted in yellow*) include release of histamine, kallikreins, and epinephrine, leading to delayed vasodilation. Delayed local chemical responses from contracting muscles sustain early cardiovascular responses. Cutaneous thermoreceptors trigger

N25-7

Central Commands for Exercise Originating Outside the Medulla

Contributed by Emile Boulpaep

An increase in sympathetic output from the medullary cardiovascular center, by itself, would explain the immediate *ventricular response* during exercise. Increased sympathetic output from medullary centers would also explain the immediate vasoconstriction in inactive muscles and in the splanchnic, renal, and cutaneous circulations. However, sympathetic signals originating in the medulla *cannot* account for yet another immediate exercise response that occurs in dogs (though not humans and other primates)—a rapid vasodilation that occurs only in *active* skeletal muscle. On the contrary, experimental stimulation of medullary centers would constrict *all* muscle beds.

- 1. Increased cardiac output.** Increased sympathetic output to the heart causes early tachycardia and increased contractility, resulting in a rapid upsurge of cardiac output.
- 2. Vasoconstriction.** Sympathetic output from the medulla causes vasoconstriction in inactive muscle regions as well as in the renal, splanchnic, and cutaneous circulations. The net effect is to make more blood available for diversion to the contracting muscles. Except during maximal exercise, the increase in splanchnic and renal resistance does not result in a fall in local blood flow to the abdominal viscera and kidneys. Rather, because the arterial pressure increases along with the renal and splanchnic vascular resistance, the *absolute* blood flow remains close to resting levels in these tissues, even as the flow to the skeletal muscle increases markedly. However, *fractional* blood flow (i.e., local blood flow normalized to cardiac output) does fall in these regions. In the early phase of exercise, skin blood flow also decreases. However, cutaneous blood flow eventually rises, which reflects the attempt of the temperature-regulatory system to prevent body temperature from rising too much (see [pp. 1200–1201](#)).
- 3. Early vasodilation in active muscle.** In dogs—although not in humans or other primates—at the initiation of exercise, central command stimulates hypothalamic neurons whose axons bypass the medullary cardiovascular centers and synapse on preganglionic sympathetic neurons in the spinal cord (see [p. 539](#)). The postganglionic neurons synapse on cholinergic sympathetic vasodilator fibers that innervate the vascular smooth muscle of skeletal muscle and trigger early peripheral vasodilation in active skeletal muscle. As discussed in the next section, the delayed local “chemical” response later reinforces this vasodilation.

The increased alertness that accompanies the anticipation of exercise can elicit all the components of the early response to exercise. The early response resembles the fight-or-flight reaction. In humans, the anticipatory cardiovascular adjustments prepare the body for the increased metabolism of the exercising skeletal muscle. For sprinters at the start of a 100-m dash, the anticipatory response prepares them to deliver an increased cardiac output and simultaneously to divert the increased blood flow away from tissues that do not require increased blood flow.

Muscle and baroreceptor reflexes, metabolites, venous return, histamine, epinephrine, and increased temperature reinforce the response to exercise

In addition to the events orchestrated by the command center, the integrated cardiovascular response to exercise includes the following:

- 1. Exercise pressor reflex.** A neural drive called the exercise pressure reflex originates within the exercising muscle itself. Contraction activates stretch receptors that sense muscle tension and may also activate chemoreceptors that sense metabolites. Signals from these receptors travel through small thinly myelinated ($A\delta$ or group III in [Table 12-1](#)) and unmyelinated (C or group IV) sensory fibers from skeletal muscle to the spinal cord and then on to the medullary cardiovascular control centers. This sensory input reinforces the central input to the cardiovascular control center and thus sustains the sympathetic outflow.
- 2. Arterial baroreflexes.** Elevated mean arterial pressure resulting from high cardiac output and vasoconstriction outside active muscle would normally slow the heart. However, during exercise, central command resets the sensitivity of the **arterial baroreflex** so that the heart slows only at much higher arterial pressures. Conversely, if massive vasodilation in exercising skeletal muscle would reduce total peripheral resistance, the baroreceptor reflex maintains mean arterial pressure.
- 3. Vasodilation triggered by metabolites in skeletal muscle.** *Metabolites* released locally (see [Fig. 25-7](#)) dilate the resistance vessels and recruit capillaries that had received no blood flow at rest (see [pp. 563–564](#)). As a result of this decrease in resistance, in concert with the increase in cardiac output, blood flow to active skeletal muscle can be as much as 20 times that to resting skeletal muscle. This vasodilator effect of metabolites thus more than overcomes any vasoconstrictive tendency produced by norepinephrine.
- 4. Increased venous return.** The central command discussed in the preceding section explains the early increase in cardiac output during exercise. The mechanical and the chemical limbs described in [Figure 25-6](#) further sustain the high cardiac output. Mechanically, the **muscle pump** increases venous return, and stroke volume rises by the **Starling mechanism**. Chemical mediators cause a vasodilation of active muscle beds that results in the rapid mobilization of blood from the central blood volume to exercising muscle.
- 5. Histamine release.** Cells near the arterioles may release their intracellular stores of histamine, a potent vasodilator (see [Table 20-8](#)). Although these histamine-containing cells are quiescent when sympathetic nerves release *norepinephrine*, they release histamine when sympathetic tone wanes. Because of relaxation of the arterioles and precapillary sphincters, the pressure in the muscle capillaries rises, leading to increased extravasation of fluid and enhanced lymph flow.
- 6. Epinephrine release.** During severe exercise, preganglionic sympathetic fibers to the adrenal medulla stimulate epinephrine release. The systemic effects of circulating epinephrine on cardiac β_1 adrenoceptors enhance the neural effects on the heart, thus increasing cardiac output. Circulating epinephrine also acts on vascular β_2 adrenoceptors, augmenting vasodilation mainly in skeletal muscle and heart.

7. Regulation of body core temperature. As exercise continues, increased metabolism causes body core temperature to rise, activating **temperature-sensitive cells** in the hypothalamus (see [p. 1199](#)). This activation has two effects, both of which promote heat loss through the skin as part of a temperature-regulatory response (see [p. 1200](#)). First, the hypothalamus signals the medulla to inhibit its sympathetic vasoconstrictor outflow to the skin, thereby increasing cutaneous blood flow. Recall that vasoconstriction is part of the early response to exercise (see above). Second, the hypothalamus activates sympathetic cholinergic fibers to sweat glands, causing an increase in sweat production as well as an indirect cutaneous vasodilation that may involve kinin formation. In addition, these neurons may co-release neurotransmitters that directly dilate cutaneous vessels (see [p. 571](#)).

Response to Hemorrhage

If a person rapidly loses <10% or 20% of total blood volume from a large *vein*, the inadequate intravascular volume causes sequential decreases in central blood volume, venous return, ventricular filling, stroke volume, cardiac output, and thus mean arterial pressure. However, if the blood loss comes from a large peripheral *artery*, the mean arterial pressure in central arteries does not fall until cardiac output falls secondary to decreased venous return. Of course, if the blood loss occurs from a blown aortic aneurysm, mean arterial pressure falls immediately.

Large hemorrhages, in which one loses 30% or more of total blood volume, produce **hypovolemic shock**. Shock is a state of peripheral circulatory failure that is characterized by inadequate perfusion of the peripheral tissues. During shock, the *systolic* arterial pressure is usually <90 mm Hg, and the *mean* arterial pressure is <70 mm Hg. For reasons that will become clear, by the time one records a significant fall in mean arterial pressure, other signs of shock are evident. The first signs may be narrowing of the pulse pressure and a sensation of faintness when sitting or standing. The subject in hypovolemic shock has cold and moist (i.e., “clammy”) skin as well as a rapid and weak pulse. Moreover, urine output drops to <25 mL/hr, even if fluid intake had been normal.

After its abrupt initial fall, arterial pressure tends to return to normal (Fig. 25-8, red curve), although blood pressure falls irreversibly (blue dashed curve) in some cases. Under favorable circumstances, the body restores blood pressure toward normal values by mobilizing two lines of defense. First, circulatory control mechanisms act on the heart and blood vessels to restore cardiac output and to increase peripheral resistance. Second, mechanisms of capillary exchange and fluid conservation restore the intravascular volume.

FIGURE 25-8 Changes in blood pressure with hemorrhage. At time zero, the investigator removes enough blood from the experimental animal to lower mean arterial pressure to 45 mm Hg.

After hemorrhage, cardiovascular reflexes restore mean

arterial pressure

Several cardiovascular reflexes cooperate to compensate for the fall in mean arterial pressure. These reflexes originate from four major groups of receptors (numbered 1 to 4 in [Fig. 25-9](#)):

- 1. High-pressure baroreceptors.** The fall in arterial pressure leads to a decrease in the firing rate of afferents from the carotid and aortic baroreceptors (see [p. 534](#)). The resulting enhanced sympathetic output and diminished vagal output increase heart rate and cardiac contractility and also produce venoconstriction and selective arteriolar constriction. These responses cooperate to re-establish the arterial pressure.
- 2. Low-pressure baroreceptors.** Reduced blood volume directly decreases effective circulating volume, which in turn lessens the activity of low-pressure stretch receptors (see [p. 547](#)). The resulting increased sympathetic outflow causes vasoconstriction in a number of vascular beds, particularly the kidney, reducing glomerular filtration rate and urine output. In response to decreased stretch, low-pressure receptors at various sites in the circulation ultimately have divergent effects on heart rate. The atrial stretch receptors also instruct the hypothalamus to enhance release of AVP, which reduces renal water excretion (see [pp. 817–818](#)). During shock, the vasoconstrictor effects of AVP appear to be important for maintaining peripheral vascular resistance. Reduced atrial stretch also lowers the level of circulating atrial natriuretic peptide (ANP; see [p. 547](#)), thereby reducing salt and water loss by the kidneys (see [p. 843](#)).
- 3. Peripheral chemoreceptors.** As blood pressure drops, perfusion of the carotid and aortic bodies declines, causing local hypoxia near the glomus cells and an increase in the firing rate of the chemoreceptor afferents (see [pp. 710–712](#)), a response enhanced by increased sympathetic tone to the peripheral chemoreceptor vessels (see [pp. 711–712](#)). Increased *chemoreceptor* discharge leads to increased firing of the sympathetic vasoconstrictor fibers and ventilatory changes that indirectly increase heart rate (see [p. 544](#)).
- 4. Central chemoreceptors.** Severe hypotension results in brain ischemia, which leads to a fall in the P_{O_2} of brain ECF as well as a rise in P_{CO_2} and a fall in pH. The acidosis has a profound effect on the central chemoreceptors in the medulla (see [p. 713](#), leading to a sympathetic output (see [p. 546](#)) several-fold more powerful than that caused by baroreceptor reflexes (see [p. 546](#)).

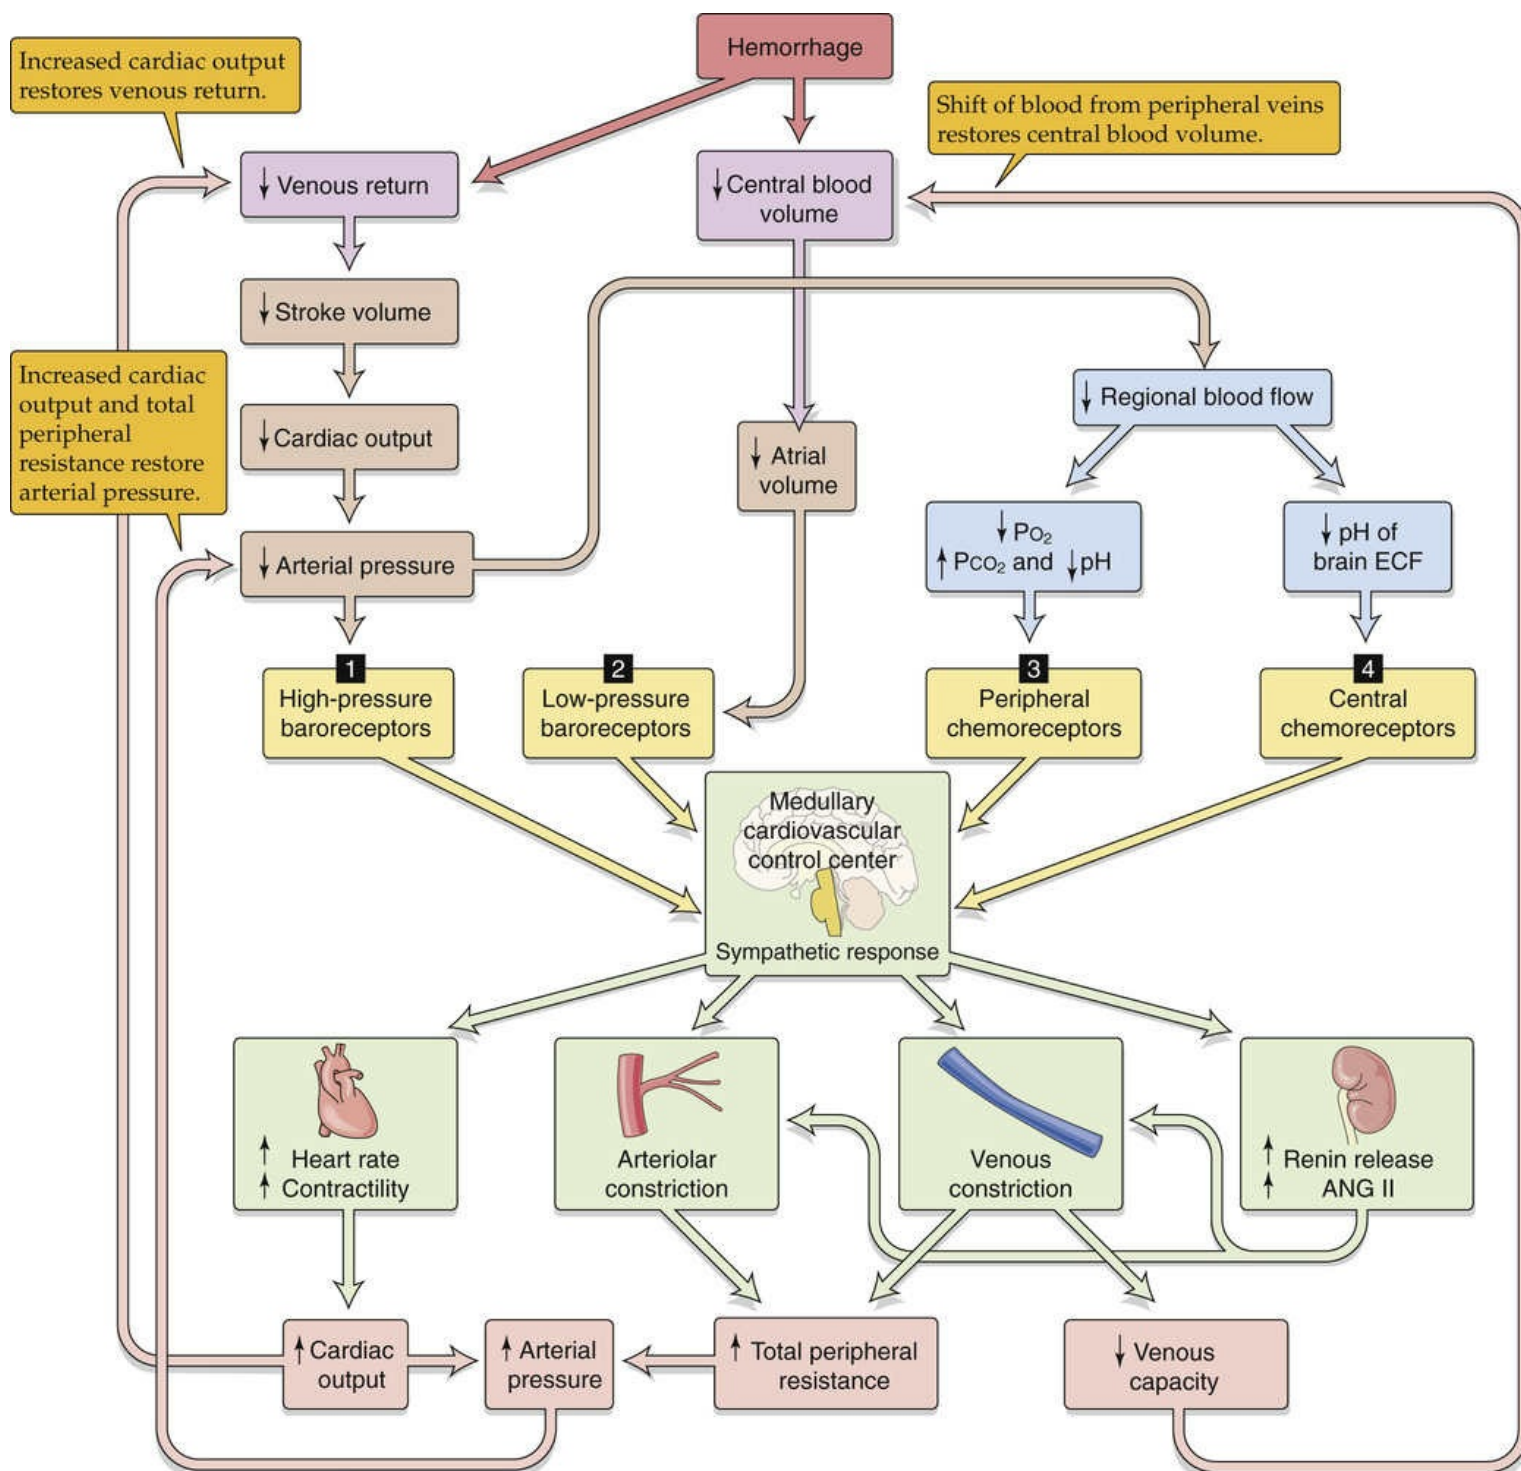

FIGURE 25-9 Integrated response to hemorrhage. Blood loss triggers four kinds of receptors (numbered 1 to 4) to produce an integrated response orchestrated by the medulla.

These four reflex pathways have in common the activation of a massive sympathetic response that results in the release of norepinephrine from postganglionic sympathetic neurons. In addition, the sympathetic response triggers the **adrenal medulla** to release epinephrine and norepinephrine roughly in proportion to the severity of the hemorrhage. Lowering of the mean arterial pressure to 40 mm Hg causes circulating levels of epinephrine to rise 50-fold and those of norepinephrine, 10-fold. The consequences of the four combined reflex actions are the following responses (see Fig. 25-9).

Tachycardia and Increased Contractility

Increased sympathetic activity increases heart rate roughly in proportion to the volume of shed blood. Thus, the degree of tachycardia is an index of the severity of the hemorrhage. Increased sympathetic tone

increases myocardial contractility but can increase stroke volume only after venous return also improves.

Arteriolar Constriction

Sympathetic constriction of the resistance vessels is most pronounced in the blood vessels of the *extremities, skin, skeletal muscle, and abdominal viscera*. Although both precapillary and postcapillary resistance vessels constrict, the *precapillary* response initially dominates. As a result, capillary pressure falls precipitously, leading to the transcapillary refill discussed in the next section. *Renal* blood flow falls rapidly after hemorrhage as a result of the fall in blood pressure but recovers after a few minutes because of autoregulation (see [p. 750](#)). The responses of both high- and low-pressure stretch receptors lead to enhanced sympathetic vasoconstrictor traffic to the kidney. Although renal blood flow has a high threshold for this sympathetic traffic, the sympathetic vasoconstriction eventually overrides renal autoregulation if arterial pressure remains low or continues to fall. In hypovolemic shock, renal blood flow falls to a proportionately greater extent than does cardiac output, which explains why severe hemorrhage often results in acute renal failure. Blood flow in the medulla of the kidney is less compromised than in the cortex, leading to “medullary washout” of the hypertonic interstitial fluid in the renal medulla (see [pp. 813–815](#)) and an inability to produce a concentrated urine. Both *coronary blood flow and cerebral blood flow* initially fall after hemorrhage, but autoregulation can largely restore blood flow to normal.

Venous Constriction

The fall in blood volume with hemorrhage occurs primarily in the large-capacitance vessels, especially those that contain the central blood volume. These vessels are very sensitive to sympathetic stimulation (which causes constriction) and less so to local metabolites (which causes dilation). The sympathetic venous constriction decreases both the *capacity* and the compliance of the large veins, thereby tending to restore central venous pressure. In addition, sympathetic venous constriction increases **postcapillary resistance**, which is important for transcapillary refill (see below).

Circulating Vasoactive Agonists

As already discussed, sympathetic stimulation of the adrenal medulla causes circulating epinephrine levels to rise (see [p. 585](#)). In addition, sympathetic stimulation of the granular cells in the juxtaglomerular apparatus of the kidney leads to an increased release of renin and, ultimately, increased plasma levels of angiotensin II (ANG II) (see [p. 553](#)). In hemorrhagic shock, ANG II rises to concentrations that are vasoconstrictive. Activation of the sympathetic system also triggers sympathetic cholinergic stimulation of the sweat glands (see [p. 571](#)), causing the patient's extremities to become clammy.

With moderate blood losses (10% to 20%), these four responses can increase total peripheral resistance sufficiently to keep arterial pressure at about normal levels. However, cardiac output remains depressed.

After hemorrhage, transcapillary refill, fluid conservation, and thirst restore the blood volume

The reflexes discussed in the preceding section compensate for the principal *consequences* of blood loss—decreased blood pressure and reduced cardiac output. The responses discussed here compensate for the *primary disturbance*, the loss of blood volume.

Transcapillary Refill

The movement of fluid from the interstitium to the blood plasma is the major defense against reduced blood volume. Starling forces (see pp. 467–468) are critically important during hemorrhage and hypovolemic shock. Immediately after hemorrhage, a phase of **hemodilution** develops, as was first observed during World War I, when medics noted that injured soldiers arrived at the first-aid station with diluted blood (i.e., low hematocrit). Within an hour, interstitial fluid replaces ~75% of the shed blood volume. Studies performed around World War II showed that the dilution of **hemoglobin** is more pronounced than the dilution of **plasma proteins** after hemorrhage. Therefore, not only do fluid and electrolytes move from the interstitium to the blood, but proteins also enter the vascular compartment.

Transcapillary refill involves two steps. The first is **fluid movement** from the interstitium to the vasculature. Capillary hydrostatic pressure (P_c) (Fig. 25-10A) depends on arteriolar and venular pressures as well as on the relation of the precapillary to the postcapillary resistance (see pp. 451–452). Immediately after the hemorrhage, the upstream arteriolar pressure and the downstream venular pressure both fall, causing P_c to fall (see Fig. 25-10B). The Starling forces thus produce a large net movement of fluid and small electrolytes from the interstitium into the capillaries. As compensation occurs, total peripheral resistance increases, in part restoring arteriolar pressure (see Fig. 25-10C). However, because precapillary resistance increases more than does postcapillary resistance, P_c remains relatively low, sustaining the net movement of fluid into the capillaries. Normally, little protein would enter with the fluid because nonfenestrated capillary walls reflect proteins very effectively (see p. 468). The entry of protein-free fluid into the capillary gradually modifies the three other Starling forces. First, the interstitial fluid volume decreases, lowering interstitial hydrostatic pressure (P_{if}). Second, the plasma proteins become diluted, so that capillary colloid osmotic pressure (π_c) falls. Finally, the removal of a protein-free solution from the interstitium raises colloid osmotic pressure in the bulk interstitium (π_{if}) and in the subglycocalyx fluid (π_{sg} ; see pp. 471–472). The result of these dissipating Starling forces is that transcapillary refill gradually wanes and eventually ceases.

A NORMAL

B UNCOMPENSATED HEMORRHAGE

C COMPENSATED HEMORRHAGE

D DECOMPENSATED HEMORRHAGE

FIGURE 25-10 Effect of hemorrhage on capillary hydrostatic pressure. **A**, In this figure (which is similar to Fig. 19-4A), R_{pre} and R_{post} are the precapillary and postcapillary resistances, respectively. Here, the ratio $R_{post}/R_{pre} = 0.35$. **B**, The fall in capillary hydrostatic pressure reverses the Starling forces, causing net movement of fluid from the interstitium to the capillary lumen. **C**, Sympathetic stimulation increases total peripheral resistance ($R_{post}/R_{pre} = 0.25$ in this example). **D**, Capillary pressure rises ($R_{post}/R_{pre} = 0.45$ in this example).

The second step in transcapillary refill is the appearance of **plasma proteins** in the blood. These

proteins probably enter the blood across fenestrae of the mesenteric and hepatic capillaries, two regions in which the interstitium has a very high interstitial colloid osmotic pressure. In addition, hemorrhage rapidly stimulates albumin synthesis by the liver. Plasmapheresis, the artificial removal of plasma proteins from the blood, has the same effect on albumin synthesis, suggesting that a reduction in the concentration of plasma proteins per se stimulates the liver to make albumin.

Water from the **intracellular** compartments ultimately replaces the lost **interstitial** fluid. What the driving force is for water to leave the cells and to enter the interstitium is somewhat controversial. The blood osmolality often rises after hemorrhage, which presumably reflects interstitial hyperosmolality. The additional interstitial osmoles come from ischemic tissues that release the products of proteolysis, glycolysis, and lipolysis. Therefore, interstitial hyperosmolality may provide the **osmotic** drive for the movement of water from the intracellular to the interstitial compartment.

Renal Conservation of Salt and Water

Arterial hypotension and lowered renal blood flow reduce the glomerular filtration rate (see [p. 739](#)) and therefore diminish the urinary excretion of salt and water. In addition to the direct hemodynamic effects, the reduced effective circulating volume promotes the renal retention of Na^+ by four mechanisms, which are discussed more fully in [Chapter 40](#). First, reduced effective circulating volume activates the renin-angiotensin cascade (see [pp. 841–842](#)), increasing aldosterone release and thus enhancing salt and water reabsorption by the distal nephron. Second, increased sympathetic nerve activity (see [p. 842](#)) promotes Na^+ retention by altering renal hemodynamics, enhancing renin release, and stimulating Na^+ reabsorption by renal tubule cells. Third, the release of AVP reduces water excretion (see [p. 843](#)). Finally, reduced effective circulating volume inhibits release of ANP (see [p. 843](#)) and thus promotes renal Na^+ retention. Therefore, the overall response of the kidney to blood loss is to reduce the excretion of water and salt, thereby contributing to the conservation of ECF. However, the renal response only *conserves* fluid; by itself, it does not *add* any water to the ECF.

Thirst

The blood hyperosmolality caused by hemorrhage (discussed two paragraphs above) stimulates thirst osmoreceptors (see [pp. 845–846](#)). A far more potent stimulus for thirst (see [p. 849](#))—as well as salt appetite—is the reduced effective circulating volume and blood pressure caused by severe hemorrhage. These urges, if fulfilled, actually provide some of the raw materials for replacement of the blood lost in hemorrhage.

Positive-feedback mechanisms cause irreversible hemorrhagic shock

In some cases, hemorrhagic shock can be irreversible. After an initial fall in arterial pressure and perhaps some recovery, arterial pressure and the perfusion of peripheral tissues may inexorably deteriorate (see [Fig. 25-8](#), blue dashed curve). Moreover, in these cases, the fall in arterial pressure does not reverse even if the physician intervenes at this time and replaces the volume of blood lost as the result of hemorrhage.

The best experimental model for irreversible hemorrhagic shock is **prolonged hypotension**. Typically, the researcher acutely removes blood from an experimental animal—thereby reducing blood pressure to some low target value—and then *clamps* the mean arterial pressure at this low target by either removing or infusing blood as the normal physiological responses evolve. Studies of this kind reveal that

hemorrhagic shock can become irreversible as a result of the failure of multiple response components: (1) the vasoconstrictor response, (2) the capillary refill response, (3) the cardiac response, and (4) the CNS response.

Failure of the Vasoconstrictor Response

With prolonged hemorrhagic hypotension, the total peripheral resistance—which first increases in response to sympathetic stimulation—tends to return to prehemorrhage levels. This failure to maintain vasoconstriction has several origins. First, desensitization of the vascular adrenoceptors or depletion of neurotransmitters in the nerve terminals close to the blood vessels may cause “sympathetic escape.” Second, the ischemic tissues release metabolites and other vasodilator compounds that act on local blood vessels, thereby counteracting the vasoconstricting stimuli. In the late phases of irreversible shock, humans may become completely unresponsive to a range of vasoconstrictor drugs. Third, plasma AVP levels may have fallen substantially from the peak value during the early phase of hemorrhage—which perhaps reflects a decreased ability of the low-pressure baroreceptor reflex to trigger hypothalamic neurons to release AVP or a depletion of AVP stores. Under these conditions, restoration of AVP levels to their initial peak can markedly increase blood pressure.

Failure of the Capillary Refill

Some blood vessels are able to sustain the initial increase in resistance better than others are. Over time, precapillary sphincters fail first, followed by the precapillary resistance vessels (i.e., arterioles), the postcapillary resistance vessels, and the capacitance vessels. [Figure 25-10D](#) shows an example in which, after prolonged hypotension, the precapillary constrictor response has fully faded, whereas the postcapillary response is partially maintained. Because the ratio $R_{\text{post}}/R_{\text{pre}}$ has risen, the midcapillary pressure (see [pp. 451–452](#)) increases from 16 mm Hg (see [Fig. 25-10C](#)) to 21 mm Hg (see [Fig. 25-10D](#)). You will recall that early during hemorrhage, the net Starling forces reverse, favoring the movement of fluid from the interstitium to the blood. The gradual increase of $R_{\text{post}}/R_{\text{pre}}$ (see [Fig. 25-10D](#)) reverses this reversal, so that fluid once again leaves the capillary, even though the blood volume has not yet been restored. Thus, after the initial large influx of water and electrolytes into the capillary lumen, not only does transcapillary refill decline, but a net loss occurs. This phenomenon contributes to the hemoconcentration that occasionally occurs in prolonged hemorrhagic states.

Failure of the Heart

Several factors may contribute to the weakening of the heart. Acidosis reduces $[\text{Ca}^{2+}]_i$ in the myocardium and thus reduces contractility. In severe cases, subendocardial hemorrhage and necrosis of the heart muscle render the myocardium nonfunctional. Various organs may also release cardiotoxic shock factors, which exert a negative inotropic effect on the heart (see [pp. 530–532](#)). Ultimately hypovolemic shock converts to cardiogenic shock.

CNS Depression

Moderate ischemia, by its effects on the central chemoreceptors, stimulates the cardiovascular control centers in the brain (see [p. 585](#)). However, prolonged cerebral ischemia depresses neural activity throughout the brain, thereby weakening the sympathetic output and in turn causing a decay in both vascular and cardiac responses. A progressive fall in the circulating levels of catecholamines of adrenal

origin further worsens the outcome.

Comparative Physiology of Respiration

External respiration is the exchange of O_2 and CO_2 between the atmosphere and the mitochondria

For millennia, people have regarded breathing as being synonymous with life. Life begins and ends with breathing. The Bible states that God “breathed into [Adam's] nostrils the breath of life” and then later used part of Adam's ventilatory apparatus—a rib—to give life to Eve.

In the fourth and fifth centuries BC, writings attributed to Hippocrates suggested that the primary purpose of breathing is to cool the heart. It was not until the 18th century that the true role of breathing began to emerge as several investigators studied the chemistry of gases. Chemists had recognized similarities between combustion and breathing but thought that both involved the release of a “fire-essence” called phlogiston. According to their theory, neither combustion nor life could be supported once air became saturated with phlogiston.

In the 1750s, Joseph Black [N26-1](#) found that heating calcium carbonate produces a gas he called “fixed air,” now known to be **carbon dioxide (CO_2)**. He also found that animal respiration produces this gas. Shortly thereafter, Henry Cavendish [N26-2](#) found that fermentation and putrefaction also produce fixed air. The early 1770s saw the codiscovery of **oxygen (O_2)** by Carl Scheele [N26-3](#) (who called it “fire air”) and Joseph Priestley [N26-4](#) (who called it “dephlogistonated air”). In 1785, Henry Cavendish [N26-2](#) found that dephlogistonated air represents ~20% of atmospheric air. Priestley found that combustion, putrefaction, and breathing all *consume* dephlogistonated air, and all reduce the volume of room air by ~20%. Conversely, he found that green plants *produce* dephlogistonated air, which he quantitated by reacting it with nitric oxide (a colorless gas) to produce nitrogen dioxide (a red gas).

Joseph Black (1728–1799)

Contributed by Walter Boron

Joseph Black, a Scottish physician and chemist, made three landmark discoveries. He discovered the concepts of **latent heat** and **specific heat**. Most important for respiratory physiology, he also discovered **carbon dioxide (CO_2)**, which he called “fixed air.” In the critical experiments, Black found that either heating or adding acid to calcium carbonate ($CaCO_3$) produced fixed air. This work revolutionized chemistry by showing that other gases exist besides ordinary “air” and that a chemical reaction can involve a gas.

Black also demonstrated the reverse: bubbling fixed air through a solution containing calcium hydroxide caused the precipitation of $CaCO_3$. Black used this assay to demonstrate that animal respiration produces fixed air.

N26-2

Henry Cavendish (1731–1810)

Contributed by Walter Boron

Henry Cavendish is known for recognizing that **hydrogen gas** (H_2 , or as he called it, “inflammable air”) is made up of an element. Along with James Watt and Antoine Lavoisier, Cavendish found that inflammable air reacts with oxygen (“dephlogistonated air”) to produce water (Lavoisier did similar work). Cavendish interpreted these data in terms of phlogiston; it was Lavoisier who made the modern interpretation and gave hydrogen its name. Cavendish—along with Joseph Priestly,  N26-4 Joseph Black,  N26-1 and others—is sometimes regarded as a pneumatic chemist.

Cavendish was not only brilliant but also extraordinarily shy. He made many discoveries that were never published but nevertheless predated the discoveries credited to others (Charles's and Dalton's laws dealing with gases and Ohm's and Coulomb's laws dealing with electricity). N26-3

Carl Wilhelm Scheele (1742–1786)

Contributed by Walter Boron

Carl Scheele was a Swedish pharmacist and chemist who made several important discoveries in the early history of chemistry. Unfortunately, many of his key discoveries were published after those of his competitors. He died at an early age, apparently from the toxic effects of the chemicals that he studied.

Scheele obtained what he called “fire air” in 1771, first from manganese dioxide (MnO_2) and then from HgO and other oxygen-containing compounds. Priestley obtained “dephlogistonated air” from HgO in 1774.

N26-4

Joseph Priestley (1733–1804)

Contributed by Walter Boron

Joseph Priestley was a theologian, philosopher, and chemist who—along with Carl Wilhelm Scheele—is generally credited with the discovery of **oxygen** (O_2), which he called “dephlogistonated air.” In his key experiment, which dates from 1774, Priestley focused the sun's rays on mercuric oxide (HgO), producing dephlogistonated air. Moreover, Priestley showed that dephlogistonated air was 5- to 6-fold more

effective at supporting breathing or combustion than “common atmospherical air.”

Carl Wilhelm Scheele N26-3 discovered a gas that he called “fire air” (O_2), probably in 1771 (i.e., 3 years before Priestley). However, Scheele's work was not published until 1777. Scheele obtained fire air first from manganese dioxide (MnO_2) and then from HgO and other oxygen-containing compounds.

Priestley was a staunch supporter of the phlogiston theory; it was Antoine Lavoisier N26-5 who put the observations of Priestley on sound theoretical grounds.

Priestley's political views (e.g., supporting the American and French Revolutions) and religious views (e.g., supporting religious dissent and contributing to the founding of the Unitarian Church) forced him to flee to America, although not before his home was burned by rioters. He spent the last 10 years of his life in rural Pennsylvania, never having putting aside the phlogiston theory.

For more information about Priestley, visit the following websites:

1. http://en.wikipedia.org/wiki/Joseph_Priestley.
2. <http://www.historyguide.org/intellect/priestley.html>.
3. <http://www.chemheritage.org/discover/online-resources/chemistry-in-history/themes/early-chemistry-and-gases/priestley.aspx>.

In the mid-1770s, Priestley presented his findings to Antoine Lavoisier N26-5—often regarded as the father of modern chemistry. Lavoisier quickly put Priestley's empirical observations into a theoretical framework that he used to demolish the phlogiston theory, which Priestley held to his death. Lavoisier recognized that dephlogistonated air, which he named “oxygen,” represents the ~20% of room air consumed by combustion in Priestley's experiments, leaving behind “nonvital” air, or **nitrogen** (N_2). Furthermore, he proposed that O_2 is consumed because it reacts with one substance to produce another. The mathematician Joseph-Louis Lagrange N26-6 suggested that O_2 consumption and CO_2 production occur not in the lungs but in isolated tissues, as Lazzaro Spallanzani later rigorously demonstrated in the late 18th century. N26-7

N26-5

Antoine Lavoisier (1743–1794)

Contributed by Walter Boron

Antoine-Laurent de Lavoisier—known simply as Antoine Lavoisier after the French Revolution—was a French nobleman who is sometimes regarded as the father of modern chemistry. He did not make any discoveries of chemicals to which others could not also lay claim (e.g., hydrogen gas in the case of Cavendish N26-2), nor develop any highly novel experimental apparatus. Rather, his contributions were mainly theoretical, supported by quantitative experiments that extended the work of others (e.g., Black, Scheele, Priestley, Cavendish) and put their work in a sound theoretical framework.

In his 1789 treatise on chemistry—regarded by some as the first modern textbook of chemistry—Lavoisier presented a unifying theory that elucidated the concept of a chemical **element** and how these can form chemical **compounds**. He pioneered the concepts of stoichiometry and the conservation of mass, and argued strongly against the phlogiston theory. As is sometimes the case in science, a number of the major proponents of the phlogiston theory were unmoved; however, the next generation of chemists found

Lavoisier's arguments convincing and the phlogiston theory was abandoned.

The chemistry of the respiratory gases played a central role in Lavoisier's thinking. He recognized that both combustion and breathing involve the consumption of O_2 and production of CO_2 .

Lavoisier defended Lagrange and other foreign-born scientists whose rights were being abridged by the government. During the Reign of Terror, Lavoisier was summarily tried, convicted, and executed on May 8, 1794. For more information about Antoine Lavoisier, visit the following websites:

N26-6

Joseph-Louis Lagrange (1736–1813)

Contributed by Walter Boron

Giuseppe Lodovico Lagrangia—an astronomer and one of the greatest mathematicians of his time—was born in Turin, moved to Berlin in 1766, and then moved to Paris in 1786. He survived the French Revolution and died in France.

Lagrange's contribution to biology—specifically to respiratory physiology—is a conclusion that he based entirely on theory: he concluded that respiration (i.e., combustion) within the body could not take place entirely within the lungs because this would be inconsistent with the even distribution of heat throughout the body.

Lazzaro Spallanzani (1729–1799)

Contributed by Walter Boron

Lazzaro Spallanzani was an ordained Catholic priest and scientist who made contributions in a wide range of biological disciplines, including reproduction, regeneration (e.g., of amphibian limbs), and respiration. He argued strongly against the theory of spontaneous generation. His work on respiration, published posthumously, demonstrated that several tissues consume O_2 and evolve CO_2 .

For more information about Spallanzani, consult the following sources:

6. Keilin D: The History of Cell Respiration and Cytochrome. Cambridge, UK, Cambridge University Press, 1966.

Thus, by the end of the 18th century, chemists and physiologists appreciated that combustion, putrefaction, and respiration all involve chemical reactions that consume O_2 and produce CO_2 . Subsequent advances in the chemistry of gases by Boyle, Henry, Avogadro, and others laid the theoretical foundation for the physiology of O_2 and CO_2 . Thus, respiration was a unifying theme in the early histories of physiology, chemistry, and biochemistry.

Later work showed that mitochondrial respiration (i.e., the oxidation of carbon-containing compounds to form CO_2) is responsible for the O_2 consumption and CO_2 production observed by Spallanzani. This aspect of respiration is often called **internal respiration** or oxidative phosphorylation (see [p. 1185](#)).

In the chapters on respiratory physiology, we focus on **external respiration**, the dual processes of (1) transporting O_2 from the atmosphere to the mitochondria and (2) transporting CO_2 from the mitochondria to the atmosphere. We will also see that CO_2 transport is intimately related to acid-base homeostasis.

Diffusion is the major mechanism of external respiration for small aquatic organisms

The most fundamental mechanism of O_2 and CO_2 transport is **diffusion** (see [p. 108](#)). Random movements of molecules such as O_2 and CO_2 , whether in a gaseous phase or dissolved in water, result in a net movement of the substance from regions of high concentration to regions of low concentration ([Fig. 26-1A](#), inset). No expenditure of energy is involved. The driving force for diffusion is the concentration gradient.

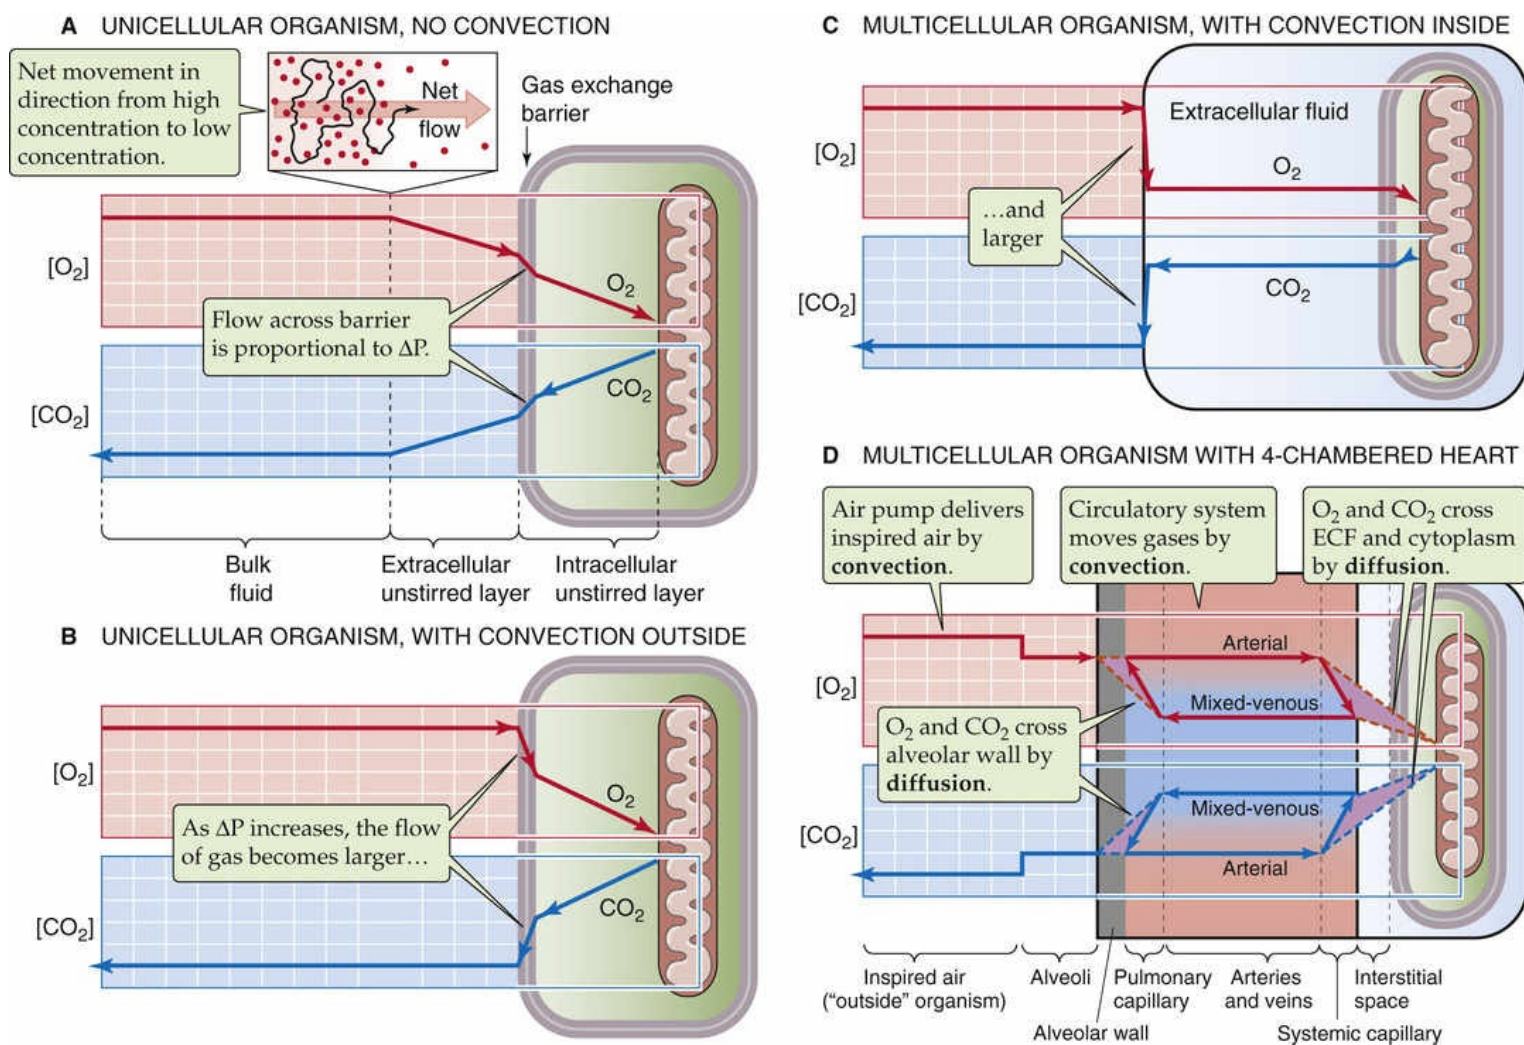

FIGURE 26-1 Diffusion of O_2 and CO_2 for a single-celled organism. In **A** to **D**, the y-axis of the grids shows the dissolved concentration (or partial pressure) of O_2 and CO_2 . The x-axis represents distance (not to scale). In **D**, the broken red and blue lines and the enclosed violet triangles represent the magnitude of the gradients driving O_2 and CO_2 diffusion. The red (O_2) and blue (CO_2) pathways represent the circuit of blood from the pulmonary capillaries to the systemic capillaries and back again. ECF, extracellular fluid.

Imagine a unicellular organism suspended in a beaker of pond water at 37°C . The water is in equilibrium with an atmosphere that has the usual composition of O_2 and CO_2 (Table 26-1). The partial pressures of O_2 (P_{O_2}) and of CO_2 (P_{CO_2}) in the *dry* air are slightly higher than their corresponding values in the *wet* air immediately above the surface of the water (Box 26-1). It is these partial pressures in wet air that determine the concentrations of dissolved O_2 ($[O_2]_{\text{dis}}$) and dissolved CO_2 ($[CO_2]_{\text{dis}}$) in the water (Box 26-2). Thus, the P_{O_2} in the wet air—as well as the water beneath it—will be ~ 149 mm Hg (or torr), and the P_{CO_2} will be an almost negligible 0.2 mm Hg. These numbers describe the composition of the **bulk phase** of the pond water (see Fig. 26-1A, left side), at some distance from the organism. However, because the mitochondria within the organism continuously consume O_2 and produce CO_2 , the P_{O_2} at the surface of the mitochondria will be lower than the bulk-phase P_{O_2} , whereas the P_{CO_2} at the mitochondrial surface will be higher than the bulk-phase P_{CO_2} (see Fig. 26-1A, right side). These differences in partial pressure cause O_2 to diffuse from the bulk pond water toward the mitochondria and the CO_2 to diffuse in the opposite direction.

TABLE 26-1
Composition of Air

	DRY AIR ATMOSPHERE		WET AIR TRACHEA	
GAS	FRACTION IN AIR (%)	PARTIAL PRESSURE AT SEA LEVEL (mm Hg)	FRACTION IN AIR (%)	PARTIAL PRESSURE AT SEA LEVEL (mm Hg)
Nitrogen	78.09	593.48	73.26	556.78
Oxygen	20.95	159.22	19.65	149.37
Carbon dioxide	0.03	0.23	0.03	0.21
Argon	0.93	7.07	0.87	6.63
Water	0	0	6.18	47
Total	100	760	100	760

Box 26-1

Wet Gases

Partial Pressures of O₂ and CO₂ in Solutions That Are Equilibrated with Wet Air

Imagine that a beaker of water is equilibrated with a normal atmosphere and that both water and atmosphere have a temperature of 37°C. For dry air (i.e., air containing no water vapor), O₂ makes up ~21% of the total gas by volume (see Table 26-1). Thus, if the ambient pressure—or **barometric pressure (P_B)**—is 760 mm Hg, the partial pressure of O₂ (P_{O₂}) is 21% of 760 mm Hg, or 159 mm Hg (Fig. 26-2). However, if the air-water interface is reasonably stationary, water vapor will saturate the air immediately adjacent to the liquid. What is the P_{O₂} in this wet air? At 37°C, the partial pressure of water (P_{H₂O}) is 47 mm Hg. Of the total pressure of the wet air, P_{H₂O} makes up 47 mm Hg, and the components of the dry air make up the remaining 760 – 47, or 713 mm Hg. Thus, the partial pressure of O₂ in this wet air is

Fraction of dry
air that is O₂

$$P_{O_2} = \overline{F}_{O_2} \cdot (P_B - P_{H_2O})$$

$$= (21\%) \cdot (760 \text{ mm Hg} - 47 \text{ mm Hg})$$

$$= 149 \text{ mm Hg}$$

FIGURE 26-2 Wet versus dry gases. Note that the O₂ partial pressure is less in wet than in dry air.

The CO₂ composition of dry air is ~0.03% (see Table 26-1). Thus, the partial pressure of CO₂ in wet air is

$$\begin{aligned}
 P_{\text{CO}_2} &= F_{\text{CO}_2} \cdot (P_B - P_{\text{H}_2\text{O}}) \\
 &= (0.03\%) \cdot (760 \text{ mm Hg} - 47 \text{ mm Hg}) \\
 &= 0.21 \text{ mm Hg}
 \end{aligned}$$

These examples are realistic for respiratory physiology. As we inhale relatively cool and dry air, the nose and other upper respiratory passages rapidly warm and moisturize the passing air so that it assumes the composition of wet air given in Table 26-1.

Partial Pressures and Henry's Law

Respiratory physiologists generally express the concentration of a gas, whether it is mixed with another gas (e.g., O₂ mixed with N₂, as is the case for air) or dissolved in an aqueous solution (e.g., O₂ dissolved in water), in terms of partial pressure. **Dalton's law** states that the total pressure (P_{total}) of a mixture of gases is the sum of their individual **partial pressures**. Imagine that we are dealing with an ideal gas (Z) mixed with other gases. Because the ratio of the partial pressure of Z (P_Z) to the total pressure (P_{total}) is its mole fraction (X_Z),

$$P_Z = X_Z \cdot P_{\text{total}}$$

Thus, if P_Z in one sample of gas were twice as high as in another, X_Z (i.e., concentration of Z) would also be twice as high.

It may not be immediately obvious why—when Z is dissolved in aqueous solutions—it is still reasonable to express the concentration of Z in terms of P_Z. According to **Henry's law**, the concentration of O₂ dissolved in water ([O₂]_{dis}) is proportional to P_{O₂} in the gas phase:

$$[\text{O}_2]_{\text{dis}} = s \cdot P_{\text{O}_2}$$

The proportionality constant *s* is the **solubility**; for O₂, *s* is ~0.0013 mM/mm Hg at 37°C for a solution mimicking blood plasma. The solubility of CO₂ is ~23-fold higher. Consider a beaker of water at 37°C equilibrated with an atmosphere having a P_{O₂} of 100 mm Hg, the partial pressure in mammalian *arterial* blood plasma (Fig. 26-3A, solution #1):

$$\begin{aligned} [\text{O}_2]_{\text{dis}} &= \left(0.0013 \frac{\text{mM}}{\text{mm Hg}} \right) \cdot (100 \text{ mm Hg}) \\ &= 0.13 \text{ mM} \end{aligned}$$

A HENRY'S LAW

B DIFFUSION OF DISSOLVED GAS

FIGURE 26-3 Henry's law and the diffusion of dissolved gases.

Now consider a second beaker equilibrated with an atmosphere having a P_{O_2} of 40 mm Hg, the partial pressure of O_2 in *mixed-venous* blood (see Fig. 26-3A, solution #2):

$$[\text{O}_2]_{\text{dis}} = \left(0.0013 \frac{\text{mM}}{\text{mm Hg}} \right) \cdot (40 \text{ mm Hg})$$

$$= 0.05 \text{ mM}$$

If we now place samples of these two solutions on opposite sides of a semipermeable barrier in a closed container (see Fig. 26-3B), the O_2 gradient across this barrier expressed in terms of concentrations ($\Delta[\text{O}_2]$) is $0.13 - 0.05$ or 0.08 mM . Expressed in terms of partial pressures (ΔP_{O_2}), this same gradient is $100 - 40 = 60 \text{ mm Hg}$.

Imagine now that we take a 5-mL sample of each of the solutions in the beakers in Figure 26-3A, drawing the fluid up into syringes, sealing the syringes, putting them on ice, and sending them to a clinical laboratory for analysis—as is routinely done with samples of arterial blood. Even though there is no gas phase in equilibrium with either of the solutions in the syringes, the laboratory will report the O_2 levels in millimeters of mercury (mm Hg). These are the partial pressures of O_2 with which the solutions were or would have to be equilibrated to achieve the $[\text{O}_2]_{\text{dis}}$ in the liquid samples.

N26-8

Gas Laws

Contributed by Walter Boron

In the mid-17th century, Robert Boyle demonstrated that the relation between the pressure (P) and volume (V) of a *real* gas at a fixed temperature is essentially hyperbolic. **Boyle's law** states that P and V for an *ideal* gas vary inversely:

$$PV = \text{Constant \#1} \quad (\text{NE 26-1})$$

At the molecular level, the pressure exerted by a fixed number of gas molecules—the total force of gas per unit surface area of the container—reflects the number of collisions molecules make with the walls of the container. If we reduce the container's volume by half, the number of collisions doubles for each square centimeter of the container's walls, and, therefore, pressure doubles.

A century after Boyle's work, Jacques Charles found that the volume of a gas varies linearly with absolute temperature (T, in kelvin) if pressure is constant:

$$V = (\text{Constant \#2}) \times T$$

or

$$\frac{V}{T} = \text{Constant \#2}$$

(NE 26-2)

At the molecular level, **Charles's law** states that increasing the temperature increases the velocity of gas molecules, which forces the perfectly compliant container to increase in size.

Combining these two laws yields the so-called **Boyle-Charles law**:

$$\frac{PV}{T} = \text{Constant \#3}$$

(NE 26-3)

For an ideal gas, “constant #3” is nothing more than $n \cdot R$, where n is the number of moles and R is the universal gas constant. Incorporating n and R into Equation NE 26-3 yields the **ideal gas law**:

$$PV = nRT$$

(NE 26-4)

If we compare the relationship among pressure, volume, and temperature for a fixed number of moles of the gas under two conditions, we see that

$$\frac{P_1 \cdot V_1}{T_1} = \frac{P_2 \cdot V_2}{T_2}$$

(NE 26-5)

With this simple equation, one better appreciates what happens when barometric pressure increases during diving or decreases during ascent to high altitude.

The barometric pressure (P_B) is the sum of the **partial pressures** of the individual gases in the air mixture (**Dalton's law**; see Box 26-2). Thus, in the case of ordinary *dry* air (see Table 26-1), most of the sea-level P_B of 760 mm Hg is due to N_2 (~593 mm Hg) and O_2 (~159 mm Hg), with smaller contributions from trace gases such as argon (~7 mm Hg) and CO_2 (~0.2 mm Hg). Thus, as P_B increases during diving beneath the water, or as P_B decreases during ascent to high altitude, the partial pressure of each constituent gas will change in proportion to the change in P_B . This relationship is important for O_2 delivery to tissues, because a key variable that determines the O_2 saturation of hemoglobin (Hb) is P_{O_2} in the inspired air (see p. 681).

The conducting airways humidify inspired air so that it becomes fully saturated with H_2O vapor at body temperature (see Box 26-1). The H_2O vapor then occupies part of the space in the lungs. At a body temperature of $37^\circ C$, P_{H_2O} is 47 mm Hg. If P_B is 760 mm Hg, only $760 - 47 = 713$ mm Hg is available for the sum of P_{O_2} , P_{N_2} , and P_{CO_2} . Because H_2O readily evaporates from (or condenses into) liquid water, its partial pressure does not change with changes in P_B .

The diffusion of O_2 follows a gradient of decreasing P_{O_2} (see Fig. 26-1A). The region over which P_{O_2} falls gradually from the bulk pond water toward the outer surface of the plasma membrane is the **extracellular unstirred layer**, so named because no convective mixing occurs in this zone. A similar gradual decline in P_{O_2} drives O_2 diffusion through the **intracellular unstirred layer**, from the inner surface of the plasma membrane to the mitochondria. The abrupt fall in P_{O_2} across the plasma membrane reflects some resistance to gas flow. The profile for P_{CO_2} is similar, although with the opposite orientation.

The rate at which O_2 or CO_2 moves across the surface of the organism is the **flow** (units: moles/s). According to a simplified version of **Fick's law** (see p. 108), flow is proportional to the concentration

difference across this barrier. Because we know from Henry's law that the concentration of a dissolved gas is proportional to its partial pressure in the gas phase, flow is also proportional to the partial-pressure difference (ΔP):

$$\text{Flow} \propto \Delta P$$

(26-1)

Simple diffusion is the mechanism by which O_2 and CO_2 move *short* distances in the respiratory system: between the air and blood in the alveoli, and between the mitochondria and blood of the peripheral circulation.

Convection enhances diffusion by producing steeper gradients across the diffusion barrier

A purely diffusive system can establish only a relatively small ΔP across the gas exchange barrier of the organism (see Fig. 26-1A). Yet, for small organisms, even this relatively small ΔP is adequate to meet the demands for O_2 uptake and CO_2 removal. However, when the organism's diameter exceeds ~ 1 mm, simple diffusion becomes inadequate for gas exchange. One way of ameliorating this problem is to introduce a mechanism for **convection** on the outside surface of the organism. For a paramecium, the beating cilia bring bulk-phase water—having a P_{O_2} of ~ 154 mm Hg at 25°C and a P_{CO_2} of ~ 0.2 mm Hg—very near to the cell's surface. This mixing reduces the size of the extracellular unstirred layer, thereby increasing the P_{O_2} and decreasing the P_{CO_2} on the outer surface of the organism. The net effect is that the partial-pressure gradients for both O_2 and CO_2 increase across the gas exchange barrier (see Fig. 26-1B), leading to a proportionate increase in the flow of both substances.

A filter feeder, such as an oyster or a clam, pumps bulk-phase water past its organ of gas exchange. Because of the relatively low solubility of O_2 in water, such an organism may need to pump 16,000 mL of water to extract a mere 1 mL of O_2 gas. In fish, which are far more efficient, the ratio may be considerably lower, $\sim 400 : 1$.

In mammals, the bulk phase is the atmosphere and the external convective system is an air pump that includes the chest wall, the respiratory muscles, and the passages through which the air flows (i.e., from the nose up to the alveoli). **Ventilation** is the process of moving air into and out of the lungs. Amphibians move air into their lungs by swallowing it. Reptiles, birds, and mammals expand their lungs by developing a negative pressure inside the thorax. Because of the much higher O_2 content of air (about 210 mL O_2 /L of air at standard temperature and pressure/dry, or STPD; Box 26-3), as opposed to water (~ 35 mL O_2 /L of water), humans need to move far less air than oysters need to move water. For example, a human may ventilate the alveoli with 4000 mL of fresh air every minute and extract from this air 250 mL of O_2 gas, a ratio of $16 : 1$.

Box 26-3

Conventions for Measurement of Volumes of Gases

BTPS

Gases within the lung are saturated with water vapor at 37°C (310 K). At this temperature, P_{H_2O} is 47 mm Hg (see Box 26-1). If the glottis is open and no air is flowing, then the total pressure of the air in the lungs is P_B , which we will assume to be 760 mm Hg. In this case, the partial pressure of *dry* gases in the lungs is $(760 - 47) = 713$ mm Hg. The convention is to report the volume of gases in the lungs—and changes in the volume of these gases—at body temperature and pressure, saturated with water vapor, or **BTPS**. Such volumes include both wet and dry gases.

ATPS

If a volume of air is exhaled from the lungs (ΔV_{BTPS}) into a spirometer, the “floor” of which is formed by water (see Fig. 26-8), the exhaled air will now be at ambient temperature and pressure, saturated with water vapor, or **ATPS**. Thus, we must correct the volume change (ΔV_{ATPS}) registered by the spirometer (at ATPS) to know the volume that this same gas had occupied in the lungs (at BTPS). Two factors are at work as warm alveolar air moves into a cooler spirometer: (1) P_{H_2O} decreases and some gaseous H_2O condenses into liquid H_2O , according to the temperature dependence of P_{H_2O} ; and (2) the pressure exerted by the dry gas molecules decreases, according to Charles's law. **N26-8** If we start from the Boyle-Charles law,

$$\frac{P_{BTPS} \cdot \Delta V_{BTPS}}{T_{BTPS}} = \frac{P_{ATPS} \cdot \Delta V_{ATPS}}{T_{ATPS}}$$

it is possible to show that **N26-12**

$$\Delta V_{BTPS} = \frac{(P_B - P_{H_2O \text{ at } T_{\text{ambient}}})}{(P_B - P_{H_2O \text{ at } T_{\text{body}}})} \cdot \frac{T_{\text{body}}}{T_{\text{ambient}}} \cdot \Delta V_{ATPS}$$

Here, T_{body} and T_{ambient} are absolute temperatures.

If T_{body} is 37°C (310 K), then the corresponding P_{H_2O} is 47 mm Hg. If T_{ambient} is 25°C (or 298 K), then the corresponding P_{H_2O} is 24 mm Hg. For these conditions, the conversion from an ATPS volume to a BTPS volume becomes

$$\Delta V_{BTPS} = \frac{(760 - 24)}{(760 - 47)} \cdot \frac{310 \text{ K}}{298 \text{ K}} \cdot \Delta V_{ATPS} = 1.074 \cdot \Delta V_{ATPS}$$

Thus, the same wet gas that occupies 1000 mL in the spirometer at ATPS occupies 1074 mL in the lungs at BTPS.

STPD

The convention is to report the volume of gases in the blood (e.g., dissolved CO_2 or O_2 bound to hemoglobin) in the same way that chemists would—at standard temperature and pressure/dry, or **STPD**.

The standard temperature is 0°C (273 K), and the standard pressure is 760 mm Hg. You may recall from introductory chemistry that a mole of an ideal gas occupies 22.4 L at STPD. If you wish to convert a ΔV_{STPD} to a ΔV_{BTPS} , it is possible to show that **N26-13**

$$\Delta V_{\text{BTPS}} = \frac{P_{\text{B}}}{P_{\text{B}} - P_{\text{H}_2\text{O at } T_{\text{body}}}} \cdot \frac{T_{\text{body}}}{T_{\text{standard}}} \cdot \Delta V_{\text{STPD}}$$

For a body temperature of 37°C, the conversion from a BTPS volume to an STPD volume becomes

$$\Delta V_{\text{BTPS}} = \frac{760}{760 - 47} \cdot \frac{310\text{K}}{273\text{K}} \cdot \Delta V_{\text{STPD}} = 1.21 \cdot \Delta V_{\text{STPD}}$$

Thus, the same dry gas that occupies 1000 mL under standard chemical conditions occupies 1210 mL in the body at BTPS.

N26-12

Conversion from ΔV_{BTPS} to ΔV_{ATPS}

Contributed by Walter Boron

The basis for our derivation will be the ideal gas law:

$$PV = nRT \quad (\text{NE 26-11})$$

We are interested in following *a portion of the total volume of gas in the lungs* as this volume moves from the lungs—at **BTPS**—to a spirometer in equilibrium with liquid water—at **ATPS**. In the lungs, the volume exiting is ΔV_{BTPS} . We will focus on the number of gas molecules in the volume ΔV_{BTPS} :

$$n = \frac{P_{\text{BTPS}} \cdot \Delta V_{\text{BTPS}}}{RT_{\text{BTPS}}} \quad (\text{NE 26-12})$$

Let us assume that the pressure inside the lungs (P_{BTPS}) is the same as barometric pressure (P_{B}), which is true when no air is flowing and the glottis is open:

$$n = \frac{P_{\text{B}} \cdot \Delta V_{\text{BTPS}}}{RT_{\text{BTPS}}} \quad (\text{NE 26-13})$$

The n in Equation NE 26-13 has two components: H_2O and the **dry gases** (i.e., everything other than H_2O). The number of dry-gas molecules is proportional to the partial pressure of the dry gases. Thus,

$$n^{\text{dry}} = \frac{P_{\text{BTPS}}^{\text{dry}} \cdot \Delta V_{\text{BTPS}}}{RT_{\text{BTPS}}} \\ = \frac{(P_B - P_{\text{BTPS}}^{\text{H}_2\text{O}}) \cdot \Delta V_{\text{BTPS}}}{RT_{\text{BTPS}}} \quad \text{(NE 26-14)}$$

For example, if P_B is 760 mm Hg and body temperature is 37°C , then the number of dry molecules is

$$n^{\text{dry}} = \frac{\overbrace{(760-47)}^{\text{mm Hg}} \cdot \Delta V_{\text{BTPS}}}{\underbrace{R(273+37)}_K} \\ = \frac{(713 \text{ mm Hg}) \cdot \Delta V_{\text{BTPS}}}{R \cdot (310 \text{ K})} \quad \text{(NE 26-15)}$$

Now, what volume would these same dry gas molecules occupy after exhalation into a spirometer at ambient temperature (T_{ATPS})? We will assume that the ambient pressure is P_B . Rearranging the ideal gas law, we get

$$\Delta V_{\text{ATPS}}^{\text{dry}} = \frac{n^{\text{dry}} \cdot RT_{\text{ATPS}}}{P_B} \quad \text{(NE 26-16)}$$

Substituting into Equation NE 26-16 the value for n^{dry} from Equation NE 26-14 yields

$$\Delta V_{\text{ATPS}}^{\text{dry}} = \underbrace{\frac{(P_B - P_{\text{BTPS}}^{\text{H}_2\text{O}}) \cdot \Delta V_{\text{BTPS}}}{RT_{\text{BTPS}}}}_{n^{\text{dry}}} \cdot \frac{RT_{\text{ATPS}}}{P_B} \quad \text{(NE 26-17)}$$

Canceling R and rearranging terms, we get

$$\Delta V_{\text{ATPS}}^{\text{dry}} = \frac{(P_B - P_{\text{BTPS}}^{\text{H}_2\text{O}})}{P_B} \cdot \frac{T_{\text{ATPS}}}{T_{\text{BTPS}}} \cdot \Delta V_{\text{BTPS}} \quad \text{(NE 26-18)}$$

For example, if P_B is 760 mm Hg and ambient temperature is 25°C , then the volume occupied by the

dry molecules exhaled from the lungs is

$$\begin{aligned}\Delta V^{\text{dry}} &= \frac{(760-47)}{760} \cdot \frac{(273+25)}{(273+37)} \cdot \Delta V_{\text{BTPS}} \\ &= \frac{713}{760} \cdot \frac{298\text{K}}{310\text{K}} \cdot \Delta V_{\text{BTPS}} \\ &= 0.902 \cdot \Delta V_{\text{BTPS}} \\ &\quad \text{(NE 26-19)}\end{aligned}$$

In other words, if the dry gas molecules occupied 1 L in the lungs, they would occupy only 902 mL in the spirometer.

However, this volume of dry-gas molecules does not represent all of the gas that we exhaled ... we also exhaled *water vapor*. What volume does the water vapor occupy after we exhale it into the spirometer? The answer to this question may sound a bit strange, but the volume (or number) of water molecules exhaled from the lungs does not determine the volume (or number) of water molecules in the spirometer. The reason is that the partial pressure of H_2O in the spirometer—the gas phase of which is in equilibrium with liquid H_2O —depends not on the amount of H_2O vapor that is exhaled but only on ambient temperature. Consider four examples:

If body temperature is *higher than ambient temperature* (i.e., $P_{\text{H}_2\text{O}}$ is higher in the body than in the spirometer), then some of the exhaled H_2O molecules condense into the liquid of the spirometer. This is the usual case. Once in the spirometer, the dry-gas molecules from the lungs are accompanied by fewer gaseous H_2O molecules than had accompanied them in the lungs!

If the body temperature were the *same as ambient temperature*, then the number of H_2O molecules that accompanied the exhaled dry gas in the lungs would be the same as the number of H_2O molecules that accompany this exhaled dry gas in the spirometer. In other words, ΔV_{BTPS} would be the same as ΔV_{ATPS} .

If the body temperature were *lower than ambient temperature*, then the exhaled H_2O molecules would be joined in the gas phase of the spirometer by additional H_2O molecules evaporating from the spirometer's liquid water. In other words, once in the spirometer, the dry-gas molecules from the lungs would be accompanied by more gaseous H_2O molecules than they had been accompanied by in the lungs!

Finally, imagine that, instead of exhaling into the spirometer a volume ΔV of BTPS air—consisting of both dry air and H_2O vapor—we instead introduce into the spirometer only the *dry air* at body temperature contained within ΔV_{BTPS} . This dry air will be joined in the gas phase of the spirometer by H_2O molecules that evaporate from the spirometer's liquid water ... and the final ΔV in the spirometer will be the same as if we had exhaled BTPS (i.e., wet) air into the spirometer!

Thus, in computing the total change in spirometer volume (ΔV_{ATPS}) we do not need to consider the number of H_2O molecules exhaled from the lungs; we only need to compute how many gaseous H_2O molecules must accompany the exhaled dry-gas molecules once these dry-gas molecules are in the friendly confines of the spirometer. We will approach this problem by computing the ratio of dry to total gas molecules contained in ΔV_{ATPS} . Within the volume ΔV_{ATPS} —inside the spirometer—the ratio of number of gas molecules is the same as the ratio of their respective pressures:

$$\frac{n^{\text{dry}}}{n_{\text{ATPS}}^{\text{total}}} = \frac{P_{\text{ATPS}}^{\text{dry}}}{P_{\text{ATPS}}^{\text{total}}}$$

(NE 26-20)

Because total pressure is P_B , and because the partial pressure of the dry gases is the difference between P_B and the vapor pressure of H_2O ,

$$\frac{n^{\text{dry}}}{n_{\text{ATPS}}^{\text{total}}} = \frac{(P_B - P_{\text{ATPS}}^{H_2O})}{P_B}$$

(NE 26-21)

Because the volume occupied by the gases is proportional to the number of gas molecules,

$$\frac{V_{\text{ATPS}}^{\text{dry}}}{\Delta V_{\text{ATPS}}^{\text{total}}} = \frac{n^{\text{dry}}}{n_{\text{ATPS}}^{\text{total}}} = \frac{(P_B - P_{\text{ATPS}}^{H_2O})}{P_B}$$

(NE 26-22)

Solving for the total ΔV_{ATPS} , we get

$$\Delta V_{\text{ATPS}}^{\text{total}} = V_{\text{ATPS}}^{\text{dry}} \times \frac{P_B}{(P_B - P_{\text{ATPS}}^{H_2O})}$$

(NE 26-23)

Equation NE 26-23 tells us that, if we know the volume that the exhaled dry gases occupy once they are in the spirometer, we can easily compute the total volume occupied by these dry molecules *and their obligated H_2O molecules*. Substituting into Equation NE 26-23 our expression for ΔV of the dry molecules at ATPS in Equation NE 26-18, we get

$$\Delta V_{\text{ATPS}}^{\text{total}} = \frac{(P_B - P_{\text{BTSP}}^{H_2O})}{P_B} \cdot \underbrace{\frac{T_{\text{ATPS}}}{T_{\text{BTSP}}} \cdot \Delta V_{\text{BTSP}}}_{V_{\text{ATPS}}^{\text{dry}}} \cdot \frac{P_B}{(P_B - P_{\text{ATPS}}^{H_2O})}$$

(NE 26-24)

Canceling P_B terms yields

$$\Delta V_{\text{ATPS}}^{\text{total}} = \frac{(P_B - P_{\text{BTSP}}^{H_2O})}{(P_B - P_{\text{ATPS}}^{H_2O})} \cdot \frac{T_{\text{ATPS}}}{T_{\text{BTSP}}} \cdot \Delta V_{\text{BTSP}}$$

(NE 26-25)

Thus, if P_B is 760 mm Hg and ambient temperature is 25°C, then

$$\begin{aligned}\Delta V_{\text{ATPS}}^{\text{total}} &= \frac{(760-47)}{(760-24)} \cdot \frac{298\text{K}}{310\text{K}} \cdot \Delta V_{\text{BTPS}} \\ &= 0.931 \cdot \Delta V_{\text{BTPS}}\end{aligned}$$

(NE 26-26)

If we wish to convert back from ΔV_{ATPS} to ΔV_{BTPS} , then the comparable equations are

$$\Delta V_{\text{BTPS}} = \frac{(P_B - P_{\text{H}_2\text{O}}^{\text{ATPS}})}{(P_B - P_{\text{H}_2\text{O}}^{\text{BTPS}})} \cdot \frac{T_{\text{BTPS}}}{T_{\text{ATPS}}} \cdot \Delta V_{\text{ATPS}}^{\text{total}}$$

(NE 26-27)

and

$$\begin{aligned}\Delta V_{\text{BTPS}} &= \frac{(760-24)}{(760-47)} \cdot \frac{310\text{K}}{298\text{K}} \cdot \Delta V_{\text{ATPS}}^{\text{total}} \\ &= 1.0738 \cdot \Delta V_{\text{ATPS}}\end{aligned}$$

(NE 26-28)

Equation NE 26-28 is the same as the last equation under the heading “ATPS” in Box 26-3.

N26-13

Conversion from ΔV_{BTPS} to ΔV_{STPD}

Contributed by Walter Boron

The basis for our derivation will be the ideal gas law:

$$PV = nRT \quad \textbf{(NE 26-29)}$$

We are interested in following *a portion of the total volume of gas in the lungs* as this volume moves from the lungs—at **BTPS**—to a spirometer in equilibrium with liquid water—at **ATPS**. In the lungs, the volume exiting is ΔV_{BTPS} . We will focus on the number of gas molecules in the volume ΔV_{BTPS} :

$$n = \frac{P_{\text{BTPS}} \cdot \Delta V_{\text{BTPS}}}{RT_{\text{BTPS}}}$$

(NE 26-30)

Let us assume that the pressure inside the lungs (P_{BTPS}) is the same as barometric pressure (P_{B}), which is true when no air is flowing and the glottis is open:

$$n = \frac{P_{\text{B}} \cdot \Delta V_{\text{BTPS}}}{RT_{\text{BTPS}}}$$

(NE 26-31)

The n in Equation NE 26-31 has two components: H_2O and the **dry gases** (i.e., everything other than H_2O). The number of dry-gas molecules is proportional to the partial pressure of the dry gases. Thus,

$$\begin{aligned} n^{\text{dry}} &= \frac{P_{\text{BTPS}}^{\text{dry}} \cdot \Delta V_{\text{BTPS}}}{RT_{\text{BTPS}}} \\ &= \frac{(P_{\text{B}} - P_{\text{BTPS}}^{\text{H}_2\text{O}}) \cdot \Delta V_{\text{BTPS}}}{RT_{\text{BTPS}}} \end{aligned}$$

(NE 26-32)

For example, if P_{B} is 760 mm Hg and body temperature is 37°C , then the number of dry molecules is

$$\begin{aligned} n^{\text{dry}} &= \frac{\overbrace{(760-47)}^{\text{mm Hg}} \cdot \Delta V_{\text{BTPS}}}{R \underbrace{(273+37)}_{\text{K}}} \\ &= \frac{(713 \text{ mm Hg}) \cdot \Delta V_{\text{BTPS}}}{R \cdot (310 \text{ K})} \end{aligned}$$

(NE 26-33)

Up to this point, the discussion has been identical to that in **N26-12**, where we asked what volume this dry gas (as well as its obligated water vapor) would occupy at ATPS. In this webnote, we instead ask what volume these exhaled dry gas molecules would occupy at **standard temperature** and **standard pressure**. The definitions are the following:

$$\text{Standard temperature} = T_{\text{STPD}} = 0^\circ\text{C} = 273 \text{ K} \quad (\text{NE 26-34})$$

$$\text{Standard pressure} = P_{\text{STPD}} = 1 \text{ atmosphere} = 760 \text{ mm Hg} \quad (\text{NE 26-35})$$

Rearranging the ideal gas law, we get

$$\Delta V_{\text{STPD}} = \frac{n^{\text{dry}} \cdot R T_{\text{STPD}}}{P_{\text{STPD}}}$$

(NE 26-36)

Substituting into Equation NE 26-36 the value for n^{dry} from Equation NE 26-32 yields

$$\Delta V_{\text{STPD}} = \frac{(P_B - P_{\text{H}_2\text{O}}^{\text{BTPS}}) \cdot \Delta V_{\text{BTPS}}}{\underbrace{R T_{\text{BTPS}}}_{n^{\text{dry}}}} \cdot \frac{R T_{\text{STPD}}}{P_{\text{STPD}}}$$

(NE 26-37)

Canceling R and rearranging terms, we get

$$\Delta V_{\text{STPD}} = \frac{(P_B - P_{\text{H}_2\text{O}}^{\text{BTPS}})}{P_{\text{STPD}}} \cdot \frac{T_{\text{STPD}}}{T_{\text{BTPS}}} \cdot \Delta V_{\text{BTPS}}$$

(NE 26-38)

For example, if P_B is 760 mm Hg, then the volume occupied by the dry molecules exhaled from the lungs is

$$\begin{aligned} \Delta V_{\text{STPD}} &= \frac{(760-47)}{760} \cdot \frac{(273)}{(273+37)} \cdot \Delta V_{\text{BTPS}} \\ &= \frac{713}{760} \cdot \frac{273\text{K}}{310\text{K}} \cdot \Delta V_{\text{BTPS}} \\ &= 0.826 \cdot \Delta V_{\text{BTPS}} \end{aligned}$$

(NE 26-39)

In other words, if the dry gas molecules occupied 1 L in the lungs, they would occupy only 826 mL in the spirometer.

If we wish to convert back from ΔV_{STPD} to ΔV_{BTPS} , then the comparable equations are

$$\Delta V_{\text{BTPS}} = \frac{P_{\text{STPD}}}{(P_B - P_{\text{H}_2\text{O}}^{\text{BTPS}})} \cdot \frac{T_{\text{BTPS}}}{T_{\text{STPD}}} \cdot \Delta V_{\text{STPD}}$$

(NE 26-40)

and

$$\Delta V_{\text{BTPS}} = \frac{760}{(760-47)} \cdot \frac{310\text{K}}{273\text{K}} \cdot \Delta V_{\text{STPD}} \\ = 1.2104 \cdot \Delta V_{\text{ATPS}} \\ \text{(NE 26-41)}$$

Equation NE 26-41 is the same as the last equation under the heading “STPD” in Box 26-3.

Although we are 1000-fold more efficient than oysters, the principle of external convective systems is the same: ensure that the external surface of the gas exchange barrier is in close contact with a fluid whose composition matches—as closely as is practical—that of the bulk phase. How “closely” is “practical”? The composition of alveolar air approaches that of wet inspired air as alveolar ventilation approaches infinity (see [p. 680](#)). Because high ventilatory rates have a significant metabolic cost, the body must trade off optimizing alveolar P_{O_2} and P_{CO_2} on the one hand against minimizing the work of ventilation on the other. In the average adult human, the compromise that has evolved is an alveolar ventilation of ~ 4000 mL/min, an alveolar P_{O_2} of ~ 100 mm Hg (versus 149 mm Hg in a wet atmosphere at 37°C), and an alveolar P_{CO_2} of ~ 40 mm Hg (versus 0.2 mm Hg).

A clinical example in which the external convective system fails is barbiturate poisoning. Here, drug intoxication inhibits the respiratory control centers in the medulla (see [p. 700](#)), so that ventilation slows or even stops. The consequence is that the unstirred layer between the bulk-phase atmosphere and the alveolar blood-gas barrier becomes extremely large (i.e., the distance between the nose and the alveoli). As a result, alveolar P_{O_2} falls to such low levels that the ΔP_{O_2} across the alveolar wall cannot support an O_2 flow and an arterial $[\text{O}_2]$ that is compatible with life. Cessation of ventilation also causes the alveolar P_{CO_2} to rise to such high levels that the CO_2 flow from blood to alveolar air is unacceptably low.

An *external* convective system maximizes gas exchange by continuously supplying bulk-phase water or air to the external surface of the gas exchange barrier, thereby maintaining a high external P_{O_2} and a low external P_{CO_2} . A **circulatory system** is an *internal* convective system that maximizes flow of O_2 and CO_2 across the gas exchange barrier by delivering, to the inner surface of this barrier, blood that has as low a P_{O_2} and as high a P_{CO_2} as is practical. **Perfusion** is the process of delivering blood to the lungs. [Figure 26-1C](#) shows a primitive—and hypothetical—internal convective system, one that essentially stirs the entire internal contents of the organism, so that the P_{O_2} of the bulk internal fluids is uniform, right up to the surface of the mitochondria. The result is that the ΔP_{O_2} across the gas exchange barrier is rather large, but the ΔP_{O_2} between the bulk internal fluid and the mitochondria is rather small.

[Figure 26-1D](#) summarizes the P_{O_2} and P_{CO_2} profiles for a sophisticated circulatory system built around a four-chambered heart and separate pulmonary and systemic circulations. The circulatory system carries (by convection) low- P_{O_2} blood from a systemic capillary near the mitochondria to the alveolar wall. At the beginning of a pulmonary capillary, a high alveolar-to-blood P_{O_2} gradient ensures a high O_2 inflow (by diffusion), and blood P_{O_2} rises to match the alveolar (i.e., external) P_{O_2} by the time the blood leaves the pulmonary capillary. Finally, the systemic arterial blood carries (by convection) this high- P_{O_2} blood to the systemic capillaries, where a high blood-to-mitochondria P_{O_2} gradient maximizes the O_2 flux into the mitochondria (by diffusion). The opposite happens with CO_2 . Thus, separate pulmonary and systemic

circulations ensure maximal gradients for gas diffusion in both the pulmonary and systemic capillaries.

The scenario outlined in [Figure 26-1D](#) requires the four-chambered heart characteristic of mammals as well as of advanced reptiles and birds. The right ventricle pumps low- P_{O_2} /high- P_{CO_2} blood received from the peripheral veins to the lungs, whereas the left ventricle pumps high- P_{O_2} /low- P_{CO_2} blood received from pulmonary veins to the periphery (i.e., mitochondria). Maintenance of maximal gradients for O_2 and CO_2 diffusion in both the pulmonary and systemic capillaries at the mitochondria requires that right and left ventricular blood not mix. However, this sort of mixing is exactly what occurs in fish and amphibians, whose hearts have a common ventricle. In these animals, the aortic blood has P_{O_2} and P_{CO_2} values that are intermediate between the extreme values of venous blood returning from the systemic circulation and the blood returning from the gas exchange barrier. The result is less than optimal P_{O_2} and P_{CO_2} gradients at both the gas exchange barrier and the mitochondria.

In humans, the internal convective system may fail when diseased heart valves cause a decrease in cardiac output. Another example is the shunting of blood between the pulmonary and the systemic circulations, as may occur in newborns with congenital anomalies (e.g., atrial or ventricular septal defects). The result is the same sort of mixing of systemic venous and gas exchange barrier blood that occurs in amphibians and fish. Thus, patients with shunts cannot establish normal P_{O_2} and P_{CO_2} gradients in the pulmonary and peripheral capillaries and thus cannot generate normal flows of O_2 and CO_2 .

Surface area amplification enhances diffusion

The passive flow of O_2 or CO_2 across a barrier is proportional not only to the concentration gradient but also to the area of the barrier: [N26-9](#)

$$\text{Flow} \propto \Delta P \times \text{Area} \\ (26-2)$$

N26-9

Flow Versus Flux

Contributed by Emile Boulpaep, Walter Boron

On page 595 of the text, we state that the flow of a gas across the blood-gas barrier is proportional to (1) the driving force—in this case the partial-pressure gradient (ΔP) of the gas—across the barrier, and (2) the area of the barrier. This concept is embodied in Equation 26-2 (shown here as Equation NE 26-6):

$$\text{Flow} \propto \Delta P \times \text{Area} \\ (\text{NE } 26-6)$$

Note that flow has the units of mass per unit time, such as mL/s. The flow per unit *area* is known as the **flux**, which might have the units of mL/(cm² s). Thus, the area term does not appear in the equation that

describes flux:

$$\text{Flux} \propto \Delta P$$

(NE 26-7)

Equation NE 26-7 is a restatement of Fick's law, which we introduced in the text in Equation 5-13 and also Equation 20-4. For a more detailed discussion of Fick's law see [EN20-2](#).

In the case of the lung, pulmonary specialists do not work with *flux* values, but with *flow* values because the surface area over which diffusion occurs is generally not known.

Indeed, higher animals have increased their ability to exchange O_2 and CO_2 with their environment by increasing the **surface area** across which gas exchange takes place. For example, mollusks (e.g., squid) and fish have gills, which they form by evaginating the gas exchange barrier, thus greatly amplifying its surface area. Higher land animals amplify their gas exchange barriers by invaginating them, forming lungs. In an amphibian such as the adult frog, the lungs are simple air sacs with a relatively small surface area. Not surprisingly, a large portion of their gas exchange must occur across the skin. The gas exchange barrier is considerably more sophisticated in reptiles, which line their lungs with alveoli or even subdivide them with alveoli-lined barriers. The net effect is to increase the surface-to-volume ratio of the lungs. Mammals increase the area available for diffusion even more, by developing highly complex lungs with bronchi and a large number of alveoli.

In humans, the lung surface is so large and so thin that O_2 and CO_2 transport across the alveolar wall is ~3-fold faster than necessary—at least when the person is resting at sea level. Nevertheless, this redundancy is extremely important during exercise (when cardiac output can increase markedly), for life at high altitude (where the P_{O_2} is low), and in old age (when lung function diminishes). A substantial decrease in surface area, or thickening of the barrier, can be deleterious. Examples are the surgical removal of a lung (which reduces the total surface for gas exchange by about half) and pulmonary edema (which increases the effective thickness of the barrier). Thus, if an individual with a thickened barrier loses a lung, the remaining surface area may not be large enough to sustain adequate rates of gas exchange.

Respiratory pigments such as hemoglobin increase the carrying capacity of the blood for both O_2 and CO_2

In mammals, the external convective system (i.e., ventilatory apparatus), the internal convective system (i.e., circulatory system), and the barrier itself (i.e., alveolar wall) are so efficient that the diffusion of O_2 and CO_2 is not what limits the exchange of gases, at least not in healthy subjects at sea level.

Imagine what would happen if the mixed-venous blood flowing down a pulmonary capillary contained only water and salts. The diffusion of O_2 from the alveolar air space into the “blood” is so fast—and the solubility of O_2 in saline is so low (see [Box 26-2](#))—that before the blood could move ~1% of the way down the capillary, the P_{O_2} of the blood would match the P_{O_2} of the alveolar air (i.e., all of the O_2 that *could* move *would* have moved). For the remaining ~99% of the capillary, the P_{O_2} gradient across the barrier would be nil, and no more O_2 would flow into the blood. As a result, at a normal cardiac output, the blood could never carry away enough O_2 from the lungs to the tissues to sustain life. The same would

be true in reverse for the elimination of CO₂.

Animals solve this problem with respiratory pigments, specialized metalloproteins that—via the metal—reversibly bind O₂, greatly increasing the carrying capacity of blood for O₂. In some arthropods and mollusks, the pigment is **hemocyanin**, which coordinates two copper atoms. Polychaete worms and brachiopods use **hemerythrins**, which coordinate two iron atoms. However, the most common—and most efficient—respiratory pigments are the **hemoglobins**, which coordinate a porphyrin ring that contains iron. All vertebrates as well as numerous unrelated groups of animals use hemoglobin, which is the chief component of erythrocytes or red blood cells.

The presence of hemoglobin markedly improves the dynamics of O₂ uptake by blood passing through the lungs. Under normal conditions, hemoglobin reversibly binds ~96% of the O₂ that diffuses from the alveolar air spaces to the pulmonary-capillary blood, greatly increasing the carrying capacity of blood for O₂. Hemoglobin also plays a key role in the transport or **carriage** of CO₂ by reversibly binding CO₂ and by acting as a powerful pH buffer. In **anemia**, the hemoglobin content of blood is reduced, thus lowering the carrying capacity of blood for O₂ and CO₂. An individual with anemia can compensate only if the systemic tissues extract more O₂ from each liter of blood or if cardiac output increases. However, there are limits to the amount of O₂ that tissues can extract or to the level to which the heart can increase its output.

Pathophysiology recapitulates phylogeny ... in reverse

It should be clear from the pathophysiological examples discussed that when a key component of the respiratory system fails in a higher organism, external respiration becomes more like that of an organism lower on the evolutionary ladder. For example, a failure of a mammal's air pump makes this individual behave more like a unicellular aquatic organism without cilia. A reduction in the surface area of the alveoli in a mammal creates the same problems faced by an amphibian with simple sack-like lungs. A major shunt in the circulatory system makes a mammal behave more like a fish. In severe anemia, a mammal faces the same problems as a lower life form with a less efficient respiratory pigment.

Organization of the Respiratory System in Humans

Humans optimize each aspect of external respiration—ventilation, circulation, area amplification, gas carriage, local control, and central control

The human respiratory system ([Fig. 26-4](#)) has two important characteristics. First, it uses highly efficient convective systems (i.e., ventilatory and circulatory systems) for long-distance transport of O_2 and CO_2 . Second, it reserves diffusion exclusively for short-distance movements of O_2 and CO_2 . The key components of this respiratory system are the following:

- 1. An air pump.** The external convective system consists of the upper respiratory tract and large pulmonary airways, the thoracic cavity and associated skeletal elements, and the muscles of respiration. These components deliver air to and remove air from the alveolar air spaces—**alveolar ventilation**. Inspiration occurs when muscle contractions increase the volume of the thoracic cavity, thereby lowering intrathoracic pressure; this causes the alveoli to expand passively, which in turn lowers alveolar pressure. Air then flows from the environment to the alveoli, down a pressure gradient. A quiet expiration occurs when the muscles relax. We discuss the mechanics of ventilation in [Chapter 27](#).
- 2. Mechanisms for carrying O_2 and CO_2 in the blood.** Red blood cells are highly specialized for transporting O_2 from the lungs to the peripheral tissues and for transporting CO_2 in the opposite direction. They have extremely high levels of hemoglobin and other components that help to rapidly load and unload huge amounts of O_2 and CO_2 . In the pulmonary capillaries, hemoglobin binds O_2 , thereby enabling the blood to carry ~65-fold more O_2 than saline. In the systemic capillaries, hemoglobin plays a key role in the carriage of CO_2 —produced by the mitochondria—to the lungs. Hemoglobin accomplishes this task by chemically reacting with some of the CO_2 and by buffering the H^+ formed as carbonic anhydrase converts CO_2 to HCO_3^- and H^+ . Thus, hemoglobin plays a central role in acid-base chemistry, as discussed in [Chapter 28](#), as well as in the carriage of O_2 and CO_2 , treated in [Chapter 29](#).
- 3. A surface for gas exchange.** The gas exchange barrier in humans consists of the alveoli, which provide a huge but extremely thin surface area for passive diffusion of gases between the alveolar air spaces and the pulmonary capillaries. We discuss the anatomy of the alveoli below in this chapter and explore pulmonary gas exchange in [Chapter 30](#). A similar process of gas exchange occurs between the systemic capillaries and mitochondria.
- 4. A circulatory system.** The internal convective system in humans consists of a four-chambered heart and separate systemic and pulmonary circulations. We discuss the flow of blood to the lungs—**perfusion**—in [Chapter 31](#).
- 5. A mechanism for locally regulating the distribution of ventilation and perfusion.** Efficient gas exchange requires that the ratio of ventilation to perfusion be uniform for all alveoli to the extent possible. However, neither the delivery of fresh air to the entire population of alveoli nor the delivery of mixed-

venous blood to the entire population of pulmonary capillaries is uniform throughout the lungs. The lungs attempt to maximize the uniformity of ventilation-perfusion ratios by using sophisticated feedback control mechanisms to regulate local air flow and blood flow, as discussed in [Chapter 31](#).

6. A mechanism for centrally regulating ventilation. Unlike the rhythmicity of the heart, which is intrinsic to that organ, that of the respiratory system is not intrinsic to the lungs or the chest wall. Instead, respiratory control centers in the **central nervous system** rhythmically stimulate the muscles of inspiration. Moreover, these respiratory centers appropriately modify the pattern of ventilation during exercise or other changes in physical or mental activity. Sensors for arterial P_{O_2} , P_{CO_2} , and pH are part of feedback loops that stabilize these three “blood gas” parameters. We discuss these subjects in [Chapter 32](#).

FIGURE 26-4 Respiratory apparatus in humans.

Respiratory physiologists have agreed on a set of symbols to describe parameters that are important for pulmonary physiology and pulmonary function testing ([Table 26-2](#)).

TABLE 26-2
Symbol Conventions in Respiratory Physiology

Respiratory Mechanics		Gas Exchange	
Main Symbols			
C	Compliance	C	Concentration (or content) in a liquid
		D	Diffusion capacity
f	Respiratory frequency	f	Respiratory frequency
		F	Fraction
P	Pressure	P	Pressure
		\dot{Q}	Flow of blood (perfusion)
R	Resistance	R	Gas exchange ratio
		S	Saturation of hemoglobin
V	Volume of gas	V	Volume of gas
\dot{V}	Flow of gas	\dot{V}	Ventilation
Modifiers (subscripts)			
		a	Systemic arterial
A	Alveolar	A	Alveolar
AW	Airway		
B	Barometric	B	Barometric
		c	Pulmonary capillary
		E	Expired
		I	Inspired
		v	Systemic venous (in any vascular bed)
		\bar{v}	Mixed systemic venous

Conducting airways deliver fresh air to the alveolar spaces

We will discuss lung development on [pages 1155–1156](#). In the embryo, each lung invaginates into a separate pleural sac, which reflects over the surface of the lung.

The **parietal pleura**, the wall of the sac that is farthest from the lung, contains blood vessels that are believed to produce an ultrafiltrate of the plasma called **pleural fluid**. About 10 mL of this fluid normally occupies the virtual space between the parietal and the **visceral pleura**. The visceral pleura lies directly on the lung and contains lymphatics that drain the fluid from the pleural space. When the production of pleural fluid exceeds its removal, the volume of pleural fluid increases (**pleural effusion**), limiting the expansion of the lung. Under normal circumstances, the pleural fluid probably lubricates the pleural space, facilitating physiological changes in lung size and shape.

The lungs themselves are divided into **lobes**, three in the right lung (i.e., upper, middle, and lower lobes) and two in the left (i.e., upper and lower lobes). The right lung, which is less encumbered than the left by the presence of the heart, makes up ~55% of total lung mass and function.

We refer to the progressively bifurcating pulmonary airways by their **generation number** ([Fig. 26-5](#)): The zeroth generation is the trachea, the first-generation airways are the right and left mainstem bronchi, and so on. Inasmuch as the right mainstem bronchus has a greater diameter than the left and is more nearly parallel with the trachea, inhaled foreign bodies more commonly lodge in the right lung than in the left. Humans have ~23 generations of airways. As generation number increases (i.e., as airways become smaller), the amount of cilia, the number of mucus-secreting cells, the presence of submucosal glands, and the amount of cartilage in the airway walls all gradually decrease. The mucus is important for trapping small foreign particles. The cilia sweep the carpet of mucus—kept moist by secretions from the submucosal glands—up toward the pharynx, where swallowing eventually disposes of the mucus. The cartilage is important for preventing airway collapse, which is especially a problem during expiration

(see [Chapter 27](#)). Airways maintain some cartilage to about the 10th generation, up to which point they are referred to as **bronchi**.

FIGURE 26-5 Generations of airways.

Beginning at about the 11th generation, the now cartilage-free airways are called **bronchioles**. Because they lack cartilage, bronchioles can maintain a patent lumen only because the pressure surrounding them may be more negative than the pressure inside and because of the outward pull (radial traction or tethering) of surrounding tissues. Thus, bronchioles are especially susceptible to collapse during expiration. Up until generation ~16, no alveoli are present, and the air cannot exchange with the pulmonary-capillary blood. The airways from the nose and lips down to the alveoli-free bronchioles are the **conducting airways**, which serve only to move air by convection (i.e., like water moving through a pipe) to those regions of the lung that participate in gas exchange. The most distal conducting airways are the **terminal bronchioles** (generation ~16). The aggregate volume of conducting airways, the **anatomical**

dead space, amounts to ~150 mL in healthy young males and >100 mL in females. The anatomical dead space is only a small fraction of the total lung capacity, which averages 5 to 6 L in adults, depending on the size and health of the individual.

Alveolar air spaces are the site of gas exchange

Alveoli first appear budding off bronchioles at generation ~17. These **respiratory bronchioles** participate in gas exchange over at least part of their surface. Respiratory bronchioles extend from generation ~17 to generation ~19, the density of alveoli gradually increasing with generation number (see Fig. 26-5). Eventually, alveoli completely line the airways. These **alveolar ducts** (generations 20 to 22) finally terminate blindly as **alveolar sacs** (generation 23). The aggregation of all airways arising from a single terminal bronchiole (i.e., the respiratory bronchioles, alveolar ducts, and alveolar sacs), along with their associated blood and lymphatic vessels, is a **terminal respiratory unit** or **primary lobule**.

The cross-sectional area of the trachea is ~2.5 cm². Unlike the situation in systemic arteries (see p. 447), in which the aggregate cross-sectional area of the branches always exceeds the cross-sectional area of the parent vessel, the aggregate cross-sectional area falls from the trachea through the first four generations of airways (Fig. 26-6). Because all of the air that passes through the trachea also passes through the two mainstem bronchi and so on, the product of aggregate cross-sectional area and linear velocity is the same for each generation of conducting airways. Thus, the linear velocity of air in the first four generations is higher than that in the trachea, which may be important during coughing (see p. 719). In succeeding generations, the aggregate cross-sectional area rises, at first slowly and then very steeply. As a result, the linear velocity falls to very low values. For example the terminal bronchioles (generation 16) have an aggregate cross-sectional area of ~180 cm², so that the average linear velocity of the air is only $(2.5 \text{ cm}^2)/(180 \text{ cm}^2) = 1.4\%$ of the value in the trachea.

FIGURE 26-6 Dependence of aggregate cross-sectional area and of linear velocity on generation number. At generation 3, the aggregate cross-sectional area has a minimum (not visible) where velocity has its maximum. (Data from Bouhuys A: *The Physiology of Breathing*. New York, Grune & Stratton, 1977.)

As air moves into the respiratory bronchioles and further into the terminal respiratory unit, where

linear velocity is minuscule, convection becomes less and less important for the movement of gas molecules, and diffusion dominates. Notice that the long-distance movement of gases from the nose and lips to the end of the generation-16 airways occurs by *convection*. However, the short-distance movement of gases from generation-17 airways to the farthest reaches of the alveolar ducts occurs by *diffusion*, as does the movement of gases across the gas exchange barrier ($\sim 0.6\ \mu\text{m}$).

The **alveolus** is the fundamental unit of gas exchange. Alveoli are hemispheric structures with diameters that range from 75 to 300 μm . The ~ 300 million alveoli have a combined surface area of 50 to 100 m^2 and an aggregate maximal volume of 5 to 6 L in the two lungs. Both the diameter and the surface area depend on the degree of lung inflation. The lungs have a relatively modest total volume (i.e., ~ 5.5 L), very little of which is invested in conducting airways (i.e., ~ 0.15 L). However, the alveolar area is tremendously amplified. For example, a sphere with a volume of 5.5 L would have a surface area of only 0.16 m^2 , which is far less than 1% of the alveolar surface area.

The alveolar lining consists of two types of epithelial cells, type I and type II alveolar pneumocytes. The cuboidal type II cells exist in clusters and are responsible for elaborating **pulmonary surfactant**, which substantially eases the expansion of the lungs (see [pp. 613–614](#)). The type I cells are much thinner than the type II cells. Thus, even though the two cell types are present in about equal numbers, the type I cells cover 90% to 95% of the alveolar surface and represent the shortest route for gas diffusion. After an injury, type I cells slough and degenerate, whereas type II cells proliferate and line the alveolar space, re-establishing a continuous epithelial layer. Thus, the type II cells appear to serve as repair cells.

The pulmonary capillaries are usually sandwiched between two alveolar air spaces. In fact, the blood forms an almost uninterrupted sheet that flows like a twisted ribbon between abutting alveoli. At the type I cells, the alveolar wall (i.e., pneumocyte plus endothelial cell) is typically 0.15 to 0.30 μm thick. Small holes (**pores of Kohn**)  [N26-10](#) perforate the septum separating two abutting alveoli. The function of these pores, which are surrounded by capillaries, is unknown.

N26-10

Pores of Kohn

Contributed by Emile Boulpaep, Walter Boron

The so-called pores of Kohn are named after H.N. Kohn, who in 1893 described pores through the alveolar wall in lungs from patients with pneumonia. He thought that these pores were *pathological*. However, nearly a half-century earlier, others had described alveolar pores in *normal* lungs. Kohn's mentor later named the pores after his student, and the name stuck.

Modern ultrastructural findings are consistent with the hypothesis that the pores of Kohn are fixation artifacts. If lungs are fixed by instilling the fixative into the trachea, one can observe small holes in the alveolar wall (Cordingley, 1972). However, if the lungs are fixed by perfusing the pulmonary blood vessels, the alveolar wall is continuous (i.e., no pores are to be seen).

Whether the pores are fixation artifacts or not, they are so small (about half the diameter of a pulmonary capillary) that it is unlikely that they play an important role in collateral ventilation; that is, the movement of air between adjacent alveoli.

For an excellent review, consult Mitzner's chapter in *The Lung*.

The lung receives two blood supplies: the pulmonary arteries and the bronchial arteries ([Fig. 26-7](#)).

The **pulmonary arteries**, by far the major blood supply to the lung, carry the relatively deoxygenated mixed-venous blood. After arising from the right ventricle, they bifurcate as they follow the bronchial tree, and their divisions ultimately form a dense, richly anastomosing, hexagonal array of capillary segments that supply the alveoli of the terminal respiratory unit. The pulmonary capillaries have an average internal diameter of $\sim 8\ \mu\text{m}$, and each segment of the capillary network is $\sim 10\ \mu\text{m}$ in length. The average erythrocyte spends ~ 0.75 second in the pulmonary capillaries as it traverses up to three alveoli. After gas exchange in the alveoli, the blood eventually collects in the pulmonary veins.

FIGURE 26-7 Blood supply to the airways.

The **bronchial arteries** are branches of the aorta and thus carry freshly oxygenated blood. They supply the conducting airways. At the level of the respiratory bronchioles, capillaries derived from bronchial arteries anastomose with those derived from pulmonary arteries. Because capillaries of the bronchial circulation drain partially into pulmonary veins, there is some **venous admixture** of the partially deoxygenated blood from the bronchial circulation and the newly oxygenated blood (see [p. 891](#)). This mixing represents part of a small physiological **shunt**. A small amount of the bronchial blood drains into the azygos and accessory hemiazygos veins.

The lungs play important nonrespiratory roles, including filtering the blood, serving as a reservoir for the left ventricle, and performing several biochemical conversions

Although their main function is to exchange O_2 and CO_2 between the atmosphere and the blood, the lungs also play important roles that are not directly related to external respiration.

Olfaction

Ventilation is essential for delivery of odorants to the olfactory epithelium (see pp. 354–356). Sniffing behavior, especially important for some animals, allows one to sample the chemicals in the air without the risk of bringing potentially noxious agents deep into the lungs.

Processing of Inhaled Air Before It Reaches the Alveoli

Strictly speaking, the warming, moisturizing, and filtering of inhaled air in the conducting airways is a respiratory function. It is part of the cost of doing the business of ventilation. **Warming** of cool, inhaled air is important so that gas exchange in the alveoli takes place at body temperature. If the alveoli and the associated blood were substantially cooler than body temperature, the solubility of these alveolar gases in the cool pulmonary-capillary blood would be relatively high. As the blood later warmed, the solubility of these gases would decrease, resulting in air bubbles (i.e., emboli) that could lodge in small systemic vessels and cause infarction. **Moisturizing** is important to prevent the alveoli from becoming desiccated. Finally, **filtering** of large particles is important to prevent small airways from being clogged with debris that may also be toxic.

Warming, moisturizing, and filtering are all more efficient with nose breathing than with mouth breathing. The nose, including the nasal turbinates, has a huge surface area and a rich blood supply. Nasal hairs tend to filter out large particles (greater than $\sim 15\ \mu\text{m}$ in diameter). The turbulence set up by these hairs—as well as the highly irregular surface topography of the nasal passages—increases the likelihood that particles larger than $\sim 10\ \mu\text{m}$ in diameter will **impact** and embed themselves in the mucus that coats the nasal mucosa. Moreover, air inspired through the nose makes a right-angle turn as it heads toward the trachea. The inertia of larger particles causes them to strike the posterior wall of the nasopharynx, which coincidentally is endowed with large amounts of lymphatic tissue that can mount an immunological attack on inspired microbes. Of the larger particles that manage to escape filtration in the upper airways, almost all will impact the mucus of the trachea and the bronchi.

Smaller particles (2 to $10\ \mu\text{m}$ in diameter) also may impact a mucus layer. In addition, gravity may cause them to **sediment** from the slowly moving air in small airways and to become embedded in mucus. Particles with diameters below $\sim 0.5\ \mu\text{m}$ tend to reach the alveoli suspended in the air as **aerosols**. The airways do not trap most ($\sim 80\%$) of these aerosols but expel them in the exhaled air.

The lung has a variety of strategies for dealing with particles that remain on the surface of the alveoli or penetrate into the interstitial space. Alveolar macrophages (on the surface) or interstitial macrophages may phagocytose these particles, enzymes may degrade them, or lymphatics may carry them away. In addition, particles suspended in the fluid covering the alveolar surface may flow with this fluid up to terminal bronchioles, where they meet a layer of mucus that the cilia propel up to progressively larger airways. There, they join larger particles—which entered the mucus by impaction or sedimentation—on their journey to the oropharynx. Coughing and sneezing (see Box 32-4), reflexes triggered by airway irritation, accelerate the movement of particulates up the conducting airways.

Left Ventricular Reservoir

The highly compliant pulmonary vessels of the prototypic 70-kg human contain ~440 mL of blood (see [Table 19-2](#)), which is an important buffer for filling of the left ventricle. For example, if one clamps the pulmonary artery of an experimental animal so that no blood may enter the lungs, the left side of the heart can suck enough blood from the pulmonary circulation to sustain cardiac output for about two beats.

Filtering Small Emboli from the Blood

The mixed-venous blood contains microscopic emboli, small particles (e.g., blood clots, fat, air bubbles) capable of occluding blood vessels. If these emboli were to reach the systemic circulation and lodge in small vessels that feed tissues with no collateral circulation, the consequences—over time—could be catastrophic. Fortunately, the pulmonary vasculature can trap these emboli before they have a chance to reach the left side of the heart. If the emboli are sufficiently few and small, the affected alveoli can recover their function. Keep in mind that alveolar cells do not need the circulation to provide them with O₂ or to remove their CO₂. In addition, after a small **pulmonary embolism**, alveolar cells may obtain nutrients from anastomoses with the bronchial circulation. However, if pulmonary emboli are sufficiently large or frequent, they can cause serious symptoms or even death. A liability of the blood filtration function is that emboli made up of cancer cells may find the perfect breeding ground for support of metastatic disease.

Biochemical Reactions

The entire cardiac output passes through the lungs, exposing the blood to the tremendous surface area of the pulmonary-capillary endothelium. It is apparently these cells that are responsible for executing biochemical reactions that selectively remove many agents from the circulation while leaving others unaffected ([Table 26-3](#)). Thus, the lung can be instrumental in determining which signaling molecules in the mixed-venous blood reach the systemic arterial blood. The pulmonary endothelium also plays an important role in converting angiotensin I (a decapeptide) to angiotensin II (an octapeptide), a reaction that is catalyzed by angiotensin-converting enzyme (see [p. 841](#)).

TABLE 26-3
Handling of Agents by the Pulmonary Circulation

UNAFFECTED	LARGELY REMOVED
PGA ₁ , PGA ₂ , PGI ₂	PGE ₁ , PGE ₂ , PGF _{2α} , leukotrienes
Histamine, epinephrine, dopamine	Serotonin, bradykinin
Angiotensin II, arginine vasopressin, gastrin, oxytocin	Angiotensin I (converted to angiotensin II)

PG, prostaglandin.

Lung Volumes and Capacities

The spirometer measures changes in lung volume

The maximal volume of all the airways in an adult—the nasopharynx, the trachea, and all airways down to the alveolar sacs—is typically 5 to 6 L. Respiratory physiologists have defined a series of lung “volumes” and “capacities” that, although not corresponding to a particular anatomical locus, are easy to measure with simple laboratory instruments and that convey useful information for clinical assessment.

A **spirometer** measures the volume of air inspired and expired and therefore the change in lung volume. Spirometers today are complex computers, many so small that they can easily be held in the palm of one hand. The subject blows against a predetermined resistance, and the device performs all the calculations and interpretations. Nevertheless, the principles of spirometric analysis are very much the same as those for the “old-fashioned” spirometer shown in [Figure 26-8A](#), which is far easier to conceptualize. This simple spirometer has a movable inverted bell that is partially submerged in water. An air tube extends from the subject's mouth, through the water, and emerges in the bell, just above water level. Thus, when the subject exhales, air enters the bell and lifts it. The change in bell elevation, which we can record on moving paper, is proportional to the volume of air that the subject exhales. Because air in the lungs is saturated with water vapor at 37°C (body temperature and pressure, saturated with water vapor, or **BTPS**), and the air in the spirometer is ambient temperature and pressure, saturated with water vapor, or **ATPS**, we must apply a temperature correction to the spirometer reading (see [Box 26-3](#)).

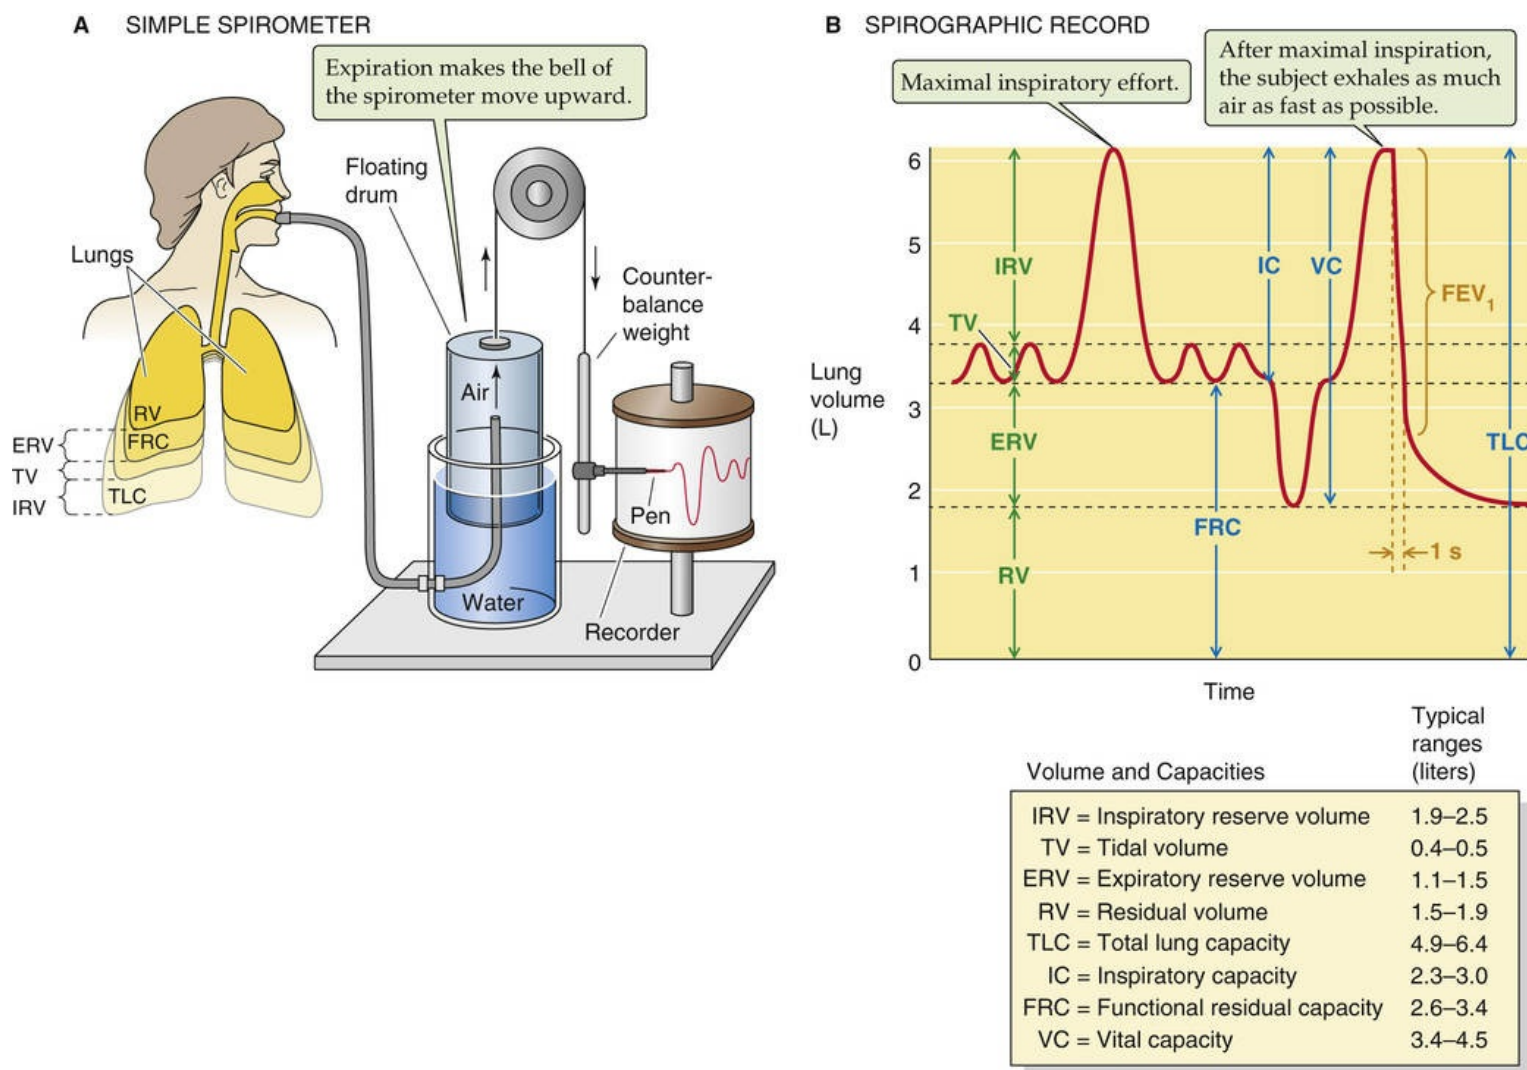

FIGURE 26-8 Workings of a simple spirometer.

The amount of air entering and leaving the lungs with each breath is the **tidal volume** (V_T or TV). During quiet respirations, the V_T is ~ 500 mL. The initial portion of the spiograph of [Figure 26-8B](#) illustrates changes in lung volume during quiet breathing. The product of V_T and the frequency of breaths is **total ventilation**, given in liters (BTPS) per minute.

Because, with a typical Western diet, metabolism consumes more O_2 (~ 250 mL/min) than it produces CO_2 (~ 200 mL/min; see [pp. 1187–1188](#)), the volume of air entering the body with each breath is slightly greater ($\sim 1\%$) than the volume leaving. In reporting changes in lung volume, respiratory physiologists have chosen to measure the volume leaving—the **expired lung volume** (V_E).

At the end of a quiet inspiration, the additional volume of air that the subject *could* inhale with a maximal effort is known as the **inspiratory reserve volume (IRV)**. The magnitude of IRV depends on several factors, including the following:

- 1. Current lung volume.** The greater the lung volume after inspiration, the smaller the IRV.
- 2. Lung compliance.** A decrease in compliance, a measure of how easy it is to inflate the lungs, will cause IRV to fall as well.
- 3. Muscle strength.** If the respiratory muscles are weak, or if their innervation is compromised, IRV will decrease.

4. **Comfort.** Pain associated with injury or disease limits the desire or ability to make a maximal inspiratory effort.
5. **Flexibility of the skeleton.** Joint stiffness, caused by diseases such as arthritis and kyphoscoliosis (i.e., curvature of the spine), reduces the maximal volume to which one can inflate the lungs.
6. **Posture.** IRV falls when a subject is in a recumbent position, because it is more difficult for the diaphragm to move the abdominal contents.

After a quiet expiration, the additional volume of air that one can expire with a maximal effort is the **expiratory reserve volume (ERV)**. The magnitude of the ERV depends on the same factors listed before and on the strength of abdominal and other muscles needed to produce a maximal expiratory effort.

Even after a maximal expiratory effort, a considerable amount of air remains inside the lungs—the **residual volume (RV)**. Because a spirometer can measure only the air entering or leaving the lungs, it obviously is of no use in ascertaining the RV. However, we will see that other methods are available to measure RV. Is it a design flaw for the lungs to contain air that they cannot exhale? Would it not be better for the lungs to exhale all their air and to collapse completely during a maximal expiration? Total collapse would be detrimental for at least two reasons: (1) After an airway collapses, an unusually high pressure is required to reinflate it. By minimizing airway collapse, the presence of an RV optimizes energy expenditure. (2) Blood flow to the lungs and other parts of the body is continuous, even though ventilation is episodic. Thus, even after a maximal expiratory effort, the RV allows a continuous exchange of gases between mixed-venous blood and alveolar air. If the RV were extremely low, the composition of blood leaving the lungs would oscillate widely between a high P_{O_2} at the peak of inspiration and a low P_{O_2} at the nadir of expiration.

The four primary **volumes** that we have defined—TV, IRV, ERV, and RV—do not overlap (see [Fig. 26-8B](#)). The lung capacities are various combinations of these four primary volumes:

1. **Total lung capacity (TLC)** is the sum of all four volumes.
2. **Functional residual capacity (FRC)** is the sum of ERV and RV and is the amount of air remaining inside the respiratory system after a quiet expiration. Because FRC includes RV, we cannot measure it using only a spirometer.
3. **Inspiratory capacity (IC)** is the sum of IRV and TV. After a quiet expiration, the IC is the maximal amount of air that one could still inspire.
4. **Vital capacity (VC)** is the sum of IRV, TV, and ERV. In other words, VC is the maximal achievable TV and depends on the same factors discussed above for IRV and ERV. In patients with pulmonary disease, the physician may periodically monitor VC to follow the progress of the disease.

At the end of the spirographic record in [Figure 26-8B](#), the subject made a maximal inspiratory effort and then exhaled as rapidly and completely as possible. The volume of air exhaled in 1 second under these conditions is the **forced expiratory volume in 1 second (FEV_1)**. In healthy young adults, FEV_1 is ~80% of VC. FEV_1 depends on all the factors that affect VC as well as on airway resistance. Thus, FEV_1 is a valuable measurement for monitoring a variety of pulmonary disorders and the effectiveness of

treatment.

The volume of distribution of helium or nitrogen in the lung is an estimate of the RV

Although we cannot use a spirometer to measure RV or any capacity containing RV (i.e., FRC or TLC), we can use two general approaches to measure RV, both based on the **law of conservation of mass**. In the first approach, we compute RV from the volume of distribution of either helium (He) or nitrogen (N_2). However, any nontoxic gas would do, as long as it does not rapidly cross the blood-gas barrier. In the second approach, discussed in the next section, we compute RV by the use of Boyle's law.

The principle underlying the **volume of distribution** approach is that the concentration of a substance is the ratio of mass (in moles) to volume (in liters). If the mass is constant, and if we can measure the mass and concentration, then we can calculate the volume of the physiological compartment in which the mass is distributed. In our case, we ask the subject to breathe a gas that cannot escape from the airways. From the experimentally determined mass and concentration of that gas, we calculate lung volume.

Helium-Dilution Technique

We begin with a spirometer containing air with 10% He—this is the *initial* He concentration, $[He]_{\text{initial}} = 10\%$ (Fig. 26-9A). We use He because it is poorly soluble in water and therefore diffuses slowly across the alveolar wall (see pp. 661–663). In this example, the initial spirometer volume, $V_{S,\text{initial}}$, including all air up to the valve at the subject's mouth, is 2 L. The amount of He in the spirometer system at the outset of our experiment is thus $[He]_{\text{initial}} \times V_{S,\text{initial}}$, or $(10\%) \times (2 \text{ L}) = 0.2 \text{ L}$.

A HELIUM-DILUTION TECHNIQUE

B NITROGEN-WASHOUT TECHNIQUE

C PLETHYSMOGRAPHIC APPROACH

FIGURE 26-9 Volume-of-distribution and plethysmographic methods for measurement of lung volume. In C, the spirometer is usually replaced in modern plethysmographs by an electronic pressure gauge. In such instruments, the change in lung volume is computed from the change in pressure inside the plethysmograph (see Fig. 27-11).

We now open the valve at the mouth and allow the subject to breathe spirometer air until the He distributes evenly throughout the spirometer and airways. After equilibration, the *final* He concentration ($[\text{He}]_{\text{final}}$) is the same in the airways as it is in the spirometer. The volume of the “system”—the spirometer volume (V_S) plus lung volume (V_L)—is fixed from the instant that we open the valve between the spirometer and the mouth. When the subject inhales, V_L increases and V_S decreases by an equal amount. When the subject exhales, V_L decreases and V_S increases, but ($V_L + V_S$) remains unchanged. Because the system does not lose He, the total He content after equilibration must be the same as it was at the outset. In our example, we assume that $[\text{He}]_{\text{final}}$ is 5%.

If the spirometer and lung volumes at the end of the experiment are the same as those at the beginning,

N26-11

$$[\text{He}]_{\text{initial}} \cdot V_S = [\text{He}]_{\text{final}} \cdot (V_S + V_L)$$

(26-3)

N26-11

Helium-Dilution Technique

Contributed by Emile Boulpaep, Walter Boron

In the text, we assumed that the spirometer volume (V_S) at the time we opened the stopcock in Figure 26-9A was the same as the spirometer volume at the end of the experiment. We also implicitly assumed that the same was true of the lung volume (V_L). However, this need not be true. At the instant we open the stopcock, the total volume of the system—that is, the sum of V_S and V_L —is in principle a constant. As the subject inhales, the V_L increases but V_S decreases, and vice versa. If the spirometer volume at the end of the experiment ($V_{S,\text{final}}$) were different from the spirometer volume at the beginning ($V_{S,\text{initial}}$), then Equation 26-3 in the text would be replaced by the following:

$$[\text{He}]_{\text{initial}} \times V_{S,\text{initial}} = [\text{He}]_{\text{final}} \cdot \underbrace{(V_{S,\text{final}} + V_{L,\text{final}})}_{\text{Total volume of system}}$$

(NE 26-8)

Here, $[\text{He}]_{\text{initial}}$ is the initial concentration of helium in the spirometer and $[\text{He}]_{\text{final}}$ is the final concentration of helium in the spirometer and in the lung's airways. Thus, solving for final lung volume ($V_{L,\text{final}}$), we get

$$V_{L,final} = \frac{[He]_{initial} \times V_{S,initial}}{[He]_{final}} - V_{S,final}$$

(NE 26-9)

If we use the above equation, it does not matter whether the initial and final spirometer volumes are the same. The computed $V_{L,final}$ is the lung volume at the instant we take a reading of $V_{S,final}$. For example, even if the lungs were at FRC at the instant that the stopcock was opened (i.e., at the beginning of the experiment), if the lungs were at RV at the time we measure $V_{L,final}$, (i.e., at the end of the experiment) then Equation NE 26-9 will yield RV. In fact, $V_{L,final}$ can be anywhere between the RV and TLC.

If, at the end of the experiment, the subject adjusts his or her lung volume to be the same as at the beginning, then the initial and final spirometer volumes will also be the same (i.e., $V_{S,initial} = V_{S,final}$). In this case, Equation NE 26-9 simplifies to Equation 26-4 (shown here as Equation NE 26-10):

$$V_L = V_S \cdot \left(\frac{[He]_{initial}}{[He]_{final}} - 1 \right)$$

(NE 26-10)

Solving for lung volume, we get

$$V_L = V_S \cdot \left(\frac{[He]_{initial}}{[He]_{final}} - 1 \right)$$

(26-4)

If we now insert the values from our experiment,

$$V_L = 2L \cdot \left(\frac{10\%}{5\%} - 1 \right) = 2L$$

(26-5)

V_L corresponds to the lung volume at the instant we open the valve and allow He to begin equilibrating. If we wish to measure FRC, we open the valve just after the completion of a *quiet* expiration. If we open the valve after a *maximal* expiration, then the computed V_L is RV. Because the subject rebreathes the air mixture in the spirometer until [He] stabilizes, the He-dilution approach is a **closed-circuit** method.

N₂-Washout Method

Imagine that you have a paper cup that contains a red soft drink. You plan to “empty” the cup but wish to know the “residual volume” of soft drink that will remain stuck to the inside of the cup (V_{cup}) after it is emptied. First, before emptying the cup, you determine the concentration of red dye in the soft drink; this is $[red\ dye]_{cup}$. Now empty the cup. Although you do not yet know V_{cup} , the product $[red\ dye]_{cup} \times V_{cup}$ is

the *mass* of residual red dye that remains in the cup. Next, add hot water to the cup, swish it around inside the glass, and dump the now reddish water into a graduated cylinder. After repeating this exercise several times, you see that virtually all the red dye is now in the graduated cylinder. Finally, determine the volume of fluid in the cylinder (V_{cylinder}) and measure its red dye concentration. Because $[\text{red dye}]_{\text{cup}} \times V_{\text{cup}}$ is the same as $[\text{red dye}]_{\text{cylinder}} \times V_{\text{cylinder}}$, you can easily calculate the residual volume of the soft drink that had been in the glass. This is the principle behind the N_2 -washout method.

Assume that the initial lung volume is V_L and that the initial concentration of nitrogen gas in the lungs is $[\text{N}_2]_{\text{initial}}$. Thus, the *mass* of N_2 in the lungs at the outset is $[\text{N}_2]_{\text{initial}} \times V_L$. We now ask the subject to breathe through a mouthpiece equipped with a special valve (see Fig. 26-9B). During inspiration, the air comes from a reservoir of 100% O_2 ; the key point is that this inspired air contains no N_2 . During expiration, the exhaled air goes to a sack with an initial volume of zero. Each inspiration of 100% O_2 dilutes the N_2 in the lungs. Each expiration sends a fraction of the remaining N_2 into the sack. Thus, the $[\text{N}_2]$ in the lungs falls stepwise with each breath until eventually the subject has washed out into the sack virtually all the N_2 that had initially been in the lungs. Also entering the sack are some of the inspired O_2 and all expired CO_2 . The standard period for washing out of the N_2 with normal breathing is 7 minutes, after which the sack has a volume of V_{sack} and an N_2 concentration of $[\text{N}_2]_{\text{sack}}$. Because the mass of N_2 now in the sack is the same as that previously in the lungs,

$$[\text{N}_2]_{\text{initial}} \cdot V_L = [\text{N}_2]_{\text{sack}} \cdot V_{\text{sack}} \quad (26-6)$$

Thus, the lung volume is

$$V_L = V_{\text{sack}} \cdot \frac{[\text{N}_2]_{\text{sack}}}{[\text{N}_2]_{\text{initial}}} \quad (26-7)$$

To illustrate, consider an instance in which $[\text{N}_2]_{\text{initial}}$ is 75%. If the volume of gas washed into the sack is 40 L, there is roughly a total ventilation of 6 L/min for 7 minutes, and $[\text{N}_2]_{\text{sack}}$ is 3.75%, then

$$V_L = 40\text{L} \cdot \frac{3.75\%}{75\%} = 2\text{L} \quad (26-8)$$

What particular lung volume or capacity does V_L represent? The computed V_L is the lung volume at the instant the subject begins to inhale the 100% O_2 . Therefore, if the subject had just finished a quiet expiration before beginning to inhale the O_2 , V_L would be FRC; if the subject had just finished a maximal expiratory effort, V_L would represent RV.

The key element in the N_2 -washout method is the requirement that during the period of O_2 breathing, all

N₂ previously in the lungs—and no more—end up in the sack. In other words, we assume that N₂ does not significantly diffuse between blood and alveolar air during our 7-minute experiment. Because N₂ has a low water solubility, and therefore the amount dissolved in body fluids is very low at normal barometric pressure, the rate of N₂ diffusion across the alveolar wall is very low (see pp. 661–663). Thus, our assumption is very nearly correct. In principle, we could preload the lung with any nontoxic, water-insoluble gas (e.g., He), and then wash it out with any different gas (e.g., room air). Because the subject inhales from one reservoir and exhales into another in the N₂-washout method, it is an **open-system** technique.

The plethysmograph, together with Boyle's law, is a tool for estimation of RV

We also can compute V_L from small *changes* in lung pressure and volume that occur as a subject attempts to inspire through an obstructed airway. This approach is based on **Boyle's law**, which states that if the temperature and number of gas molecules are constant, the product of pressure and volume is a constant:

$$P \cdot V_L = \text{Constant} \\ (26-9)$$

To take advantage of this relationship, we have the subject step inside an airtight box called a **plethysmograph** (from the Greek *plethein* [to be full]), which is similar to a telephone booth. The subject breathes through a tube that is connected to the outside world (see Fig. 26-9C). Attached to this tube is a gauge that registers pressure at the mouth and an electronically controlled shutter that can, on command, completely obstruct the tube. The Mead-type plethysmograph shown in Figure 26-9C has an attached spirometer. As the subject inhales, lung volume and the volume of the subject's body increase by the same amount, displacing an equal volume of air from the plethysmograph into the spirometer, which registers the increase in lung volume (ΔV_L).

As the experiment starts, the shutter is open, and the subject quietly exhales, so that V_L is FRC. Because no air is flowing at the end of the expiration, the mouth and alveoli are both at barometric pressure, which is registered by the pressure gauge (P). We now close the shutter, and the subject makes a small inspiratory effort, typically only ~50 mL, against the closed inlet tube. The subject's inspiratory effort will cause lung volume to increase to a new value, V_L + ΔV_L (see graph in Fig. 26-9C). However, the number of gas molecules in the airways is unchanged, so this *increase* in volume must be accompanied by a *decrease* in airway pressure (ΔP) to a new value, P – ΔP . Because no air is flowing at the peak of this inspiratory effort, the pressure measured by the gauge at the mouth is once again the same as the alveolar pressure. According to Boyle's law,

$$\underbrace{P \cdot V_L}_{\text{Initial PV product}} = \underbrace{(P - \Delta P) \cdot (V_L + \Delta V_L)}_{\text{PV product at peak of inspiratory effort}}$$

(26-10)

Rearranging [Equation 26-10](#) yields the initial lung volume:

$$V_L = \Delta V_L \cdot \frac{P - \Delta P}{\Delta P}$$

(26-11)

As an example, assume that ΔV_L at the peak of the inspiratory effort is 50 mL and that the corresponding pressure decrease in the airways is 12 mm Hg. If the initial pressure (P) was 760 mm Hg,

$$V_L = 0.050 \text{ L} \cdot \frac{(760 - 12) \text{ mm Hg}}{12 \text{ mm Hg}} = 3.1 \text{ L}$$

(26-12)

What lung volume or capacity does 3.1 L represent? Because, in our example, the inspiratory effort against the closed shutter began after a quiet expiratory effort, the computed V_L is FRC. If it had begun after a maximal expiration, the measured V_L would be RV.

CHAPTER 27

Mechanics of Ventilation

Walter F. Boron

The field of **pulmonary mechanics**—the physics of the lungs, airways, and chest wall—deals with how the body moves air in and out of the lungs, producing a *change* in lung volume (V_L). When we examine these mechanical properties while no air is flowing, we are studying **static** properties. The situation becomes more complicated under **dynamic** conditions, when the lungs are changing volume and air is flowing either in or out.

Static Properties of the Lung

The balance between the outward elastic recoil of the chest wall and the inward elastic recoil of the lungs generates a subatmospheric intrapleural pressure

The interaction between the lungs and the thoracic cage determines V_L . The lungs have a tendency to collapse because of their **elastic recoil**, a *static property* represented by the inwardly directed arrows in [Figure 27-1A](#). The chest wall also has an elastic recoil. However, this elastic recoil tends to pull the thoracic cage outward (see [Fig. 27-1B](#)). The stage is thus set for an interaction between the lungs and the chest wall: at equilibrium, the inward elastic recoil of the lungs exactly balances the outward elastic recoil of the chest wall (see [Fig. 27-1C](#)). This interaction between lungs and chest wall does not occur by direct attachment but via the **intrapleural space** between the visceral and parietal pleurae (see [p. 597](#)). This space is filled with a small amount of pleural fluid and is extremely thin (5 to 35 μm). Because the lungs and chest wall pull away from each other on opposite sides of the intrapleural space, the **intrapleural pressure (P_{ip})** is less than barometric pressure (P_B); that is, the intrapleural space is a *relative vacuum*. Although the designation P_{ip} implies that we are referring exclusively to the intrapleural space, this description is not entirely accurate. Indeed, P_{ip} is probably similar to the pressure in several other regions of the chest cavity in addition to the intrapleural space:

1. The virtual space between the chest wall or diaphragm and the parietal pleura
2. The virtual space between the lung and the visceral pleura
3. The interstitial space that surrounds all pulmonary airways
4. Around the heart and vessels
5. Around and—to the extent that smooth-muscle tone can be neglected—inside the esophagus

A ELASTIC RECOIL OF LUNGS**B ELASTIC RECOIL OF CHEST WALL****C ELASTIC RECOILS OF LUNGS AND CHEST WALL IN BALANCE****FIGURE 27-1** Opposing elastic recoils of the lungs and chest wall.

It is helpful to think of P_{IP} as the intrathoracic pressure—the pressure everywhere in the thorax except in the lumens of blood vessels, lymphatics, or airways. **N27-1**

N27-1**Measurement of P_{IP}**

Contributed by Walter Boron

Measuring P_{IP} is intrinsically difficult because the space between the visceral and parietal pleurae is very thin (5 to 35 μm). The approaches include use of a pleural needle, pleural catheter, esophageal balloon, pleural balloon, or rib capsule (embedded in a rib) in direct contact with pleural fluid.

Each of these methods reports a vertical gradient in pleural pressure, on the order of 0.5 cm $\text{H}_2\text{O}/\text{cm}$ in head-up dogs. This pressure gradient drives a *downward viscous flow* of pleural fluid, presumably along the flat surfaces of the ribs. According to a model, recirculation of pleural fluid would be achieved by an *upward flow* of fluid along the margins of adjacent lobes of the lungs (here the fluid-filled space is larger, which leads to a reduced resistance), energized by movements of the beating heart and ventilating lungs. Finally, a transverse flow of pleural fluid from these margins back to the flat portions of the ribs would complete the circuit.

Lai-Fook SJ. Pleural mechanics and fluid exchange. *Physiol Rev.* 2004;84:385–410.

The vacuum is not uniform throughout the intrapleural space. When the subject is upright, the vacuum is greatest (i.e., P_{IP} is least) near the apex of the lungs and progressively falls along the longitudinal axis to its lowest value near the bases of the lungs (**Fig. 27-2**). If a subject whose lungs are ~30 cm tall has finished a quiet expiration, and if P_B is 760 mm Hg, P_{IP} is ~753 mm Hg near the apices of the lungs and ~758 mm Hg near the bases. The P_{IP} gradient is about what one would expect, given the density of the lungs. Note that P_{IP} is subatmospheric throughout the chest cavity. Because respiratory physiologists

historically measured these small pressures with water manometers rather than with less sensitive mercury manometers, it has become customary to express P_{IP} in *centimeters of H_2O* relative to a PB of 0 cm H_2O . Thus, P_{IP} is about -10 cm H_2O at the apex and -2.5 cm H_2O at the base of the lungs.

FIGURE 27-2 Intrapleural pressures. The values are those after a quiet expiration (i.e., FRC).

The reasons for the apex-to-base P_{IP} gradient are **gravity** and **posture**. When an individual stands vertically on the surface of the earth, gravity pulls the lungs downward and away from the apex of the thoracic cage. This force creates a greater vacuum (i.e., a lower P_{IP}) at the apex. Gravity also pushes the bases of the lungs into the thoracic cavity, reducing the vacuum there. Standing on one's head would invert these relationships. Lying on one's side would create a P_{IP} gradient along a frontal-horizontal axis (i.e., from side to side), although the P_{IP} gradient would be much smaller because the side-to-side dimension of the thorax (and therefore the gradient created by the weight of the lungs) is less than the longitudinal dimension. In outer space, the P_{IP} gradient would vanish. Thus, the local P_{IP} depends on the position within the gravitational field.

For most of the remainder of this book, we ignore the P_{IP} gradient and refer to an average P_{IP} of about -5 cm H_2O after a quiet expiration (see Fig. 27-2).

Contraction of the diaphragm and selected intercostal muscles increases the volume of the thorax, producing an inspiration

We have seen that the opposing elastic recoils of the lungs and chest wall create a negative P_{IP} that keeps the lungs expanded. Any change in the balance between these elastic recoils will cause V_L to change as well. For example, imagine a healthy person with a functional residual capacity (FRC) of 3 L and a P_{IP} of -5 cm H_2O . If that person now develops **pulmonary fibrosis**, which increases the elastic recoil of the lungs, FRC would decrease because a P_{IP} of -5 cm H_2O would no longer be adequate to keep the resting V_L at 3 L. Moreover, as the lungs shrink, P_{IP} would become more negative, causing chest volume to decrease as well. Under normal circumstances, the key elastic recoil is the one we control: the elastic recoil of the chest wall, which we change moment to moment by modulating the tension of the muscles of

respiration.

The **muscles of inspiration** expand the chest, increasing the elastic recoil of the chest wall and making P_{IP} more negative. Despite the P_{IP} gradient from the apex to the base of the lungs when no air is flowing at FRC (see [Fig. 27-2](#)), the ΔP_{IP} during inspiration is similar throughout the thoracic cavity. Responding to this enhanced intrathoracic vacuum, the lungs expand passively. The increase in V_L is virtually the same as the increase in thoracic volume. The muscles that produce a quiet inspiration are called the **primary muscles of inspiration** and include the diaphragm and many intercostal muscles.

The most important component of the increase in chest volume is the rise in the chest cavity's rostral-caudal diameter, a result of the action of the **diaphragm**. Stimulated by the phrenic nerves (derived from cervical roots C3 to C5), the diaphragm contracts and moves downward into the abdomen ~1 cm during quiet ventilation.

The **external and internal intercostal muscles**, innervated by segmental spinal nerves, span the space between adjacent ribs. The action of each such muscle depends partly on its orientation but especially—because of the shape of the rib cage—on its position along the rostral-caudal axis and around the dorsal-ventral circumference of the rib cage. Thus, not all external intercostals are inspiratory, and not all internal intercostals are expiratory. Inspiratory neurons preferentially stimulate the most rostral and dorsal *external* intercostals and the parasternal *internal* intercostals, both of which have inspiratory mechanical advantages.  **N27-2** The contraction of these muscles has two consequences ([Fig. 27-3A](#)). First, the rib cage and the tissues between the ribs stiffen and are therefore better able to withstand the increasingly negative P_{IP} . Second, thoracic volume increases as (a) ribs 2 through 10 rotate upward and outward, increasing the transverse diameter (bucket-handle effect; see [Fig. 27-3B](#)) and (b) the upper ribs rotate the sternum upward and outward, increasing the anterior-posterior diameter (water pump-handle effect).

A INSPIRATION

The most rostral and dorsal subsets of the **external** intercostal muscles (gold)—as well as the parasternal subset of the **internal** intercostal muscles (blue)—have an *inspiratory* mechanical advantage.

B BUCKET-HANDLE AND WATER PUMP-HANDLE EFFECTS

C EXPIRATION

The most caudal subset of the **internal** intercostal muscles (blue)—as well as the caudal-ventral subset of the **external** intercostal muscles (gold) and the triangularis sterni muscle (transversus thoracis)—have an *expiratory* mechanical advantage.

FIGURE 27-3 Actions of major respiratory muscles. External intercostal muscles slope obliquely between the ribs, mostly *forward* and downward. Internal intercostal muscles also slope obliquely between the ribs, but mostly *backward* and downward.

N27-2

Actions of External and Internal Intercostal Muscles

Contributed by Walter Boron

Contrary to conventional wisdom, recent work shows that not all external intercostal muscles are inspiratory and that not all internal intercostal muscles are expiratory. For an exhaustive analysis of this subject, consult the review below.

Reference

De Troyer A, Kirkwood PA, Wilson TA. Respiratory action of the intercostal muscles. *Physiol Rev.* 2005;85:717–756.

During a **forced** inspiration, the **accessory** (or **secondary**) **muscles** of inspiration also come into play:

1. **Scalenes.** These muscles lift the first two ribs.
2. **Sternocleidomastoids.** These muscles lift the sternum outward, contributing to the water pump–handle effect.

3. **Neck and back muscles.** These elevate the pectoral girdle (increasing the cross-sectional area of the thorax) and extend the back (increasing the rostral-caudal length).

4. **Upper respiratory tract muscles.** The actions of these muscles decrease airway resistance.

Relaxation of the muscles of inspiration produces a quiet expiration

During a *quiet* inspiration, *normal* lungs store enough energy in their elastic recoil to fuel a quiet expiration, just as stretching of a rubber band stores enough energy to fuel the return to initial length. Thus, a quiet expiration is normally passive, accomplished simply by relaxation of the muscles of inspiration. Thus, *there are no primary muscles of expiration.*

Expiration is not *always* entirely passive. One example is a forced expiration in an individual with normal airway resistance. Another is even a quiet expiration of a person with a disease that increases airway resistance (e.g., asthma, chronic bronchitis, emphysema). In either case, the **accessory muscles of expiration** help make P_{ip} more positive:

1. **Abdominal muscles** (internal and external oblique, rectoabdominal, and transverse abdominal muscles). Contraction of these muscles (see Fig. 27-3C) increases intra-abdominal pressure and forces the diaphragm upward into the chest cavity, decreasing the rostral-caudal diameter of the thorax and increasing P_{ip} .

2. **Intercostals.** The most ventral and caudal *external* intercostals, the most dorsal and lateral of the caudal *internal* intercostals, and an intercostal-like muscle called the triangularis sterni all have an expiratory mechanical advantage. Expiratory neurons selectively stimulate these muscles so as to reduce both the anterior-posterior and the transverse diameters of the thorax. These actions are particularly important for coughing.

3. **Neck and back muscles.** Lowering of the pectoral girdle reduces the cross-sectional area of the thorax, whereas flexion of the trunk reduces the rostral-caudal diameter.

During a forced *inspiration*, the accessory muscles of inspiration use their energy mainly to increase V_L (rather than to overcome resistance to airflow); the lungs store this extra energy in their elastic recoil. During a forced *expiration*, the accessory muscles of expiration use their energy mainly to overcome the resistance to airflow, as discussed below.

An increase of the static compliance makes it easier to inflate the lungs

Imagine that a person experiences a puncture wound to the chest cavity, so that air enters the thorax from the atmosphere, raising P_{ip} to the same level as P_B . This condition is called a **pneumothorax** (from the Greek *pneuma* [air]). With no vacuum to counter their elastic recoil, alveoli will collapse—a condition known as **atelectasis**. The upper part of Figure 27-4A illustrates an extreme hypothetical case in which pressure is atmospheric throughout the thorax. Even though the lungs are collapsed, V_L is not zero because proximal airways collapse before smaller ones farther downstream, trapping air. The resulting **minimal**

air volume is ~10% of total lung capacity (TLC), typically ~500 mL.

A PNEUMOTHORAX AND LUNG REINFLATION

B STATIC PRESSURE-VOLUME DIAGRAM

FIGURE 27-4 Collapse and reinflation of the lungs. In **A**, we assume that P_{IP} rises to P_B , so that P_{TP} falls to zero, collapsing the lungs.

We now wish to re-expand the collapsed lungs to their original volume (i.e., FRC). What are the forces at work during such a re-expansion? The force responsible for distending an airway is the **transmural pressure (P_{TM})**—the *radial* pressure difference across an airway wall at any point along the tracheobronchial tree:

$$P_{TM} = P_{AW} - P_{IP} \quad (27-1)$$

P_{AW} is the pressure inside the airway, and P_{IP} is the pressure in the interstitial space surrounding the airway. A special case of P_{TM} is the transmural pressure across the *alveolar* wall—**transpulmonary pressure (P_{TP})**:

$$P_{TP} = P_A - P_{IP} \quad (27-2)$$

P_A is **alveolar pressure**. When the glottis is open and no air is flowing, the lungs are under **static conditions**, and P_A must be 0 cm H₂O:

$$\begin{array}{l} \text{Static conditions: } P_{TP} = 0 - P_{IP} = -P_{IP} \\ \text{(glottis open)} \end{array} \quad (27-3)$$

Thus, with the glottis open under static conditions, the pressure that inflates the alveoli (i.e., P_{TP}) is simply the negative of P_{IP} . We can re-expand the lungs to FRC by any combination of an increase in P_A and a decrease in P_{IP} , as long as P_{TP} ends up at 5 cm H₂O (see Fig. 27-4A, lower panels). Thus, it makes no difference whether we increase P_A from 0 to +5 cm H₂O with P_{IP} fixed at zero (the principle behind positive-pressure ventilation in an intensive care unit) or whether we decrease P_{IP} from 0 to –5 cm H₂O with P_A fixed at zero (the principle behind physiological ventilation). In both cases, V_L increases by the same amount.

A clinician would treat the pneumothorax by inserting a chest tube through the wound into the thoracic cavity and gradually pumping out the intrathoracic air. The clinician might also insert a tube through the mouth and into the upper trachea (to ensure a patent airway), use a mechanical ventilator (to ensure gas exchange), and sedate the patient (to prevent the patient from fighting the ventilator). Between the inspiratory cycles of the ventilator, the *lungs are under static conditions* and V_L depends only on P_{TP} —that is, the difference between P_A (which is set by the ventilator) and P_{IP} . As we remove air from the thorax, P_{IP} becomes more negative and the alveoli re-expand. We can characterize the elastic (or static) properties of the lungs by plotting V_L versus P_{TP} as V_L increases (see Fig. 27-4B, purple curve). How do

we obtain the necessary data? In principle, we could determine V_L by using [Equation 26-4](#). We could read off P_A (needed to compute P_{TP}) directly from the ventilator. Finally, we could in principle measure P_{IP} by using a pressure transducer at the tip of the chest tube. Most important, we must take our readings between inspiratory cycles of the ventilator—under *static conditions*.

During the reinflation, measured under static conditions, we can divide the effect on V_L into four stages, starting at the left end of the purple curve in [Figure 27-4B](#):

Step 1: Stable V_L . In the lowest range of P_{IP} values, making P_{IP} more negative has little or no effect on V_L . For example, decreasing P_{IP} from 0 to -1 cm H₂O (i.e., increasing P_{TP} from 0 to $+1$ cm H₂O), we record no change in V_L . Why? As discussed below, it is very difficult—because of the surface tension created by the air-water interface—to pop open an airway that is completely collapsed. Until P_{TP} is large enough to overcome the collapsing effects of surface tension, a decrease in P_{IP} has no effect on V_L .

Step 2: Opening of airways. Decreasing P_{IP} beyond about -8 cm H₂O produces V_L increases that are at first small, reflecting the popping open of proximal airways with the greatest compliance. Further decreasing P_{IP} produces larger increases in V_L , reflecting the expansion of already-open airways as well as recruitment of others.

Step 3: Linear expansion of open airways. After all the airways are already open, making P_{IP} increasingly more negative inflates all airways further, causing V_L to increase in a roughly linear fashion.

Step 4: Limit of airway inflation. As V_L approaches TLC, decreases in P_{IP} produce ever smaller increases in V_L , which reflects decreased airway and chest-wall compliance and the limits of muscle strength.

What would happen if, having inflated the lungs to TLC, we allowed P_{IP} to increase to 0 cm H₂O once again? Obviously, the V_L would decrease. However, the lungs follow a different path during deflation (see [Fig. 27-4B](#), red curve), creating a **P_{IP} - V_L loop**. The difference between the inflation and the deflation paths—**hysteresis**—exists because a greater P_{TP} is required *to open* a previously closed airway, owing to a deficit of surfactant at the air-water interface, than *to keep* an open airway from closing, due to the abundance of surfactant. We will discuss surfactant in the next section. The horizontal dashed line in [Figure 27-4B](#) shows that *inflating* previously collapsed lungs to FRC requires a P_{IP} of -12 cm H₂O (purple point), whereas *maintaining* previously inflated lungs at FRC requires a P_{IP} slightly less negative than -5 cm H₂O (red point). During normal ventilation, the lungs exhibit much less hysteresis, and the green P_{IP} - V_L loop in [Figure 27-4B](#) lies close to the red deflation limb of our original loop. The changes in V_L in [Figure 27-4B](#) reflect mainly changes in the volume of *alveoli*, with a small contribution from conducting airways.

We will now focus on just the red curve in [Figure 27-4B](#), a portion of which is the middle curve in [Figure 27-5](#). Here, P_{TP} is $+5$ cm H₂O when V_L is at FRC. As the subject makes a normal inspiration with a tidal volume (V_T) of 500 mL, P_{TP} increases (i.e., P_{IP} decreases) by 2.5 cm H₂O. The ratio of ΔV_L to ΔP_{TP} (i.e., the slope of the P_{TP} - V_L curve) is the compliance, a measure of the distensibility of the lungs. In our

example,

$$C = \frac{\Delta V_T}{\Delta P_{TP}} = \frac{0.5L}{(7.5 - 5.0) \text{ cm H}_2\text{O}} = 0.2 \frac{L}{\text{cm H}_2\text{O}}$$

(27-4)

FIGURE 27-5 Static pressure-volume curves for healthy and diseased lungs.

Because we made this measurement under conditions of zero airflow, C is the **static compliance**. Static compliance, like V_L , is mainly a property of the alveoli. The elastance of the lungs, which is a measure of their *elastic recoil*, is the reciprocal of the compliance ($E = 1/C$). Lungs with a high compliance have a low elastic recoil, and vice versa.

Figure 27-5 also shows representative P_{TP} - V_L relationships for lungs of patients with pulmonary fibrosis (bottom curve) and emphysema (top curve). In **pulmonary fibrosis**, the disease process causes deposition of fibrous tissue, so that the lung is stiff and difficult to inflate. Patients with **restrictive lung disease**, by definition, have a decreased C (i.e., a decreased slope of the V_L - P_{TP} relationship in Fig. 27-5) at a given V_L . The same ΔP_{TP} that produces a 500-mL V_L increase in normal lungs produces a substantially *smaller* V_L increase in fibrotic lungs. In other words, static compliance ($\Delta V_L / \Delta P_{TP}$) is much less, or elastic recoil is much greater.

In **emphysema**, the situation is reversed. The disease process, a common consequence of cigarette smoking, destroys pulmonary tissue and makes the lungs floppy. An important part of the disease process is the destruction of the extracellular matrix, including elastin, by elastase released from macrophages. Normal mice that are exposed to cigarette smoke develop emphysema rapidly, whereas the disease does not develop in “smoker” mice lacking the macrophage elastase gene. The same increase in P_{TP} that

produces a 500-mL V_L increase in normal lungs produces a substantially *larger* V_L increase in lungs with emphysema. In other words, static compliance is much greater (i.e., much less elastic recoil).

Because it requires work to inflate the lungs against their elastic recoil, one might think that a little emphysema might be a good thing. Although it is true that patients with emphysema exert less effort to inflate their lungs, the cigarette smoker pays a terrible price for this small advantage. The destruction of pulmonary architecture also makes emphysematous airways more prone to collapse during expiration, which drastically increases airway resistance.

Two additional points are worth noting. First, compliance (i.e., slope of the P_{TP} - V_L curve) decreases as V_L increases from FRC to TLC (see Fig. 27-5). Second, the P_{TP} - V_L curve is the amalgam of pressure-volume relationships of all alveoli. Different alveoli have different P_{TP} - V_L curves and may experience different intrapleural pressures, depending on their position within a gravitational field (see Fig. 27-2). This inhomogeneity of static parameters contributes to regional differences in ventilation (see pp. 687–689; Box 27-1).

Box 27-1

Restrictive Pulmonary Disease

Two major categories of pulmonary disease—restrictive and obstructive—can severely reduce **total ventilation**; that is, the amount of air entering and leaving the lungs per unit of time. We discuss obstructive diseases (which affect the resistance of the conducting airways) in Box 27-2.

Pulmonologists use the term **restrictive lung disease** in an inclusive sense to refer to any disorder that reduces FRC, vital capacity, or TLC (see Fig. 26-8B) and thereby makes the lungs difficult to inflate. Pure restrictive disease does not affect airway resistance. Restrictive disease can target the *lung parenchyma* or three *extrapulmonary* structures, as outlined in the next four paragraphs.

Lung Parenchyma

Restrictive diseases of the lung parenchyma decrease the static compliance of the lung—mainly a property of the alveoli. To overcome increased elastic recoil, the patient must make extra effort to inhale. The patient compensates by making rapid but shallow inspirations. In newborns, an example is **infant respiratory distress syndrome**, caused by a deficiency in surfactant. **Pulmonary edema** is a buildup of fluid in the interstitial space between the alveolar and capillary walls and, eventually, the alveolar space. Interstitial inflammation of a variety of etiologies (e.g., infection, drugs, environmental exposure) can lead to the deposition of fibrous tissue and a group of diseases called **diffuse interstitial pulmonary fibrosis**.

Pleura

A buildup in the intrapleural space of either air (pneumothorax) or fluid (pleural effusion) can restrict the expansion of a vast number of alveoli.

Chest Wall

Rigidity of the chest wall makes it difficult to increase thoracic volume even if the neuromuscular system (see next) can generate normal forces. **Ankylosing spondylitis** is an inflammatory disorder of the axial skeleton that may reduce the bucket-handle rotation of the ribs during quiet inspirations and the flexion and extension of the trunk during forced inspirations and expirations. In **kyphoscoliosis** (angulation and rotation of the spine), deformation of the vertebrae and ribs may reduce ventilation. In both conditions,

impairment of coughing predisposes to lung infections.

Neuromuscular System

The central nervous system may fail to stimulate the respiratory muscles adequately, or the muscles may fail to respond appropriately to stimulation. In **polio**, the virus occasionally attacks respiratory control centers in the brainstem (see p. 702). **Amyotrophic lateral sclerosis (ALS)** or Lou Gehrig disease) leads to the destruction of premotor and motor neurons, including those to the muscles of respiration (see p. 700). Indeed, dyspnea on exertion is a common early symptom of ALS. Certain **drug overdoses** (e.g., barbiturate poisoning) may temporarily inhibit respiratory control centers in the brainstem. In the absence of supportive therapy (i.e., mechanical ventilation), the respiratory failure can be fatal. The pain that accompanies surgery or other injuries to the chest can also severely limit the ability to ventilate. **Local paralysis** of intercostal muscles allows the enhanced intrathoracic vacuum to suck in intercostal tissues during inspiration. This paradoxical movement reduces the efficiency of inspiration. Paradoxical movement may also occur with broken ribs, a condition known as **flail chest**.

Surface tension at the air-water interface of the airways accounts for most of the elastic recoil of the lungs

What is the basis of the elastic recoil that determines the static compliance of the lungs? The elasticity of pulmonary cells and the extracellular matrix (e.g., elastin and collagen), what we might think of as the “anatomical” component of elastic recoil, generally accounts for a small part. The basis of most of the recoil was suggested in 1929 by von Neergaard, who excised lungs from cats and inflated them by applying positive pressure to the trachea under two conditions. When he filled the lungs with air, the P_{TP} - V_L curve looked similar to the one we have seen before (Fig. 27-6A, blue curve). However, when he degassed the airways and reinflated them with saline, he found that (1) the P_{TP} - V_L relationship (see Fig. 27-6A, orange curve) exhibited far less hysteresis, and (2) the static compliance was substantially greater (i.e., much less pressure was required to inflate the lungs). These changes occurred because the saline-filled lungs lacked the air-water interface that generated surface tension in the air-filled lungs. It is this surface tension that is responsible for a large fraction of the lung's elastic recoil.

A EFFECT OF SURFACE TENSION ON COMPLIANCE

B FLAT AIR-WATER INTERFACE

C DEFINITION OF SURFACE TENSION

D SPHERICAL AIR-WATER INTERFACE

FIGURE 27-6 Effect of surface tension on the lung.

Surface tension is a measure of the force acting to pull a liquid's surface molecules together at an air-liquid interface (see Fig. 27-6B). Water molecules in the bulk liquid phase are equally attracted to surrounding water molecules in all directions, so that the net force acting on these “deep” water molecules is zero. However, water molecules at the surface are equally attracted to others in all

directions but “up,” where no molecules are available to pull surface water molecules toward the air phase. Thus, a net force pulls surface molecules away from the air-water interface toward the bulk water phase.

We can think of the surface water molecules as beads connected by an elastic band. The force that pulls a water molecule down into the bulk also creates a *tension* between the molecules that remain at the surface, in a direction that is *parallel* to the surface. If we try to overcome this tension and stretch the air-water interface (see Fig. 27-6C), thus increasing its area, we must apply force (\mathcal{F}) to bring water molecules from the bulk liquid (a low-energy state) to the surface (a high-energy state). If the body of water on which we tug has a length of l , then the surface tension (T) is

$$T = \frac{\mathcal{F}}{l}$$

(27-5)

For a simple air-water interface at 37°C, the surface tension is ~70 dynes/cm.

A drop of water falling through the air tends to form into a sphere because this shape has the smallest surface area and thus the lowest energy. Put differently, when the drop is spherical, it is impossible for any additional water molecules to leave the surface.

In the reverse scenario, a spherical air bubble surrounded by water (see Fig. 27-6D), unbalanced forces acting on surface water molecules cause them to dive into the bulk, which decreases the surface area and creates tension in the plane of the air-water interface. This surface tension acts like a belt tightening around one's waist. It tends to decrease the volume of compressible gas inside the bubble and increases its pressure. At equilibrium, the tendency of increased pressure to expand the gas bubble balances the tendency of surface tension to collapse it. The Laplace equation describes this equilibrium:

🔗N27-3

N27-3

Laplace's Law for a Sphere

Contributed by Emile Boulpaep, Walter Boron

Imagine a soap bubble that is perfectly spherical. At equilibrium, the tendency of the transmural pressure (P) to expand the bubble exactly balances the tendency of the surface tension (T) to collapse the bubble. An infinitesimally small change in the radius of the sphere (dr) would produce infinitesimally small changes in both the area of the sphere (dA) and the volume of the sphere (dV). The infinitesimally small amount of pressure \times volume work done in expanding the volume would equal the tension \times area work done in expanding the surface area:

$$\underbrace{dW}_{\text{dynes} \cdot \text{cm}} = \underbrace{P}_{\frac{\text{dynes}}{\text{cm}^2}} \underbrace{dV}_{\text{cm}^3} = \underbrace{T}_{\frac{\text{dynes}}{\text{cm}}} \underbrace{dA}_{\text{cm}^2}$$

(NE 27-1)

Because the volume of a sphere is $(4/3)\pi r^3$,

$$dV = d \underbrace{\left(\frac{4}{3} \pi r^3 \right)}_{\text{Volume}} = 4\pi r^2 dr$$

(NE 27-2)

Similarly, the area of a sphere is $4\pi r^2$. Thus,

$$dA = d \underbrace{(4\pi r^2)}_{\text{Volume}} = 8\pi r dr$$

(NE 27-3)

Substituting the expressions for dV (see Equation NE 27-2) and dA (see Equation NE 27-3) into Equation NE 27-1, we have

$$P dV = P (4\pi r^2 dr) = T (8\pi r dr) = T dA$$

(NE 27-4)

Rearranging and solving for P , we have

$$P = \frac{2T}{r}$$

(NE 27-5)

In our example of a soap bubble—and also in the hypothetical example of a perfectly spherical alveolus— T is a constant, r is the independent variable, and P is the dependent variable. Thus, a sphere with a smaller radius must have a larger transmural pressure to remain in equilibrium.

The article by Prange discusses the limitations in applying Laplace's law to alveoli. As noted in the text on page 613, the alveoli are neither perfect spheres nor uniform spheres. Moreover, their interiors are interconnected, and individual alveoli often share walls with their adjacent neighbors (**principle of interdependence**).

Reference

Prange HD. Laplace's law and the alveolus: A misconception of anatomy and a misapplication of physics. *Adv Physiol Educ*. 2003;27:34–40.

$$P = \frac{2T}{r}$$

(27-6)

P is the *dependent* variable, the surface tension T is a *constant* for a particular interface, and the bubble radius r is the *independent* variable. Therefore, the smaller the bubble's radius, the greater the

pressure needed to keep the bubble inflated. See [pages 455–457](#) for a description of how Laplace's treatment applies to blood vessels.

Our bubble-in-water analysis is important for the lung because a thin layer of water covers the inner surface of the alveolus. Just as surface tension at the air-water interface of our gas bubble causes the bubble to constrict, it also causes alveoli and other airways to constrict, contributing greatly to elastic recoil.

The analogy between air bubbles and alveoli breaks down somewhat because an alveolus only approximates a part of a sphere. A second complicating factor is that not all alveoli are the same size; some may have a diameter that is three or four times larger than that of others. Third, alveoli are interconnected.

[Figure 27-6E](#) shows what would happen if two imaginary air bubbles in water were connected by a tube with a valve that allows us to make or break the connection between the bubbles. For both, assume that the surface tension T is 70 dynes/cm. The valve is initially closed. The first bubble has a radius of 0.010 cm. The second is only half as wide. At equilibrium, the pressure required to keep the smaller bubble inflated is twice that necessary to keep the larger bubble inflated (see calculations in [Fig. 27-6E](#)). If we now open the valve between the two bubbles, air will flow from the smaller bubble to the larger bubble. To make matters worse for the smaller bubble, the smaller it becomes, the greater is the pressure needed to stabilize its shrinking radius. Because its pressure is less than required, air continues to flow out of the smaller bubble until it implodes completely.

In principle, the lung faces a similar problem. Smaller alveoli tend to collapse into larger ones. As we shall see, pulmonary surfactant minimizes this collapsing tendency by lowering surface tension. However, even without surfactant, the collapse of small alveoli could proceed only so far because each alveolus is tethered to adjacent alveoli, which help hold it open—the **principle of interdependence**.

Why would it matter if many smaller alveoli collapsed into a few larger alveoli? Such a collapse would reduce the total alveolar surface area available for diffusion of O_2 and CO_2 (see [p. 661](#)). Thus, from a teleological point of view, it is important for the lung to keep the alveoli as uniformly inflated as possible.

Pulmonary surfactant is a mixture of lipids—mainly dipalmitoylphosphatidylcholine—and apoproteins

As noted above, surface tension accounts for most of the elastic recoil in normal lungs. However, if it were not for pulmonary surfactant, total elastic recoil would be even higher, and the lungs would be far more difficult to inflate. During quiet breathing, surfactant reduces surface tension to ~ 25 dynes/cm or less, far below the value of 70 dynes/cm that exists at a pure air-water interface.

The term **surfactant** means a surface-active agent. Because surfactants have both a *hydrophilic* region (strongly attracted to water) and a *hydrophobic* region (strongly repelled by water), they localize to the surface of an air-water interface. An example of a synthetic surfactant is dishwashing detergent. As a younger student, you may have done a simple experiment in which you filled a small-diameter cup with water and carefully floated a thin sewing needle—lengthwise—on the surface. The needle, like an insect that walks on water, is supported by surface tension, which pulls in the plane of the air-water interface. When you add a drop of liquid detergent to the surface of the water, the needle instantly sinks. Why? The detergent greatly reduces the surface tension.

Detergent molecules orient themselves so that their hydrophilic heads point toward (and interact with)

the most superficial water molecules, whereas the hydrophobic tails point toward the air (Fig. 27-7). The hydrophilic surfactant *heads* pull strongly upward on the most superficial water molecules, greatly reducing the net force on these surface water molecules and minimizing their tendency to dive into the bulk water. What prevents surfactant at the air-surfactant interface from diving into the bulk water? The hydrophobic *tails* exert a counterforce, pulling the surfactant upward toward the air. The situation is not unlike that of a fishing line with a bobber at one end and a sinker at the other: as long as the bobber is sufficiently buoyant, it remains at the water's surface. Thus, unlike surface water molecules, which are subjected to a large net force pulling them into the bulk, surfactant experiences a much smaller net force. The greater the surface density of surfactant molecules at the air-water interface (i.e., the smaller the surface occupied by water molecules), the smaller the surface tension.

FIGURE 27-7 Effect of a surface-active agent on surface tension.

Pulmonary surfactant is a complex mixture of lipids and proteins. Type II alveolar cells (see p. 599), cuboidal epithelial cells that coexist with the much thinner type I cells, synthesize and secrete pulmonary surfactant. Clara cells in the respiratory bronchioles manufacture at least some components of pulmonary surfactant. Lipids make up ~90% of surfactant and are responsible for the surface-active properties. About half of the lipid is **dipalmitoylphosphatidylcholine (DPPC)**. Figure 27-8 shows the synthesis and structure of DPPC (also known as dipalmitoyl lecithin), which contains two *fully saturated* 16-carbon fatty-acid chains (i.e., palmitates). The second most common lipids in pulmonary surfactant are phosphatidylcholine molecules with *unsaturated* fatty-acid chains. Compared with cell membranes, phosphatidylglycerol (~11% of lipid) is overrepresented in surfactant.

N27-12

DPPC Synthesis near Birth

Contributed by Ervin Jones, Walter Boron

Dipalmitoylphosphatidylcholine (DPPC)—also known as dipalmitoyl lecithin—is the major component of pulmonary surfactant. As outlined in Figure 27-8, the condensation of diacylglycerol with cytosine diphosphate choline ultimately leads to the production of DPPC. In the fetus, shortly before birth, an increase in plasma cortisol levels upregulates several enzymes that are important for the synthesis of DPPC, including fatty-acid synthase and phosphocholine transferase.

Proteins account for the remaining ~10% of pulmonary surfactant. Plasma proteins (mainly albumin) and secretory immunoglobulin A make up about half of the protein, and four **apoproteins** (SP-A, SP-B, SP-C, and SP-D) make up the rest. **SP-A** and **SP-D** are water soluble and have collagen-like domains (Table 27-1). Both contribute to “innate immunity” by acting as opsonins to coat bacteria and viruses, thereby promoting phagocytosis by macrophages resident in the alveoli. In addition, SP-A  **N27-4** may be important for feedback control that limits surfactant secretion. The two hydrophobic apoproteins, **SP-B** and **SP-C**, are intrinsic membrane proteins that greatly increase the rate at which surfactant enters the air-water interface and then spreads as a surface film. The hereditary absence of SP-B leads to respiratory distress that is fatal unless the newborn receives a lung transplant.

Surfactant Apoprotein SP-A

Contributed by Walter Boron

EFigure 27-1 Representation of apoprotein SP-A.

The lipid components of pulmonary surfactant enter type II cells from the bloodstream ([Fig. 27-9A](#)). Type II cells use the secretory pathway (see [pp. 34–35](#)) to synthesize the four apoproteins, all of which undergo substantial post-translational modification. The final assembly of surfactant occurs in **lamellar bodies**, which are $\sim 1\ \mu\text{m}$ in diameter and consist of concentric layers of lipid and protein (see [Fig. 27-9B](#)). Some of the material in these lamellar bodies represents newly synthesized components, and some of it represents recycled surfactant components retrieved from the alveolar surface. Each hour, the normal lung secretes into the alveolar space $\sim 10\%$ of the material present in the lamellar bodies.

FIGURE 27-9 Generation of pulmonary surfactant. In **B**, the structures with concentric layers are lamellar bodies, which are continuous with tubular myelin (grid-like structures). (B, Courtesy of Dr. M. C. Williams, University of California, San Diego.)

The secretion of pulmonary surfactant occurs by constitutive exocytosis (see p. 35). In the fetus, both synthesis and secretion are quite low until immediately before birth, when a surge in maternal glucocorticoid levels triggers these processes (see p. 1156). Infants born prematurely may thus lack sufficient levels of surfactant and may develop **infant respiratory distress syndrome (IRDS)**; see p. 1156). In postnatal life, several stimuli enhance the surfactant secretion, including hyperinflation of the lungs (e.g., sighing and yawning), exercise, and pharmacological agents (e.g., β -adrenergic agonists, Ca^{2+} ionophores).

After its secretion into the thin layer of water that covers the alveolar epithelium, freed from the physical constraints of confinement to a lamellar body, pulmonary surfactant undergoes major structural changes. In this aqueous layer, surfactant takes on the form of a meshwork known as **tubular myelin** (see Fig. 27-9B), which is rich in surfactant apoproteins. It is not clear whether surfactant normally passes through the tubular-myelin state before forming a surface film at the air-water interface. However, tubular myelin is not *required*; SP-A knockout mice lack tubular myelin but have a normal surface film.

Two mechanisms remove components of pulmonary surfactant from the surface of alveoli. Alveolar macrophages degrade some of the surfactant. Type II cells take up the rest, and either recycle or destroy it.

Pulmonary surfactant reduces surface tension and increases compliance

The pulmonary surfactant present at the alveolar air-water interface has three major effects.

First, because surfactant reduces surface tension, it increases compliance, making it far easier to inflate the lungs. If surfactant suddenly disappeared from the lungs, mimicking the situation in IRDS, total elastic recoil would increase (i.e., compliance would *decrease*) twofold or more, causing small airways to collapse partially. The situation would be similar to that described by the fibrosis curve in [Figure 27-5](#). Because the compliance of the lungs is far lower than normal, an infant with IRDS—compared with a normal infant—must produce far larger changes in P_{TP} (or P_{IP}) to achieve the same increase in V_L . Therefore, infants with low surfactant levels must expend tremendous effort to contract their inspiratory muscles and expand the lungs.

Second, by reducing surface tension, surfactant minimizes fluid accumulation in the alveolus. In the absence of surfactant, the large surface tension of the liquid layer between the air and the alveolar type I cells would cause the “air bubble” to collapse, drawing fluid into the alveolar space from the interstitium. The net effect would be to increase the thickness of the liquid layer and thereby impair gas diffusion. With normal levels of surfactant, the surface tension of the water layer is low, and the tendency to draw fluid from the interstitium to the alveolar space is balanced by the negative interstitial hydrostatic pressure (i.e., P_{IP}), which favors fluid movement from the alveolar space into the interstitium.

Third, surfactant helps keep alveolar size relatively uniform during the respiratory cycle. Imagine that we start—after a quiet expiration—with two alveoli having the same radius (e.g., 100 μm) and the same surface density of surfactant (to yield a surface tension of 20 dynes/cm), as indicated by the inner dashed circles of the two alveoli in [Figure 27-10](#). However, either the conducting airway leading to the lower alveolus has a higher resistance or the lower alveolus itself has more fibrous tissue. Either way, the lower alveolus inflates more slowly during inspiration and—at any time—has a smaller volume than the upper one. This size difference has two negative consequences: (1) The total surface area of the two alveoli is less than if they had inflated equally, which impairs gas diffusion. (2) Because the final volume increase of the upper alveolus may be greater than that of the lower one, its ventilation may be greater. Such unevenness of ventilation impairs effective gas exchange (see [p. 693](#)).

FIGURE 27-10 Braking action of surfactant on inflation.

Fortunately, surfactant helps alveoli dynamically adjust their rates of inflation and deflation, so that ventilation is more uniform among alveoli. During rapid inflation, the alveolar surface expands more rapidly than additional surfactant can reach the surface from a surfactant pool beneath the surface. Thus, surfactant on the surface is thought to break up like a flow of ice on the sea, with open areas of pure water between clusters of surfactant. With more exposed water at the surface, surface tension increases. Surface tension may double during inspiration, compared with the resting value at FRC. This effect would be exaggerated in rapidly expanding alveoli, which would develop a higher surface tension more quickly than slowly expanding alveoli. This higher surface tension produces a greater elastic recoil that opposes further expansion. Thus, the dilution of surfactant tends to put more of a brake on rapidly expanding airways, slowing their expansion to more nearly match that of alveoli that tend to inflate more slowly. 🗨️

N27-5

Role of Surfactant in the “Static” Pressure-Volume Loop

Contributed by Emile Boulpaep, Walter Boron

The classic static pressure-volume loop exhibits considerable hysteresis (see large loop formed by purple and red curves in Fig. 27-4). This hysteresis is due in large part to the movement of surfactant into the air-water interface as the lung inflates from RV to TLC, and to the movement of surfactant out of the air-water interface as the lung deflates from TLC to RV.

During normal, quiet breathing, the pressure-volume loop (see small green loop in Fig. 27-4B) lies near the deflation limb (red in Fig. 27-4B) of the “classic” loop. The quiet-breathing loop differs from the classic loop in three respects. First, the green quiet-breathing loop covers a much smaller range of pressures and volumes. Second, the green quiet-breathing loop exhibits very little hysteresis because relatively less surfactant moves into the air-water interface during inspiration and out of the air-water interface during expiration at these small V_T values. Third, at comparable lung volumes, the average compliance in the quiet-breathing loop (i.e., the slope of a line drawn between the two ends of the loop) is less than the static compliance of the classic loop's deflation limb. Again, this difference arises because during quiet breathing, less surfactant is present at the air-water interface, causing the lungs to be stiffer.

During quiet breathing, the pool of surfactant available to move into and out of the air-water interface with each V_T gradually decreases as the result of the catabolism of surfactant (see Fig. 27-9). As a result, the lungs gradually stiffen. In other words, the fall in compliance makes the lungs more difficult to inflate. In fact, some alveoli collapse, a condition termed **atelectasis**. This collapse is particularly prevalent in *dependent* regions of the lungs (e.g., the base of the lung in an upright individual), which reflects the relatively less negative P_{IP} near the base of the lung (see Fig 27-2) and thus the smaller degree of inflation. Fortunately, stretch receptors in the lung sense this atelectasis and trigger a large inspiratory effort to TLC—a **sigh** or a **yawn** (see Box 32-4). Sighing and, even more so, yawning are powerful stimuli for trafficking surfactant to the air-water interface, increasing compliance and reversing the atelectasis.

The opposite appears to happen during expiration, when the surface area of rapidly contracting alveoli falls more rapidly than surfactant can dive back down into the subsurface pool. The compression of surfactant causes surface tension to fall precipitously. Surface tension during expiration may fall to half the resting value at FRC. The more rapidly an alveolus shrinks, the more quickly its surface tension falls, the lower is its elastic recoil, and the greater is its tendency to re-expand. This action puts a brake on rapidly contracting alveoli, slowing their rate of shrinkage to more closely match that of slowly contracting alveoli. These changes in surfactant contribute to the small amount of hysteresis in a P_{IP} - V_L loop during quiet breathing (green loop in [Fig. 27-4B](#)).

Dynamic Properties of the Lung

When air is flowing—that is, under dynamic conditions—one must not only exert the force necessary to maintain the lung and chest wall at a certain volume (i.e., static component of force), but also exert an extra force to overcome the inertia and resistance of the tissues and air molecules (i.e., dynamic component of force).

Airflow is proportional to the difference between alveolar and atmospheric pressure, but inversely proportional to airway resistance

The flow of air through tubes is governed by the same principles governing the flow of blood through blood vessels and the flow of electrical current through wires (see [Equation 17-1](#)). Airflow is proportional to driving pressure (ΔP) but inversely proportional to **total airway resistance (R_{AW})**:

$$\dot{V} = \frac{\Delta P}{R_{AW}} = \frac{P_A - P_B}{R_{AW}} \quad (27-7)$$

\dot{V} (units: L/s) is airflow; the dot above the V indicates the time derivative of volume. For the lung, the driving pressure is the difference between alveolar pressure (P_A) and barometric pressure (P_B). Thus, for a fixed resistance, more *airflow* requires a greater ΔP (i.e., more effort). Viewed differently, to achieve a desired airflow, a greater *resistance* requires a greater ΔP .

When airflow is laminar—that is, when air molecules move smoothly in the same direction—we can apply Poiseuille's law, which states that the resistance (R) of a tube is proportional to the viscosity of the gas (η) and length of the tube (l) but inversely proportional to the fourth power of the radius:

$$R = \frac{8}{\pi} \cdot \frac{\eta l}{r^4} \quad (27-8)$$

This equation is the same as [Equation 17-11](#) for laminar blood flow. In general, changes in viscosity and length are not very important for the lung, although the resistance while breathing helium is greater than that while breathing nitrogen, the major component of air, because helium has a greater viscosity. However, the key aspect of [Equation 27-8](#) is that airflow is extraordinarily sensitive to changes in airway **radius**. The fourth-power dependence of R on radius means that a 10% decrease in radius causes a 52% increase in R —that is, a 34% *decrease* in airflow. Although Poiseuille's law strictly applies only to laminar flow conditions, as discussed below, airflow is even more sensitive to changes in radius when airflow is *not* laminar.

In principle, it is possible to compute the total airway resistance of the tracheobronchial tree from

anatomical measurements, applying Poiseuille's law when the flow is laminar and analogous expressions for airways in which the flow is not laminar. In 1915, Rohrer used this approach, along with painstaking measurements of the lengths and diameters of the airways of an autopsy specimen, to calculate the R_{AW} of the tracheobronchial tree. However, it is not practical to *compute* R_{AW} values, especially if we are interested in physiological or pathological changes in R_{AW} . Therefore, for both physiologists and physicians, it is important to *measure* R_{AW} directly. Rearrangement of Equation 27-7 yields an expression from which we can compute R_{AW} , provided that we know the driving pressure and the airflow that it produces:

$$R_{AW} = \frac{\Delta P}{\dot{V}} = \frac{P_A - P_B}{\dot{V}} \left(\text{units: } \frac{\text{cm H}_2\text{O}}{\text{L/s}} \right)$$

(27-9)

We can measure airflow directly with a **flowmeter** (pneumotachometer) built into a tube through which the subject breathes. Measuring the driving pressure is more problematic because of the difficulty in measuring P_A during breathing. In 1956, DuBois and colleagues met this challenge by cleverly using Boyle's law  N26-8 and a **plethysmograph** to measure P_A (Fig. 27-11). For example, if the peak \dot{V} during a quiet inspiration is -0.5 L/s (by convention, a negative value denotes inflow) and P_A at the same instant is $-1 \text{ cm H}_2\text{O}$ (from the plethysmograph), then

$$R_{AW} = \frac{\Delta P}{\dot{V}} = \frac{P_A - P_B}{\dot{V}} = \frac{-1 \text{ cm H}_2\text{O}}{-0.5 \text{ L/s}} = 2 \frac{\text{cm H}_2\text{O}}{\text{L/s}}$$

(27-10)

A SUBJECT AT REST

B SUBJECT BREATHING AGAINST A CLOSED SHUTTER

C SUBJECT BREATHING THROUGH AN OPEN SHUTTER

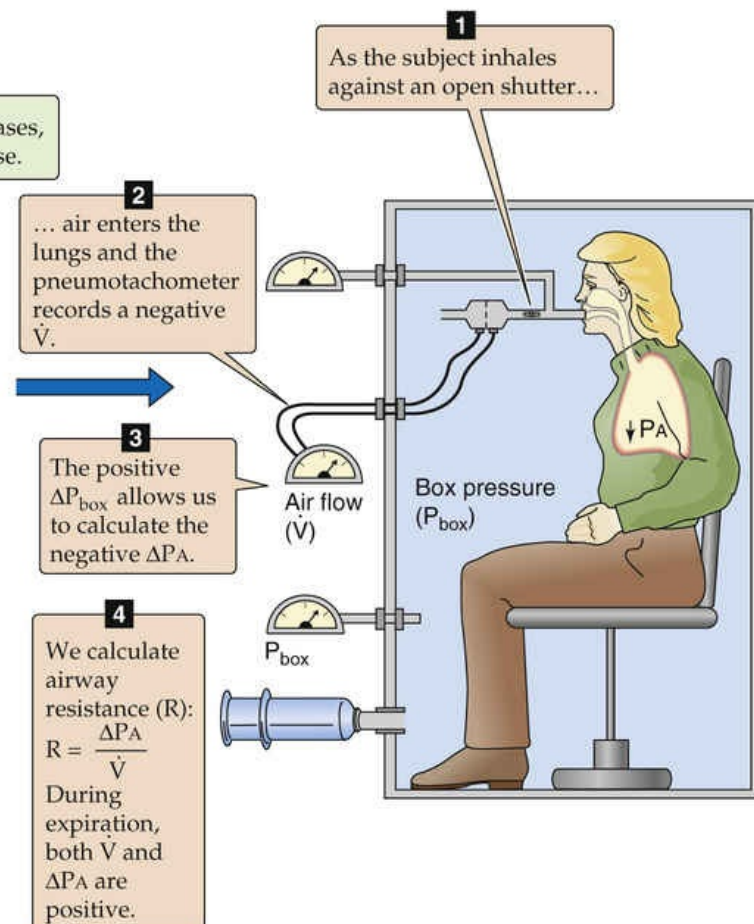

FIGURE 27-11 Measurement of P_A during airflow. This plethysmograph is similar to the one in [Figure 26-9](#) except that the spirometer is replaced by a sensitive device for measurement of the pressure inside the plethysmograph (P_{box}). The subject breathes plethysmograph air through a tube that has an electronically controlled shutter as well as meters for measurement of airflow and pressure at the mouth. In **B**, with the subject making an inspiratory effort against a closed shutter, pressure at the mouth equals P_A . We obtain the calibration ratio $\Delta P_A / \Delta P_{box}$, which allows us to convert future changes in the P_{box} to changes in P_A . In **C**, the subject inspires through an open shutter. During the first moments of inspiration, the thorax expands before much air enters the lungs. Because alveoli expand without much of an increase

in the number of gas molecules, PA must fall. Conversely, because the thorax encroaches on the plethysmograph air, which has hardly lost any gas molecules to the lungs, P_{box} must rise. From the calibration ratio $\Delta P_A/\Delta P_{\text{box}}$, we calculate ΔP_A from ΔP_{box} during inspiration. PA at any point during the respiratory cycle is the sum of the known PB and the measured ΔP_A .

In normal individuals, R_{AW} is $\sim 1.5 \text{ cm H}_2\text{O}/(\text{L/s})$ but can range from 0.6 to 2.3. Resistance values are higher in patients with respiratory disease and can exceed $10 \text{ cm H}_2\text{O}/(\text{L/s})$ in extreme cases.

The resistance that we measure in this way is the *airway resistance*, which represents $\sim 80\%$ of total pulmonary resistance. The remaining 20% represents **tissue resistance**—that is, the friction of pulmonary and thoracic tissues as they slide past one another as the lungs expand or contract.

In the lung, airflow is transitional in most of the tracheobronchial tree

We have seen that laminar airflow is governed by a relationship that is similar to Ohm's law. What happens when the airflow is not laminar? And can we predict whether the airflow is likely to be laminar? The flow of a fluid down a tube is **laminar** when particles passing any particular point always have the same speed and direction. Because of their viscosity, real fluids move fastest down the midline of the tube, and velocity falls to zero as we approach the wall of the tube (Fig. 27-12A), as discussed for blood on page 416. If the average velocity of the fluid flowing down the tube passes a critical value, flow becomes **turbulent**; local irregular currents, called vortices, develop randomly, and they greatly increase resistance to flow. Under ideal laboratory conditions, airflow generally is laminar when the dimensionless **Reynolds number (Re)** is < 2000 (see p. 416):

$$Re = \frac{2r\bar{v}\rho}{\eta}$$

(27-11)

Here r is the radius of the tube, \bar{v} is the velocity of the gas averaged over the cross section of the tube, ρ is the density of the gas, and η is its viscosity. When Re exceeds ~ 3000 , flow tends to be turbulent. Between Re values of 2000 and 3000, flow is unstable and may switch between laminar and turbulent.

FIGURE 27-12 Laminar, transitional, and turbulent flow. In **A**, laminar airflow (\dot{V}) is proportional to the driving pressure ($\Delta P = P_1 - P_2$). In **C**, where turbulent airflow is proportional to the square root of the driving pressure, a greater ΔP (i.e., effort) is needed to produce the same \dot{V} as in **A**.

Reynolds developed [Equation 27-11](#) to predict turbulence when fluids flow through tubes that are long, straight, smooth, and unbranched. Pulmonary airways, however, are short, curved, bumpy, and bifurcated. The branches are especially problematic, because they set up small eddies (see [Fig. 27-12B](#)). Although these eddies resolve farther along the airways, the air soon encounters yet other bifurcations, which

establish new eddies. This sort of airflow is termed **transitional**. Because of the complex geometry of pulmonary airways, the critical Re in the lungs is far lower than the ideal value of 2000. In fact, Re must be less than ~ 1 for lung airflow to be laminar. Such low Re values and thus laminar flow are present only in the small airways that are distal to terminal bronchioles (see p. 597).

Airflow is transitional throughout most of the tracheobronchial tree. Only in the trachea, where the airway radius is large and linear air velocities may be extremely high (e.g., during exercise, coughing), is airflow truly turbulent (see Fig. 27-12C).

The distinction among laminar, transitional, and turbulent airflow is important because these patterns influence how much energy one must invest to produce airflow. When flow is *laminar* (see Equation 27-7), airflow is proportional to ΔP and requires relatively little energy. When flow is *transitional*, one must apply more ΔP to produce the same airflow because producing vortices requires extra energy. Thus, the “effective resistance” increases. When flow is *turbulent*, airflow is proportional not to ΔP but to $\sqrt{\Delta P}$. Thus, we must apply an even greater ΔP to achieve a given flow (i.e., effective resistance is even greater).

The smallest airways contribute only slightly to total airway resistance in healthy lungs

As discussed above, airway resistance for healthy individuals is $\sim 1.5 \text{ cm H}_2\text{O}/(\text{L/s})$. Because effective resistance can increase markedly with increases in airflow—owing to transitional and turbulent airflow—it is customary to measure resistances at a fixed, relatively low flow of $\sim 0.5 \text{ L/s}$. The second column of Table 27-2 shows how R_{AW} normally varies with location as air moves from lips to alveoli during a quiet inspiration. A striking feature is that the greatest aggregate resistance is in the pharynx-larynx and large airways (diameter $> 2 \text{ mm}$, or before about generation 8). Of the R_{AW} of $1.5 \text{ cm H}_2\text{O}/(\text{L/s})$ in a normal subject, 0.6 is in the upper air passages, 0.6 is in the large airways, and only 0.3 is in the small airways.

TABLE 27-2
Airway Resistance*

LOCUS	NORMAL	COPD
Pharynx-larynx	0.6	0.6
Airways $> 2 \text{ mm}$ diameter	0.6	0.9
Airways $< 2 \text{ mm}$ diameter	0.3	3.5
Total airway resistance	1.5	5.0

*Units of resistance are $\text{cm H}_2\text{O}/(\text{L/s})$.

Because R increases with the fourth power of airway radius (see Equation 27-8), it might seem counterintuitive that the small airways have the lowest aggregate resistance. However, although each small airway has a high individual resistance, so many are aligned in parallel that their aggregate resistance is very low. **N27-6** We see this same pattern of resistance in the vascular system, where capillaries make a smaller contribution than arterioles to aggregate resistance.

N27-6

Aggregate Resistance of Small Airways

Contributed by Emile Boulpaep, Walter Boron

In the text we point out that, although each small airway has a high individual resistance compared to each large airway, there are so many of these small airways aligned in parallel that their aggregate resistance is very low.

In Chapter 17, we introduce the concept of how to compute the aggregate resistance of a group of blood vessels (or resistors) arranged in parallel. We used Equation 17-3, which we reproduce here:

$$\frac{1}{R_{\text{total}}} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \dots$$

(NE 27-6)

If we assume that each of N parallel branches has the same resistance R_i (i.e., $R_i = R_1 = R_2 = R_3 = R_4 = \dots$), then the overall resistance is

$$\frac{1}{R_{\text{total}}} = \frac{1}{R_i} + \frac{1}{R_i} + \frac{1}{R_i} + \dots = \frac{N}{R_i}$$

(NE 27-7)

Thus,

$$R_{\text{total}} = \frac{R_i}{N}$$

(NE 27-8)

As an example, let us compare the aggregate resistance at generations 10 and 16. At generation 10, the airway diameter may be ~ 1.2 mm ($r = 0.6$ mm), whereas at generation 16, the diameter might be 0.6 mm ($r = 0.3$ mm). Because the radius has fallen by a factor of 2 between generations 10 and 16, the fourth-power relationship between radius and resistance (see Equation 27-8) tells us that the unitary resistance of each airway must increase by a factor of 16. However, there are 2^6 -fold more airways at generation 16 than at generation 10. Thus, if we make the simplifying assumption that the airway length is the same for the two generations, we would conclude that the aggregate resistance *falls* to 16/64 or 25% of the initial value as we move from generation 10 to generation 16.

Table 27-2 also shows how R_{AW} varies for a typical patient with moderately severe **chronic obstructive pulmonary disease (COPD)**, a condition in which emphysema or chronic bronchitis increases R_{AW} (Box 27-2). COPD is a common and debilitating consequence of cigarette smoking, far more common than the lung cancer that receives so much attention in the lay press. Notice *where* the disease strikes. Even though COPD increases total airway resistance to 5.0 cm H₂O/(L/s)—3.3-fold greater than in our normal subject—pharynx-larynx resistance does not change at all, and large-airway resistance increases only modestly. Almost all of the increment in R_{AW} is due to a nearly 12-fold increase in the resistance of the smallest airways! According to Equation 27-8, we could produce a 12-fold increase in R_{AW} by decreasing radius by about half.

Box 27-2

Obstructive Pulmonary Disease

Two major categories of pulmonary disease can markedly reduce total ventilation: the *restrictive* pulmonary diseases (see Box 27-1) and the **obstructive pulmonary diseases**, in which the pathological process causes an increase in airway resistance—primarily a property of the **conducting airways** (see p. 597).

The condition can be acute, as with the aspiration of a **foreign body**, the buildup of **mucus** in an airway lumen, or the constriction of the airway lumen due to the contraction of smooth muscle in **asthma** (see Box 27-3).

COPD is defined as an increase in airway resistance caused by **chronic bronchitis** (long-standing inflammation of the bronchi or bronchioles), **emphysema** (destruction of alveolar walls, producing a smaller number of large alveoli), or a combination of the two. In the United States, COPD is the fourth leading cause of death. The major risk factor is cigarette smoking, although the inherited absence of α_1 -antitrypsin (see Table 18-1) also predisposes to COPD. Inflammation leads to the infiltration of the walls of conducting airways by macrophages, activated T lymphocytes, and neutrophils as well as the infiltration of alveolar walls by activated lymphocytes. The release of neutrophil elastase and other proteases overwhelms natural antiproteases, such as α_1 -antitrypsin. Bronchitis increases airway resistance by narrowing the lumen. With its destruction of alveolar walls, emphysema increases the static compliance, which, by itself, would make it easier to inhale. However, the destruction of parenchyma also reduces the mechanical tethering (see p. 620) of conducting airways, leading to an exaggerated collapse of these airways during expiration (see p. 626) and thus to an increase in airway resistance.

Although small airways normally have a very low aggregate resistance, it is within these small airways that COPD has its greatest and earliest effects. Even a doubling of small-airway resistance from 0.3 to 0.6 cm H₂O/(L/s) in the early stages of COPD would produce such a small increment in R_{AW} that it would be impossible to identify the COPD patient in a screening test based on resistance measurements. As discussed on [pages 687–689](#), approaches that detect the nonuniformity of ventilation are more sensitive for detection of early airway disease. In addition to COPD, the other common cause of increased R_{AW} is **asthma** ([Box 27-3](#)).

Box 27-3

Asthma

Asthma is a very common condition, occurring in 5% to 10% of the American population. Asthma is primarily an *inflammatory* disorder; the familiar bronchospasm is secondary to the underlying inflammation. One hypothesis is that asthma represents the inappropriate activation of immune responses designed to combat parasites in the airways. When a susceptible person inhales a trigger (e.g., pollen), inflammatory cells rush into the airways, releasing a multitude of cytokines, leukotrienes, and other humoral substances (e.g., histamine) that induce bronchospasm.

The patient experiencing an acute asthma attack is usually easy to recognize. The classic presentation includes shortness of breath, wheezing, and coughing. Triggers include allergens, heat or cold, a host of occupational irritants, and exercise. The patient can often identify the specific trigger. Spirometry can confirm the diagnosis; the most characteristic feature is a decreased FEV₁. Many asthmatic patients use

peak flowmeters at home because the severity of symptoms does not always correlate with objective measurements of the disease's severity.

The type of treatment depends on the frequency and severity of the attacks. For patients with infrequent attacks that are not particularly severe, it is often possible to manage the disease with an inhaled β_2 -adrenergic agonist, used only when needed. These medications, easily delivered by a metered-dose inhaler that can be carried around in one's pocket or purse, act on β_2 -adrenergic receptors to oppose bronchoconstriction. A patient who requires such an agent more than one or two times a week should receive an inhaled corticosteroid on a regular basis to suppress inflammation. Inhaled corticosteroids generally lack the side effects of oral corticosteroids, but oral corticosteroids may be required in a patient with sustained and severe asthma. Many patients rely on regular dosing of long-acting β -agonist inhalers and inhaled corticosteroids to keep their asthma under control. Theophylline (a phosphodiesterase inhibitor that raises $[cAMP]_i$; see p. 51), once a mainstay of asthma therapy, is now used far less commonly. Inhaled anticholinergic agents are more useful in COPD patients than in asthmatic patients but can be beneficial in some individuals who cannot tolerate the side effects of β -adrenergic agonists (notably tachycardia). Smooth-muscle relaxants (e.g., cromakalim-related drugs; see p. 198) and other anti-inflammatory agents (e.g., leukotriene inhibitors) also play a role in asthma therapy.

Regardless of its cause, increased R_{AW} greatly increases the energy required to move air into and out of the lungs. If the increase in R_{AW} is severe enough, it can markedly limit exercise. In extreme cases, even walking may be more exercise than the patient can manage. The reason is obvious from the pulmonary version of Ohm's law (see [Equation 27-7](#)). The maximal ΔP (ΔP_{max}) that we can generate between atmosphere and alveoli during inspiration, for example, depends on how low we can drive *alveolar pressure* using our muscles of inspiration. For a given ΔP_{max} , a 3.3-fold increase in R_{AW} (COPD column in [Table 27-2](#)) translates to a 3.3-fold reduction in maximal airflow (\dot{V}_{max}). [N27-7](#)

N27-7

Effect of Increased Airway Resistance on Maximal Airflow

Contributed by Emile Boulpaep, Walter Boron

Beginning on page 619 of the text, we presented an example in which COPD increased airway resistance (R_{AW}) by a factor of 3.3 (from 1.5 to 5.0 respiratory resistance units of $\text{cm H}_2\text{O}/[\text{L/s}]$; see [Table 27-2](#)). If the maximal ΔP that the subject can generate between atmosphere and alveoli (ΔP_{max}) were to remain normal, then the maximal airflow (\dot{V}_{max} ; units: L/s) would also decrease by a factor of 3.3:

$$\dot{V}_{max} = \frac{P_{A_{max}}}{R_{AW}}$$

(NE 27-9)

Although the relationship between \dot{V}_{max} and the maximal amount of O_2 taken up per minute ($\dot{V}_{\text{O}_2 \text{ max}}$; see pp. 1213–1214) is not directly proportional, it is intuitively obvious that as \dot{V}_{max} falls, $\dot{V}_{\text{O}_2 \text{ max}}$ must also fall

... and with it, the maximal amount of exercise that the individual can perform. Thus, if a *healthy* individual—running with maximal effort—were capable of jogging a kilometer in, say, 5 minutes, then a COPD patient might at best be able to walk that distance over a much longer time. With further increases in R_{AW} , the maximal exercise capacity of the COPD patient would gradually decline, and with sufficiently severe disease, the patient might have difficulty even walking along a perfectly flat surface without aid of supplemental oxygen.

Vagal tone, histamine, and reduced lung volume all increase airway resistance

Several factors can modulate R_{AW} , including the autonomic nervous system (ANS), humoral factors, and changes in the volume of the lungs themselves. The vagus nerve, part of the **parasympathetic** division of the ANS, releases acetylcholine, which acts on an M_3 muscarinic receptor on bronchial smooth muscle (see p. 341). The result is bronchoconstriction and therefore an increase in R_{AW} . The muscarinic antagonist atropine blocks this action. Irritants such as cigarette smoke cause a reflex bronchoconstriction (see pp. 717–718) in which the vagus nerve is the efferent limb.

Opposing the action of the vagus nerve is the **sympathetic** division of the ANS, which releases norepinephrine and dilates the bronchi and bronchioles, but reduces glandular secretions. However, these effects are weak because norepinephrine is a poor agonist of the β_2 -adrenergic receptors that mediate this effect via cAMP (see pp. 342–343).

Humoral factors include **epinephrine**, released by the adrenal medulla. Circulating epinephrine is a far better β_2 agonist than is norepinephrine and therefore a more potent bronchodilator. **Histamine** constricts bronchioles and alveolar ducts and thus increases R_{AW} . Far more potent is the bronchoconstrictor effect of the leukotrienes LTC_4 and LTD_4 .

One of the most powerful determinants of R_{AW} is **lung volume**. R_{AW} is extremely high at residual volume (RV) but decreases steeply as V_L increases (Fig. 27-13A). One reason for this effect is obvious: all pulmonary airways—including the conducting airways, which account for virtually all of R_{AW} —expand at high V_L , and resistance falls steeply as radius increases (see Equation 27-8). A second reason is the principle of interdependence (see p. 613)—alveoli tend to hold open their neighbors by exerting radial traction or **mechanical tethering** (see Fig. 27-13B). This principle is especially important for conducting airways, which have thicker walls than alveoli and thus a lower compliance. At high V_L , alveoli dilate more than the adjacent bronchioles, pulling the bronchioles farther open by mechanical tethering. Patients with **obstructive lung disease**, by definition, have an increased R_{AW} at a given V_L (see Fig. 27-13A). However, because these patients tend to have a higher-than-normal FRC, they breathe at a higher V_L , where airway resistance is—for them—relatively low.

A DEPENDENCE OF TOTAL AIRWAY RESISTANCE ON LUNG VOLUME

B MECHANICAL TETHERING

FIGURE 27-13 Airway resistance.

Intrapleural pressure has a static component ($-P_{TP}$) that determines lung volume and a dynamic component (PA) that determines airflow

In [Equation 27-2](#), we defined transpulmonary pressure as the difference between alveolar and intrapleural pressure ($P_{TP} = P_A - P_{IP}$). What is the physiological significance of these three pressures, and how do we control them?

P_{IP} is the parameter that the brain—through the muscles of respiration—directly controls. Rearranging the definition of P_{TP} in [Equation 27-2](#) yields

$$P_{IP} = (-P_{TP}) + P_A \quad (27-12)$$

Thus, P_{IP} has two components, $-P_{TP}$ and P_A , as summarized in [Figure 27-14](#) and [Table 27-3](#). As we will see in the next section, P_{TP} and P_A literally flow from P_{IP} .

FIGURE 27-14 Static and dynamic components of P_{IP} .

TABLE 27-3

Static Versus Dynamic Properties of the Lungs

PROPERTY	STATIC	DYNAMIC
Anatomical correlate	Alveoli	Conducting airways
Key “constant”	Static compliance, C	Airway resistance, R_{AW}
Key pressure	P_{TP} ($P_{TP} = P_A - P_{IP}$)	P_A
Key parameter	V_L ($C = \Delta V_L / \Delta P_{TP}$)	\dot{V} ($\dot{V} = P_A / R_{AW}$)
Pathology	Restrictive disease (e.g., fibrosis), caused by $\downarrow C$	Obstructive disease (e.g., COPD), caused by $\uparrow R_{AW}$

Transpulmonary Pressure

P_{TP} is a *static* parameter. It does not cause airflow. Rather, along with static compliance, P_{TP} determines V_L . The curve in the lower left part of [Figure 27-14](#)—like the middle plot of [Figure 27-5](#)—describes how V_L depends on P_{TP} . That is, this curve describes the P_{TP} required to overcome the elastic (i.e., static) forces that oppose lung expansion but makes no statement about \dot{V} . We have already seen that the slope of this curve is static compliance (see [p. 610](#)), a property mainly of the alveoli, and that a decrease in C can produce *restrictive* lung disease (see [p. 610](#)). Note that P_{TP} not only determines V_L under static conditions, when there is no airflow, but also under dynamic conditions (i.e., during inspiration and expiration). However, the brain does not directly control P_{TP} .

Alveolar Pressure

P_A is a dynamic parameter. It does not determine V_L directly. Instead, along with airway resistance, P_A

determines *airflow*. The curve in the lower right part of [Figure 27-14](#) describes how \dot{V} depends on PA. That is, this curve describes the PA required to overcome inertial and resistive (i.e., dynamic) forces that oppose airflow but makes no statement about V_L . The slope of this plot is airway **conductance**, the reciprocal of R_{AW} , [N27-8](#) which is mainly a property of the conducting airways. A decrease in R_{AW} can produce *obstructive* lung disease. When PA is zero, \dot{V} must be zero, regardless of whether V_L is at RV or TLC or anywhere in between. If the PA is positive and the glottis is open, air flows from alveoli to atmosphere, regardless of V_L . If PA is negative, air flows in the opposite direction. As is the case with P_{TP} , the brain does not directly control PA.

N27-8

Airway Resistance

Contributed by Emile Boulpaep, Walter Boron

In the lower right panel of [Figure 27-14](#), we have assumed that airway resistance (R_{AW}) is constant during a respiratory cycle, so that the $PA-\dot{V}$ curve is a straight line. However, R_{AW} changes with lung volume (see red and teal curves in [Fig. 27-13A](#)) and, as discussed on pages 626–627, airway collapse during expiration causes R_{AW} to be greater during expiration than during inspiration.

During inspiration, a sustained negative shift in P_{IP} causes PA to become transiently more negative

During a quiet respiratory cycle—an inspiration of 500 mL, followed by an expiration—the body first generates negative and then positive values of PA. The four large gray panels of [Figure 27-15](#) show the idealized time courses of five key parameters. [N27-9](#) The uppermost panel is a record of V_L . The next panel is a pair of plots, $-P_{TP}$ and P_{IP} . The third shows the record of PA. The bottom panel shows a simultaneous record of \dot{V} .

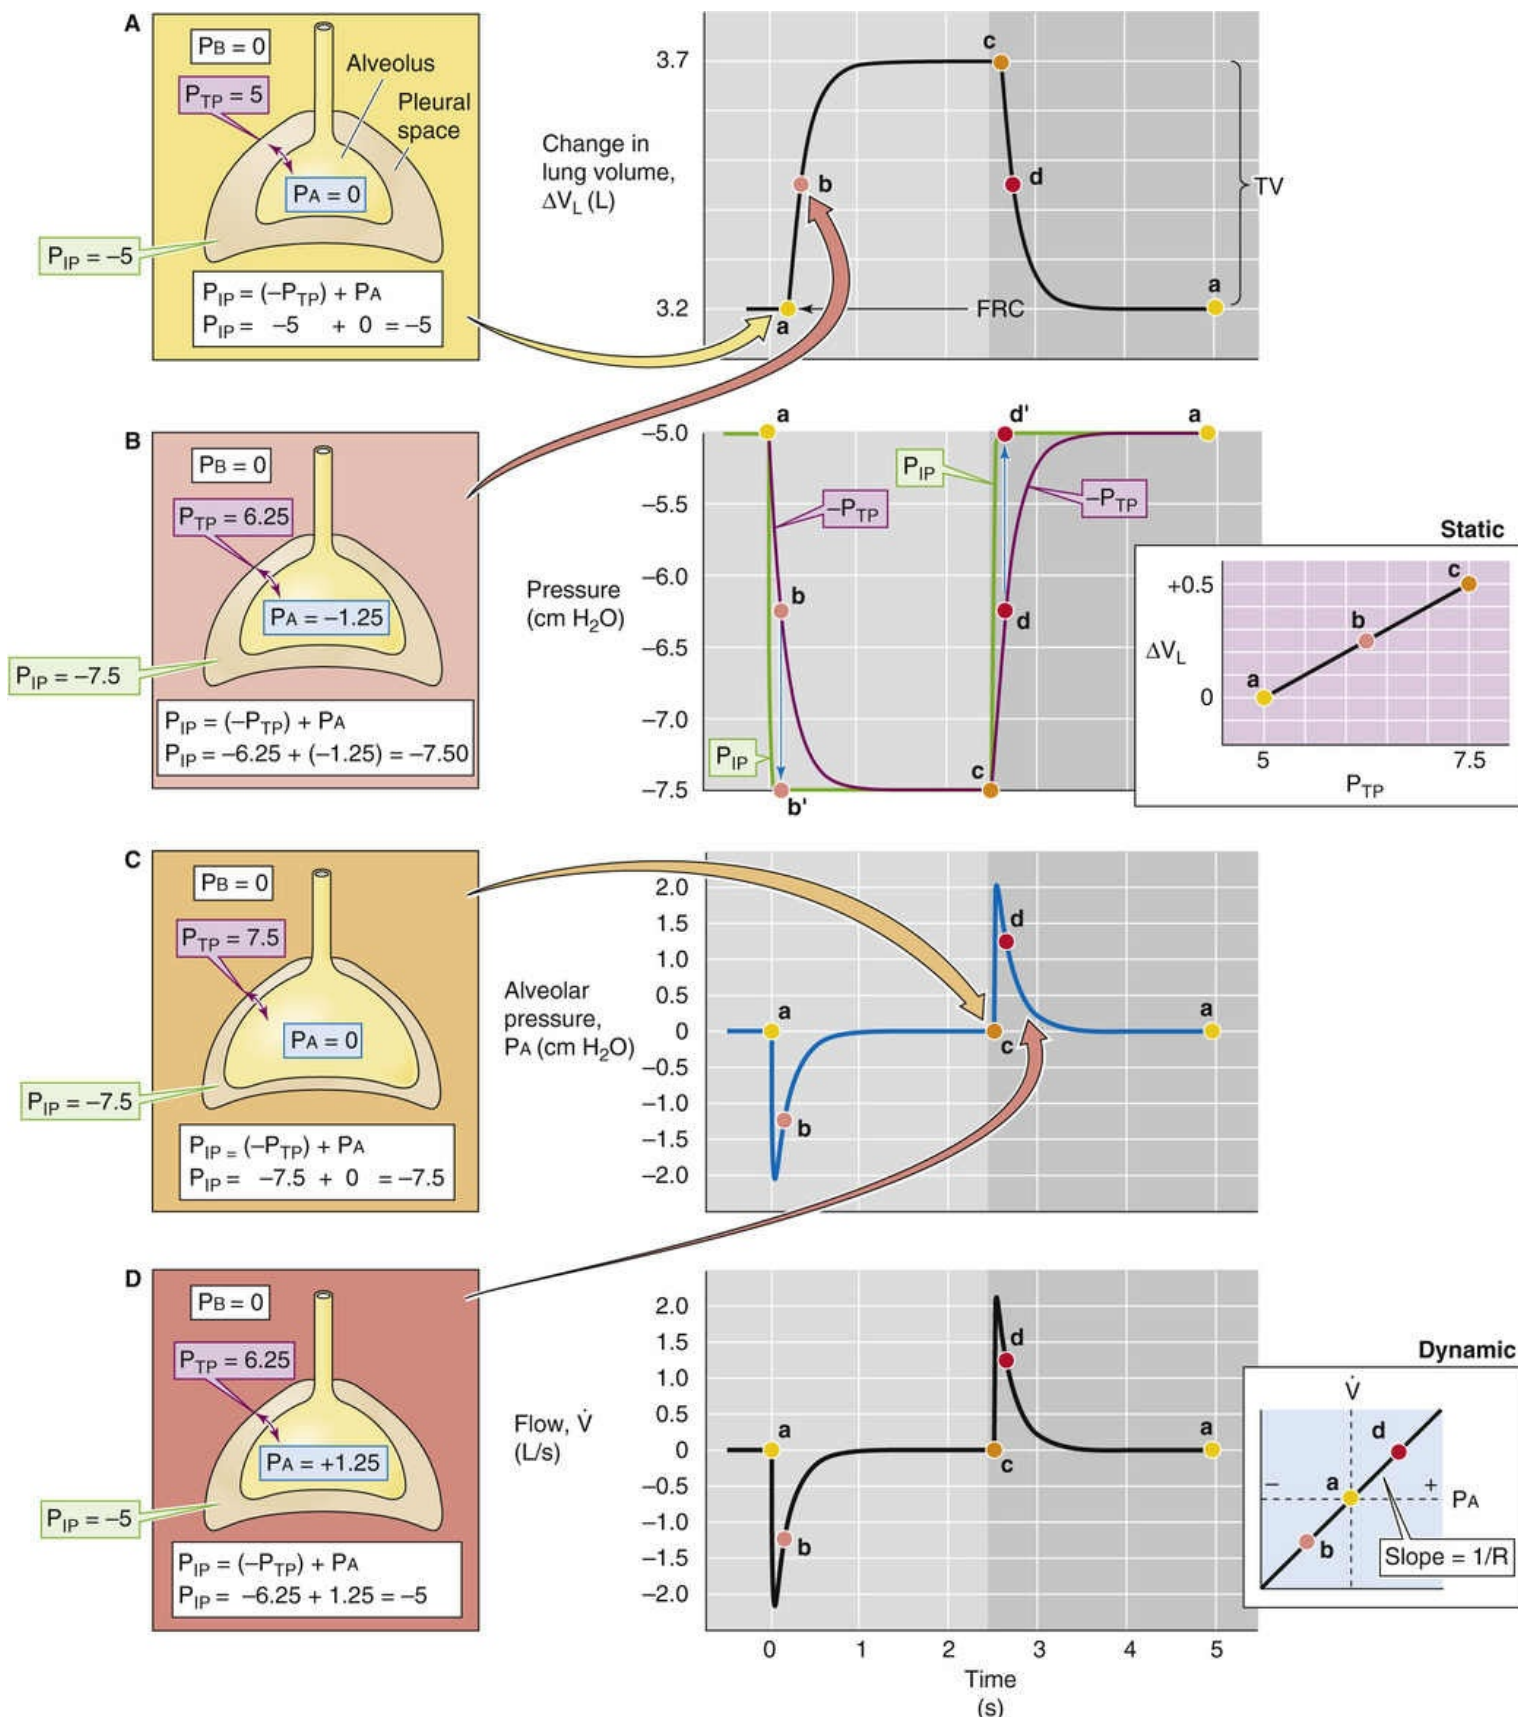

FIGURE 27-15 The respiratory cycle. P_B , P_{IP} , P_{TP} , and P_A are all in centimeters of H₂O. The colored points (labeled a, b, c, and d) in each of the central panels correspond to the illustrations on the left with the same-colored backgrounds. The two panels on the far right are taken from Figure 27-14.

The four large graphs with gray backgrounds in Figure 27-15 represent a hypothetical respiratory cycle. We generated the tracings using a rather simple computer model, making the following assumptions:

1. Throughout the respiratory cycle, the *static compliance* (C) was a constant $0.2 \text{ L/cm H}_2\text{O}$.
2. Throughout the respiratory cycle, the *resistance* (R) was a constant $1 \text{ cm H}_2\text{O}/(\text{L/s})$.
3. The initial lung volume (V_L) was 3.2 L , corresponding to time zero in the graphs (i.e., point *a* in the four panels).
4. During inspiration, the subject shifted P_{IP} from $-5 \text{ cm H}_2\text{O}$ to $-7.5 \text{ cm H}_2\text{O}$ with an exponential time course (time constant = 0.01 second). This value of τ for P_{IP} results in a τ for V_L of $\sim 0.2 \text{ seconds}$, consistent with the theoretical requirement that $\tau_{V_L} = R \times C = 1 \times 0.2 = 0.2 \text{ second}$. Thus, P_{IP} is the prime mover, the parameter that our hypothetical subject controlled. A second consequence is that because (a) P_{IP} changes by $2.5 \text{ cm H}_2\text{O}$ and (b) the compliance is $0.2 \text{ L/cm H}_2\text{O}$, the total change in lung volume (ΔV_L) was 0.5 L .
5. Expiration was the reverse of inspiration, with P_{IP} shifting from -7.5 to $-5.0 \text{ cm H}_2\text{O}$ with a time constant, once again, of 0.01 seconds . Again, the τ for V_L was $\sim 0.2 \text{ seconds}$.

In the actual modeling, we divided the inspiration and expiration into multiple 10-ms intervals. Each interval had two phases, one in which we allowed the change in P_{IP} to change the lung volume—but with no airflow—and a second in which we allowed air to flow as dictated by the alveolar pressure (P_A) and airway resistance.

First phase. At time zero (point *a* in the four panels), we imagined that we plugged the trachea with a cork and then allowed the subject to begin the inspiratory effort for a duration of 10 ms . P_{IP} became slightly more negative according to the aforementioned exponential time course. At the end of the 10-ms period, we computed the new value of V_L , knowing the current value of P_{IP} and the compliance and also assuming that the air molecules inside the lung obeyed the ideal gas law ($P_A \cdot V_L = nRT$). Keep in mind that because we plugged the trachea with a cork, the number of air molecules in the lung was fixed during the 10-ms period of inspiratory effort. Thus, we could compute the new value of P_A . From this new value of P_A and the current value of P_{IP} , we could compute the P_{TP} after 10 ms . Thus, at the end of the first phase, we have new values for P_{IP} , V_L , P_A , and P_{TP} .

Second phase. Once we knew the new value of P_A , we removed our hypothetical cork for 10 ms and allowed air to flow into the lung, governed by the equation $\dot{V} = \Delta P/R$. Note that ΔP is the difference between P_B and P_A . At the end of 10 ms , we replaced the cork (the flow of air is far from complete!). Knowing how many air molecules entered during the 10-ms interval, and assuming that P_{IP} has not changed, we can now recompute all the relevant parameters and start the first phase of the *second* cycle.

Thus, although we assumed the time course of the green P_{IP} -versus-time curve in the second gray panel of Figure 27-15, all of the other curves follow directly from the calculations and the assumed parameters. The time constant (τ) for V_L that falls out of our computer simulation is $\sim 0.2 \text{ second}$. As we will see in  **N27-10** the theoretical time constant for a change in lung volume is the product $R \times C$. In the model we

have been discussing, $R \times C$ evaluates to a time constant of 0.2 seconds, which agrees well with our simulation. Note that the τ we assumed for the change in P_{IP} was 0.01 second, which is considerably faster than the τ for the change in V_L and thus is not rate limiting.

N27-10

Calculating the Time Constant for a Change in Lung Volume

Contributed by Emile Boulpaep, Walter Boron

It should not be very surprising that the τ for the time course of V_L is 0.2 second. Just as for electrical circuits, where the time constant of a resistor-capacitor network is $R \times C$, where R is resistance and C is capacitance, the time constant for inflating a lung is the product of the airway resistance and the static compliance:

$$\tau = R \times C$$

(NE 27-10)

For healthy human lungs, we might assume that R is $\sim 1 \text{ cm H}_2\text{O}/(\text{L/s})$ —on page 617 we pointed out that normal values for R might range from 0.6 to 2.3 $\text{cm H}_2\text{O}/(\text{L/s})$. We also might assume that C is $\sim 0.2 \text{ L}/\text{cm H}_2\text{O}$ (see Box 26-1). Thus, our predicted time constant is

$$\tau = R \times C = \left(1 \frac{\text{cm H}_2\text{O} \times \text{s}}{\text{L}} \right) \times \left(0.2 \frac{\text{L}}{\text{cm H}_2\text{O}} \right) = 0.2 \text{ s}$$

(NE 27-11)

If R increased 5-fold from 1 to 5 $\text{cm H}_2\text{O}/(\text{L/s})$, the time constant would also quintuple:

$$\tau = R \times C = \left(5 \frac{\text{cm H}_2\text{O} \times \text{s}}{\text{L}} \right) \times \left(0.2 \frac{\text{L}}{\text{cm H}_2\text{O}} \right) = 1.0 \text{ s}$$

(NE 27-12)

Note that the time constant that we have computed is a theoretical minimum. The actual τ can only be as small as $R \times C$ if the individual making an inspiratory or expiratory effort decides to change P_{IP} (or is capable of changing P_{IP}) very rapidly compared to $R \times C$. If the person decides to inhale or exhale slowly, then of course the actual time course with which V_L changes can be far larger than $R \times C$. As an extreme example, if an oboe player decides to exhale over a period of many tens of seconds, the time constant no longer depends on the mechanical properties of the lung, but on the activity of the cerebral cortex.

On the right side of [Figure 27-15](#) are the static P_{TP} - V_L curve and the dynamic P_A - \dot{V} relationship (both copied from [Fig. 27-14](#)). On the left side is a series of four cartoons that represent snapshots of the key pressures (i.e., P_{IP} , P_{TP} , and P_A) at four points during the respiratory cycle:

- Before inspiration begins. The lungs are under static conditions at a volume of FRC.
- Halfway through inspiration. The lungs are under dynamic conditions at a volume of FRC + 250 mL.
- At the completion of inspiration. The lungs are once again under static conditions but at a volume of FRC + 500 mL.
- Halfway through expiration. The lungs are under dynamic conditions at a volume of FRC + 250 mL.
- At the end of expiration/ready for the next inspiration. The lungs are once again under static conditions at a volume of FRC.

The V_L record in the top gray panel of [Figure 27-15](#) shows that V_L rises more or less exponentially during inspiration and similarly falls during expiration.

Knowing the time course of V_L , we obtained the P_{TP} values in the second gray panel of [Figure 27-15](#) by reading them off the static P_{TP} - V_L diagram to the right and plotted them as $-P_{TP}$ (for consistency with [Equation 27-12](#)). As V_L increases during inspiration, P_{TP} increases (i.e., $-P_{TP}$ becomes more negative). The opposite is true during expiration. Remember that P_{TP} (along with static compliance) determines V_L at any time.

The P_{IP} record in the second gray panel of [Figure 27-15](#) shows that P_{IP} is the same as $-P_{TP}$ whenever the lungs are under static conditions (points *a*, *c*, and *a*). However, during inspiration, P_{IP} rapidly becomes more negative than $-P_{TP}$ but then merges with $-P_{TP}$ by the end of inspiration. The difference between P_{IP} and $-P_{TP}$ is P_A , which must be negative to produce airflow into the lungs. During expiration, P_{IP} is more positive than $-P_{TP}$.

The P_A record in the third gray panel of [Figure 27-15](#) shows that P_A is zero under static conditions (points *a*, *c*, and *a*). During inspiration, P_A rapidly becomes negative but then relaxes to zero by the end of inspiration. The opposite is true during expiration. The P_A values in this plot represent the differences between the P_{IP} and $-P_{TP}$ plots in the preceding panel.

We computed \dot{V} (bottom gray panel) from the relationship in [Equation 27-7](#): $\dot{V} = (P_A - P_B)/R_{AW}$. Remember that P_A (along with R_{AW}) determines \dot{V} at any time. Here, we assume that R_{AW} is fixed during the respiratory cycle at 1 cm H₂O/(L/s). Thus, the \dot{V} record has the same time course as P_A .

The key message in [Figure 27-15](#) is that during inspiration, the negative shift in P_{IP} has two effects. The body invests some of the energy represented by ΔP_{IP} into transiently making P_A more negative (dynamic component). The result is that air *flows* into the lungs and V_L increases; but this investment in P_A is only transient. Throughout inspiration, the body invests an increasingly greater fraction of its energy in making P_{TP} more positive (static component). The result is that the body *maintains* the new, higher V_L . By the end of inspiration, the body invests all of the energy represented by ΔP_{IP} in maintaining V_L and none in further expansion. The situation is not unlike that faced by Julius Caesar as he, with finite resources, conquered Gaul. At first, he invested all of his resources in expanding his territory at the expense of the feisty Belgians; but as the conquered territory grew, he was forced to invest an increasingly greater fraction of his resources in maintaining the newly conquered territory. In the end, he necessarily invested all of his resources in maintaining his territory and was unable to expand further.

Dynamic compliance falls as respiratory frequency rises

In the preceding section, we examined pressure, volume, and flow changes during an idealized respiratory cycle of 5 seconds, which corresponds to a respiratory frequency of 12 breaths/min. The top curve in [Figure 27-16A](#) shows a normal V_L time course during an inspiration. As for any exponential process, the **time constant (τ)** [N27-10](#) is the interval required for ΔV_L to be ~63% complete. For healthy lungs, τ is ~0.2 second. Thus, for inspiration, the increase in V_L is 63% complete after 0.2 second, 86% complete after 0.4 second, 95% complete after 0.6 second, and so on. We will make the simplifying assumption that the time available for inspiration is half this time or 2.5 seconds, which represents >12 time constants! Thus, if the V_T after infinite time were 500 mL, the ΔV_L measured 2.5 seconds after initiation of inspiration would also be ~500 mL (see [Fig. 27-16A](#), green point on top curve). In [Figure 27-16B](#), we replot this value as the green point at a frequency of 12 breaths/min on the top curve (i.e., normal lungs).

A EFFECT OF AIRWAY RESISTANCE ON RATE OF INFLATION

B EFFECT OF AIRWAY RESISTANCE ON TIDAL VOLUME

C EFFECT OF RESPIRATORY FREQUENCY ON TIDAL VOLUME

FIGURE 27-16 Dynamic compliance. In **A** and **B**, the colored points represent changes in volume at respiratory frequencies of 12, 24, and 48 breaths/min.

For a respiratory frequency of 24 breaths/min, 1.25 seconds is available for inspiration. At the end of

this time, the ΔV_L is ~ 499 mL (see Fig. 27-16B, blue point on the top curve).

If we further increase the respiratory frequency to 48 breaths/min, only 0.625 second is available for inspiration. At the end of this period, only slightly more than three time constants, the ΔV_L is ~ 478 mL (see Fig. 27-16B, red point on top curve). Thus, over a wide range of frequencies, ΔV_L is largely unchanged. Only when respiratory frequency approaches extremely high values does ΔV_L begin to fall off.

The situation is very different for a subject with substantially increased airway resistance. If R_{AW} increased 5-fold, τ would also increase 5-fold to 1 second. **N27-10** As a result, the trajectory of V_L also would slow by a factor of 5 (see Fig. 27-16A, bottom curve). If we could wait long enough during an inspiration, these unhealthy lungs would eventually achieve a ΔV_L of 500 mL. The problem is that we cannot wait that long. Therefore, if the frequency is 12 breaths/min and inspiration terminates after only 2.5 seconds (i.e., only 2.5 time constants), the ΔV_L would be only 459 mL (see Fig. 27-16B, green point on bottom curve). Thus, even at a relatively low frequency, the patient with increased R_{AW} achieves a ΔV_L that is well below normal.

For a respiratory frequency of 24 breaths/min, when only 1.25 seconds is available for inspiration, the ΔV_L is only 357 mL (see Fig. 27-16B, blue point on bottom curve). At a respiratory frequency of 48 breaths/min, when only 0.625 second is available for inspiration, the ΔV_L is only 232 mL (see Fig. 27-16B, red point on bottom curve). Thus, the ΔV_L for the subject with increased R_{AW} falls rapidly as frequency increases.

We can represent the *change* in V_L during cyclic breathing by a parameter called **dynamic compliance**:

$$C_{\text{dynamic}} = \frac{\Delta V_L}{-\Delta P_{IP}} \quad (27-13)$$

Note that C_{dynamic} is proportional to ΔV_L in Figure 27-16B. Under truly static conditions (i.e., frequency of 0), $-\Delta P_{IP}$ equals ΔP_{TP} , and *dynamic* compliance is the same as *static* compliance (C or C_{static}) that we introduced in Equation 27-4. As frequency increases, C_{dynamic} falls below C_{static} . The degree of divergence increases with resistance. For the normal lung in Figure 27-16B, ΔV_L and thus C_{dynamic} fall by only $\sim 5\%$ as frequency rises from 0 to 48 breaths/min. However, for the lung with a 5-fold increased airway resistance, C_{dynamic} falls by $>50\%$ as frequency rises from 0 to 48 breaths/min.

The above pathological pattern is typical of asthma; R_{AW} is elevated, but C_{static} is relatively normal. In emphysema, both R_{AW} and C_{static} are elevated (see Fig. 27-5, upper curve). Thus, a plot of C_{dynamic} versus frequency would show that C_{dynamic} is initially greater than C_{static} at low respiratory frequencies, but it falls below C_{static} as frequency increases. What do these frequency-dependent decreases in C_{dynamic} mean for a patient? The greater the respiratory frequency, the less time is available for inspiration or expiration, and the smaller the V_T (see Fig. 27-16C). **N27-11**

N27-11

Implications of High-Frequency Breathing in a Patient with

a High Time Constant

Contributed by Emile Boulpaep, Walter Boron

As discussed in the text, a patient with increased airway resistance will require longer than normal to inflate the lungs by the expected V_T during an inspiratory effort (i.e., τ is increased, as in Fig. 27-16A) and will require longer than normal to deflate the lungs to the FRC during an expiratory effort. As a consequence, as such a patient breathes with ever-increasing respiratory frequencies, the effective V_T will fall (see Fig. 27-16C). The effect on the ventilation of alveoli is even more severe.

As we shall see in Chapter 31, even in healthy lungs, not all of the V_T reaches the alveoli—a fixed amount (~ 150 mL per breath) is wasted ventilating the conducting airways (see pp. 675–676), which have no alveoli. Only the part of the V_T in excess of, say, 150 mL actually reaches the alveoli. Thus, as the V_T gradually falls at increasing respiratory frequencies, the first volume to fall is the air ventilating the alveoli. The fall in V_T in a patient with increased airway resistance (i.e., an increased τ) can therefore cause alveolar ventilation to fall far more steeply than the total ventilation.

This analysis greatly oversimplifies what happens in the lungs of real people. Although we have treated the lungs as if there were one value for R_{AW} and one for C_{static} , each conducting airway has its own airway resistance and each alveolar unit has its own static compliance, and these values vary with parameters such as V_L , posture, and hormonal status. As a result, some alveolar units have greater time constants than others. Airway disease may make some of these time constants substantially higher. As respiratory frequency increases, alveoli with relatively high time constants will have less time to undergo volume changes. As a result, these “slow” airways—compared with the “faster” airways—will make progressively smaller contributions to the overall ventilation of the lungs. At sufficiently high frequencies, very slow airways may drop out of the picture entirely.

Transmural pressure differences cause airways to dilate during inspiration and to compress during expiration

We have noted three factors that modulate airway caliber: (1) the ANS, (2) humoral substances, and (3) V_L (see Fig. 27-13). A fourth factor that modulates R_{AW} is flow of air through the conducting airway itself. Airflow alters the pressure difference across the walls of an airway, and this change in **transmural pressure** (P_{TM}) can cause the airway to dilate or to collapse. Figure 27-17A through C depicts the pressures along a single hypothetical airway, extending from the level of the alveolus to the lips, under three conditions: during inspiration (Fig. 27-17A), at rest (Fig. 27-17B), and during expiration (Fig. 27-17C). In all three cases, the lung is at the same volume, FRC; the only difference is whether air is flowing into the lung, not flowing at all, or flowing out of the lung. Because V_L is at FRC, P_{TP} (the P_{TM} for the alveoli) is 5 cm H₂O in all three cases.

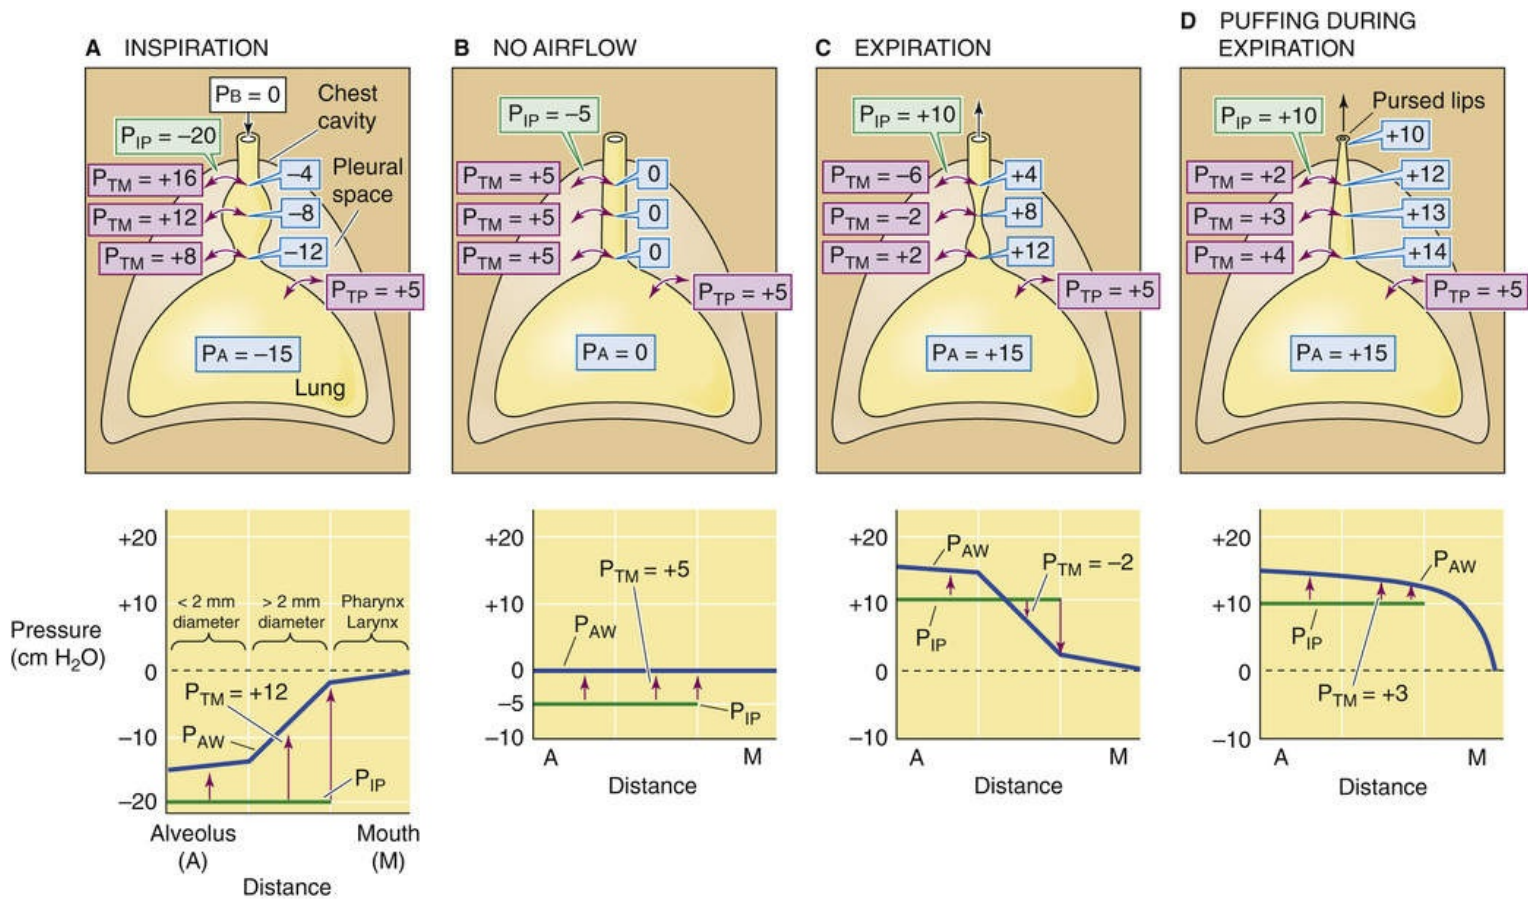

FIGURE 27-17 Dilation and collapse of airways with airflow. In all four panels, V_L is FRC. P_{TM} is the transmural pressure across conducting airways. P_{AW} and values in pale blue balloons represent pressures inside conducting airways (all in centimeters of H_2O). Graphs at bottom show P_{AW} profiles along airways (blue curve) from alveolus to mouth. P_{IP} is constant throughout the thorax (green curve). The upward (i.e., positive) P_{TM} arrows tend to expand the airways, whereas the downward (i.e., negative) P_{TM} arrows tend to squeeze them.

Static Conditions

First consider what happens under static conditions (see Fig. 27-17B). In the absence of airflow, the pressures inside all airways must be zero. Considering first the alveoli, P_{TP} is 5 cm H_2O and the P_A is zero, and thus P_{IP} is -5 cm H_2O . We will ignore the effects of gravity on P_{IP} and thus assume that P_{IP} is uniform throughout the chest cavity. The P_{IP} of -5 cm H_2O acts not only on alveoli but on *all* conducting airways within the thoracic cavity. For these, P_{TM} at any point is the difference between the pressure inside the airway (P_{AW}) and P_{IP} (see Equation 27-1):

$$P_{TM} = P_{AW} - P_{IP} = 0 - (-5 \text{ cm } H_2O) = +5 \text{ cm } H_2O \quad (27-14)$$

In other words, a transmural pressure of $+5$ cm H_2O acts on *all* thoracic airways (but *not* the trachea in the neck, for example), tending to expand them to the extent that their compliance permits.

Inspiration

Now consider what happens during a vigorous inspiration (see [Fig. 27-17A](#)). We first exhale to a V_L below FRC and then vigorously inhale, so that the P_A is $-15 \text{ cm H}_2\text{O}$ at the instant that V_L passes through FRC. Because the lung is at FRC, P_{TP} is $+5 \text{ cm H}_2\text{O}$. The P_{IP} needed to produce a P_A of $-15 \text{ cm H}_2\text{O}$ is

$$\begin{aligned} P_{IP} &= (-P_{TP}) + P_A \\ &= -5 \text{ cm H}_2\text{O} + (-15 \text{ cm H}_2\text{O}) \\ &= -20 \text{ cm H}_2\text{O} \end{aligned} \quad (27-15)$$

This “inspiring” P_{IP} of $-20 \text{ cm H}_2\text{O}$ is just enough to produce the desired airflow and also to maintain the alveoli at precisely the same volume that they had under static conditions. But how does this exceptionally negative P_{IP} affect airways upstream from the alveoli? P_{AW} gradually decays from $-15 \text{ cm H}_2\text{O}$ in the alveoli to zero at the lips. The farther we move from the alveoli, the less negative is P_{AW} , and thus the greater is P_{TM} .

As an illustration, consider a point about halfway up the airway's resistance profile, where P_{AW} is $-8 \text{ cm H}_2\text{O}$:

$$\begin{aligned} P_{TM} &= P_{AW} - P_{IP} \\ &= -8 \text{ cm H}_2\text{O} - (-20 \text{ cm H}_2\text{O}) \\ &= +12 \text{ cm H}_2\text{O} \end{aligned} \quad (27-16)$$

Thus, the transmural pressure opposing the elastic recoil at this point has increased from $+5 \text{ cm H}_2\text{O}$ at rest (see [Fig. 27-17B](#)) to $+12 \text{ cm H}_2\text{O}$ during this vigorous inspiration (see [Fig. 27-17A](#)). Because P_{TM} has increased, the airway will dilate. The tendency to dilate increases as we move from the alveoli to larger airways. As shown in the graph in the lower part of [Figure 27-17A](#), P_{AW} (and thus P_{TM} , as indicated by the upward arrows) gradually increases. Note that the very positive P_{TM} values that develop in the larger airways determine only the *tendency* to dilate. The extent to which an airway *actually* dilates also depends on its compliance. The amount of cartilage supporting the airways gradually increases from none for 11th-generation airways to a substantial amount for the mainstem bronchi. Because the increasing amount of cartilage in the larger airways decreases their compliance, they have an increasing ability to resist changes in caliber produced by a given change in P_{TM} .

Expiration

As might be expected, conducting airways tend to collapse during expiration (see [Fig. 27-17C](#)). We first inhale to a V_L above FRC and then exhale vigorously, so that P_A is $+15 \text{ cm H}_2\text{O}$ at the instant that V_L passes through FRC. Because the lung is at FRC, P_{TP} is $+5 \text{ cm H}_2\text{O}$. The P_{IP} needed to produce a P_A of $+15 \text{ cm H}_2\text{O}$ is

$$\begin{aligned}
 P_{IP} &= (-P_{TP}) + P_A \\
 &= -5 \text{ cm H}_2\text{O} + (+15 \text{ cm H}_2\text{O}) \\
 &= +10 \text{ cm H}_2\text{O} \\
 &\quad (27-17)
 \end{aligned}$$

This P_{IP} of +10 cm H₂O is 5 less than the P_A and thus maintains the alveoli at the same volume that prevailed under static conditions and during inspiration. What is the effect of this very positive P_{IP} on the upstream airways? P_{AW} must decrease gradually from +15 cm H₂O in the alveoli to zero at the lips. The farther we move from the alveolus, the lower the P_{AW} and thus the lower the P_{TM} . At a point about halfway up the airway's resistance profile, where P_{AW} is +8 cm H₂O,

$$\begin{aligned}
 P_{TM} &= P_{AW} - P_{IP} \\
 &= +8 \text{ cm H}_2\text{O} - (+10 \text{ cm H}_2\text{O}) \\
 &= -2 \text{ cm H}_2\text{O} \\
 &\quad (27-18)
 \end{aligned}$$

Thus, at this point during a vigorous expiration, the transmural pressure opposing elastic recoil has fallen sharply from +5 cm H₂O at rest (which tends to mildly inflate the airway) to -2 cm H₂O during expiration (which actually tends to squeeze the airway). As we move from the alveoli to larger airways, P_{AW} gradually decreases. That is, P_{TM} gradually shifts from an ever-decreasing inflating force (positive values) to an ever-increasing squeezing force (negative values), as indicated by the change in the orientation of the arrows in the lower panel of [Figure 27-17C](#). Fortunately, these larger airways—with the greatest collapsing tendency—have the most cartilage and thus some resistance to the natural collapsing tendency that develops during expiration. In addition, mechanical tethering (see [p. 620](#)) helps all conducting airways surrounded by alveoli to resist collapse. Nevertheless, R_{AW} is greater during expiration than it is during inspiration.

The problem of airway compression during expiration is exaggerated in patients with **emphysema**, a condition in which the alveolar walls break down. This process results in fewer and larger air spaces with fewer points of attachment and less mutual buttressing of air spaces. Although the affected alveoli have an increased compliance and thus a larger diameter at the end of an inspiration, they are flimsy and exert less mechanical tethering on the conducting airways they surround. Thus, patients with emphysema have great difficulty exhaling because their conducting airways are less able to resist the tendency to collapse. However, these patients make their expirations easier in three ways. We could predict them all from our knowledge of dynamic respiratory mechanics:

1. **They exhale slowly.** A low \dot{V} during expiration translates to a less positive P_A and thus a less positive P_{IP} , which minimizes the tendency to collapse.
2. **They breathe at higher V_L .** A high V_L maximizes the mechanical tethering that opposes airway collapse during expiration and thus minimizes R_{AW} (see [Fig. 27-13A](#)).
3. **They exhale through pursed lips.** This maneuver—known as puffing—creates an artificial high resistance at the lips. Because the greatest pressure drop occurs at the location of the greatest resistance,

puffing causes a greater share of the P_{AW} drop to occur across the lips than along collapsible, cartilage-free airways. Thus, puffing maintains relatively high P_{AW} values farther along the tracheobronchial tree (see [Fig. 27-17D](#)) and reduces collapsing tendencies throughout. The greatest collapsing tendencies are reserved for the largest airways that have the most cartilage (see [p. 597](#)). Of course, the patient pays a price for puffing: \dot{V} and thus the ventilation of the alveoli are low.

Because of airway collapse, expiratory flow rates become independent of effort at low lung volumes

Cartilage and mechanical tethering (see [p. 620](#)) oppose the tendency of conducting airways to collapse during expiration. Because tethering increases as V_L increases, we expect airways to better resist collapse when V_L is high. To see if this is true, we will examine how expiratory airflow varies with effort (i.e., P_A) at different V_L .

Imagine that we make a maximal inspiration and then hold our breath with glottis open ([Fig. 27-18A](#)). Thus, P_A is zero. In addition, P_{TP} is +30 cm H₂O to maintain TLC. From [Equation 27-12](#), $P_{IP} = (-P_{TP}) + P_A = -30$ cm H₂O. Now, starting from TLC, we make a maximal expiratory effort. [Figure 27-18B](#) summarizes the pressures in the alveoli and thorax at the instant we begin exhaling but before V_L has had time to change. P_{TP} is still +30 cm H₂O, but P_A is now +40 cm H₂O (to produce a maximal expiration) and P_{IP} is therefore +10 cm H₂O. As V_L decreases during the course of the expiration, we will monitor \dot{V} , V_L , and P_A .

A NO AIRFLOW AT TLC**B MAXIMAL FORCED EXPIRATION FROM TLC****C EXPIRATORY FLOW-VOLUME CURVE****D EXPIRATORY FLOW-EFFORT CURVE**

FIGURE 27-18 Dependence of airflow on effort. In **D**, note that if airway resistance were fixed, increased effort (i.e., increased P_A) would yield a proportionate increase in \dot{V} , as indicated by the red line. However, increased effort tends to narrow airways, raising resistance and tending to flatten the curves. As V_L decreases (e.g., 4 or 3 L), airflow becomes independent of effort with increasingly low effort. P_B , P_{IP} , P_{TP} , and P_A are all in centimeters of H₂O.

The top curve in [Figure 27-18C](#) shows how \dot{V} changes as a function of V_L when, starting from TLC, we make a maximal expiratory effort. Notice that \dot{V} rises to its maximal value at a V_L that is somewhat less than TLC and then gradually falls to zero as V_L approaches RV. The data in this top curve, obtained with maximal expiratory effort (i.e., at maximal P_A), will help us determine how expiratory flow varies with effort. To get the rest of the necessary data, we repeat our experiment by again inhaling to TLC and again exhaling to RV. However, with each trial, we exhale with less effort (i.e., at smaller P_A)—efforts labeled as high, medium, and low in [Figure 27-18C](#).

If we draw a vertical line upward from a V_L of 5 L in [Figure 27-18C](#), we see that, at this very high V_L , \dot{V} gets larger and larger as the effort increases from low to medium to high to maximal. Because these efforts correspond to increasing PA values, we can plot these four \dot{V} data points (all obtained at a V_L of 5 L) versus PA in the top curve of [Figure 27-18D](#). Because \dot{V} increases continuously with the PA, flow is **effort dependent** at a V_L of 5 L. If the airways were made of steel, this plot of \dot{V} versus PA would be a straight line. Because the actual plot bends downward at higher values of PA (i.e., greater efforts), R_{AW} must have increased with effort (i.e., the airways collapsed somewhat).

Returning to [Figure 27-18C](#), we see that an important characteristic of these data is that the \dot{V} -versus- V_L curve for maximal expiratory effort defines an envelope that none of the other three curves could penetrate. Thus, at a V_L of 4 L, \dot{V} is ~ 7 L/s, regardless of whether the expiratory effort is high or maximal (i.e., the two points overlies one another on the graph). At a V_L of 3 L, the *four curves* have practically merged, so that \dot{V} is ~ 5 L/s regardless of effort. Thus, at lung volumes that are < 3 L, it does not matter how much effort we make; the expiratory flow can never exceed a certain value defined by the envelope.

Shifting back to [Figure 27-18D](#), we see that for the lower two \dot{V} -versus-PA plots, \dot{V} increases with PA—up to a point. Further increases in effort (i.e., PA) are to no avail because they produce a proportional increase in R_{AW} —expiration-induced airway collapse. Thus, the more positive values of P_{IP} not only produce more positive values of PA but also increase R_{AW} , so that PA/R_{AW} and thus \dot{V} remain constant.

At low lung volumes, flow becomes **effort independent** because the reduced mechanical tethering cannot oppose the tendency toward airway collapse that always exists during expiration. Moreover, at progressively lower V_L , flow becomes effort independent earlier. In other words, particularly at low lung volumes, it simply does not pay to try any harder.

Acid-Base Physiology

Walter F. Boron

Acid-base physiology is really the study of the proton, or hydrogen ion (H^+). Although they are present in exceedingly low concentrations in most intracellular and extracellular fluids, protons nevertheless have a major impact on biochemical reactions and on a variety of physiological processes that are critical for the homeostasis of the entire body and individual cells. Not surprisingly, the body has evolved sophisticated systems to maintain $[\text{H}^+]$ values within narrow and precise ranges in the blood plasma, intracellular fluid, and other compartments.

This chapter provides the introduction to acid-base physiology, including the chemistry of buffers, the $\text{CO}_2/\text{HCO}_3^-$ buffer system, the competition between the $\text{CO}_2/\text{HCO}_3^-$ buffer system and other buffers, and the regulation of intracellular pH. In other chapters, we discuss how blood pH—and, by extension, the pH of extracellular fluid—is under the dual control of the respiratory system, which regulates plasma $[\text{CO}_2]$ (see [Chapter 31](#)), and the kidneys, which regulate plasma $[\text{HCO}_3^-]$ (see [Chapter 39](#)). In addition, we discuss the control of cerebrospinal fluid pH in [Chapter 32](#).

pH and Buffers

pH values vary enormously among different intracellular and extracellular compartments

According to Brønsted's definition, an **acid**  **N28-1** is any chemical substance (e.g., CH_3COOH , NH_4^+) that can donate an H^+ . A **base** is any chemical substance (e.g., CH_3COO^- , NH_3) that can accept an H^+ . The term **alkali** can be used interchangeably with **base**.

N28-1

Hydrogen Ions in Aqueous Solutions

Contributed by Emile Boulpaep, Walter Boron

Hydrogen ions do not truly exist as “free” protons in aqueous solutions. Instead, a shell of water molecules surrounds a proton, forming an extended complex sometimes denoted as H_3O^+ (hydronium ion) or H_9O_4^+ . Nevertheless, for practical purposes, we will treat the proton as if it were free. Also—as we do elsewhere in this book—we shall refer to *concentrations* of H^+ , bicarbonate (HCO_3^-), and other ions. Bear in mind, however, that it is more precise to work with ion **activities** (i.e., the effective concentrations of ions in realistic, nonideal solutions).

$[\text{H}^+]$ varies over a large range in biological solutions, from >100 mM in gastric secretions to <10 nM in pancreatic secretions. In 1909, the chemist Sørensen introduced the **pH scale** in an effort to simplify the notation in experiments in which he was examining the influence of $[\text{H}^+]$ on enzymatic reactions. He based the pH scale on powers of 10:  **N28-2**

$$\text{pH} \equiv -\log_{10}[\text{H}^+]$$

(28-1)

N28-2

Origin of the *p* of pH

Contributed by Walter Boron

Although the conventional wisdom is that the *p* of pH stands for the *power of 10*, Norby's analysis of Sørensen's original papers reveals a far more accidental explanation.

Sørensen used *p* and *q* to represent two solutions in an electrometric experiment. He arbitrarily assigned the standard *q* solution an $[\text{H}^+]$ of 1 *N* (normal). That is, his standard solution had an $[\text{H}^+]$ of 1 *N*, which is $C_q = 10^{-q}$. His unknown, therefore, had an $[\text{H}^+]$ of $C_p = 10^{-p}$. Using this approach, Sørensen proposed the nomenclature $p^+_H \dots$ and nowadays, we use simply pH.

We thank Christian Aalkjaer of the University of Aarhus in Denmark for bringing Norby's paper to our attention.

Thus, when $[H^+]$ is 10^{-7} M, the pH is 7.0. The higher the $[H^+]$, the lower the pH (Table 28-1). It is worth remembering that a 10-fold change in $[H^+]$ corresponds to a pH shift of 1, whereas a 2-fold change in $[H^+]$ corresponds to a pH shift of ~ 0.3 .

TABLE 28-1
Relationship between $[H^+]$ and pH Values

	$[H^+]$ (m)	pH	
×10	1×10^{-6}	6.0	1 pH unit
	1×10^{-7}	7.0	
	1×10^{-8}	8.0	
×2	8×10^{-8}	7.1	0.3 pH unit
	4×10^{-8}	7.4	
	2×10^{-8}	7.7	
	1×10^{-8}	8.0	

Even small changes in pH can have substantial physiological consequences because most biologically important molecules contain chemical groups that can either donate an H^+ (e.g., $R-COOH \rightarrow R-COO^- + H^+$) and thereby act as a weak acid, or accept an H^+ (e.g., $R-NH_2 + H^+ \rightarrow R-NH_3^+$) and thus behave as a weak base. To the extent that these groups donate or accept protons, a pH shift causes a change in net electrical charge (or valence) that can, in turn, alter biological activity either directly (e.g., by altering the affinity for a charged ligand) or indirectly (e.g., by altering molecular conformation).

pH-sensitive molecules include a variety of enzymes, receptors and their ligands, ion channels, transporters, and structural proteins. For most proteins, pH sensitivity is modest. The activity of the Na-K pump (see pp. 115–117), for example, falls by about half when the pH shifts by ~ 1 pH unit from the optimum pH, which is near the resting pH of the typical cell. However, the activity of phosphofructokinase, a key glycolytic enzyme (see p. 1176), falls by $\sim 90\%$ when pH falls by only 0.1. The overall impact of pH changes on cellular processes can be impressive. For example, cell proliferation in response to mitogenic activation is maximal at the normal, resting intracellular pH but may fall as much as 85% when intracellular pH falls by only 0.4.

Table 28-2 lists the pH values in several body fluids. Because the pH of neutral water at $37^\circ C$ is 6.81, most major body compartments are alkaline.

TABLE 28-2
Approximate pH Values of Various Body Fluids

COMPARTMENT	pH
Gastric secretions (under conditions of maximal acidity)	0.7
Lysosome	5.5
Chromaffin granule	5.5
Neutral H ₂ O at 37°C	6.81
Cytosol of a typical cell	7.2
Cerebral spinal fluid (CSF)	7.3
Arterial blood plasma	7.4
Mitochondrial inner matrix	7.5
Secreted pancreatic fluid	8.1

Buffers minimize the size of the pH changes produced by adding acid or alkali to a solution

A **buffer** is any substance that reversibly consumes or releases H⁺. In this way, buffers help to stabilize pH. Buffers do not *prevent* pH changes, they only help to *minimize* them.

Consider a hypothetical buffer B for which the protonated form HB⁽ⁿ⁺¹⁾, with a valence of *n* + 1, is in equilibrium with its deprotonated form B⁽ⁿ⁾, which has the valence of *n*:

Here, HB⁽ⁿ⁺¹⁾ is a **weak acid** because it does not fully dissociate; B⁽ⁿ⁾ is its **conjugate weak base**. Conversely, B⁽ⁿ⁾ is a **weak base** and HB⁽ⁿ⁺¹⁾ is its conjugate weak acid. The **total buffer concentration**, [TB], is the sum of the concentrations of the protonated and unprotonated forms:

$$[TB]=[HB^{(n+1)}]+[B^{(n)}] \tag{28-3}$$

The valence of the acidic (i.e., protonated) form can be positive, zero, or negative:

In these examples, NH₄⁺ (ammonium), H₂CO₃ (carbonic acid), and H₂PO₄⁻ (“monobasic” inorganic phosphate) are all weak acids, whereas NH₃ (ammonia), HCO₃⁻ (bicarbonate), and H₂PO₄²⁻ (“dibasic”

inorganic phosphate) are the respective conjugate weak bases. Each buffer reaction is governed by a **dissociation constant, K**

$$K = \frac{[B^{(n)}][H^+]}{[HB^{(n+1)}]}$$

(28-5)

If we add to a physiological solution a small amount of HCl—which is a strong acid because it fully dissociates—the buffers in the solution consume almost all added H^+ :

For each H^+ buffered, one $B^{(n)}$ is *consumed*. The tiny amount of H^+ that is *not buffered* remains free in solution and is responsible for a decrease in pH.

If we instead titrate this same solution with a strong base such as NaOH, H^+ derived from $HB^{(n+1)}$ neutralizes almost all the added OH^- :

For each OH^- buffered, one $B^{(n)}$ is *formed*. The tiny amount of added OH^- that is not neutralized by the buffer equilibrates with H^+ and H_2O and is responsible for an increase in pH. 🍷**N28-3**

N28-3

Buffering of H^+

Contributed by Walter Boron

For each H^+ buffered in Equation 28-6, one $B^{(n)}$ is *consumed*. For each OH^- buffered in Equation 28-7, one $B^{(n)}$ is *formed*. Because almost all of the added H^+ or OH^- is buffered, the change in the concentration of the unprotonated form of the buffer (i.e., $\Delta[B^{(n)}]$) is a good index of the amount of strong acid or base added per liter of solution.

A useful measure of the strength of a buffer is its **buffering power (β)**, which is the number of moles of strong base (e.g., NaOH) that one must add to a liter of solution to increase pH by 1 pH unit. This value is equivalent to the amount of strong acid (e.g., HCl) that one must add to decrease the pH by 1 pH unit. Thus, buffering power is

$$\beta \equiv \frac{\overbrace{\Delta[\text{Strong base}]}^{\text{moles/liter}}}{\Delta\text{pH}} = - \frac{\overbrace{\Delta[\text{Strong acid}]}^{\text{moles/liter}}}{\Delta\text{pH}} \quad (28-8)$$

In the absence of $\text{CO}_2/\text{HCO}_3^-$, the buffering power of whole blood (which contains erythrocytes, leukocytes, and platelets) is $\sim 25 \text{ mM/pH unit}$. This value is known as the **non- HCO_3^- buffering power** ($\beta_{\text{non-HCO}_3^-}$). In other words, we would have to add 25 mmol of NaOH to a liter of whole blood to increase the pH by 1 unit, assuming that β is constant over this wide pH range. For blood plasma, which lacks the cellular elements of whole blood, $\beta_{\text{non-HCO}_3^-}$ is only $\sim 5 \text{ mM/pH unit}$, which means that only about one fifth as much strong base would be needed to produce the same pH increase.

According to the Henderson-Hasselbalch equation, pH depends on the ratio $[\text{CO}_2]/[\text{HCO}_3^-]$

The most important physiological buffer pair is CO_2 and HCO_3^- . The impressive strength of this buffer pair is due to the volatility of CO_2 , which allows the lungs to maintain stable CO_2 concentrations in the blood plasma despite ongoing metabolic and buffer reactions that produce or consume CO_2 . Imagine that a beaker contains an aqueous solution of 145 mM NaCl (pH = 6.81), but no buffers. We now expose this solution to an atmosphere containing CO_2 (Fig. 28-1). The concentration of dissolved CO_2 ($[\text{CO}_2]_{\text{Dis}}$) is governed by **Henry's law** (see Box 26-2):

$$[\text{CO}_2]_{\text{Dis}} = s \cdot P_{\text{CO}_2} \quad (28-9)$$

FIGURE 28-1 Interaction of CO₂ with water.

At the temperature (37°C) and ionic strength of mammalian blood plasma, the **solubility coefficient, s** , is $\sim 0.03 \text{ mM/mm Hg}$. Because the alveolar air with which arterial blood equilibrates has a P_{CO_2} of $\sim 40 \text{ mm Hg}$, or torr, $[\text{CO}_2]_{\text{Dis}}$ in arterial blood is

$$[\text{CO}_2]_{\text{a}} = (0.03 \text{ mM/mm Hg}) \cdot 40 \text{ mm Hg} = 1.2 \text{ mM}$$

(28-10)

So far, the entry of CO₂ from the atmosphere into the aqueous solution has had *no effect* on pH. The reason is that we have neither generated nor consumed H⁺. CO₂ itself is neither an acid nor a base. If we were considering dissolved N₂ or O₂, our analysis would end here because these gases do not further interact with simple aqueous solutions. The aqueous chemistry of CO₂, however, is more complicated, because CO₂ reacts with the solvent (i.e., H₂O) to form carbonic acid:

This **CO₂ hydration reaction** is very slow. **N28-4** In fact, it is far too slow to meet certain physiological needs. The enzyme **carbonic anhydrase**, **N18-3** present in erythrocytes and elsewhere, catalyzes a reaction that effectively bypasses this slow hydration reaction. Carbonic acid is a weak acid that rapidly dissociates into H⁺ and HCO_3^- :

N28-4

Out-of-Equilibrium $\text{CO}_2/\text{HCO}_3^-$ Solutions

Contributed by Walter Boron

As described on page 629, adding CO_2 to an aqueous solution initiates a series of two reactions that, in the end, produce HCO_3^- and protons:

In the absence of carbonic anhydrase (CA), the first reaction—the hydration of CO_2 to form carbonic acid—is extremely slow. The second is extremely fast. At equilibrium, the overall rate of the two forward reactions must be the same as the overall rate of the reverse reactions:

The first of these reverse reactions is extremely rapid, whereas the second—the dehydration of H_2CO_3 to form CO_2 and water—is extremely slow in the absence of CA. As noted in the text, we can treat the system as if only one reaction were involved:

Moreover, we can describe this pseudoreaction by a single equilibrium constant. As shown by Equation 28-15, we can describe the equilibrium condition in logarithmic form by the following equation:

$$\text{pH} = \text{pK} + \log_{10} \left(\frac{[\text{HCO}_3^-]}{[\text{CO}_2]} \right)$$

(NE 28-4)

In other words, considering only *equilibrium* conditions, it is impossible to change pH or $[\text{HCO}_3^-]$ or $[\text{CO}_2]$ one at a time. If we change one of the three parameters (e.g., pH), we must change at least one of

the other two (i.e., $[\text{HCO}_3^-]$ or $[\text{CO}_2]$). Unfortunately, there are many cases in which the addition of CO_2 and HCO_3^- markedly enhances some process. For example, at identical values of intracellular pH, the activation of quiescent cells by mitogens is far more robust in the presence than in the absence of the physiological $\text{CO}_2/\text{HCO}_3^-$ buffer. Which buffer component is critical in this case, CO_2 or HCO_3^- ? There are also many cases in which a stress such as respiratory acidosis or metabolic acidosis triggers a particular response. For example, respiratory acidosis stimulates HCO_3^- reabsorption by the kidney—a metabolic compensation to a respiratory acidosis, as discussed beginning on pages 641–642 in the text. Again, we can ask which altered parameter signals the kidney to increase its reabsorption of HCO_3^- , the rise in $[\text{CO}_2]$ or the fall in pH?

In the 1990s, the laboratory of Walter Boron realized that it could exploit the slow equilibrium $\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3$ to create $\text{CO}_2/\text{HCO}_3^-$ solutions that are temporarily *out of equilibrium*. eFigure 28-1A illustrates how one can make an out-of-equilibrium (OOE) “pure” CO_2 solution that contains a physiological level of CO_2 , has a physiological pH, but contains virtually no HCO_3^- . The approach is to use a dual syringe pump to rapidly mix the contents of two syringes, each flowing at the same rate. One syringe contains a double dose of CO_2 (e.g., 10% CO_2) at a pH that is so low (e.g., pH 5.40) that, given a pK of ~ 6.1 , very little HCO_3^- is present. The other syringe contains a well-buffered, relatively alkaline solution that contains no CO_2 or HCO_3^- . The pH of this second solution is chosen so that at the instant of mixing at the T connection, the solution has a pH of 7.40. Of course, the $[\text{CO}_2]$ after mixing is 5% (which corresponds to a P_{CO_2} of ~ 37 mm Hg), and the $[\text{HCO}_3^-]$ is virtually zero. The solutions flow so rapidly that they reach the cell of interest before any significant re-equilibration of the CO_2 and HCO_3^- . Moreover, a suction device continuously removes the solution. As a result, the cells are continuously exposed to a freshly generated OOE solution.

eFigure 28-1B illustrates how one could make the opposite solution—a “pure” HCO_3^- solution that has a physiological $[\text{HCO}_3^-]$ and pH but virtually no $[\text{CO}_2]$. The OOE approach can be used to make solutions with virtually any combination of $[\text{CO}_2]$, $[\text{HCO}_3^-]$, and pH—at least for moderate pH values. At extremely alkaline pH values, the reaction $\text{CO}_2 + \text{OH}^- \rightarrow \text{HCO}_3^-$ generates HCO_3^- so fast that it effectively short-circuits the OOE approach. Conversely, at extremely acid pH values, the rapid reaction $\text{H}^+ + \text{HCO}_3^- \rightleftharpoons \text{H}_2\text{CO}_3$ creates relatively high levels of H_2CO_3 so that even the uncatalyzed reaction $\text{H}_2\text{CO}_3 \rightarrow \text{CO}_2 + \text{H}_2\text{O}$ is high enough to short-circuit the OOE approach. Nevertheless, at almost any pH of interest to physiologists, OOE technology allows one to change $[\text{CO}_2]$, $[\text{HCO}_3^-]$, and pH one at a time.

Work on renal proximal tubules with OOE solutions has shown that proximal tubules have the ability to sense rapid shifts in the CO_2 concentration of the basolateral (i.e., blood-side) solution that surrounds the outside of the tubule. This work suggests that the tubule has a sensor for CO_2 that is independent of any changes in pH or HCO_3^- . The tubule uses this CO_2 -sensing mechanism in its response to respiratory acidosis (see pp. 637–638). This metabolic compensation involves a rapid increase in the rate at which it transports HCO_3^- from the tubule lumen to the blood, and thus a partial correction of the acidosis.

Work on neurons cultured from the hippocampus suggests that certain neurons can detect rapid decreases in the extracellular HCO_3^- concentration ($(\text{HCO}_3^-)_o$), independent of any changes in pH_o or $[\text{CO}_2]_o$. The cell may use this detection system to stabilize intracellular pH (pH_i) during extracellular metabolic

acidosis, which would otherwise lower pH_i .

This **dissociation reaction** is the first point at which pH falls. Note that the formation of HCO_3^- (the conjugate weak base of H_2CO_3) necessarily accompanies the formation of H^+ in a stoichiometry of 1 : 1. The observation that pH decreases, even though the above reaction produces the weak base HCO_3^- , is sometimes confusing. A safe way to reason through such an apparent paradox is to focus always on the fate of the proton: if the reaction forms H^+ , pH falls. Thus, even though the dissociation of H_2CO_3 leads to generation of a weak base, pH falls because H^+ forms along with the weak base.

Unlike the hydration of CO_2 , the dissociation of H_2CO_3 is extremely fast. Thus, in the absence of carbonic anhydrase, the slow CO_2 hydration reaction limits the speed at which increased $[\text{CO}_2]_{\text{Dis}}$ leads to the production of H^+ . HCO_3^- can accept a proton to form its conjugate weak acid (i.e., H_2CO_3) or release a second proton to form its conjugate weak base (i.e., CO_3^{2-}). Because this latter reaction generally is of only minor physiological significance for buffering in mammals, we will not discuss it further.

We may treat the hydration and dissociation reactions that occur when we expose water to CO_2 as if only one reaction were involved:

Moreover, we can define a dissociation constant for this pseudoequilibrium:

$$K = \frac{[\text{H}^+][\text{HCO}_3^-]}{[\text{CO}_2]}$$

(28-14)

In logarithmic form, this equation becomes [N28-5](#)

N28-5

Derivation of the Henderson-Hasselbalch Equation

Contributed by Emile Boulpaep, Walter Boron

As shown in Equation 28-13,

We can define a dissociation constant for this pseudoequilibrium:

$$K' = \frac{[H^+][HCO_3^-]}{[CO_2][H_2O]}$$

(NE 28-5)

Factoring out $[H_2O]$, we can define an apparent equilibrium constant:

$$K'[H_2O] = K = \frac{[H^+][HCO_3^-]}{[CO_2]}$$

$$K = \frac{[H^+][HCO_3^-]}{[CO_2]}$$

(NE 28-6)

The equation immediately above is Equation 28-14 in the text. K at 37°C is $\sim 10^{-6.1}$ M or $10^{-3.1}$ mM. Taking the log (to the base 10) of each side of this equation, and remembering that $\log(a \times b) = \log(a) + \log(b)$, we have

$$\log K = \log[H^+] + \log \frac{[HCO_3^-]}{[CO_2]}$$

(NE 28-7)

Remembering that $\log[H^+] \equiv -\text{pH}$ and $\log K \equiv -\text{p}K$, we may insert these expressions into Equation NE 28-7 and rearrange to obtain

$$\text{pH} = \text{p}K + \log \frac{[HCO_3^-]}{[CO_2]}$$

(NE 28-8)

This expression is the same as Equation 28-15 in the text. Finally, we may express $[CO_2]$ in terms of P_{CO_2} , recalling from Henry's law that $[CO_2] = s \times P_{CO_2}$:

$$\text{pH} = \text{p}K + \log \frac{[HCO_3^-]}{s \times P_{CO_2}}$$

(NE 28-9)

This is the *Henderson-Hasselbalch* equation, a logarithmic restatement of the CO_2/HCO_3^- equilibrium in Equation NE 28-5 above.

$$\text{pH} = \text{pK} + \log \frac{[\text{HCO}_3^-]}{[\text{CO}_2]}$$

(28-15)

Finally, we may express $[\text{CO}_2]$ in terms of P_{CO_2} , recalling from Henry's law that $[\text{CO}_2] = s \cdot P_{\text{CO}_2}$:

$$\text{pH} = \text{pK} + \log \frac{[\text{HCO}_3^-]}{s \cdot P_{\text{CO}_2}}$$

(28-16)

This is the **Henderson-Hasselbalch** equation, a logarithmic restatement of the $\text{CO}_2/\text{HCO}_3^-$ equilibrium in Equation 28-14. Its central message is that pH depends not on $[\text{HCO}_3^-]$ or P_{CO_2} per se, but on their ratio. Human arterial blood has a P_{CO_2} of ~40 mm Hg and an $[\text{HCO}_3^-]$ of ~24 mM. If we assume that the pK governing the $\text{CO}_2/\text{HCO}_3^-$ equilibrium is 6.1 at 37°C, then

$$\text{pH} = 6.1 + \log \frac{24 \text{ mM}}{(0.03 \text{ mM/mm Hg}) \times 40 \text{ mm Hg}} = 7.40$$

(28-17)

Thus, the Henderson-Hasselbalch equation correctly predicts the normal pH of arterial blood.

$\text{CO}_2/\text{HCO}_3^-$ has a far higher buffering power in an open than in a closed system

The buffering power of a buffer pair such as $\text{CO}_2/\text{HCO}_3^-$ depends on three factors:

1. **Total concentration of the buffer pair, [TB].** Other things being equal, β is proportional to [TB].
2. **The pH of the solution.** The precise dependence on pH will become clear below.
3. **Whether the system is open or closed.** That is, can one member of the buffer pair equilibrate between the “system” (the solution in which the buffer is dissolved) and the “environment” (everything else)?

If neither member of the buffer pair can enter or leave the system, then $\text{HB}^{(n+1)}$ can become $\text{B}^{(n)}$, and vice versa, but [TB] is fixed. This is a **closed system**. An example of a closed-system buffer is inorganic phosphate in a beaker of water, or a titratable group on a protein in blood plasma. In a closed system, the buffering power of a buffer pair is  **N28-6**

N28-6

Derivation of Expressions for Buffering Power in Closed

and Open Systems

Contributed by Emile Boulpaep, Walter Boron

How does buffering power, in either a closed or open system, depend on pH?

Closed System

We start with a restatement of Equation 28-8, in which we define buffering power as the amount of strong base that we need to add (per liter of solution) in order to increase the pH by 1 pH unit. In differential form, this definition becomes the following:

$$pH = pK + \log \frac{[HCO_3^-]}{s \times P_{CO_2}}$$
$$\beta \equiv \frac{d[\text{Strong Base Added}]}{dpH}$$

(NE 28-10)

Second, because the change in the concentration of the unprotonated form of the buffer, $[B^{(n)}]$, is very nearly the same as the amount of strong base added (see Equation 28-7), Equation NE 28-10 becomes

$$\beta \equiv \frac{d[\text{Strong Base}]}{dpH} \equiv \frac{d[B^{(n)}]}{dpH}$$

(NE 28-11)

The third step is to combine Equation 28-3, reproduced below,

$$K = \frac{[B^{(n)}][H^+]}{[HB^{(n+1)}]}$$

(NE 28-12)

and Equation 28-5, reproduced below,

$$[TB] = [HB^{(n+1)}] + [B^{(n)}]$$

(NE 28-13)

to obtain an expression that describes how $[B^{(n)}]$ depends on the concentration of total buffer, $[TB]$, and $[H^+]$:

$$[B^{(n)}] = [TB] \frac{K}{[H^+] + K}$$

(NE 28-14)

Finally, we obtain the closed-system buffering power by taking the derivative of $[B^{(n)}]$ in Equation NE 28-14 with respect to pH. If we hold $[TB]$ constant while taking this derivative (i.e., if we assume that the buffer can neither enter nor leave the system), we obtain the following expression for β_{closed} :

$$\beta_{\text{closed}} = \left(\frac{d[B^{(n)}]}{dpH} \right)_{[TB]} = 2.3[TB] \frac{[H^+] K}{([H^+] + K)^2}$$

(NE 28-15)

Open System

How does β_{open} depend on P_{CO_2} and pH? The first two steps of this derivation are the same as for the open system, except that we recognize that, for the $\text{CO}_2/\text{HCO}_3^-$ buffer pair, $[B^{(n)}]$ is $[\text{HCO}_3^-]$:

$$\beta = \frac{d[\text{Strong Base Added}]}{dpH} = \frac{d[\text{HCO}_3^-]}{dpH}$$

(NE 28-16)

For the open system, the third step is to rearrange the Henderson-Hasselbalch equation (see Equation 28-16, reproduced below),

$$\text{pH} = \text{p}K + \log \frac{[\text{HCO}_3^-]}{s \cdot P_{\text{CO}_2}}$$

(NE 28-17)

and rearrange it to solve for $[\text{HCO}_3^-]$:

$$[\text{HCO}_3^-] = s \times P_{\text{CO}_2} \times 10^{(\text{pH} - \text{p}K)}$$

(NE 28-18)

If we take the derivative of $[\text{HCO}_3^-]$ in the above equation with respect to pH, holding P_{CO_2} constant, the result is β_{open} :

$$\beta_{\text{open}} = 2.3 \times s \times P_{\text{CO}_2} \times 10^{(\text{pH} - \text{p}K)}$$

(NE 28-19)

Because Equation NE 28-18 tells us that everything after “2.3” in the above equation is, in fact, “[HCO_3^-],” we obtain the final expression for β_{open} :

$$\beta_{\text{open}} = 2.3 \times [\text{HCO}_3^-]$$

(NE 28-20)

This is Equation 28-20 in the text.

$$\beta_{\text{closed}} = 2.3[\text{TB}] \frac{[\text{H}^+] \cdot K}{([\text{H}^+] + K)^2}$$

(28-18)

Two aspects of Equation 28-18 are of interest. First, at a given $[\text{H}^+]$, β_{closed} is proportional to $[\text{TB}]$. Second, at a given $[\text{TB}]$, β_{closed} has a bell-shaped dependence on pH (green curve in Fig. 28-2A). β_{closed} is maximal when $[\text{H}^+] = K$ (i.e., when $\text{pH} = \text{pK}$). Most non-HCO_3^- buffers in biological fluids behave as if they are in a closed system. Although many fluids are actually *mixtures* of several non-HCO_3^- buffers, the total $\beta_{\text{non-HCO}_3^-}$ in such a mixture is the sum of their β_{closed} values, each described by Equation 28-18. The red curve in Figure 28-2B shows how total $\beta_{\text{non-HCO}_3^-}$ varies with pH for a solution containing a mixture of nine buffers (including the one described by the green curve), each present at a $[\text{TB}]$ of 12.6 mM, with pK values evenly spaced at intervals of 0.5 pH unit. In this example, total $\beta_{\text{non-HCO}_3^-}$ is remarkably stable over a broad pH range and has a peak value that is the same as that of whole blood: 25 mM/pH unit. Indeed, whole blood is a complex mixture of many non-HCO_3^- buffers. The most important of these are titratable groups on hemoglobin and, to a far lesser extent, other proteins. Even less important than the “other proteins” are small molecules such as inorganic phosphate. The $[\text{TB}]$ values for these many buffers are not identical, and the pK values are not evenly spaced. Nevertheless, the buffering power of whole blood is nearly constant near the physiological pH.

A SINGLE BUFFER

B MULTIPLE BUFFERS

FIGURE 28-2 Buffering power in a closed system. In **B**, the solution contains nine buffers, each at a concentration of 12.6 mM and with pK values evenly spaced 0.5 pH unit apart.

The other physiologically important condition under which a buffer can function is in an **open system**. Here, one buffer species (e.g., CO_2) equilibrates between the system and the environment. A laboratory

example is a solution containing CO_2 and HCO_3^- in which dissolved CO_2 equilibrates with gaseous CO_2 in the atmosphere (see Fig. 28-1). A physiological example is blood plasma, in which dissolved CO_2 equilibrates with gaseous CO_2 in the alveoli. In either case, $[\text{CO}_2]_{\text{Dis}}$ is fixed during buffering reactions. However, the **total CO_2** — $[\text{CO}_2] + [\text{HCO}_3^-]$ —can vary widely. Because total CO_2 can rise to very high values, $\text{CO}_2/\text{HCO}_3^-$ in an open system can be an extremely powerful buffer. Consider, for example, a liter of a solution having a pH of 7.4, a P_{CO_2} of 40 mm Hg (1.2 mM CO_2), and an $[\text{HCO}_3^-]$ of 24 mM—but *no other buffers* (Fig. 28-3, stage 1). What happens when we add 10 mmol of HCl? Available $[\text{HCO}_3^-]$ neutralizes almost all of the added H^+ , forming nearly 10 mmol H_2CO_3 and then nearly 10 mmol CO_2 plus nearly 10 mmol H_2O (see Fig. 28-3, stage 2A). The CO_2 that forms does not accumulate, but evolves to the atmosphere so that $[\text{CO}_2]_{\text{Dis}}$ is constant. What is the final pH? If $[\text{CO}_2]_{\text{Dis}}$ remains at 1.2 mM in our open system, and if $[\text{HCO}_3^-]$ decreases by almost exactly 10 mM (i.e., the amount of added H^+), from 24 to 14 mM, the Henderson-Hasselbalch equation predicts a fall in pH from 7.40 to 7.17, corresponding to an increase in free $[\text{H}^+]$ of

$$\begin{aligned}\Delta[\text{H}^+] &= (10^{-7.17} - 10^{-7.40}) \text{ M} \\ &= 0.000,068 \text{ mM} - 0.000,040 \text{ mM} \\ &= 0.000,028 \text{ mM} \\ &\quad \textbf{(28-19)}\end{aligned}$$

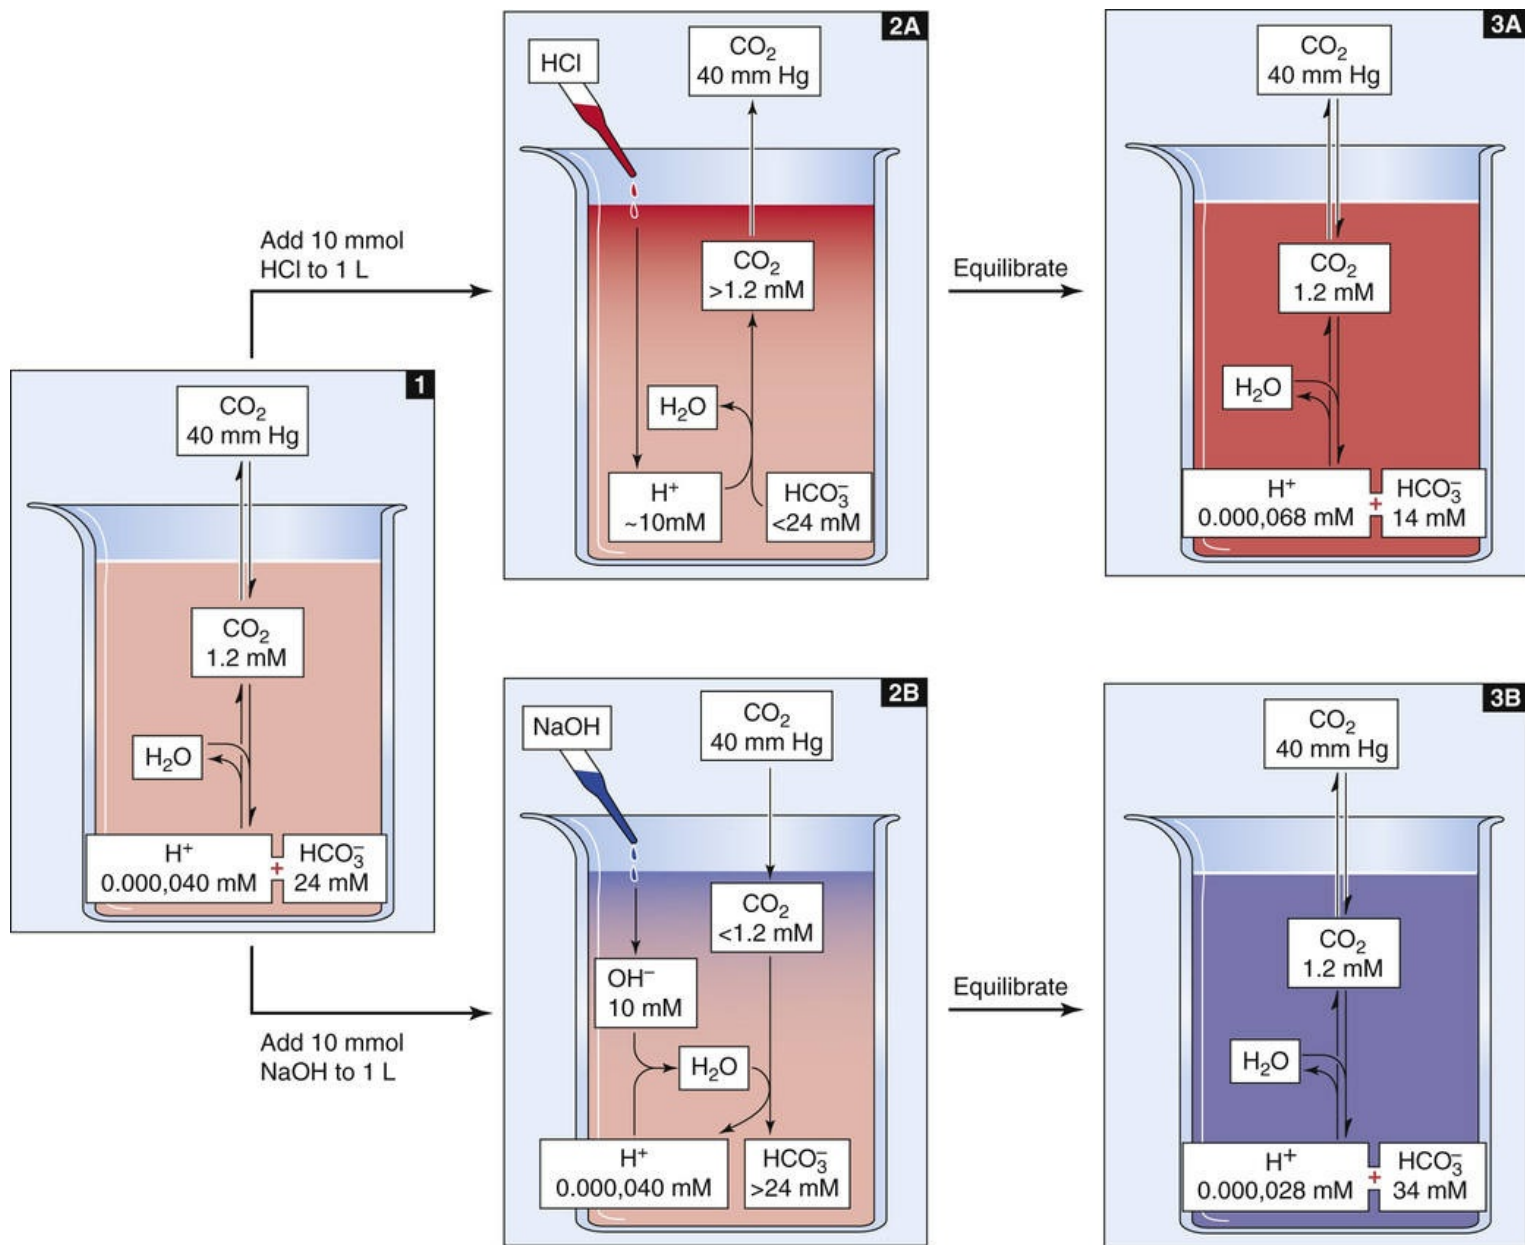

FIGURE 28-3 Buffering of strong acids and bases by $\text{CO}_2/\text{HCO}_3^-$ in an open system.

Even though we have added 10 *millimoles* of HCl to 1 L, $[\text{H}^+]$ increased by only 28 *nanomolar* (see Fig. 28-3, stage 3A). Therefore, the open-system buffer has neutralized 9.999,972 mmol of the added 10 mmol H^+ . The buffering provided by $\text{CO}_2/\text{HCO}_3^-$ in an open system (β_{open}) is so powerful because only depletion of HCO_3^- limits neutralization of H^+ . The buildup of CO_2 is not a limiting factor because the atmosphere is an infinite sink for newly produced CO_2 .

The opposite acid-base disturbance occurs when we add a strong base such as NaOH. Here, the buffering reactions are just the reverse of those in the previous example. If we add 10 mmol of NaOH to 1 L of solution, almost all added OH^- combines with H^+ derived from CO_2 that enters from the atmosphere (see Fig. 28-3, stage 2B). One HCO_3^- ion forms for each OH^- neutralized. Buffering power in this *open system* is far higher than that in a closed system because CO_2 availability does not limit neutralization of added OH^- . Only the buildup of HCO_3^- limits neutralization of more OH^- . In this example, even though we added 10 *millimoles* NaOH, free $[\text{H}^+]$ decreased by only 12 *nanomolars* (see Fig. 28-3, stage 3B) as pH rose from 7.40 to 7.55.

Whether $\text{CO}_2/\text{HCO}_3^-$ neutralizes an acid or a base, the open-system buffering power is **N28-6**

$$\beta_{\text{open}} = 2.3 \cdot [\text{HCO}_3^-] \quad (28-20)$$

Notice that β_{open} does not have a maximum. Because β_{open} is proportional to $[\text{HCO}_3^-]$, β_{open} rises exponentially with pH when P_{CO_2} is fixed (Fig. 28-4, blue curve). In normal arterial blood (i.e., $[\text{HCO}_3^-] = 24 \text{ mM}$), β_{open} is $\sim 55 \text{ mM/pH unit}$. As we have already noted, the buffering power of all non-HCO_3^- buffers ($\beta_{\text{non-HCO}_3^-}$) in whole blood is $\sim 25 \text{ mM/pH unit}$. Thus, in whole blood, β_{open} represents more than two thirds of the total buffering power. The relative contribution of β_{open} is far more striking in interstitial fluid, which lacks the cellular elements of blood and also has a lower protein concentration.

FIGURE 28-4 Buffering power of the $\text{CO}_2/\text{HCO}_3^-$ system. At pH 7.4 on the blue curve, the solution has the same composition as does arterial blood plasma: a P_{CO_2} of 40 mm Hg and an $[\text{HCO}_3^-]$ of 24 mM. If the system is “open” (i.e., CO_2 equilibrates with atmosphere), β_{open} is $\sim 55 \text{ mM/pH unit}$ at pH 7.40 and rises exponentially with pH (see Equation 28-20). If the system is closed, β_{closed} is only $\sim 2.6 \text{ mM/pH unit}$ at pH 7.4 and is maximal at the pK of the buffer (see Equation 28-18).

$\text{CO}_2/\text{HCO}_3^-$ does not *necessarily* behave as an open-system buffer. In the previous example, we could have added NaOH to a $\text{CO}_2/\text{HCO}_3^-$ solution in a capped syringe. In such a closed system, not only does accumulation of HCO_3^- limit neutralization of OH^- , but the availability of CO_2 is limiting as well. Indeed, for fluid having the composition of normal arterial blood, the *closed-system* $\text{CO}_2/\text{HCO}_3^-$ buffering power is only 2.6 mM/pH unit (see Fig. 28-4, black curve), $<5\%$ of the β_{open} value of 55 mM/pH unit . You might think that the only reason the closed-system buffering power was so low in this example is that the pH of 7.4 was 1.3 pH units above the pK. However, even if pH were equal to the pK of 6.1, the closed-system $\text{CO}_2/\text{HCO}_3^-$ buffering power in our example would be only $\sim 14 \text{ mM/pH unit}$, about one quarter of the open-system value at pH 7.4. A physiological example in which the $\text{CO}_2/\text{HCO}_3^-$ system is “poorly open” is **ischemia**, wherein a lack of blood flow minimizes the equilibration of tissue CO_2 with blood CO_2 . Thus, ischemic tissues are especially susceptible to large pH shifts.

Acid-Base Chemistry When $\text{CO}_2/\text{HCO}_3^-$ Is the Only Buffer

In this section, we consider buffering by CO_2 and HCO_3^- when these are the *only* buffers present in the solution. We defer to the following section the more complex example in which *both* $\text{CO}_2/\text{HCO}_3^-$ and non- HCO_3^- buffers are present in the same solution.

In the absence of other buffers, doubling P_{CO_2} causes pH to fall by 0.3 but causes almost no change in $[\text{HCO}_3^-]$

Figure 28-5 represents 1 L of a solution with the same $\text{CO}_2/\text{HCO}_3^-$ composition as arterial blood plasma but no buffers other than $\text{CO}_2/\text{HCO}_3^-$. What are the consequences of increasing P_{CO_2} in the gas phase? The resulting increase in $[\text{CO}_2]_{\text{Dis}}$ causes the $\text{CO}_2/\text{HCO}_3^-$ equilibrium to shift toward formation of H^+ and HCO_3^- . This disturbance is an example of a **CO_2 titration**, because we initiated it by altering P_{CO_2} . More specifically, it is a **respiratory acidosis**—“acidosis” because pH falls, and “respiratory” because pulmonary problems (Table 28-3) are the most common causes of an increase in the P_{CO_2} of arterial blood (see p. 680).

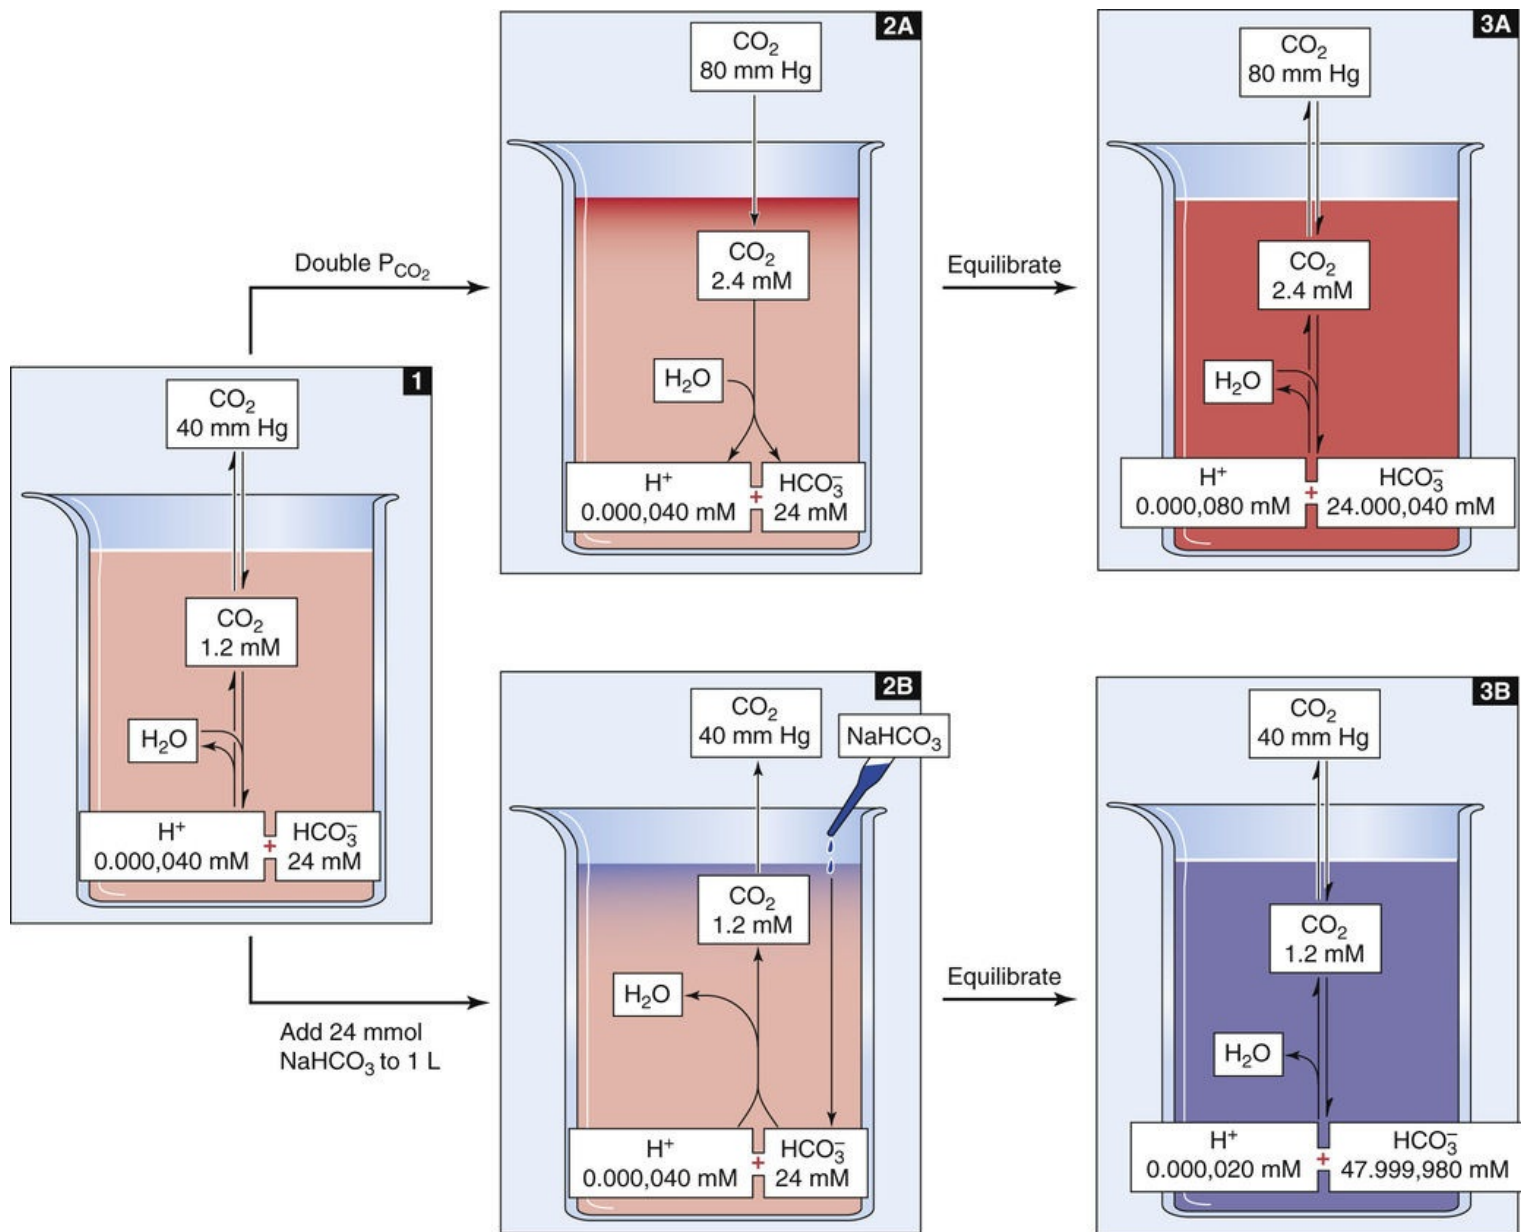

FIGURE 28-5 Doubling of CO_2 or HCO_3^- concentrations.

TABLE 28-3
The Four Major Acid-Base Disorders

DISORDER	PROXIMATE CAUSE(S)	CLINICAL CAUSES	CHANGES IN ARTERIAL ACID-BASE PARAMETERS
Respiratory acidosis	↑ P _{CO₂}	↓ Alveolar ventilation (e.g., drug overdose) ↓ Lung-diffusing capacity (e.g., pulmonary edema) Ventilation-perfusion mismatch	pH: ↓ [HCO ₃ ⁻]: ↑ P _{CO₂} : ↑
Respiratory alkalosis	↓ P _{CO₂}	↑ Alveolar ventilation caused by: Hypoxia (e.g., acclimatization to high altitude) Anxiety Aspirin intoxication	pH: ↑ [HCO ₃ ⁻]: ↓ P _{CO₂} : ↓
Metabolic acidosis	Addition of acids other than CO ₂ or H ₂ CO ₃ Removal of alkali (fixed P _{CO₂})	↓ Urinary secretion of H ⁺ (e.g., renal failure) Ketoacidosis (e.g., diabetes mellitus) Lactic acidosis (e.g., shock) HCO ₃ ⁻ loss (e.g., severe diarrhea)	pH: ↓ [HCO ₃ ⁻]: ↓ P _{CO₂} : No change
Metabolic alkalosis	Addition of alkali Removal of acids other than CO ₂ or H ₂ CO ₃ (fixed P _{CO₂})	HCO ₃ ⁻ load (e.g., NaHCO ₃ therapy) Loss of H ⁺ (e.g., severe vomiting)	pH: ↑ HCO ₃ ⁻ : ↑ P _{CO₂} : No change

In the absence of non-HCO₃⁻ buffers, how far pH falls during respiratory acidosis depends on the initial pH and P_{CO₂}, as well as on the final P_{CO₂}. For example, doubling P_{CO₂} from 40 mm Hg (see Fig. 28-5, stage 1) to 80 mm Hg causes [CO₂]_{Dis} to double to 2.4 mM (see Fig. 28-5, stage 2A). At this point, the 1-L system is far *out* of equilibrium and can return to equilibrium only if some CO₂ (X mmol) combines with X H₂O to form X H⁺ and X HCO₃⁻. Thus, according to Equation 28-14, the following must be true at equilibrium:

$$\underbrace{10^{-6.1} \text{ M}}_{\text{or}} \underbrace{10^{-3.1} \text{ mM}}_K = \frac{\overbrace{[\text{H}^+]}^{(0.000,040 \text{ mM} + x)} \overbrace{[\text{HCO}_3^-]}{(24 \text{ mM} + x)}}{\underbrace{2.4 \text{ mM}}_{[\text{CO}_2]}}$$

(28-21)

Solving this equation for X yields an extremely small value, nearly 40 nmol, or 0.000,040 mmol. X represents the **flux** of CO₂ that passes through the reaction sequence CO₂ + H₂O → H₂CO₃ → H⁺ + HCO₃⁻ to re-establish the equilibrium. CO₂ from the atmosphere replenishes the CO₂ consumed in this reaction, so that [CO₂]_{Dis} remains at 2.4 mM after the new equilibrium is achieved (see Fig. 28-5, stage 3A). The reason that the flux X is so small is that, with no other buffers present, every H⁺ formed remains free in solution. Thus, only a minuscule amount of H⁺ need be formed before [H⁺] nearly doubles from 40 to nearly 80 nM. However, [HCO₃⁻] undergoes only a tiny fractional increase, from 24 to 24.000,040 mM. The doubling of the denominator in Equation 28-21 is matched by a doubling of the numerator, nearly all of which is due to the near-doubling of [H⁺]. The final pH in this example of respiratory acidosis is

$$\text{pH} = -\log(80 \text{ nM}) = 7.10$$

(28-22)

Another way of arriving at the same answer is to insert the final values for $[\text{HCO}_3^-]$ and P_{CO_2} into the Henderson-Hasselbalch equation:

$$\text{pH} = 6.1 + \log \frac{24.000,040 \text{ mM}}{(0.03 \text{ nM/mmHg}) \cdot (80 \text{ mmHg})} = 7.10$$

(28-23)

The opposite acid-base disturbance, in which P_{CO_2} falls, is **respiratory alkalosis**. In a solution containing no buffers other than $\text{CO}_2/\text{HCO}_3^-$ reducing P_{CO_2} by half, from 40 to 20 mmHg, would cause all of the aforementioned reactions to shift in the opposite direction, so that pH would rise by 0.3, from 7.4 to 7.7. We could produce respiratory alkalosis in a beaker by lowering the P_{CO_2} in the gas phase. In humans, hyperventilation (see Table 28-3) lowers alveolar and thus arterial P_{CO_2} (see p. 680).

Thus, in the absence of non- HCO_3^- buffers, doubling $[\text{CO}_2]$ causes pH to fall by 0.3, whereas halving $[\text{CO}_2]$ causes pH to rise by 0.3 (see Table 28-1). Remember, the log of 2 is 0.3.

In the absence of other buffers, doubling $[\text{HCO}_3^-]$ causes pH to rise by 0.3

What would happen if we doubled $[\text{HCO}_3^-]$, rather than P_{CO_2} ? If we start with 1 L of solution that has the ionic composition of arterial blood (see Fig. 28-5, stage 1), adding 24 mmol of HCO_3^- (e.g., NaHCO_3) drives the $\text{CO}_2/\text{HCO}_3^-$ equilibrium toward CO_2 (see Fig. 28-5, stage 2B). The new equilibrium is achieved when X mmol of HCO_3^- combines with X H^+ to produce X CO_2 and X H_2O . Because the system is *open to* CO_2 , the generation of X mmol CO_2 causes no change in $[\text{CO}_2]_{\text{Dis}}$; the newly formed CO_2 simply evolves into the atmosphere. Thus, according to Equation 28-14, the following must be true at equilibrium:

$$\underbrace{10^{-6.1} \text{ M}}_{\text{or}} \underbrace{10^{-3.1} \text{ mM}}_K = \frac{\overbrace{(0.000,040 \text{ mM} - x)}^{[\text{H}^+]}}{\underbrace{1.2 \text{ mM}}_{\text{Fixed } [\text{CO}_2]}} \overbrace{(48 \text{ mM} - x)}^{[\text{HCO}_3^-]}$$

(28-24)

Solving this equation yields an X of nearly 0.000,020 mM. Thus, in the absence of other buffers, an initial doubling of $[\text{HCO}_3^-]$ from 24 to 48 mM causes $[\text{H}^+]$ to fall by nearly half, from 40 to 20 nM. Although $[\text{HCO}_3^-]$ also decreases by 20 nM, its fractional change from 48 to 47.999,980 mM is insignificant. The final pH is:

$$\text{pH} = -\log(20 \text{ nM}) = 7.70$$

(28-25)

The Henderson-Hasselbalch equation yields the same result:

$$\text{pH} = 6.1 + \log \frac{47.999,980 \text{ mM}}{(0.03 \text{ mM/mm Hg}) \cdot (40 \text{ mm Hg})} = 7.70$$

(28-26)

Thus, in the absence of non-HCO_3^- buffers, doubling $[\text{HCO}_3^-]$ causes pH to increase by ~ 0.3 . Rather than adding HCO_3^- , we could produce an identical effect by adding the same amount of strong base (e.g., NaOH), as we did in Figure 28-3, stages 2B and 3B, or by *removing* the same amount of strong acid (e.g., HCl). Although the removal of HCl from a solution in a beaker may seem artificial, the removal of gastric HCl from the body occurs during vomiting (see Table 28-3). **N28-7** We also could add a *weak* base (e.g., NH_3) or remove any *weak* acid (e.g., lactic acid) other than CO_2 or H_2CO_3 . However, to produce the same alkali load, we would have to add/remove more of a *weak* base/acid than for a *strong* base/acid. All of these maneuvers, carried out at a fixed P_{CO_2} , are examples of **metabolic alkalosis**—“alkalosis” because the pH increases, and “metabolic” because derangements in metabolism are common clinical causes.

N28-7

Metabolic Alkalosis Caused by Vomiting

Contributed by Walter Boron

Because the stomach secretes HCl into the lumen of the stomach, vomiting necessarily results in a net loss of HCl, **N28-9** and this by itself causes some degree of metabolic alkalosis (see p. 635). In addition, the loss of Cl^- leads to volume contraction, that is, a decrease in **effective circulating volume** (see pp. 554–555). The body's multipronged response to this volume contraction (see p. 838) includes a stimulation of the renin-angiotensin-aldosterone axis, the end point of which is increased retention of NaCl and the osmotically obligated H_2O . However, at the level of the renal proximal tubule, the increased levels of systemic [angiotensin II] lead not only to an increase in NaCl reabsorption, but also to an increase in NaHCO_3 reabsorption. Moreover, at the level of the distal nephron, the increased levels of aldosterone lead not only to an increase in NaCl reabsorption, but also to an increase in NaHCO_3 reabsorption. The result is that the hormonal stimuli that represent the appropriate response to volume depletion lead, as a side effect, to a metabolic alkalosis. The proper treatment of this **contraction alkalosis** is not to infuse the patient with NaHCO_3 , but rather to replenish the lost volume by delivering “normal saline” intravenously. With effective circulating volume returned to normal, the stimulus to the renin-angiotensin-aldosterone axis is removed, and the acid-base disturbance resolves.

It is interesting to note that although volume depletion causes the kidney not only to retain NaCl but also to retain NaHCO_3 inappropriately, the converse is not true. That is, respiratory or metabolic acidosis cause the kidney to retain NaHCO_3 but to decrease the reabsorption of NaCl, so as to maintain a

constant effective circulating volume.

What this all teaches us is that the defense of effective circulating volume trumps everything (including acid-base homeostasis). However, the body's mechanisms for regulating acid-base balance are far more sophisticated than those for regulating effective circulating volume. Thus, the response to acidosis or alkalosis is precise and appropriate—and does not involve inappropriate changes in effective circulating volume that would otherwise lead to hyper- or hypotension!

N28-9

Equivalency of Adding HCO_3^- , Adding OH^- , and Removing H^+

Contributed by Walter Boron

Imagine that we start with 1 L of an aqueous solution at 37°C. This solution mimics blood plasma, 5% CO_2 /24 mM HCO_3^- at pH 7.4, and the system is “open” for CO_2 (i.e., CO_2 can freely enter and leave the aqueous solution so as to keep $[\text{CO}_2]$ constant). Moreover, this solution contains a non- HCO_3^- buffer ($\text{HB}^{(n+1)} \rightleftharpoons \text{H}^+ + \text{B}^{(n)}$) with a buffering power of 25 mM/pH unit.

Add NaHCO_3

If we were to add 1 mmol of NaHCO_3 to this 1 L of solution, then $[\text{HCO}_3^-]$ would instantly increase by 1 mM. Of course, over time, subsequent reactions cause $[\text{HCO}_3^-]$ to gradually fall as the added HCO_3^- equilibrates with the pre-existing $\text{CO}_2/\text{HCO}_3^-$ buffer according to the overall reactions:

Furthermore, because the consumption of HCO_3^- goes hand in hand with the consumption of H^+ , the pH will gradually rise, which in turn upsets the equilibrium of non- HCO_3^- buffers:

Thus, the rise in pH causes the $\text{HB}^{(n+1)}/\text{B}^{(n)}$ equilibrium to shift to the right, thereby increasing $[\text{B}^{(n)}]$. As a result, the final $\Delta[\text{HCO}_3^-]$ would be <1 mM. However, the changes in $[\text{HCO}_3^-]$ and $[\text{B}^{(n)}]$ would sum to very nearly 1 mM (i.e., the amount of NaHCO_3 originally added):

$$\Delta[\text{HCO}_3^-] + \Delta[\text{B}^{(n)}] \cong 1 \text{ mM}$$

(NE 28-27)

The reason why we use “approximately equal” in the above equation is that a tiny amount of the added

HCO_3^- causes the pH to rise (i.e., it is not reflected in the $\Delta[\text{B}^{(n)}]$).

Add NaOH

Imagine that instead of adding NaHCO_3 , we add 1 mmol of NaOH to our 1 L of solution. We can *imagine* that virtually all of the added OH^- would react with the CO_2 to form an equivalent amount of HCO_3^- :

(Note: this reaction is equivalent to $\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{HCO}_3^- + \text{H}^+$.) Thus, $[\text{HCO}_3^-]$ would rise by very nearly 1 mM. The reason we say “very nearly” is that a tiny fraction of the added OH^- would equilibrate with H^+ and H_2O , causing pH to rise:

This consumption of OH^- would cause pH to rise, which in turn would cause the $\text{HB}^{(n+1)}/\text{B}^{(n)}$ equilibrium to shift to the right:

As a result $[\text{B}^{(n)}]$ would rise by a tiny amount. At the same time, however, the reaction $\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{HCO}_3^- + \text{H}^+$ is out of equilibrium because the HCO_3^- that we formed in Equation NE 28-28 yields an $[\text{HCO}_3^-]$ far too high for the prevailing $[\text{H}^+]$. Thus, Equation NE 28-28 would partially reverse, releasing more OH^- to react with H^+ , and leading to the formation of still more $\text{B}^{(n)}$. This reversal of Equation NE 28-28 (the secondary fall in $[\text{HCO}_3^-]$) would continue until eventually the reactions in both Equation NE 28-28 and Equation NE 28-30 are in equilibrium. This process is illustrated by the panels on the right side of Figure 28-7. As a result, the final $\Delta[\text{HCO}_3^-]$ would be less than the ~1 mM that we predicted in Equation NE 28-28. However, the changes in $[\text{HCO}_3^-]$ and $[\text{B}^{(n)}]$ would sum to very nearly 1 mM (i.e., the amount of NaOH added):

$$\Delta[\text{HCO}_3^-] + \Delta[\text{B}^{(n)}] \cong 1 \text{ mM}$$

(NE 28-31)

In fact, the values of $\Delta[\text{HCO}_3^-]$ and $\Delta[\text{B}^{(n)}]$ in Equation NE 28-31 (i.e., the example in which we added 1 mmol NaOH) are precisely the same as in Equation NE 28-27 (i.e., the example in which we added 1 mmol NaHCO_3).

Two provisos here. First, the reaction in Equation NE 28-28 would be very slow in the absence of added **carbonic anhydrase**. **N18-3** Nevertheless, even in the absence of carbonic anhydrase, this reaction would eventually come to equilibrium, and we could imagine that $[\text{HCO}_3^-]$ would eventually rise by very nearly 1 mM. Second, in this thought experiment, we are “imagining” that the added OH^- initially reacts only with CO_2 to form $\sim 1 \text{ mM } \text{HCO}_3^-$, and that some of this HCO_3^- then dissociates to yield some CO_2 and OH^- . In fact, a sizeable amount of the OH^- that we originally added will also react instantly with H^+ (according to Equation NE 28-29), in turn leading to the formation of $\text{B}^{(n)}$ in Equation NE 28-30.

Remove HCl

Finally, imagine that we magically remove 1 mmol of HCl from a liter of our $\text{CO}_2/\text{HCO}_3^-$ solution. In real life, we could remove this H^+ either by consuming it in a chemical (or biochemical) reaction or by transporting it out of some biological compartment (e.g., the cytosol). We could *imagine* that the HCl that we remove causes the $\text{CO}_2/\text{HCO}_3^-$ equilibrium to shift, thereby causing $[\text{HCO}_3^-]$ to rise by very nearly 1 mM:

The consumed CO_2 would come from the atmosphere. A small amount of the H^+ that we removed would lower pH:

However, the reaction in Equation NE 28-32 would be badly out of equilibrium because the rise in $[\text{HCO}_3^-]$ would be out of proportion to the fall in $[\text{H}^+]$. Thus, the reaction in Equation NE 28-32 would begin to reverse, consuming some of the $\sim 1 \text{ mM } \text{HCO}_3^-$ that we initially formed. Moreover, the $\text{HB}^{(n+1)}/\text{B}^{(n)}$ reaction would also be out of equilibrium because $[\text{H}^+]$ has fallen without any change in $[\text{B}^{(n)}]$ or $[\text{HB}^{(n+1)}]$. As a result, the following will occur:

In fact, the reaction in Equation NE 28-32 would continue to reverse, releasing some HCO_3^- as well as an equal amount of H^+ for consumption in Equation NE 28-34. Eventually, the reactions in Equations NE 28-32 through NE 28-34 would be in equilibrium. At this point,

In fact, the values of $\Delta[\text{HCO}_3^-]$ and $\Delta[\text{B}^{(n)}]$ in Equation NE 28-35 (i.e., this example in which we removed 1 mmol HCl) are precisely the same as in Equation NE 28-27 (i.e., the example in which we added 1 mmol NaHCO_3) and in Equation NE 28-31 (i.e., the example in which we added 1 mmol NaOH).

Summary

Thus, regardless of whether we add 1 mmol of NaHCO_3 , add 1 mmol of NaOH, or remove 1 mmol of HCl ... in the end, the result is the same. The $\text{CO}_2/\text{HCO}_3^-$ and the $\text{HB}^{(n+1)}/\text{B}^{(n)}$ buffer systems will both wind up being in equilibrium, and in each example, $[\text{HCO}_3^-]$ will increase by the same amount, $[\text{B}^{(n)}]$ will increase by the same amount, and pH will increase by the same amount.

The opposite acid-base disturbance—in which we remove HCO_3^- or another alkali, or add an acid other than CO_2 or H_2CO_3 —is **metabolic acidosis**. If we start with a solution having the ionic composition of arterial blood, removing half of the initial HCO_3^- or removing 12 mM NaOH or adding 12 mM HCl would cause all of the aforementioned reactions to shift in the opposite direction, so that pH would fall by 0.3, from 7.4 to 7.1. Common causes of metabolic acidosis in humans are renal failure and metabolic problems (see [Table 28-3](#)).

We saw in [Equation 28-26](#) that the pH of a $\text{CO}_2/\text{HCO}_3^-$ solution does not depend on $[\text{HCO}_3^-]$ or P_{CO_2} per se, but on their ratio. Because it is the kidney that controls $[\text{HCO}_3^-]$ in the blood plasma (see [Chapter 39](#)), and because it is the lung that controls P_{CO_2} (see [Chapter 31](#)), the pH of blood plasma is under the dual control of both organ systems, a concept embodied by a whimsical variant of the Henderson-Hasselbalch equation:

$$\text{pH} = \text{Constant} + \frac{\text{Kidney}}{\text{Lungs}}$$

(28-27)

Acid-Base Chemistry in the Presence of $\text{CO}_2/\text{HCO}_3^-$ and non-HCO_3^- Buffers—The Davenport Diagram

So far, our discussion has focused on simple systems in which the only pH buffers are either (1) one or more non-HCO_3^- buffers or (2) $\text{CO}_2/\text{HCO}_3^-$. Under these circumstances, it is relatively easy to predict the effects of acid-base disturbances. Real biological systems, however, are mixtures of $\text{CO}_2/\text{HCO}_3^-$ and many non-HCO_3^- buffers. Thus, to understand the effects of respiratory and metabolic acid-base disturbances in a biological system, we must consider multiple competing equilibria—one for $\text{CO}_2/\text{HCO}_3^-$ (described by Equation 28-16) and one for each of the non-HCO_3^- buffers (each described by its version of Equation 28-5). Obtaining a precise solution to such clinically relevant problems is impossible. One approach is to use a computer to make increasingly more precise approximations of the correct answer. Another, more intuitive approach is to use a graphical method to estimate the final pH. The Davenport diagram is the best such tool.

The Davenport diagram is a graphical tool for interpreting acid-base disturbances in blood

What happens to the pH of blood—a complex mixture that includes many non-HCO_3^- buffers—when P_{CO_2} doubles? We simplify matters by lumping together the actions of all non-HCO_3^- buffers, so that $\text{H}^+ + \text{B}^{(n)} \rightleftharpoons \text{HB}^{(n+1)}$ represents the reactions of *all* non-HCO_3^- buffers. When we raise P_{CO_2} , almost all of the newly formed H^+ reacts with $\text{B}^{(n)}$ to form $\text{HB}^{(n+1)}$ so that the free $[\text{H}^+]$ rises only slightly.

In this simplified approach, the final pH depends on two competing buffer reactions—one involving $\text{CO}_2/\text{HCO}_3^-$ and the other involving $\text{HB}^{(n+1)}/\text{B}^{(n)}$. Computing the final pH requires solving two simultaneous equations, one for each buffer reaction.

The $\text{CO}_2/\text{HCO}_3^-$ Buffer

The first of the two equations that we must solve simultaneously is a rearrangement of the Henderson-Hasselbalch equation (see Equation 28-16):

$$[\text{HCO}_3^-] = s \cdot P_{\text{CO}_2} \cdot 10^{(\text{pH} - \text{p}K_{\text{CO}_2})}$$

(28-29)

For a P_{CO_2} of 40 mm Hg, the equation requires that $[\text{HCO}_3^-]$ be 24 mM when pH is 7.40—as in normal arterial blood plasma. If pH decreases by 0.3 at this same P_{CO_2} , Equation 28-29 states that $[\text{HCO}_3^-]$ must fall by half to 12 mM. Conversely, if pH increases by 0.3, $[\text{HCO}_3^-]$ must double to 48 mM. The blue column of Table 28-4 lists the $[\text{HCO}_3^-]$ values that Equation 28-29 predicts for various pH values when P_{CO_2} is 40 mm Hg. Plotting these $[\text{HCO}_3^-]$ values against pH yields the blue curve labeled “ $P_{\text{CO}_2} = 40$ mm Hg” in Figure 28-6A. This curve, which is known as a CO_2 isobar or **isopleth** (from the Greek *isos* [equal] + *plethein* [to be full]) represents all possible combinations of $[\text{HCO}_3^-]$ and pH at a P_{CO_2} of 40 mm Hg. Table 28-4 also summarizes $[\text{HCO}_3^-]$ values prevailing at P_{CO_2} values of 20 and 80 mm Hg. Note that at a P_{CO_2} of 20 (orange column), representing respiratory alkalosis, $[\text{HCO}_3^-]$ values are half those for a P_{CO_2} of 40 at the same pH. At a P_{CO_2} of 80 (green column), representing respiratory acidosis, $[\text{HCO}_3^-]$ values are twice those at a P_{CO_2} of 40. Each of the isopleths in Figure 28-6A rises exponentially with pH. The slope of each isopleth also rises exponentially with pH and represents β_{open} for $\text{CO}_2/\text{HCO}_3^-$. At a particular pH, an isopleth representing a higher P_{CO_2} (i.e., a higher $[\text{HCO}_3^-]$) has a steeper slope, as Equation 28-20 predicts.

TABLE 28-4
Relationship between HCO_3^- and pH at Three Fixed Levels of P_{CO_2}

$[\text{HCO}_3^-]$ (mM)			
pH	$P_{\text{CO}_2} = 20$ mm Hg	$P_{\text{CO}_2} = 40$ mm Hg	$P_{\text{CO}_2} = 80$ mm Hg

A CO₂ ISOPLETHS

B TITRATION CURVES FOR NON-HCO₃⁻ BUFFERS

C EFFECT OF RESPIRATORY ACIDOSIS AND ALKALOSIS

D EFFECT OF CHANGING NON-HCO₃⁻ BUFFERING POWER

FIGURE 28-6 Davenport diagram. In **A**, the three isopleths are CO₂ titration curves. In **B**, the solution contains nine buffers, each at a concentration of 12.6 mM and with pK values evenly spaced 0.5 pH unit apart, as in [Figure 28-2B](#). In **C**, the red arrow represents the transition from a normal acid-base status for blood ("Start") to respiratory acidosis (point A) produced by raising P_{CO₂} to 80 mm Hg. Point B represents respiratory alkalosis produced by lowering P_{CO₂} to 20 mm Hg. In **D**, the labeled points represent the results of respiratory acidosis when β_{non-HCO₃⁻} is zero (point A₁), 25 mM/pH (point A), and infinity (point A₂).

Non-HCO₃⁻ Buffers

The second of the two equations that we must solve simultaneously describes the lumped reaction of all non-HCO₃⁻ buffers. To understand the origin of this equation, we begin with the green curve (surrounded by black curves) in [Figure 28-6B](#), the **titration curve** of a single non-HCO₃⁻ buffer with a pK of 7 and total buffer concentration of 12.6 mM (as for the green curve in [Fig. 28-2B](#)). At a pH of 10, [HB⁽ⁿ⁺¹⁾] for this single buffer is extremely low because almost all of the "B" is in the form B⁽ⁿ⁾. As we lower pH by

successively adding small amounts of HCl, $[\text{HB}^{(n+1)}]$ gradually rises—most steeply when pH equals pK. Indeed, at any pH, the slope of this curve is the negative of β for this single buffer. The black curves in Figure 28-6B are the titration curves for eight other buffers, each present at a $[\text{TB}]$ of 12.6 mM, with pK values evenly spaced at intervals of 0.5 pH unit on either side of 7. The red curve in Figure 28-6B is the sum of the titration curves for all nine buffers. **N28-8** Its slope—the negative of the total buffering power of all nine buffers—is remarkably constant over a broad pH range. (The red curve in Figure 28-2B shows how β , the slope of the red curve here in Figure 28-6B, varies with pH.) The red curve in Figure 28-6B represents the second of the two equations that we must solve simultaneously.

N28-8

Davenport Diagram—Constructing the Non-HCO_3^- Buffer Line

Contributed by Emile Boulpaep, Walter Boron

The non-HCO_3^- **buffer line** (the red line in Fig. 28-6B, C) describes the buffering power of *all buffers other than* $\text{CO}_2/\text{HCO}_3^-$ ($\beta_{\text{non-HCO}_3^-}$). In whole blood—here we refer to the line as the **blood buffer line**—hundreds of buffer groups may contribute to the overall non-HCO_3^- buffering power. Each of these buffer groups has its own pK and concentration, and thus its own bell-shaped curve—like the nine small curves in Figure 28-2B—describing the pH dependence of its buffering power. Each of these buffer groups also has its own titration curve, as shown in Fig. 28-6B, and the sum of these titration curves (the red curve in this figure) is the combined titration curve of these buffers (i.e., $\beta_{\text{non-HCO}_3^-}$). Notice that this red curve is nearly a straight line over the physiological pH range. In other words, in the physiological range, the slope of the red line is nearly constant, which is another way of stating that the non-HCO_3^- buffering power is nearly constant over this pH range—as illustrated in Figure 28-2B.

We already know from Equation 28-8 (reproduced below as Equation NE 28-21) that we can define buffering power in terms of the amount of strong acid added to the solution:

$$\beta_{\text{Non-HCO}_3^-} \equiv - \frac{\frac{\text{moles/L}}{\Delta[\text{Strong Acid}]}}{\Delta\text{pH}}$$

(NE 28-21)

From the perspective of the non-HCO_3^- buffers that are at work during respiratory acidosis, $\Delta[\text{strong acid}]$ is the H^+ formed from CO_2 and H_2O as a result of the increase in P_{CO_2} (see arrow from “Start” to point A in Fig. 28-6C). Because respiratory acidosis produces HCO_3^- and H^+ in a 1 : 1 ratio, the amount of HCO_3^- formed during respiratory acidosis—that is $[\text{HCO}_3^-]_{\text{final}} - [\text{HCO}_3^-]_{\text{initial}} = \Delta[\text{HCO}_3^-]$ —is the same as the amount of H^+ added ($\Delta[\text{strong acid}]$). Thus, we can replace $\Delta[\text{strong acid}]$ in Equation NE 28-21 with $\Delta[\text{HCO}_3^-]$ and therefore somewhat paradoxically express the non-HCO_3^- buffering power in terms of $[\text{HCO}_3^-]$:

$$\beta_{\text{Non-HCO}_3^-} \equiv -\frac{\Delta[\text{Strong Acid}]}{\Delta\text{pH}} \equiv -\frac{\Delta[\text{HCO}_3^-]}{\Delta\text{pH}} = \frac{[\text{HCO}_3^-]_{\text{init}} - [\text{HCO}_3^-]}{\text{pH} - \text{pH}_{\text{init}}} \quad (\text{NE 28-22})$$

$[\text{HCO}_3^-]_{\text{init}}$ and pH_{init} represent initial values (before increasing P_{CO_2} —that is, the point labeled “Start” in Fig. 28-6C), and $[\text{HCO}_3^-]$ and pH represent *final* values (after increasing P_{CO_2} —that is, point A in Fig. 28-6C). The equation describing the non-HCO_3^- buffer line is simply a rearrangement of Equation NE 28-22:

$$[\text{HCO}_3^-] = [\text{HCO}_3^-]_{\text{init}} - \beta_{\text{Non-HCO}_3^-} (\text{pH} - \text{pH}_{\text{init}}) \quad (\text{NE 28-23})$$

This equation describes a line whose slope is *negative* $\beta_{\text{non-HCO}_3^-}$. For whole blood, $\beta_{\text{non-HCO}_3^-}$ is 25 mM/pH unit, so that the slope of the line is -25 mM/pH unit in Figure 28-6C. Note that because we assumed that the buffering power of the non-HCO_3^- buffers is constant over the pH range of interest, and because this buffering power is represented by the *slope* of the non-HCO_3^- buffer curve in Figure 28-6C, the function describing this buffering power must be a straight line (i.e., a function with a constant slope).

We are now in a position to understand why, in Figure 28-6C, the non-HCO_3^- buffer line (see Equation NE 28-23) shares the same y-axis as the CO_2 isopleth (e.g., the blue curve in Fig. 28-6C), which is described by Equation 28-29, reproduced here:

$$[\text{HCO}_3^-] = s \times P_{\text{CO}_2} \times 10^{(\text{pH} - \text{pK}_{\text{CO}_2})} \quad (\text{NE 28-24})$$

In both the case of the line describing the non-HCO_3^- buffering power (see Equation NE 28-23) and the exponential curve describing the open-system CO_2 buffering power (see Equation NE 28-24), the dependent variable is $[\text{HCO}_3^-]$.

The non-HCO_3^- buffer line passes through the point describing the initial conditions (pH_{init} , $[\text{HCO}_3^-]_{\text{init}}$). In Figure 28-6C, pH_{init} is 7.40 and $[\text{HCO}_3^-]_{\text{init}}$ is 24 mM, as indicated by the point labeled “Start.” Because these initial conditions for the non-HCO_3^- buffers can change, we will see below in the text that the non-HCO_3^- buffer line can translate up and down on the Davenport diagram in metabolic alkalosis and metabolic acidosis. However, as long as $\beta_{\text{non-HCO}_3^-}$ is constant, the slope of the line is always the same.

Solving the Problem

Figure 28-6C is a Davenport diagram, a combination of the three CO_2 isopleths in Figure 28-6A and the linear part of the red non-HCO_3^- titration curve in Figure 28-6B. The red non-HCO_3^- titration line (representing $\beta_{\text{non-HCO}_3^-}$ for whole blood, 25 mM/pH unit) intersects with the CO_2 isopleth for a P_{CO_2} of 40 at the point labeled “Start,” which represents the initial conditions for arterial blood. At this intersection,

both $\text{CO}_2/\text{HCO}_3^-$ and non-HCO_3^- buffers are simultaneously in equilibrium.

We are now in a position to answer the question raised at the beginning of this section: What will be the final pH when we increase the P_{CO_2} of whole blood from 40 to 80 mm Hg? The final equilibrium conditions for this case of *respiratory acidosis* must be described by a point that lies simultaneously on the red non-HCO_3^- titration line and the green isopleth for 80 mm Hg. Obtaining the answer using the Davenport diagram requires a three-step process:

Step 1: Identify the point at the intersection of the initial P_{CO_2} isopleth and the initial non-HCO_3^- titration line (see Fig. 28-6C, “Start”).

Step 2: Identify the isopleth describing the *final* P_{CO_2} (80 mm Hg in this case).

Step 3: Follow the non-HCO_3^- titration line to its intersection with the final P_{CO_2} isopleth. In Figure 28-6C, this intersection occurs at point A, which corresponds to a pH of 7.19 and an $[\text{HCO}_3^-]$ of 29.25 mM.

As discussed above, in the *absence* of non-HCO_3^- buffers, this same doubling of P_{CO_2} causes a larger pH decrease, from 7.4 to 7.1.

By following three similar steps, we can use the Davenport diagram to predict the final pH and $[\text{HCO}_3^-]$ under conditions of a *respiratory alkalosis*. For example, what would be the effect of decreasing P_{CO_2} by half, from 40 to 20 mm Hg? In Figure 28-6C follow the red non-HCO_3^- titration line from “Start” to its intersection with the orange isopleth for a P_{CO_2} of 20 mm Hg (point B), which corresponds to a pH of 7.60 and an $[\text{HCO}_3^-]$ of 19 mM. If the solution had *not* contained non-HCO_3^- buffers, halving the P_{CO_2} would have caused a larger pH increase, from 7.4 to 7.7.

The amount of HCO_3^- formed or consumed during “respiratory” acid-base disturbances increases with $\beta_{\text{non-HCO}_3^-}$

Although it is reasonable to focus on CO_2 during respiratory acid-base disturbances, it would be wrong to assume that $[\text{HCO}_3^-]$ is constant. For example, in Figure 28-6C, where $\beta_{\text{non-HCO}_3^-}$ is 25 mM/pH unit, increasing P_{CO_2} from 40 to 80 mm Hg causes $[\text{HCO}_3^-]$ to increase from 24 to 29.25 mM. Thus, in each liter of solution, 5.25 mmol CO_2 combines with 5.25 mmol H_2O to form 5.25 mmol HCO_3^- (which we see as the $\Delta[\text{HCO}_3^-]$ value between “Start” and point A) and 5.25 mmol H^+ . Nearly all of this H^+ disappears as nearly 5.25 mmol of the deprotonated non-HCO_3^- buffers ($\text{B}^{(n)}$) consumes H^+ to form nearly 5.25 mmol of their conjugate weak acids ($\text{HB}^{(n+1)}$). Thus, the flux through the reaction sequence in Equation 28-28 is nearly 5.25 mmol for each liter of solution.

Thus, the non-HCO_3^- buffers drive the conversion of CO_2 to HCO_3^- . These buffers minimize the increase in free $[\text{H}^+]$ that a given flux of CO_2 can produce. Thus, with a high $\beta_{\text{non-HCO}_3^-}$, a large amount of CO_2 must “flux” through Equation 28-30 before the free concentrations of HCO_3^- and H^+ rise sufficiently to satisfy the $\text{CO}_2/\text{HCO}_3^-$ equilibrium (see Equation 28-14).

$\beta_{\text{non-HCO}_3^-}$ varies with the hemoglobin content of blood. Thus, patients with anemia have a low $\beta_{\text{non-HCO}_3^-}$, whereas patients with polycythemia have a high $\beta_{\text{non-HCO}_3^-}$.

Figure 28-6D illustrates the importance of $\beta_{\text{non-HCO}_3^-}$. If $\beta_{\text{non-HCO}_3^-}$ is zero, the non-HCO_3^- titration line is horizontal, and doubling P_{CO_2} from 40 to 80 mm Hg does not change $[\text{HCO}_3^-]$ significantly (see Fig. 28-6D, point A₁); this verifies our earlier conclusion (see Fig. 28-5, stage 3A). Simultaneously, pH falls by 0.3, which corresponds to a near-doubling of $[\text{H}^+]$. Thus, doubling $[\text{CO}_2]$ leads to a doubling of the product $[\text{HCO}_3^-][\text{H}^+]$, so that the ratio $[\text{HCO}_3^-][\text{H}^+]/[\text{CO}_2]$ —the equilibrium constant, K —is unchanged (Table 28-5, top row). Figure 28-6D also shows what happens if $\beta_{\text{non-HCO}_3^-}$ has the normal value of 25 mM/pH unit. Here, point A is the same as point A in Figure 28-6C, and it shows that $[\text{HCO}_3^-]$ increases by 5.25 mM, or 17% (see Table 28-5, middle row). Finally, if $\beta_{\text{non-HCO}_3^-}$ were ∞ , the non-HCO_3^- titration line would be vertical, and doubling P_{CO_2} would not change pH at all (point A₂ in Fig. 28-6D). In this case, $[\text{HCO}_3^-]$ would double, so that the doubling of the product $[\text{HCO}_3^-][\text{H}^+]$ would match the doubling of P_{CO_2} (see Table 28-5, bottom row).

TABLE 28-5
Relationship between $\beta_{\text{non-HCO}_3^-}$ and the Amount of HCO_3^- Formed in Response to a Doubling of P_{CO_2}

NON-HCO ₃ ⁻ BUFFERING POWER	ΔpH	HCO ₃ ⁻ FORMED (mM)	FRACTIONAL Δ[H ⁺]	FRACTIONAL Δ[HCO ₃ ⁻]	FRACTIONAL Δ[HCO ₃ ⁻] × Δ[H ⁺]
0	-0.30	0.000,040	1.999,997	1.000,002	2.00
25	-0.21	5.25	1.71	1.17	2.00
∞	0	24.0	1.00	2.00	2.00

Adding or removing an acid or base—at a constant P_{CO_2} — produces a “metabolic” acid-base disturbance

Above, we examined the effect of adding HCl in the *absence* of other buffers (see Fig. 28-3). Predicting the pH change for such an acid-base disturbance was straightforward because the titration of HCO_3^- to CO_2 consumed all buffered H^+ . The situation is more complex when the solution also contains non-HCO_3^-

buffers (Fig. 28-7, stage 1). When we add 10 mmol of HCl to 1 L of solution, the open-system $\text{CO}_2/\text{HCO}_3^-$ buffer pair neutralizes most of the added H^+ , ~~non- HCO_3^-~~ buffers handle some, and a minute amount of added H^+ remains free and lowers pH (see Fig. 28-7, stage 2A). Because the system is open, the CO_2 formed during buffering of the added H^+ escapes to the atmosphere. If this buffering reaction were occurring in the blood, the newly formed CO_2 would escape first into the alveolar air, and then into the atmosphere.

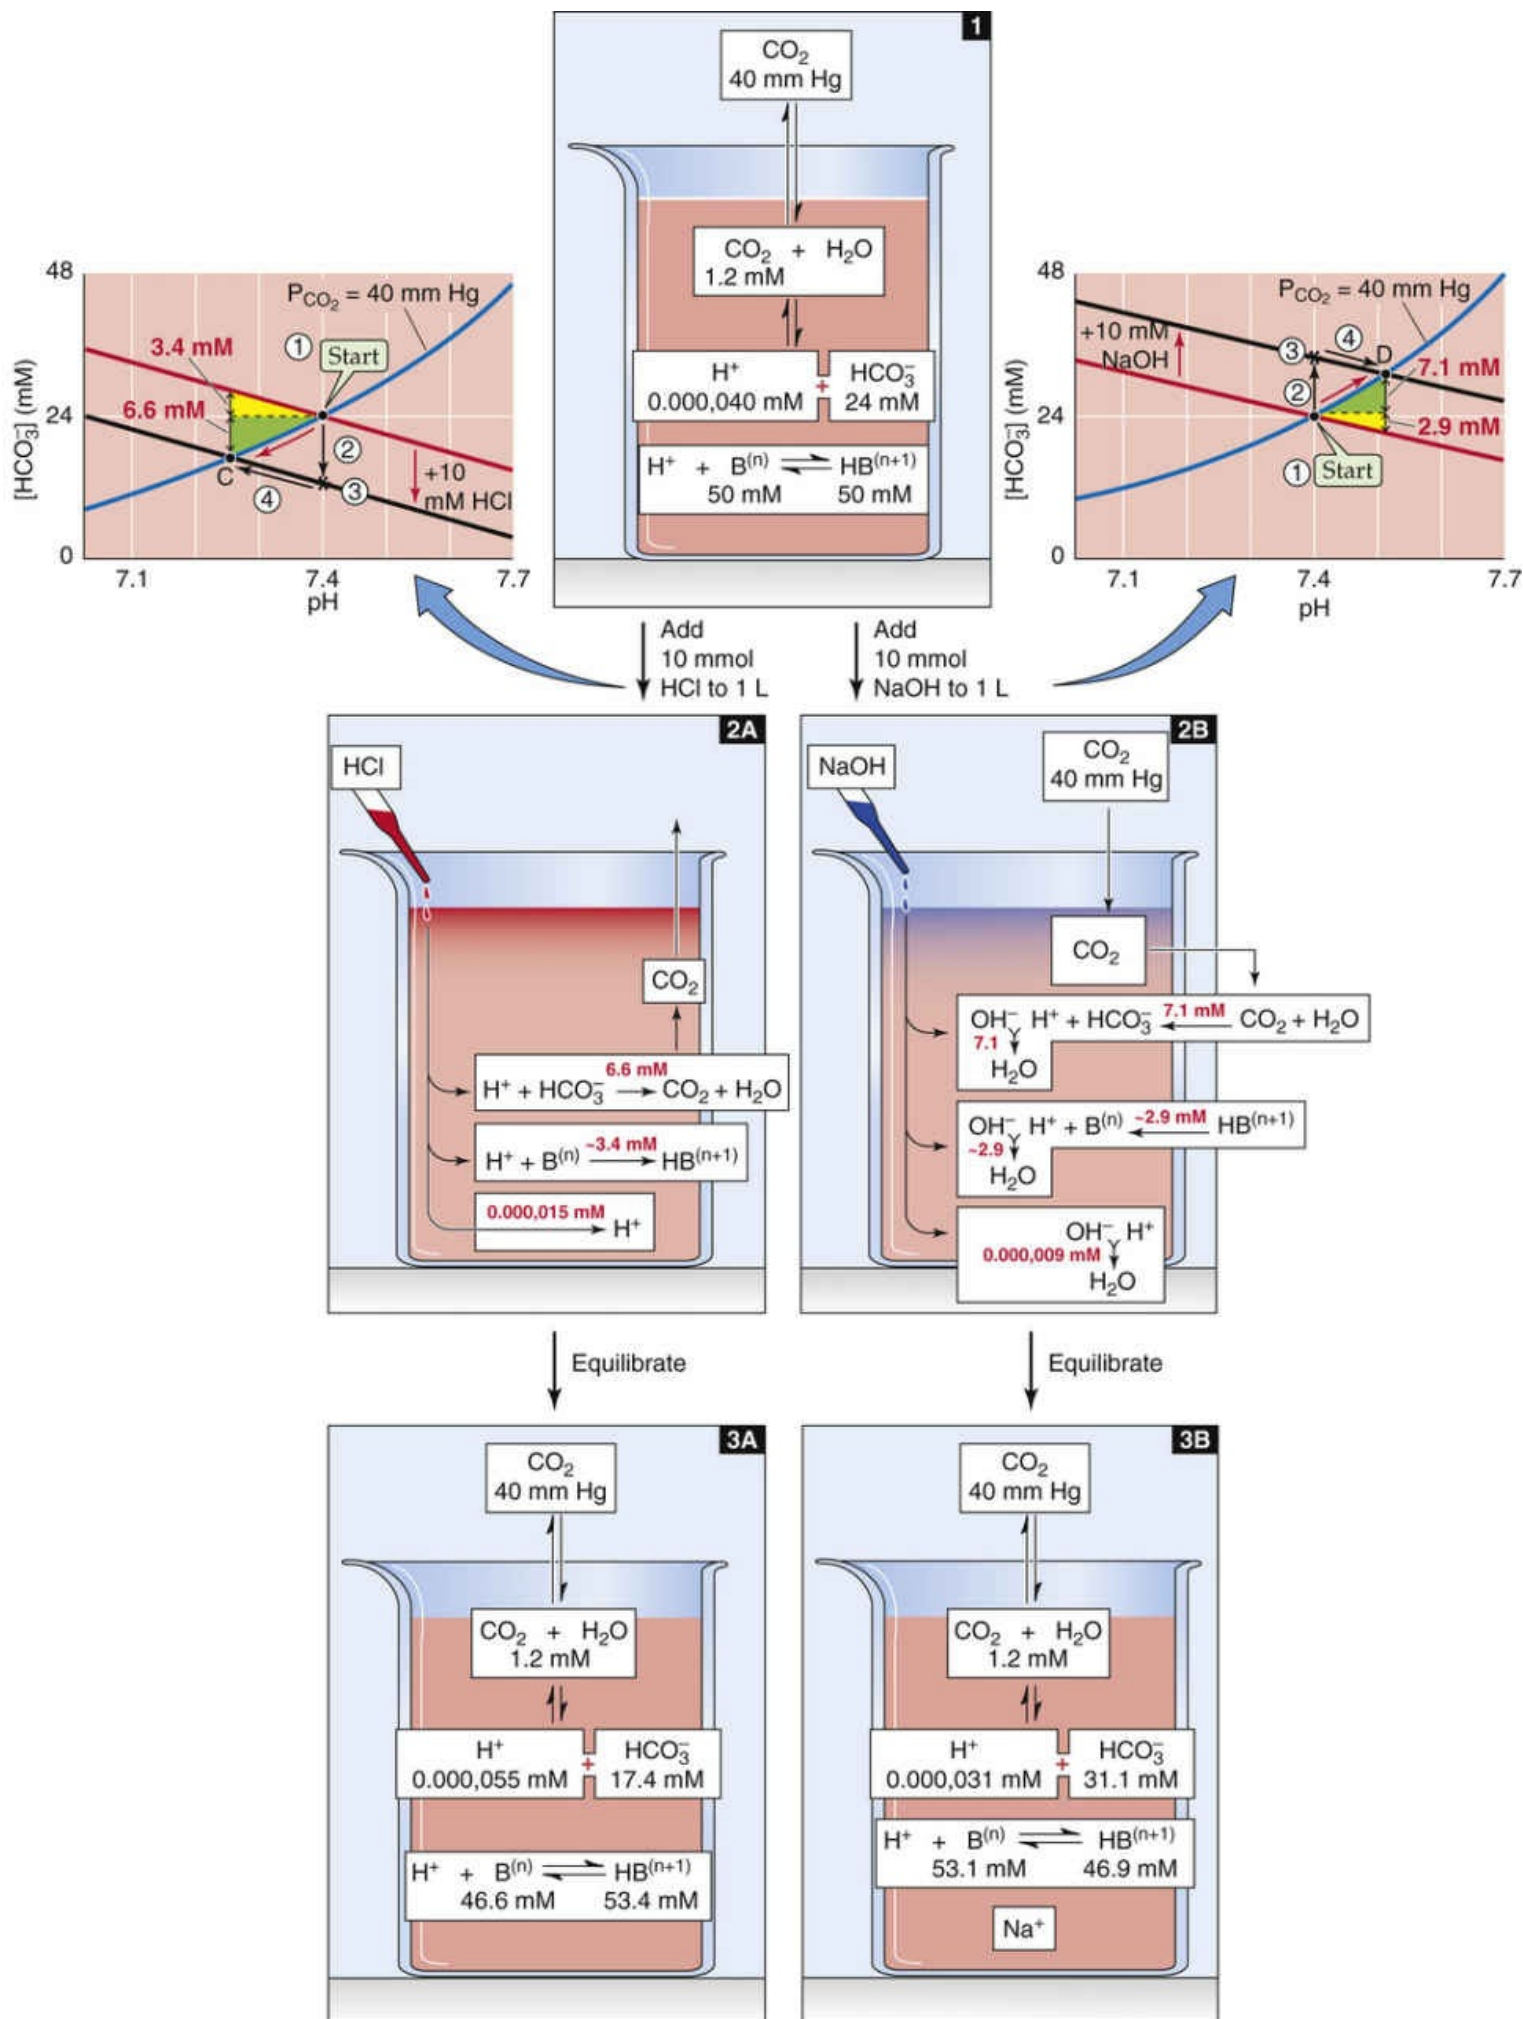

FIGURE 28-7 Metabolic acidosis and alkalosis in the presence of non- HCO_3^- buffers. The red arrows in

the Davenport diagrams represent the transition to metabolic acidosis (point C) and metabolic alkalosis (point D). This example differs from [Figure 28-3](#), in which the solution contained no buffers other than $\text{CO}_2/\text{HCO}_3^-$.

How much of the added H^+ ($\Delta[\text{strong acid}] = 10 \text{ mM}$) follows each of the three pathways in this example of *metabolic acidosis*? Answering this question requires dealing with two competing equilibria, the $\text{CO}_2/\text{HCO}_3^-$ and the non-HCO_3^- buffering reactions. As for respiratory acid-base disturbances, we cannot precisely solve the equations governing metabolic acid-base disturbances. However, we can use the Davenport diagram on the left of [Figure 28-7](#) to obtain a graphical estimate of the final pH and $[\text{HCO}_3^-]$ through a four-step process:

Step 1: Identify the point describing the initial conditions (see [Fig. 28-7](#), “Start” in graph on left).

Step 2: Following the black arrow labeled “2,” move downward (in the direction of decreased $[\text{HCO}_3^-]$) by 10 mM—the concentration of added H^+ —to the point labeled with an asterisk. In this maneuver, we assume that the reaction $\text{HCO}_3^- + \text{H}^+ \rightarrow \text{CO}_2 + \text{H}_2\text{O}$ has initially consumed *all* of the added H^+ . Of course, if this were true, the $\text{CO}_2/\text{HCO}_3^-$ reaction would be far out of equilibrium and the pH would not have changed at all. Also, the non-HCO_3^- buffers would not have had a chance to participate in the buffering of H^+ .

Step 3: Through the asterisk, draw a line (see [Fig. 28-7](#), black line in left graph) that is parallel to the non-HCO_3^- titration line.

Step 4: Following the black arrow labeled “4,” move to the intersection of the new black line and the original P_{CO_2} isopleth. This intersection occurs at point C, which corresponds to a pH of 7.26 and an $[\text{HCO}_3^-]$ of 17.4 mM. This maneuver tracks the reaction $\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{HCO}_3^- + \text{H}^+$. Non-HCO_3^- buffers consume nearly all of this H^+ in the reaction $\text{H}^+ + \text{B}^{(n)} \rightarrow \text{HB}^{(n+1)}$. As a result, $[\text{HCO}_3^-]$, $[\text{H}^+]$, and $[\text{HB}^{(n+1)}]$ all rise and the system equilibrates.

As a shortcut, we could bypass the two black arrows and simply follow the red arrow along the CO_2 isopleth from “Start” to point C.

We now can return to the question of how much of the added H^+ follows each of the three pathways in [Figure 28-7](#), stage 2A. Because $[\text{HCO}_3^-]$ decreased by $24 - 17.4 = 6.6 \text{ mM}$, the amount of H^+ buffered by $\text{CO}_2/\text{HCO}_3^-$ must have been 6.6 mmol in each liter. Almost all of the remaining H^+ that we added, nearly 3.6 mmol, must have been buffered by non-HCO_3^- buffers. A tiny amount of the added H^+ , $\sim 0.000,015 \text{ mmol}$, must have remained unbuffered and was responsible for decreasing pH from 7.40 to 7.26 (see [Fig. 28-7](#), stage 3A).

[Figure 28-7](#) also shows what would happen if we added 10 mmol of a strong base such as NaOH to our 1-L solution. The open-system $\text{CO}_2/\text{HCO}_3^-$ buffer pair neutralizes most of the added OH^- , non-HCO_3^- buffers handle some, and a minute amount of added OH^- remains unbuffered, thus raising pH (see [Fig. 28-7](#), stage 2B). The Davenport diagram on the right of [Figure 28-7](#) shows how much of the added OH^- follows each of the three pathways in this example of *metabolic alkalosis*. The approach is similar to the

one we used above for metabolic acidosis, except that in this case, we generate a new black line that is displaced 10 mM *above* the non-HCO_3^- titration line. We follow the P_{CO_2} isopleth to its intersection with this black line at point D, which corresponds to a final pH of 7.51 and an $[\text{HCO}_3^-]$ of 31.1 mM. Thus, $[\text{HCO}_3^-]$ rose by $31.1 - 24.0 = 7.1$ mM. This is the amount of added OH^- that $\text{CO}_2/\text{HCO}_3^-$ buffered. Non-HCO_3^- buffers must have buffered almost all of the remaining OH^- that we added, ~ 2.9 mmol in each liter. The unbuffered OH^- , which was responsible for the pH increase, must have been in the nanomolar range (see Fig. 28-7, stage 3B, and Box 28-1).

Box 28-1

Strong Ion Difference

Some clinicians assess acid-base disorders in terms of a virtual parameter termed **strong-ion difference (SID)**. Unlike weak acids and bases, the so-called strong cations and strong anions are fully dissociated at physiological pH. In blood,

$$\text{SID} = [\text{Na}^+] + [\text{K}^+] + [\text{Ca}^{2+}] + [\text{Mg}^{2+}] - [\text{Cl}^-]$$

Three major limitations to the SID approach are that (1) proteins and physiological processes generally depend on pH, not SID; (2) cells and the body closely regulate pH but have no known mechanism for directly sensing or regulating SID; and (3) SID neither is uniquely related to pH nor has a causal role in changing pH. Because the SID approach provides no new mechanistic insight, we focus on the classical pH/buffer approach.

During metabolic disturbances, $\text{CO}_2/\text{HCO}_3^-$ makes a greater contribution to total buffering when pH and P_{CO_2} are high and when $\beta_{\text{non-HCO}_3^-}$ is low

In Figure 28-7, $\text{CO}_2/\text{HCO}_3^-$ neutralized 7.1 mmol of the 10 mmol of OH^- added to 1 L ($\Delta\text{pH} = +0.11$) but only 6.6 mmol of the added 10 mmol of H^+ ($\Delta\text{pH} = -0.14$). The reason for this difference is that the buffering power of $\text{CO}_2/\text{HCO}_3^-$ in an open system increases exponentially with pH (see Fig. 28-4, blue curve). In the Davenport diagram, this pH dependence of β_{open} appears as the slope of the CO_2 isopleth, which increases exponentially with pH. *Thus, adding alkali will always cause a smaller pH change than adding an equivalent amount of acid.* In our example of metabolic alkalosis (see right side of Fig. 28-7), the mean β_{open} is $(7.1 \text{ mM})/(0.11 \text{ pH unit}) = 65 \text{ mM/pH unit}$ in the pH range 7.40 to 7.51 (Table 28-6). On the other hand, in our example of metabolic acidosis (see left side of Fig. 28-7), the mean β_{open} is $(6.6 \text{ mM})/(0.14 \text{ pH unit}) = 47 \text{ mM/pH unit}$ in the pH range 7.26 to 7.40, substantially less than in the more alkaline range. Because $\beta_{\text{non-HCO}_3^-}$ is 25 mM/pH unit over the entire pH range, β_{total} is greater in the alkaline pH range.

TABLE 28-6

Buffering Produced by CO₂/HCO₃⁻ and Non-HCO₃⁻ Buffers*

ADDITION	ΔpH	Δ[HCO ₃ ⁻]	$\beta_{\text{open}} = \frac{\Delta[\text{HCO}_3^-]}{\Delta\text{pH}}$	Δ[B ⁽ⁿ⁾]	$\beta_{\text{non-HCO}_3} = \frac{\Delta[\text{B}^{(n)}]}{\Delta\text{pH}}$	β _{total}
+10 mmol H ⁺	~ -0.14	~6.6 mM	47 mM/pH unit	~3.4 mM	25 mM/pH unit	72 mM/pH
+10 mmol OH ⁻	~ +0.11	~7.1 mM	65 mM/pH unit	~2.9 mM	25 mM/pH unit	89 mM/pH

*The additions are made to 1 L of solution. Initial pH = 7.40, P_{CO₂} = 40 mm Hg, [HCO₃⁻]₀ = 24 mM. β_{non-HCO₃} assumed to be 25 mM/pH unit.

We have already seen that β_{open} is proportional to [HCO₃⁻] (see Equation 28-20) and that—at a fixed pH—[HCO₃⁻] is proportional to P_{CO₂} (see Equation 28-29). Thus, other things being equal, the contribution of β_{open} to total buffering increases with P_{CO₂}. Patients with a high P_{CO₂} due to respiratory failure will, therefore, have a higher buffering power than normal individuals at the same pH.

Because CO₂/HCO₃⁻ and non-HCO₃⁻ buffers compete for added OH⁻ or H⁺, the contribution of CO₂/HCO₃⁻ to total buffering also depends on β_{non-HCO₃}. Figure 28-8 illustrates the effects of adding 10 mmol NaOH to our standard 1-L CO₂/HCO₃⁻ solution at β_{non-HCO₃} values of 0, 25 mM/pH unit, and ∞. We saw in Figure 28-3, stage 3B, that adding 10 mmol of NaOH to a 1-L solution containing CO₂/HCO₃⁻ but no other buffers causes [HCO₃⁻] to increase from 24 to 34 mM, and pH to increase from 7.40 to 7.55. To use a Davenport diagram to solve the same problem (see Fig. 28-8A), we generate a non-HCO₃⁻ titration line with slope of zero (because β_{non-HCO₃} = 0) through the “Start” point. We also draw a black line with the same slope, but displaced 10 mM higher. Following the blue P_{CO₂} = 40 isopleth from “Start” to the point where the isopleth intersects with the black line at point D₁, we see that—as expected—the final pH is 7.55 and the final [HCO₃⁻] is 34 mM. Thus, CO₂/HCO₃⁻ must buffer virtually all 10 mmol of OH⁻ added to 1 L. Because the total buffering power is simply β_{open}, the pH increase must be rather large, 0.15.

A NON- HCO_3^- BUFFERING POWER OF ZERO

B NON- HCO_3^- BUFFERING POWER OF 25 mM/pH UNIT

C NON- HCO_3^- BUFFERING POWER OF INFINITY

FIGURE 28-8 Effect of $\beta_{\text{non-HCO}_3^-}$ on the pH increase caused by metabolic alkalosis.

When $\beta_{\text{non-HCO}_3^-}$ is 25 mM/pH unit, as in the Davenport diagram in the upper right of [Figure 28-7](#) (replotted in [Fig. 28-8B](#)), $\text{CO}_2/\text{HCO}_3^-$ can buffer only 7.1 mmol because the non-HCO_3^- buffers neutralize 2.9 mmol. With the increased total buffering power, the pH increase is only 0.11.

Finally, when $\beta_{\text{non-HCO}_3^-}$ is ∞ , the black line lies right on top of the vertical non-HCO_3^- titration line (see [Fig. 28-8C](#)). Thus, neither $[\text{HCO}_3^-]$ nor pH changes at all. However, $[\text{HB}^{(n+1)}]$ increases by 10 mM because the infinitely powerful non-HCO_3^- buffers do all of the buffering.

This set of three examples—for $\beta_{\text{non-HCO}_3^-}$ values of 0, 25, and ∞ —is comparable to the set that we discussed above for *respiratory acidosis* in [Figure 28-6D](#).

A metabolic change can compensate for a respiratory disturbance

Thus far, we have considered what happens during *primary* respiratory and metabolic acid-base disturbances. When challenged by such acid or alkaline loads in the blood plasma, the body **compensates** by altering $[\text{HCO}_3^-]$ or P_{CO_2} , returning pH toward its initial value and minimizing the magnitude of the overall pH change.

In [Figure 28-9A](#) we revisit an example, originally introduced in [Figure 28-6C](#), in which we produced a primary respiratory acidosis by increasing P_{CO_2} from 40 to 80 mm Hg (red arrow in [Fig. 28-9A](#) between “Start” and point A at pH 7.19). If the high P_{CO_2} persists, the only way we can restore pH toward its initial value of 7.40 is to add an alkali (e.g., HCO_3^- or OH^-) or remove an acid (e.g., H^+), all of which are equivalent. **N28-9** Adding 10 mmol of OH^- to 1 L, for example, superimposes a metabolic *alkalosis* on the primary respiratory *acidosis*—a **metabolic compensation to respiratory acidosis**.

A METABOLIC COMPENSATION TO RESPIRATORY ACIDOSIS

B METABOLIC COMPENSATION TO RESPIRATORY ALKALOSIS

FIGURE 28-9 Metabolic compensation to primary respiratory acid-base disturbances.

The Davenport diagram predicts the consequences of adding 10 mmol of OH^- to 1 L. We start by generating a black line that is parallel to the red non-HCO_3^- titration line, but displaced upward by 10 mM. Point A_1 , the intersection of the black line and the P_{CO_2} isopleth for 80 mm Hg, represents a final pH of 7.29, still lower than the normal 7.40, but much higher than the 7.19 prevailing before compensation.

If we add an additional 14 mmol OH^- , for a total addition of 24 mmol OH^- to 1 L, pH returns to exactly its initial value of 7.40 (point A_2 in Fig. 28-9A). In other words, we can perfectly compensate for doubling P_{CO_2} from 40 (“Start”) to 80 mm Hg (point A) by adding an amount of OH^- equivalent to the amount of HCO_3^- that was present (i.e., 24 mM) at “Start.” Perfect compensation of respiratory acidosis is an example of **isohydric hypercapnia** (i.e., same pH at a higher P_{CO_2}):

$$\begin{aligned} \text{pH} &= 6.1 + \log \frac{\overbrace{\text{Doubled}[\text{HCO}_3^-]}^{48 \text{ mM}}}{\underbrace{(0.03 \text{ mM/mm Hg}) \times 80 \text{ mm Hg}}_{\text{Doubled } P_{\text{CO}_2}}} \\ &= 7.4 \end{aligned}$$

(28-31)

The kidneys are responsible for the metabolic compensation to a primary respiratory acidosis. They acutely sense high P_{CO_2} and may also chronically sense low blood pH. The response is to increase both the secretion of acid into the urine and the transport of HCO_3^- into the blood (see pp. 832–833), thereby raising plasma pH—a compensatory metabolic alkalosis. The renal compensation to a substantial respiratory acidosis is not perfect, so that pH remains below the normal value of 7.40.

The kidneys can also perform a **metabolic compensation to a respiratory alkalosis**. In Figure 28-9B we revisit a second example, originally introduced in Figure 28-6C, in which we produced a primary respiratory alkalosis by decreasing P_{CO_2} from 40 to 20 mm Hg (red arrow in Fig. 28-9B between “Start”

and point B at pH 7.60). We can compensate for most of this respiratory alkalosis by adding 10 mmol of H^+ to each liter of solution or by removing 10 mmol NaHCO_3 or NaOH , all of which produce the same effect. We generate a black line that is parallel to the red non-HCO_3^- titration line but is displaced downward by 10 mM. Point B_1 (pH 7.44), at the intersection of the black line and the P_{CO_2} isopleth for 20 mm Hg, represents a partial compensation.

If we add an additional 2 mmol H^+ , for a total addition of 12 mmol of H^+ to each liter, pH returns to exactly its initial value of 7.40 (point B_2 in Fig. 28-9B). Why is this amount so much less than the 24 mmol of OH^- that we added to each liter to compensate perfectly for a doubling of P_{CO_2} ? When we halve P_{CO_2} , we need only add an amount of H^+ equivalent to half the amount of HCO_3^- that was present ($24/2 = 12$ mM) at “Start.”

In response to a primary respiratory alkalosis, the kidneys secrete less acid into the urine and transport less HCO_3^- into the blood (see pp. 833–834), thereby lowering plasma pH—a compensatory metabolic acidosis.

A respiratory change can compensate for a metabolic disturbance

Just as metabolic changes can compensate for respiratory disturbances, respiratory changes can compensate for metabolic ones. In Figure 28-10A we return to an example originally introduced on the left side of Figure 28-7, in which we produced a primary metabolic acidosis by adding 10 mmol of HCl to 1 L of arterial blood (red arrow in Fig. 28-10A between “Start” and point C at pH 7.26). Other than removing the H^+ (or adding OH^- to neutralize the H^+), the only way we can restore pH toward the initial value of 7.40 is to lower P_{CO_2} . That is, we can superimpose a respiratory *alkalosis* on the primary metabolic acidosis—a **respiratory compensation to a metabolic acidosis**. For example, we can compensate for most of the metabolic acidosis by reducing P_{CO_2} from 40 to 30 mm Hg. Starting at C, follow the black line from the P_{CO_2} isopleth for 40 mm Hg to the new isopleth for 30 mm Hg at point C_1 (pH 7.34). This maneuver represents a *partial* compensation.

FIGURE 28-10 Respiratory compensation to primary metabolic acid-base disturbances.

If we reduce P_{CO_2} by an additional 6.6 mm Hg to 23.4 mm Hg, we produce a perfect compensation, which we represent in [Figure 28-10A](#) by following the black line from C until we reach pH 7.40 at point C_2 , which is on the P_{CO_2} isopleth for 23.4 mm Hg. Perfect compensation requires that we reduce P_{CO_2} by a fraction (i.e., $[40 - 23.4]/40 \cong 0.42$) that is identical to the ratio of added HCl to the original $[\text{HCO}_3^-]$ (i.e., $10/24 \cong 0.42$).

Not surprisingly, the respiratory system is responsible for the respiratory compensation to a primary metabolic acidosis. The low plasma pH or $[\text{HCO}_3^-]$ stimulates the peripheral chemoreceptors (see [p. 710](#)) and, if sufficiently long-standing, also the central chemoreceptors (see [pp. 713–715](#)). The result is an increase in alveolar ventilation, which lowers P_{CO_2} (see [pp. 679–680](#)) and thus provides the respiratory compensation.

The body achieves a **respiratory compensation to a primary metabolic alkalosis** in just the opposite manner. In [Figure 28-10B](#), we revisit an example originally presented on the right side of [Figure 28-7](#), in which we produce a primary metabolic alkalosis by adding 10 mmol of NaOH to 1 L (red arrow in [Fig. 28-10B](#) between “Start” and point D at pH 7.51). If we now increase P_{CO_2} from 40 to 50 mm Hg, we partially compensate for the metabolic alkalosis by moving from D to D_1 (pH 7.44). If we raise P_{CO_2} by an additional 6.7 mm Hg to ~56.7 mm Hg, the compensation is perfect, and pH returns to 7.40 (D_2).

In response to a primary metabolic alkalosis, the respiratory system decreases alveolar ventilation and thereby raises P_{CO_2} . The compensatory respiratory acidosis is the least “perfect” of the four types of compensation we have discussed. The reason is that one can decrease alveolar ventilation—and thus oxygenation—only so far before compromising one's very existence.

In a real person, each of the four primary acid-base disturbances—points A, B, C, and D in [Figures 28-9](#) and [28-10](#)—occurs in the extracellular fluid. In each case, the body's first and almost instantaneous response is to use extracellular buffers to neutralize part of the acid or alkaline load. In addition, cells rapidly take up some of the acid or alkaline load and thus participate in the buffering, as discussed below. Furthermore, renal tubule cells may respond to a *metabolic* acidosis of extrarenal origin (e.g., diabetic ketoacidosis) by increasing acid secretion into the urine, or to a metabolic alkalosis (e.g., NaHCO_3 therapy) by decreasing acid secretion—examples of *metabolic* compensation to a *metabolic* disturbance.

Points C and D in Figure 28-10 include the effects of the actual acid or alkaline load, extracellular and intracellular buffering, and any renal (i.e., “metabolic”) response.

Position on a Davenport diagram defines the nature of an acid-base disturbance

The only tools needed for characterizing acid-base status (i.e., pH, $[\text{HCO}_3^-]$, and P_{CO_2}) are a Davenport diagram and electrodes for measuring pH and P_{CO_2} . From these last two parameters, we can compute $[\text{HCO}_3^-]$ using the Henderson-Hasselbalch equation. The acid-base status of blood plasma—or of any aqueous solution—must fall into one of five major categories:

1. **Normal.** For arterial blood, pH is 7.40, $[\text{HCO}_3^-]$ is 24 mM, and P_{CO_2} is 40 mm Hg. This point was labeled “Start” in the previous figures and is the central point in Figure 28-11A through D.

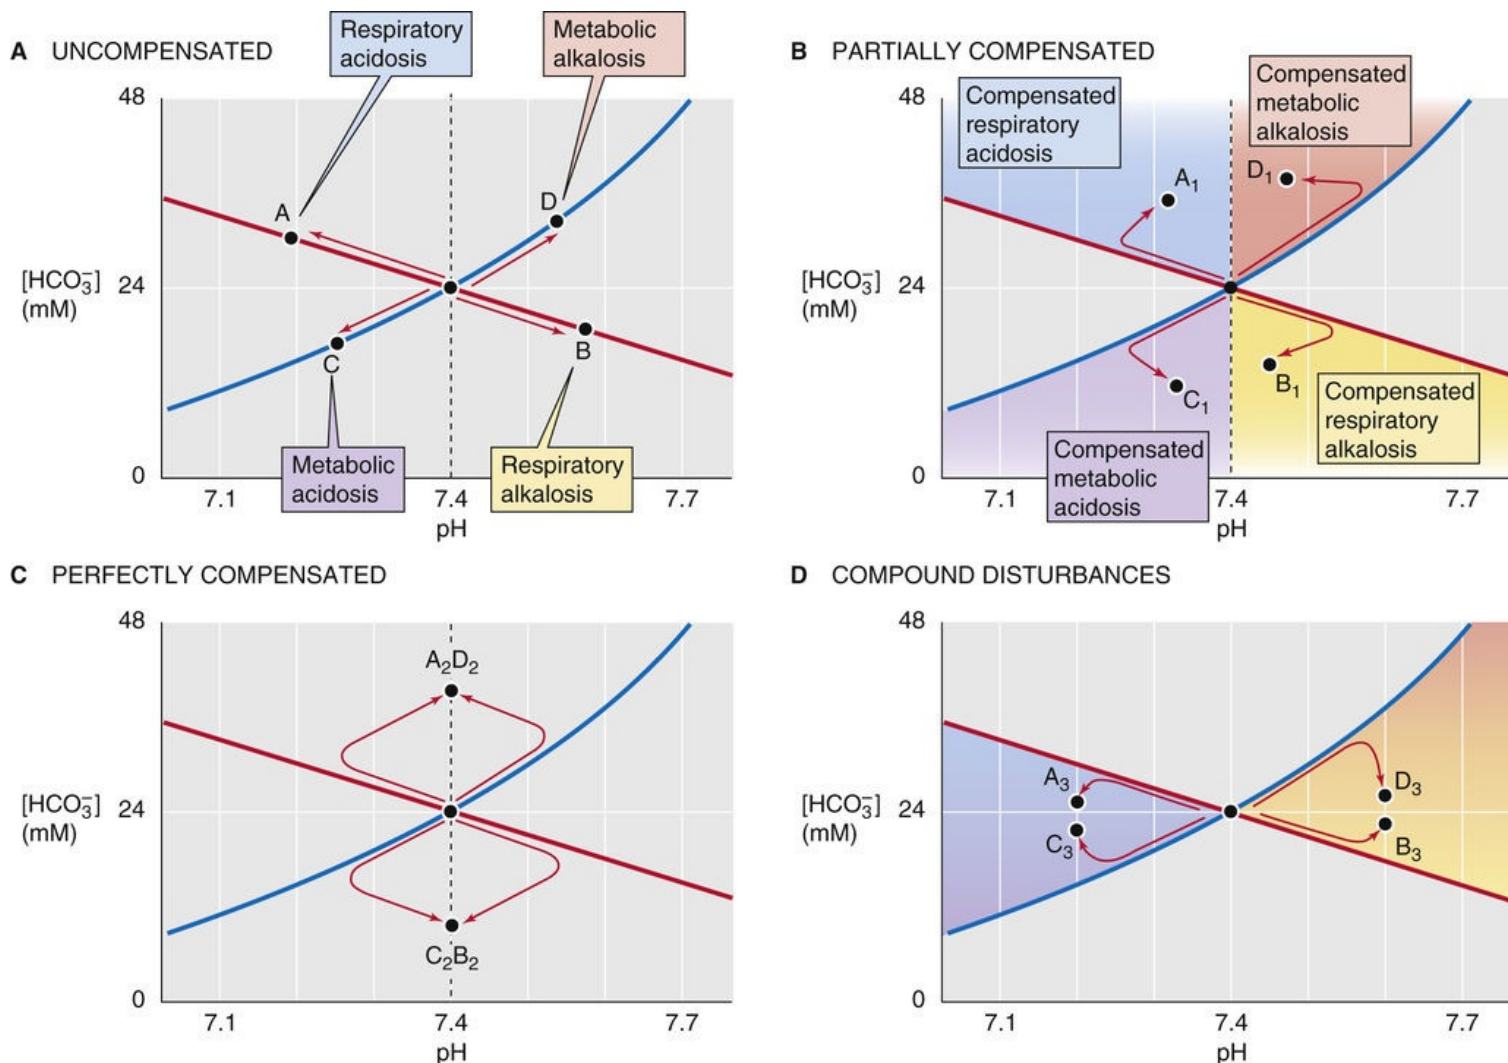

FIGURE 28-11 Acid-base states represented by position on a Davenport diagram.

2. **One of the four primary (or uncompensated) acid-base disturbances.** The coordinates for pH and $[\text{HCO}_3^-]$ fall either (a) on the non-HCO_3^- titration line, but off the 40-mm Hg isopleth for uncompensated

respiratory acidosis (point A, [Fig. 28-11A](#)) or alkalosis (point B); or (b) on the 40-mm Hg isopleth, but off the non-HCO_3^- titration line for an uncompensated metabolic acidosis (point C) or alkalosis (point D).

3. A partially compensated disturbance. The coordinates for pH and $[\text{HCO}_3^-]$ fall in any of the four colored regions of [Figure 28-11B](#). For example, point A_1 in the blue region represents a partially compensated respiratory acidosis. In a subject for whom a respiratory acidosis has existed for longer than a few hours, increased renal H^+ excretion has probably already begun producing a metabolic compensation. Depending on the extent of the original acidosis and the degree of compensation, point A_1 could lie anywhere in the blue region. We can reach similar conclusions for the other three disturbances/compensations.

4. A perfectly compensated disturbance. The point falls on the vertical line through pH 7.4. As indicated by point A_2D_2 in [Figure 28-11C](#), a perfect compensation following respiratory acidosis is indistinguishable from that following metabolic alkalosis. In either case, the final outcome is isohydric hypercapnia. Similarly, point B_2C_2 represents a perfect compensation following either metabolic acidosis or respiratory alkalosis (isohydric hypocapnia).

5. A compound respiratory/metabolic disturbance. The point falls in one of the two colored regions in [Figure 28-11D](#). For example, points A_3 and C_3 represent a respiratory acidosis complicated by metabolic acidosis, and vice versa. The second disturbance causes the pH to move even further away from “normal,” as might occur in an individual with both respiratory and renal failure (see [Table 28-3](#)). Of course, it is impossible to determine if one of the two compounding disturbances developed before the other.

pH Regulation of Intracellular Fluid

Clinicians focus on the acid-base status of blood plasma, the fluid compartment whose acid-base status is easiest to assess. However, the number of biochemical reactions and other processes that occur *outside* a cell pales in comparison to the number of those that occur *inside*. It stands to reason that the most important biological fluid for pH regulation is the cytosol. It is possible to monitor intracellular pH (pH_i) continuously in isolated cells and tissues using pH-sensitive dyes or microelectrodes. Moreover, using magnetic resonance techniques, one can monitor pH_i in living humans (e.g., in skeletal muscle). The pH of cells both influences, and is influenced by, extracellular pH.

Ion transporters at the plasma membrane closely regulate the pH inside of cells

Figure 28-12A shows a hypothetical cell with three acid-base transporters: an electroneutral Na/HCO_3 cotransporter (NBCn1; see p. 122) a $\text{Na}-\text{H}$ exchanger (NHE1; pp. 124–125), and a $\text{Cl}-\text{HCO}_3$ or anion exchanger (AE2; see p. 124). We will use NBCn1 and NHE1 as prototypic **acid extruders**, transporters that tend to *raise* intracellular pH (pH_i). Both use the energy of the Na^+ gradient to either import HCO_3^- or export H^+ from the cytosol. We will take the $\text{Cl}-\text{HCO}_3$ exchanger AE2 as the prototypic **acid loader**, a transporter that tends to *lower* pH_i . AE2, driven by the steep out-to-in Cl^- gradient, moves HCO_3^- out of the cell. The intracellular acid loading produced by $\text{Cl}-\text{HCO}_3$ exchange is a **chronic acid load** because it tends to acidify the cell as long as the transporter is active. In our example, the chronic acid extrusion via NBCn1 and NHE1 balances the chronic acid loading via AE2, producing a steady state. Several other acid extruders and acid loaders may contribute to pH_i regulation (see p. 127), and each cell type has a characteristic complement of such transporters.

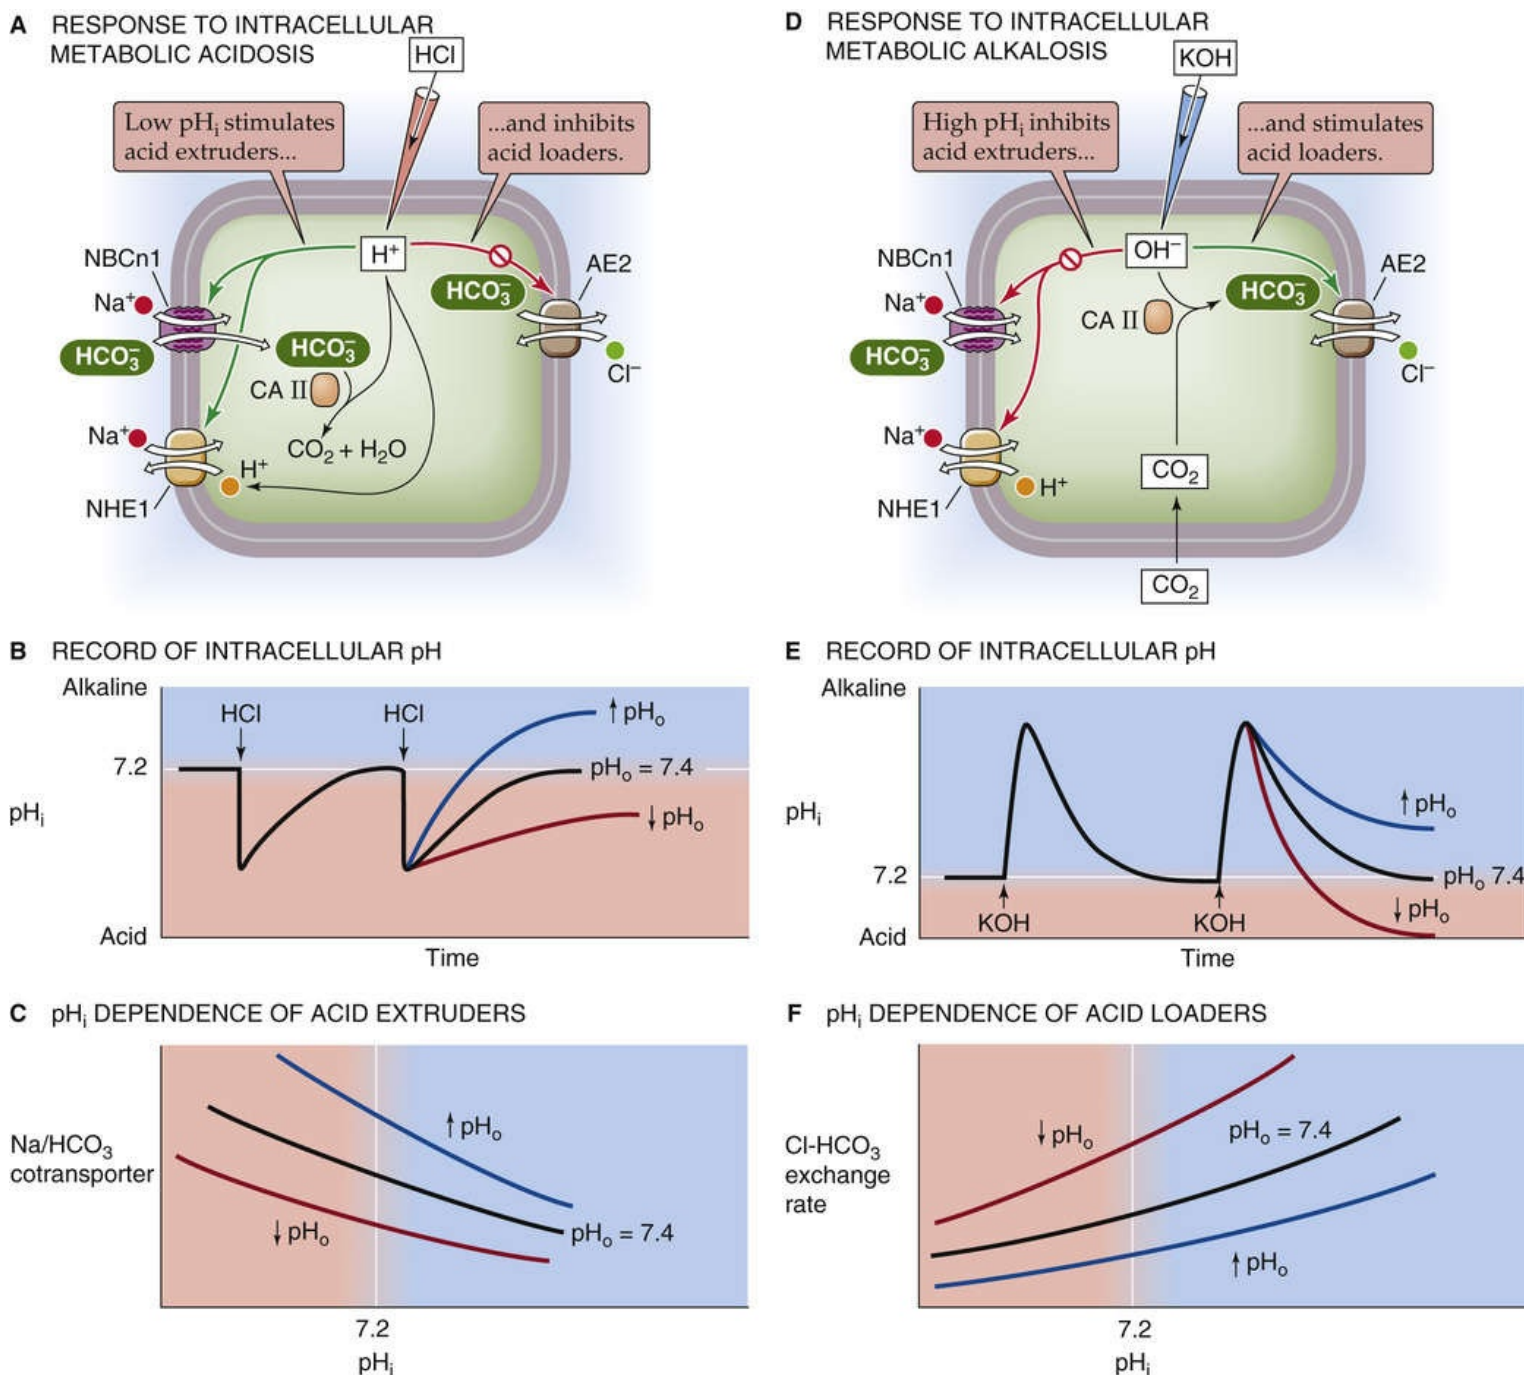

FIGURE 28-12 Recovery of a cell from intracellular acid and alkali loads. CA II, carbonic anhydrase II.

Imagine that we use a micropipette to inject HCl into the cell in [Figure 28-12A](#). This injection of an **acute acid load**—a one-time-only introduction of a fixed quantity of acid—causes an immediate fall in pH_i (see [Fig. 28-12B](#), black curve), an example of **intracellular metabolic acidosis**. If we add HCl to a beaker, the pH remains low indefinitely. However, when we acutely acid-load a cell, pH_i spontaneously recovers to the initial value. This pH_i recovery cannot be due to passive H^+ efflux out of the cell, inasmuch as the electrochemical gradient for H^+ (see [p. 127](#)) usually favors H^+ influx. Hence, the pH_i recovery reflects the active transport of acid from the cell—a *metabolic compensation to a metabolic acid load*. **N28-10**

N28-10

Acid Extruders and Acid Loaders in a Cell

Of the acid extruders that can produce pH_i recovery, the most widely distributed is the NHE1 isoform of the Na-H exchanger. However, mechanisms that mediate HCO_3^- uptake often coexist with the Na-H exchanger in the same cell and are sometimes far more powerful than the Na-H exchanger. These HCO_3^- transporters include the Na^+ -driven Cl- HCO_3^- exchanger (or NDCBE, illustrated in Fig. 5-14, no. 17) and the Na/ HCO_3^- cotransporters with Na^+ : HCO_3^- stoichiometries of 1 : 2 (NBCe1 and NBCe2, the electrogenic Na/ HCO_3^- cotransporters) and 1 : 1 (NBCn1, the electroneutral Na/ HCO_3^- cotransporter). Note that the electrogenic Na/ HCO_3^- cotransporter that operates with an Na^+ : HCO_3^- stoichiometry of 1 : 3 (see Fig. 5-14, no. 19) mediates net HCO_3^- efflux—which reflects the ionic and electrical gradients that govern its thermodynamic properties—and functions as an acid loader. However, the Na/ HCO_3^- cotransporters with Na^+ : HCO_3^- stoichiometries of 1 : 2 and 1 : 1 both mediate the net uptake of HCO_3^- and function as acid extruders.

Other transporters that extrude acid from cells include the V-type H pump and the H-K exchange pump.

Other transport processes that acid-load cells include the passive influx of H^+ as well as the efflux of HCO_3^- either through channels (e.g., gamma-aminobutyric acid or glycine-activated Cl^- channels) or through the K/ HCO_3^- cotransporter.

For a more detailed discussion of these transporters, see page 127.

During the recovery of pH_i from the acid load in Figure 28-12B, NBCn1 and NHE1 not only must extrude the quantity of H^+ previously injected into the cell (the *acute* acid load), they also must counteract whatever acid loading AE2 continues to impose on the cell (the *chronic* acid load).

Acid-extrusion rates tend to be greatest at low pH_i values and fall off as pH_i rises (see Fig. 28-12C, black curve). As discussed below, low pH_i also *inhibits* AE2 and thus acid loading. The response to low pH_i therefore involves two feedback loops operating in push-pull fashion, stimulating acid extrusion and inhibiting acid loading.

In addition to pH_i , hormones, growth factors, oncogenes, cell volume, and extracellular pH (pH_o) all can modulate these transporters. The pH_o effect is especially important. In general, a low pH_o slows the rate of pH_i recovery from acute acid loads and reduces the final steady-state pH_i (see Fig. 28-12B, red curve), whereas a high pH_o does the opposite (blue curve). The underlying cause of these pH_o effects is a shift of the pH_i dependence of acid extrusion (see Fig. 28-12C, red and blue curves) and, as we shall see, changes in acid loading.

Cells also spontaneously recover from acute alkaline loads. If we inject a cell with potassium hydroxide (KOH) (see Fig. 28-12D), pH_i rapidly increases but then slowly recovers to its initial value (see Fig. 28-12E, black curve), which reflects stimulation of acid loading and inhibition of acid extrusion. The injection of OH^- represents a metabolic alkalosis, whereas increased Cl- HCO_3^- exchange represents a metabolic compensation. **N28-10** The Cl- HCO_3^- exchanger is most active at high pH_i values (see Fig. 28-12F). As discussed previously, increases in pH_i generally inhibit acid extruders. Thus, the response to alkaline loads—like the response to acid loads—includes dual feedback loops operating in push-pull fashion, stimulating acid loading and inhibiting acid extrusion. During the pH_i recovery from an acute alkaline load, Cl- HCO_3^- exchange not only must neutralize the alkali previously injected into the cell (the

acute alkali load), but also must counteract the alkalinizing effect of acid extruders such as the Na/HCO_3 cotransporter.

Like acid extruders, $\text{Cl}-\text{HCO}_3$ exchangers are under the control of hormones and growth factors with a pH_o sensitivity that is opposite to that of the acid extruders (i.e., low pH_o enhances $\text{Cl}-\text{HCO}_3$ exchange). In general, an extracellular metabolic acidosis, with its simultaneous fall in *both* pH_o and $[\text{HCO}_3^-]$ (see Table 28-3), stimulates acid loading via $\text{Cl}-\text{HCO}_3$ exchange (see Fig. 28-12F, red curve). During the recovery from acute alkali loads, metabolic acidosis therefore causes pH_i to fall more rapidly and to reach a lower steady-state value (see Fig. 28-12E, red curve).

Indirect interactions between K^+ and H^+ make it appear as if cells have a K-H exchanger

Clinicians have long known that extracellular acidosis leads to a release of K^+ from cells, and thus hyperkalemia (see p. 795). Conversely, hyperkalemia leads to the exit of H^+ from cells, resulting in extracellular acidosis. These observations, which one can duplicate in single, isolated cells, led to the suggestion that cells generally have K-H exchangers. It is true that specialized cells in the stomach (see pp. 865–866) and kidney (see pp. 827–828) do have an ATP-driven pump that extrudes H^+ in exchange for K^+ . Moreover, the K/HCO_3 cotransporter described in certain cells could mimic a K-H exchanger. Nevertheless, the effects that long ago led to the K-H-exchange hypothesis probably reflect *indirect* interactions of H^+ and K^+ .

One example of apparent K-H exchange is that hyperkalemia causes an intracellular alkalosis. Not only is this effect *not* due to a 1 : 1 exchange of K^+ for H^+ , it is not even due to the increase in $[\text{K}^+]_o$ per se. Instead, the high $[\text{K}^+]_o$ depolarizes the cell, and this positive shift in membrane voltage can promote events such as the net uptake of HCO_3^- via the electrogenic Na/HCO_3 cotransporter (see p. 122) and thus a rise in pH_i —a **depolarization-induced alkalization**. Depolarization also can indirectly stimulate other transporters that alkalize the cell. We discuss the converse example of acidemia causing hyperkalemia on page 795: Extracellular acidosis lowers pH_i and inhibits transporters responsible for K^+ uptake, which leads to net K^+ release from cells. Although we have no evidence that a K-H exchanger exists in humans, imagining that it exists is sometimes a helpful tool for quickly predicting interactions of H^+ and K^+ in a clinical setting.

Changes in intracellular pH are often a sign of changes in extracellular pH, and vice versa

By definition, acid extrusion (e.g., Na/HCO_3 cotransport) equals acid loading (e.g., $\text{Cl}-\text{HCO}_3$ exchange) in the steady state. Disturbing this balance shifts pH_i . For example, extracellular *metabolic* acidosis inhibits acid extrusion and stimulates acid loading, thus lowering steady-state pH_i . This intracellular acidosis is not instantaneous, but develops over a minute or two. Conversely, extracellular metabolic alkalosis leads to a slow increase in steady-state pH_i . Generally, a change in pH_o shifts pH_i in the same direction, but ΔpH_i is usually only 20% to 60% of ΔpH_o . In other words, an extracellular metabolic acidosis causes a net transfer of acid from the extracellular to the intracellular space, and an extracellular metabolic alkalosis has the opposite effect. Thus, cells participate in buffering extracellular acid and

alkali loads.

Extracellular *respiratory* acidosis generally affects pH_i in three phases. First, the increase in extracellular $[CO_2]_{Dis}$ creates an inwardly directed gradient for CO_2 . This dissolved gas rapidly enters the cell (Fig. 28-13A) and produces HCO_3^- and H^+ . This **intracellular respiratory acidosis** manifests itself as a rapid fall in pH_i (see Fig. 28-13B, phase A in lower panel). Carbonic anhydrase **N18-3** greatly accelerates the formation of HCO_3^- and H^+ from CO_2 , so that pH_i can complete its decline in just a few seconds.

A RESPONSE OF CELL

B TIME COURSE OF pH CHANGES

FIGURE 28-13 Response of cell to extracellular respiratory acidosis.

The cell recovers from this acid load, but only feebly (see Fig. 28-13B, phase B in lower panel) because the decrease in pH_o inhibits acid extrusion and stimulates acid loading. Over a period of minutes, pH_i may recover only partially if at all.

Finally, the extracellular respiratory acidosis stimulates the kidneys to upregulate acid-base transporters and thus stimulate urinary acid secretion (see p. 832). The net effect, over a period of hours or days, is an extracellular metabolic compensation that causes pH_o to increase gradually (see Fig. 28-13B, phase C in upper panel). As pH_o rises, it gradually relieves the inhibition of NBCn1 and NHE1 and other acid extruders and cancels the stimulation of $Cl-HCO_3$ exchange and other acid loaders. Thus, *intracellular pH* recovers in parallel with *extracellular pH*, albeit by only 20% to 60% as much as pH_o (see Fig. 28-13B, phase C in lower panel). The pH_i recovery represents an **intracellular metabolic compensation** to the intracellular respiratory acidosis.

Not all cell types have the same resting pH_i . Moreover, different cell types often have very different complements of acid-base transporters and very different ways of regulating these transporters. Nevertheless, the example in [Figure 28-13](#) illustrates that the fate of pH_i is closely intertwined with that of interstitial fluid, and thus blood plasma. During respiratory acid-base disturbances, the lungs generate the insult, and virtually every other cell in the body must defend itself against it. In the case of metabolic acid-base disturbances, however, some cells may generate the insult, whereas the others attempt to defend themselves against it. From a teleological perspective, one can imagine that the primary reason that the body regulates the pH of the blood plasma and extracellular fluids is to allow the cells to properly regulate their pH_i . The primary reason why the clinical assessment of blood acid-base parameters can be useful is that these parameters tend to parallel cellular acid-base status.

Transport of Oxygen and Carbon Dioxide in the Blood

Walter F. Boron

Carriage of O₂

The amount of O₂ dissolved in blood is far too small to meet the metabolic demands of the body

Blood carries oxygen in two forms. More than 98% of the O₂ normally binds to hemoglobin within the **erythrocytes**, also known as red blood cells or RBCs (see pp. 434–435). A tiny fraction physically dissolves in the aqueous phases of both blood plasma and the cytoplasm of blood cells (predominantly RBCs). What is the significance of the O₂ that is bound to hemoglobin?

Imagine that we expose a liter of blood plasma, initially free of O₂, to an atmosphere having the same P_{O₂} as alveolar air—100 mm Hg. Oxygen will move from the atmosphere to the plasma until an equilibrium is established, at which time the concentration of **dissolved O₂** ([O₂]_{Dis}) in the blood obeys **Henry's law** (see p. 593):

$$[\text{O}_2]_{\text{Dis}} = k_{\text{O}_2} \cdot P_{\text{O}_2} \quad (29-1)$$

If we express P_{O₂} in units of mm Hg at 37°C and [O₂]_{Dis} in units of (mL of O₂ gas)/(dL of blood), then the solubility k_{O₂} is ~0.003 mL O₂/(dL of blood · mm Hg). For arterial blood,

$$\begin{aligned} [\text{O}_2]_{\text{Dis}} &= \frac{0.003 \text{ mL O}_2}{100 \text{ mL blood} \cdot \text{mm Hg}} \cdot 100 \text{ mm Hg} \\ &= 0.3 \text{ mL O}_2 / 100 \text{ mL blood} \end{aligned} \quad (29-2)$$

Is such an O₂-carrying capacity adequate for supplying O₂ to the systemic tissues? If these tissues could extract all the O₂ dissolved in arterial blood so that no O₂ remained in venous blood, and if cardiac output (see p. 414) were 5000 mL/min, then—according to the Fick principle (see p. 423)—the delivery of dissolved O₂ to the tissues would be

$$\begin{aligned} \overbrace{\dot{V}_{\text{O}_2}}^{\text{O}_2 \text{ delivery}} &= \frac{\overbrace{5000 \text{ mL blood}}^{\text{Blood flow}}}{\text{min}} \cdot \frac{\overbrace{0.3 \text{ mL O}_2}^{\text{O}_2 \text{ concentration in plasma}}}{100 \text{ mL blood}} \\ &= 15 \text{ mL O}_2 / \text{min} \end{aligned} \quad (29-3)$$

However, the average 70-kg human at rest consumes O₂ at the rate of ~250 mL/min. Dissolved O₂ could

supply the body's metabolic demands only if cardiac output increased by a factor of 250/15, or nearly 17-fold! Thus, the body cannot rely on dissolved O_2 as a mechanism for O_2 carriage.

Hemoglobin consists of two α and two β subunits, each of which has an iron-containing “heme” and a polypeptide “globin”

Normal adult **hemoglobin (Hb)** is a tetramer having a molecular weight of ~ 68 kDa, each monomer consisting of a heme and a globin (Fig. 29-1A). The heme is a porphyrin compound coordinated to a single iron atom. The **globin** is a polypeptide, either an α chain (141 amino acids) or a β chain (146 amino acids). The homology between the α and β chains is sufficient that they have similar conformations, a series of seven helices enveloping a single heme. Thus, the complete Hb molecule has the stoichiometry $[\alpha(\text{heme})]_2[\beta(\text{heme})]_2$ and can bind as many as four O_2 molecules, one for each iron atom. The erythroblasts (see pp. 431–433) that synthesize Hb closely coordinate the production of α chains, β chains, and heme.

A HEMOGLOBIN TETRAMER

B HEME

C CONFORMATIONAL CHANGES WITH O_2 BINDING

FIGURE 29-1 Structure of hemoglobin.

Heme is a general term for a metal ion chelated to a porphyrin ring. In the case of Hb, the metal is iron in the Fe^{2+} or ferrous state (see Fig. 29-1B). The porphyrin consists of four linked pyrrole rings that, through their nitrogen atoms, coordinate a single, centrally located Fe^{2+} . Because the iron-porphyrin complex is rich in conjugated double bonds, it absorbs photons of relatively low energy (i.e., light in the visible range). The interaction among O_2 , Fe^{2+} , and porphyrin causes the complex to have a red color when fully saturated with O_2 (e.g., arterial blood) and a purple color when devoid of O_2 (e.g., venous blood).

Hb can bind O_2 only when the iron is in the Fe^{2+} state. The Fe^{2+} in Hb can become oxidized to ferric iron (Fe^{3+}), either spontaneously or under the influence of compounds such as nitrites or sulfonamides. The result of such an oxidation is **methemoglobin (metHb)**, which is incapable of binding O_2 . Inside the RBC, a heme-containing enzyme **methemoglobin reductase** uses the reduced form of nicotinamide adenine dinucleotide (NADH) to reduce metHb back to Hb, so that only about 1.5% of total Hb is in the metHb state. In the rare case in which a genetic defect results in a deficiency of this enzyme,  **N29-1** metHb may represent 25% or more of the total Hb. Such a deficiency results in a decreased O_2 -carrying capacity, leading to tissue hypoxia.

N29-1

Methemoglobinemia

Contributed by Walter Boron

An increase in the amount of Hb with its iron in the oxidized or Fe^{3+} (i.e., ferric) state is known as **methemoglobinemia**. As discussed on pages 647–648, the problem that arises is that, with Fe^{3+} in the porphyrin ring of Hb, O_2 cannot bind, and there is a consequent reduction in the O_2 carrying capacity of the blood. The Fe^{2+} (i.e., ferrous) iron of Hb spontaneously oxidizes to Fe^{3+} , and a family of **methemoglobin reductase** enzymes normally returns the Hb to the ferrous state.

Methemoglobinemia can arise in three ways:

1. *Mutant M forms of Hb.* Normally the globin moiety of Hb cradles the porphyrin ring in such a way as to limit the accessibility of O_2 to the Fe^{2+} . In M forms of Hb (at least eight of which have been identified), point mutations in the α or β globin chains allow the O_2 to approach the Fe^{2+} more closely and to oxidize—rather than to bind to—the Fe^{2+} . This action shifts the balance between the normally slow rate of oxidation and reductase activity toward the formation of Fe^{3+} .
2. *Genetic deficiency (autosomal recessive) of one or both of the splice variants of methemoglobin reductase enzymes.* The enzyme is **reduced nicotinamide adenine dinucleotide (NADH)–cytochrome b5 reductase (cytb5: E.C.1.6.2.2)**. Two splice variants, differing in the N-terminal region, are present: (a) a soluble form with 275 amino acids, and (b) a membrane-bound form with 300 amino acids. The membrane-bound form is present mainly in the endoplasmic reticulum and mitochondrial outer membrane, where it is important for a variety of reactions (i.e., synthesis of fatty acids and cholesterol, P-450–mediated drug metabolism). A deficiency in the soluble form of RBCs—usually caused by missense mutations that reduce enzyme stability—causes **type I methemoglobinemia**, which is usually not severe. A deficiency in the membrane-bound form causes **type II methemoglobinemia**, which can cause severe mental retardation and neurological problems. The type I disease can be

treated with the reducing agents ascorbic acid and methylene blue, either singly or together.

3. *Toxin-induced oxidation of the Fe^{2+} in Hb.* Oxidation of the Fe^{2+} of Hb to Fe^{3+} can occur by three routes: (a) direct oxidation, promoted under hypoxic conditions; (b) indirect oxidation in the presence of bound O_2 , a mechanism that is important in the methemoglobinemia produced by nitrite; and (c) drug-induced oxidation, in which drug metabolites of compounds (e.g., aminobenzenes and nitrobenzenes) promote the oxidation.

The environment provided by the globin portion of Hb is crucial for the O_2 -heme interaction. To be useful, this interaction must be fully reversible under physiological conditions, allowing repetitive capture and release of O_2 . The interaction of O_2 with free Fe^{2+} normally produces Fe^{3+} , the simplest example of which is rust. Even with isolated heme, O_2 *irreversibly* oxidizes Fe^{2+} to Fe^{3+} . However, when heme is part of Hb, interactions with ~20 amino acids cradle the heme in the globin, so that O_2 loosely and *reversibly* binds to Fe^{2+} . The crucial residue is a histidine that bonds to the Fe^{2+} and donates negative charge that stabilizes the Fe^{2+} - O_2 complex. This histidine is also crucial for transmitting, to the rest of the Hb tetramer, the information that an O_2 molecule is or is not bound to the Fe^{2+} . When all four hemes are devoid of O_2 , each of the four histidines pulls its Fe^{2+} above the *plane of its porphyrin ring* by ~0.06 nm (the blue conformation in Fig. 29-1C), distorting the porphyrin ring. Thus, the Fe^{2+} -histidine bond is under strain in deoxyhemoglobin, a strain that it transmits to the rest of the α or β subunit, and thence to the rest of the Hb molecule. The various components of the Hb tetramer are so tightly interlinked, as if by a snugly fitting system of levers and joints, that no one subunit can leave this **tensed (T) state** unless they all leave it together. Because the shape of the heme in the T state sterically inhibits the approach of O_2 , empty Hb has a very low affinity for O_2 .

When one O_2 binds to one of the Fe^{2+} atoms, the Fe^{2+} tends to move down into the plane of the porphyrin ring. If the Fe^{2+} actually *could* move, it would flatten the ring and relieve the strain on the Fe^{2+} -histidine bond. When enough O_2 molecules bind, enough energy builds up and all four subunits of the Hb simultaneously snap into the **relaxed (R) state**, whether or not they are bound to O_2 . In this R state, with its flattened heme, the Hb molecule has an O_2 affinity that is ~150-fold greater than that in the T state. Thus, when P_{O_2} is zero, all Hb molecules are in the T state and have a low O_2 affinity. When P_{O_2} is very high, all Hb molecules are in the R state and have a high O_2 affinity. At intermediate P_{O_2} values, an equilibrium exists between Hb molecules in the T and R states.

Myoglobin (Mb) is another heme-containing, O_2 -binding protein that is specific for muscle (see p. 249). The globin portion of Mb arose in a gene duplication event from a primordial globin. Additional duplications along the non-Mb branch of the globin family led first to the α and β chains of Hb, and then to other α -like and β -like chains (Box 29-1). Mb functions as a *monomer*, homologous to either an α or a β

chain of Hb. Although capable of binding only a single O₂ molecule, Mb has a much higher O₂ affinity than Hb. In the capillaries, Hb can thus hand off O₂ to an Mb inside a muscle cell; this Mb then transfers its O₂ to the next Mb, and so on, which speeds diffusion of O₂ through the muscle cell. Because of the low solubility of O₂, this action is essential: There is insufficient dissolved O₂, by itself, to establish an intracellular O₂ gradient large enough to deliver adequate O₂ to mitochondria.

Box 29-1

Forms of Hemoglobin

The normal **adult form of hemoglobin ($\alpha_2\beta_2$)**, known as **HbA**, is only one of several normal forms that are present in prenatal or postnatal life. Some of these other hemoglobins contain naturally occurring α -like chains (e.g., α and ζ) or β -like chains (e.g., β , γ , δ , and ϵ), whereas others reflect post-translational modifications. Three genes for **α -like chains** (all encoding 141 amino acids) cluster on chromosome 16: At the 5' end of the cluster is one gene for a ζ chain, followed by two for the α chain. Pseudogenes for ζ and α are also present. Five genes for **β -like chains** (all encoding 146 amino acids) are clustered on chromosome 11: Starting at the 5' end is one for ϵ , followed by two for γ (γ_G encoding for glycine at position 136, γ_A for alanine), and one each for δ and β . A pseudogene for β is also present. A locus control region regulates the expression of these β -like chains during development (see pp. 80–81).

The four **prenatal hemoglobins** (Table 29-1) consist of various combinations of two α -like chains (e.g., α and ζ) and two β -like chains (e.g., ϵ and γ). Very early in life, when erythropoiesis occurs in the yolk sac, the hemoglobin products are the three **embryonic hemoglobins**. When erythropoiesis shifts to the liver and spleen at ~10 weeks' gestation, the hemoglobin product is **fetal hemoglobin**, or **HbF ($\alpha_2\gamma_2$)**. Erythrocytes containing HbF have a higher O₂ affinity than those containing HbA, owing to special properties of γ chains. The newborn's blood contains both HbA and HbF; the latter gradually falls by 1 year of age to the minute levels that are characteristic of the adult (rarely >1% to 2% of total hemoglobin). With severe stress to the erythroid system—such as marked hemolysis (see p. 429), bone marrow failure, or recovery from bone marrow transplantation—immature erythroid precursors may be forced to mature before they have differentiated sufficiently to produce HbA. In these conditions, circulating levels of HbF may increase considerably. In some hereditary cases, normal HbF persists in the adult, with no clinically significant consequences.

TABLE 29-1

Subunit Structures of Prenatal and Minor-Component Hemoglobins

Hb	α -LIKE SUBUNIT	β -LIKE SUBUNIT	TIME OF EXPRESSION
Gower 1	ζ	ϵ	Embryonic
Gower 2	α	ϵ	Embryonic
Portland	ζ	γ	Embryonic
HbF (fetal)	α	γ	Fetal
HbA ₂	α	δ	Postnatal
HbA (adult)	α	β	Postnatal

Even adult blood contains several normal **minor-component hemoglobins** (Table 29-2), which account for 5% to 10% of the total blood hemoglobin. In HbA₂ (~2.5% of total hemoglobin), δ chains replace the β chains of HbA. Although the physiological significance of HbA₂ is unknown, the δ chains reduce the sickling of sickle hemoglobin (see below). Three other minor-component hemoglobins are the

result of the nonenzymatic glycosylation of HbA. HbA_{1a}, HbA_{1b}, and HbA_{1c} form when intracellular glucose-6-phosphate reacts with the terminal amino groups of the β chains of HbA. In poorly controlled diabetes mellitus, a disease characterized by decreased insulin or insulin sensitivity (see Box 51-5), blood glucose concentrations rise and, with them, intracellular concentrations of glucose-6-phosphate. As a result, glycosylated hemoglobins may represent 10% or more of the total hemoglobin. Because hemoglobin glycosylation is irreversible, and because the RBC has a mean lifetime of 120 days, levels of these glycosylated hemoglobins are clinically useful for assessing the long-term control of blood glucose levels in diabetics.

TABLE 29-2
Makeup of Total Hb in Adult Human Blood

Hb TYPE	FRACTION OF TOTAL Hb
HbA	~92%
HbA _{1a}	0.75%
HbA _{1b}	1.5%
HbA _{1c}	3%–6%
HbA ₂	2.5%
Total	100%

Numerous abnormal hemoglobins exist, most of which are caused by single-amino-acid substitutions on one of the polypeptide chains. One of the most clinically important is HbS, or **sickle hemoglobin**, in which a valine replaces the glutamate normally present at position 6 of the β chain. Although oxygenated HbS has a normal solubility, deoxygenated HbS is only about half as soluble as deoxygenated HbA. As a result, in low-O₂ environments, HbS can crystallize into long fibers, giving the cells a sickle-like appearance. The sickled erythrocytes may disrupt blood flow in small vessels, causing many of the acute symptoms of “sickle cell crisis,” including pain, renal dysfunction, retinal bleeding, and aseptic necrosis of bone. In addition, sickle cells are prone to hemolysis (mean lifetime, <20 days), which leads to a chronic **hemolytic anemia**.

The Hb-O₂ dissociation curve has a sigmoidal shape because of cooperativity among the four subunits of the Hb molecule

Imagine that we expose whole blood (see pp. 429–431) to a gas phase with a P_{O_2} that we can set at any one of several values (Fig. 29-2). For example, we could incubate the blood with a P_{O_2} of 40 mm Hg, typical of mixed-venous blood, and centrifuge a sample to separate plasma from erythrocytes, as one would for determining hematocrit (see pp. 102 and 429). Next, we could individually determine the O₂ content of the plasma (i.e., dissolved O₂) and packed RBCs. If we know how much water is inside the RBCs, we can subtract the amount of O₂ dissolved in this water from the total O₂, arriving at the amount of O₂ bound to Hb.

FIGURE 29-2 Determination of O_2 content in blood plasma and erythrocytes.

Repeating this exercise over a range of P_{O_2} values, we obtain the red curve in [Figure 29-3](#). The right-hand y-axis gives the O_2 bound to Hb in the units $(\text{mL } O_2)/(\text{dL blood})$. The left-hand y-axis gives the same data in terms of **percent O_2 saturation** of Hb (S_{O_2} or “Sat”). To compute S_{O_2} , we need to know the maximal amount of O_2 that can bind to Hb at extremely high P_{O_2} values. Expressed in terms of grams of Hb protein, this **O_2 capacity** is $\sim 1.39 \text{ mL } O_2/\text{g Hb}$ —assuming that no metHb is present. In real life, the O_2 capacity may be closer to $1.35 \text{ mL } O_2/\text{g Hb}$ because O_2 cannot bind to Hb that either is in the Fe^{3+} state (e.g., MetHb) or, as discussed below, is bound to carbon monoxide. We can translate this O_2 capacity to a value for the maximal amount of O_2 that can bind to Hb in 100 mL of blood. If the Hb content is 15 g Hb/dL blood (i.e., normal for an adult male), then

$$\begin{aligned}
 &\text{Maximal } O_2 \text{ bound to Hb} \\
 &= (O_2 \text{ capacity of Hb}) \times (\text{Hb content of blood}) \\
 &= \frac{1.35 \text{ mL } O_2}{\text{g Hb}} \cdot \frac{15 \text{ g Hb}}{\text{dL blood}} \\
 &= \sim 20.3 (\text{mL } O_2)/\text{dL blood} \\
 &\quad \quad \quad \text{(29-4)}
 \end{aligned}$$

The percent saturation of Hb is

$$\% \text{ Saturation of Hb} = \frac{\text{O}_2 \text{ actually bound to Hb}}{\text{O}_2 \text{ capacity of Hb}} \cdot 100$$

(29-5)

FIGURE 29-3 Normal Hb-O₂ dissociation curve. The y-axis on the right shows O₂ content. For the red curve (O₂ content of Hb), we assume 15 g Hb/dL of blood and an O₂ capacity of 1.35 mL O₂/g Hb. The brown curve is the sum of the red and purple curves. The y-axis on the left, which pertains only to the red curve, gives the percentage of Hb saturation or S_{O_2} .

Notice that the curve in [Figure 29-3](#) is sigmoidal or S-shaped, owing to the **cooperativity** among the four O₂-binding sites on the Hb molecule. At low P_{O_2} values, increases in P_{O_2} produce relatively small increases in O₂ binding, which reflects the relatively low O₂ affinity of Hb in the T state. At moderate P_{O_2} values, the amount of bound O₂ increases more steeply with increases in P_{O_2} , which reflects the increased O₂ affinity as more Hb molecules shift to the R state. The P_{O_2} at which the Hb is half saturated is known as the P_{50} . Finally, the Hb-O₂ versus P_{O_2} curve flattens at high P_{O_2} values as the Hb saturates. The difference in Hb saturation at low versus high P_{O_2} values is the basis for an important clinical tool, the pulse oximeter ([Box 29-2](#)).

Box 29-2

Measuring the Oxygen Saturation of Hb Clinically

The Pulse Oximeter

The different colors of venous and arterial blood reflect difference in light absorbance between oxygenated and deoxygenated Hb. Clinicians now routinely exploit these differences to obtain simple, noninvasive measurements of the arterial O_2 saturation (Sa_{O_2}) of Hb in patients. The pulse oximeter has a probe that one attaches to the ear, finger, or any part of the body at which pulsating blood vessels are accessible externally. On one side of the pulsating vascular bed, the pulse oximeter shines red and infrared light; on the other side, it detects the light transmitted through the bed, and calculates absorbances. These total absorbances have two components: (1) a nonpulsatile component that arises from stationary tissues, including blood inside capillaries and veins; and (2) a pulsatile component that arises from blood inside arterioles and arteries. The difference between the total and nonpulsatile absorbance is thus the pulsatile component, which represents only arterial or oxygenated blood. Because oxygenated and deoxygenated Hb absorb red and infrared light differently, the pulse oximeter can calculate Sa_{O_2} from the ratio of pulsatile light absorbed at the two wavelengths. The pulse oximeter accomplishes this magic by using a sophisticated microprocessor and software to produce results that strongly agree with those provided by blood-gas analysis of a sample of arterial blood.

The pulse oximeter measures O_2 saturation in arterial blood. Because systemic capillaries and veins do not pulsate, they do not contribute to the measurement. Thus, a patient with peripheral cyanosis (e.g., purple fingertips caused by cold-induced vasoconstriction) may have a perfectly normal “central” (i.e., arterial) O_2 saturation. It is worth noting that pulse oximetry cannot detect CO poisoning because the absorbance spectra of Hb-CO and Hb- O_2 are similar.

Health professionals widely employ pulse oximetry in hospitalized patients, particularly those in intensive care units, where continuous monitoring of Sa_{O_2} is critical. These patients include those on mechanical ventilators and others, less severely ill, who have some degree of respiratory compromise. Pulse oximetry has also become popular as an outpatient tool for assessing the presence of hypoxemia during sleep and thus screening for sleep apnea (Box 32-5). Because of the insidious nature of hypoxia, pilots of light aircraft have begun to use pulse oximeters to detect developing hypoxia at high altitudes.

At the P_{O_2} prevailing in normal arterial blood (Pa_{O_2})—approximately 100 mm Hg—the Hb saturation (Sa_{O_2}) is ~97.5% or 19.7 mL O_2 /dL bound to Hb (Table 29-3). The dissolved O_2 (purple curve in Fig. 29-3) would add an additional 0.3 mL O_2 /dL for a **total O_2 content** of 20.0 mL O_2 /dL (point a on the brown curve in Fig. 29-3). In mixed-venous blood, in which P_{O_2} ($P\bar{v}_{O_2}$) is ~40 mm Hg, the Hb saturation ($S\bar{v}_{O_2}$) is ~75% or 15.2 mL O_2 /dL bound to Hb (see Table 29-3). The dissolved O_2 would add 0.1 mL O_2 /dL for a total of 15.3 mL O_2 /dL (point \bar{v} in Fig. 29-3). The difference in total O_2 content between points a and \bar{v} , the $a-\bar{v}$ difference, is the amount of O_2 that the lungs add to the blood in the pulmonary capillaries, which is the same amount that all the tissues extract from the blood in the systemic capillaries:

$$\begin{aligned}
 \overbrace{\Delta C(a - \bar{v})_{O_2}}^{\text{a-}\bar{v} \text{ difference for total } O_2 \text{ content}} &= \frac{\overbrace{20.0 \text{ mL } O_2}^{\text{O}_2 \text{ content of arterial blood}}}{\text{dL blood}} - \frac{\overbrace{15.3 \text{ mL } O_2}^{\text{O}_2 \text{ content of mixed-venous blood}}}{\text{dL blood}} \\
 &= \frac{4.7 \text{ mL } O_2}{\text{dL blood}} \\
 &\quad (29-6)
 \end{aligned}$$

TABLE 29-3
Summary of a- \bar{v} Difference in O₂ Composition of Blood

	P _{O₂} (mm Hg)	Hb SATURATION (S _{O₂})	O ₂ BOUND TO Hb (mL/dL)*	O ₂ DISSOLVED (mL/dL)	TOTAL O ₂ CONTENT (mL/dL)
a	100	97.5%	19.7	0.3	20.0
\bar{v}	40	75%	15.2	~0.1	15.3
a- \bar{v} difference	60	22.5%	4.5	~0.2	4.7

*Assuming an Hb content of 15 g Hb/dL blood and an O₂ capacity of 1.35 mL O₂/g Hb. Here, fully saturated Hb would carry 20.3 mL O₂/dL blood.

Of the total a- \bar{v} difference of 4.7 mL O₂/dL, Hb provides 4.5 mL O₂/dL or nearly 96% of the O₂ that the lungs add and the systemic tissues extract from blood (see Table 29-3). Is this a- \bar{v} difference in O₂ content enough to satisfy the metabolic demands of the body (i.e., ~250 mL O₂/min)? Using the Fick principle, as we did in Equation 29-3, we see that the combination of a cardiac output of 5 L/min and an a- \bar{v} difference of 4.7 mL/dL would be nearly adequate:

$$\begin{aligned}
 \overbrace{\dot{V}_{O_2}}^{O_2 \text{ consumption by tissues}} &= \frac{\overbrace{5000 \text{ mL blood}}^{\text{Blood flow}}}{\text{min}} \cdot \frac{\overbrace{4.7 \text{ mL } O_2}^{\text{a-}\bar{v} \text{ difference for total } O_2 \text{ content}}}{100 \text{ mL blood}} \\
 &= \sim 235 \text{ mL } O_2 / \text{min} \\
 &\quad (29-7)
 \end{aligned}$$

By either increasing cardiac output by ~6% or decreasing the P_{O₂} of mixed-venous blood, the body could meet a demand of 250 mL O₂/min. We spend our lives moving endlessly from point *a* in Figure 29-3 to point \bar{v} (as we deliver O₂ to the tissues) and then back to point *a* (as we take up more O₂ from alveolar air).

Because the plot of [O₂]_{Dis} versus P_{O₂} is linear (see Fig. 29-3, purple curve), the amount of O₂ that can dissolve in blood plasma has no theoretical maximum. Thus, breathing 100% O₂ would raise arterial P_{O₂} by ~6-fold, so that ~1.8 mL of O₂ would be dissolved in each deciliter of arterial blood. Although dissolved O₂ would make a correspondingly greater contribution to overall O₂ carriage under such unphysiological conditions, Hb would still carry the vast majority of O₂. Hence, a decrease in the Hb content of the blood—known as **anemia**—can markedly reduce O₂ carriage. The body can compensate for

decreased Hb content in the same two ways that, in the above example, we increased the \dot{V}_{O_2} from 235 to 250 mL O₂/min. First, it can increase cardiac output. Second, it can increase O₂ extraction, thereby reducing mixed-venous O₂ content. Anemia leads to pallor of the mucous membranes and skin, reflecting the decrease in the red Hb pigment. Impaired O₂ delivery may cause lethargy and fatigue. The accompanying increase in cardiac output may manifest itself as palpitations and a systolic murmur. Shortness of breath may also be a part of the syndrome.

If decreased Hb levels are detrimental, then increasing Hb content should increase the maximal O₂ content and thus provide a competitive advantage for athletes. Even in normal individuals, [Hb] in RBC cytoplasm is already extremely high (see p. 434). Hypoxia (e.g., adaptation to high altitude) leads to the increased production of erythropoietin (see pp. 431–433),  **N18-2** a hormone that somewhat increases the amount of Hb per erythrocyte, but especially increases their number. Indeed, a few instances have been highly publicized in the international press in which elite athletes have infused themselves with erythrocytes or injected themselves with recombinant erythropoietin. However, an excessive increase in hematocrit—**polycythemia**—has the adverse effect of increasing blood viscosity and thus vascular resistance (see pp. 437–439). The consequences include increased blood pressure in both the systemic and pulmonary circulations and a mismatch of ventilation to perfusion within the lung. Such a ventilation-perfusion mismatch leads to hypoxia (see p. 693), and thus *desaturation* of arterial Hb. Thus, the optimal hematocrit—presumably ~45%—is one that achieves a high maximal O₂ content, but at a reasonable blood viscosity.

The purplish color of desaturated Hb produces the physical sign known as **cyanosis**, a purplish coloration of the skin and mucous membranes. Cyanosis results not from the *absence* of saturated or oxygenated Hb, but from the *presence* of desaturated Hb. Thus, an anemic patient with poorly saturated Hb might have too little unsaturated Hb for it to manifest as cyanosis. The physician's ability to detect cyanosis also depends on other factors, such as the subject's skin pigmentation and the lighting conditions for the physical examination.

Increases in temperature, [CO₂], and [H⁺], all of which are characteristic of metabolically active tissues, cause Hb to dump O₂

Metabolically active tissues not only have a high demand for O₂, they also are warm, produce large amounts of CO₂, and are acidic. Indeed, high temperature, high P_{CO₂}, and low pH of metabolically active tissues all decrease the O₂ affinity of Hb by acting at nonheme sites to shift the equilibrium between the T and R states of Hb more toward the low-affinity T state. The net effect is that metabolically active tissues can signal Hb in the *systemic* capillaries to release more O₂ than usual, whereas less active tissues can signal Hb to release less. In the *pulmonary* capillaries—where temperature is lower than in active tissues, P_{CO₂} is relatively low and pH is high—these same properties promote O₂ uptake by Hb.

Temperature

Increasing the temperature causes the Hb-O₂ dissociation curve to *shift to the right*, whereas decreasing the temperature has the opposite effect (Fig. 29-4). Comparing the three Hb-O₂ dissociation curves in

Figure 29-4 at the P_{O_2} of mixed-venous blood (40 mm Hg), we see that the amount of O_2 bound to Hb becomes progressively less at higher temperatures. In other words, high temperature decreases the O_2 affinity of Hb and leads to release of O_2 . One mechanism of this temperature effect may be small shifts in the pK values of various amino-acid side chains, which cause shifts in net charge and thus a conformational change.

FIGURE 29-4 Effect of temperature changes on the Hb- O_2 dissociation curve.

The maximal temperature achieved in active muscle is $\sim 40^\circ\text{C}$. Of course, very low temperatures can prevail in the skin of extremities exposed to extreme cold.

Acid

In 1904, Christian Bohr, a physiologist and father of atomic physicist Niels Bohr, observed that respiratory acidosis (see p. 633) shifts the Hb- O_2 dissociation curve to the right (Fig. 29-5A). This decrease in O_2 affinity has come to be known as the **Bohr effect**. A mild respiratory acidosis occurs physiologically as erythrocytes enter the systemic capillaries. There, the increase in extracellular P_{CO_2} causes CO_2 to enter erythrocytes, which leads to a fall in intracellular pH (see p. 646). Other acidic metabolites may also lower extracellular and, therefore, intracellular pH. Thus, this intracellular respiratory acidosis has two components—a decrease in pH and an increase in P_{CO_2} . We now appreciate

that *both* contribute to the rightward shift of the Hb-O₂ dissociation curve observed by Bohr.

A RESPIRATORY ACID-BASE DISTURBANCES

B EFFECT OF pH

C EFFECT OF CO2

FIGURE 29-5 Effect of acidosis and hypercapnia on the Hb-O₂ dissociation curve (Bohr effect).

The effect of acidosis per se on the Hb-O₂ dissociation curve (see Fig. 29-5B)—the **pH-Bohr effect**—accounts for most of the overall Bohr effect. One can readily demonstrate the pH-Bohr effect in a solution of Hb by imposing a metabolic acidosis (e.g., decreasing pH at a fixed P_{CO}₂). It should not be surprising that Hb is sensitive to changes in pH because Hb is an outstanding H⁺ buffer (see p. 630):

Although Hb has many titratable groups, the ones important here are those with pK values in the physiological pH range. **N29-2** As we acidify the solution, raising the ratio $[\text{Hb}-\text{H}^+]/[\text{Hb}]$ for susceptible groups, we change the conformation of the Hb molecule, thus lowering its O_2 affinity:

N29-2

Interactions of H^+ with Hemoglobin

Contributed by Emile Boulpaep, Walter Boron

Like most proteins, Hb has many titratable groups. However, the ones that are most important physiologically are the ones whose pK values are near the physiological pH. For a general discussion of buffers, consult the passage beginning on pages 628–633. Of particular interest is the passage dealing with buffers in a closed system (see pp. 630–633) and Figure 28-2B.

Several titratable groups in the Hb molecule contribute to the pH-Bohr effect. The most important single group is the histidine at residue 146 of the β chains. When the Hb molecule is fully deoxygenated (tensed state), the protonated His-146 forms a salt bridge with the negatively charged aspartate group at position 94 of the same β chain. This salt bridge stabilizes the protonated form of His-146, so that it has a high affinity for H^+ (i.e., a relatively high pK value of ~ 8.0).

When the Hb becomes fully oxygenated (relaxed state), the twisting of the Hb molecule disrupts the salt bridge and thus destabilizes the protonated form of His-146, so that it has a low affinity for H^+ and thus a relatively low pK value of ~ 7.1 . This pK is roughly the same as the pH inside the RBC. According to Equation 28-5, the ratio $[\text{R}-\text{NH}_3^+]/[\text{R}-\text{NH}_2]$ must be 1 : 1 (so that in 50 out of every 100 Hb molecules, this group is protonated).

Now let us fully deoxygenate this Hb and return the pK of His-146 to where it was at the beginning of this example, ~ 8.0 . The pH inside the erythrocyte remains at 7.1. Equation 28-5 tells us that the ratio $[\text{R}-\text{NH}_3^+]/[\text{R}-\text{NH}_2]$ will be 8 : 1. That is, in 89 of every 100 Hb molecules, this His-146 group is protonated. Thus, for every 100 Hb molecules, 39 H^+ ions have been taken up from the solution to titrate 39 $\text{R}-\text{NH}_2$ groups to form 39 additional $\text{R}-\text{NH}_3^+$ groups at His-146.

The above is an extreme example, because the Hb does not become fully deoxygenated in the systemic capillaries. It is also a simplified example, inasmuch as multiple residues in Hb contribute to the pH-Bohr effect. Nevertheless, the example illustrates how deoxygenated Hb is better able to buffer excess protons.

In the above paragraphs, we have been emphasizing one side of the physiological coin: deoxygenation makes Hb a weaker acid (and thus causes Hb to take up H^+). However, as summarized by the reaction in Equation 29-9,

the converse is also true: the protonation of Hb lowers Hb's affinity for O₂.

This is an extreme example in which we added enough H⁺ to cause Hb to dump *all* of its O₂. Under more physiological conditions, the binding of ~0.7 mole of H⁺ causes Hb to release 1 mole of O₂. This property is important in the systemic tissues, where [H⁺] is high. The converse is also true: O₂ binding causes a conformational change in the Hb molecule, which lowers the affinity of Hb for H⁺.

Carbon Dioxide

The isolated effect of hypercapnia per se on the Hb-O₂ dissociation curve (see Fig. 29-5C) represents a small portion of the overall Bohr effect. Demonstrating such a **CO₂-Bohr effect** requires that we study the O₂ affinity of Hb at a fixed pH, increasing P_{CO₂} and HCO₃⁻ proportionally—an example of **isohydric hypercapnia** (see p. 641). As P_{CO₂} increases, CO₂ combines with unprotonated amino groups on Hb (Hb-NH₂) to form **carbamino groups** (Hb-NH-COO⁻). **N29-3** Although Hb has other amino groups, only the four amino termini of the globin chains are susceptible to appreciable carbamino formation, the β chains more so than the α chains. Because amino groups exist in a protonated form (Hb-NH₃⁺) in equilibrium with an unprotonated form, the reaction of CO₂ with Hb-NH₂ tends to shift Hb away from the Hb-NH₃⁺ form and toward the Hb-NH-COO⁻ form:

N29-3

Interactions of CO₂ with Hemoglobin

Contributed by Emile Boulpaep, Walter Boron

As discussed on page 653, CO₂ can reversibly react with the four amino groups that constitute the four N termini of the globin chains—the two α chains and, especially, the two β chains. As shown by Equation 29-10 in the text, the interaction of CO₂ with these amino termini causes the net charge on the residue to change from positive (Hb-NH₃⁺) to negative (Hb-NH-COO⁻). A consequence is the formation of salt bridges—among several positively and negatively charged amino-acid residues—that tend to stabilize the deoxygenated (or tensed) form of Hb. Thus, in the systemic capillaries, the increased levels of CO₂ favor the deoxygenated form of Hb, which is tantamount to dumping O₂. In other words, increased levels of CO₂ cause the Hb-O₂ dissociation curve to shift to the right (see Fig. 29-5C).

In the lungs, the converse takes place as the binding of O₂ to Hb causes a twisting of the Hb molecule

as it shifts from the tensed to the relaxed state. This twisting disrupts the aforementioned salt bridges and destabilizes carbamino. As a result, the Hb molecule dumps CO₂, which exits the erythrocyte and diffuses into the alveolar air space.

The overall effect of carbamino formation is therefore a negative shift in the charge on one amino-acid side chain, causing a shift in the conformation of Hb and reducing its O₂ affinity:

Thus, an increased P_{CO₂} causes Hb to unload O₂, which is important in the systemic tissues. Conversely, an increased P_{O₂} causes Hb to unload CO₂, which is important in the lungs.

In conclusion, the Hb-O₂ dissociation curve shifts to the right under conditions prevailing in the capillaries of metabolically active systemic tissues—increased temperature (see Fig. 29-4), decreased pH (see Fig. 29-5B), and increased P_{CO₂} (see Fig. 29-5C). These right shifts are synonymous with decreased O₂ affinity. Thus, high metabolic rates promote the unloading of O₂ from Hb. Clearly, blood cannot unload O₂ unless the blood gets to the tissues. Indeed, in most systemic arterioles, local hypercapnia and acidosis also are powerful stimuli for vasodilation (see p. 556), enhancing O₂ delivery to metabolically active tissues.

2,3-Diphosphoglycerate reduces the affinity of adult, but not of fetal, Hb

The affinity of Hb for O₂ is very sensitive to the presence of the glycolytic metabolite 2,3-diphosphoglycerate (2,3-DPG)  N29-4 and, to a lesser extent, organic phosphates such as ATP. The concentration of **2,3-DPG** is about the same as that of Hb. Indeed, 2,3-DPG binds to Hb in a 1 : 1 stoichiometry, interacting with a central cavity formed by the two β chains. At physiological pH, 2,3-DPG has an average of ~3.5 negative charges, which interact with eight positively charged amino-acid residues in this central cavity. O₂ binding, however, changes the shape of the central cavity, destabilizing DPG-bound Hb. As a result, deoxygenated Hb has a 100-fold higher affinity for 2,3-DPG than does oxygenated Hb. Conversely, binding of 2,3-DPG to Hb destabilizes the interaction of Hb with O₂, promoting the release of O₂:

2,3-DPG

Contributed by Emile Boulpaep, Walter Boron

2,3-Diphosphoglycerate (2,3-DPG), also known as 2,3-bisphosphoglycerate (2,3-BPG), is an intermediate in one of the later reactions in glycolysis (Fig. 58-6A). The overall reaction in question is 3-phosphoglycerate (3-PG) → 2-phosphoglycerate (2-PG), catalyzed by **phosphoglycerate mutase (PGM)**:

The actual mechanism is interesting. A specific kinase initially activates the PGM by transferring a phosphate group from the 2 position of 2,3-DPG to a **histidine** residue of the enzyme, creating PGM-P and 3-PG:

In the actual mutase reaction, this activated enzyme transfers the phosphate group to 2-PG, creating 2,3-DPG:

Finally, the enzyme can accept a phosphate group from 2,3-DPG, creating 3-PG:

Thus, 2,3-DPG is a cofactor in the mutase reaction. It also is continuously formed and consumed.

The result is a right shift in the Hb-O₂ dissociation curve (Fig. 29-6). This effect of 2,3-DPG on the O₂ affinity of Hb is important both in hypoxia and in understanding the physiology of fetal Hb.

FIGURE 29-6 Effect of 2,3-DPG on O₂ affinity of Hb. After lowlanders spent about 2 days at an altitude of ~4500 m, their cytosolic [2,3-DPG] increased by ~50%, shifting the Hb-O₂ dissociation curve to the right.

Decreasing the P_{O₂} of RBCs stimulates glycolysis, which leads to increased levels of 2,3-DPG. Indeed, chronic hypoxia, anemia, and acclimation to high altitude are all associated with an increase in 2,3-DPG levels and thus lower the O₂ affinity of Hb. Reducing the affinity is a two-edged sword. At the relatively high P_{O₂} in alveoli, where the Hb-O₂ dissociation curve is fairly flat, this decrease in O₂ affinity reduces O₂ uptake—but only slightly. At the low P_{O₂} in systemic tissues, where the Hb-O₂ dissociation curve is steep, this decrease in O₂ affinity markedly increases the O₂ release. The net effect is enhanced O₂ unloading to metabolizing tissues, which is more important than P_{O₂} per se.

In Figure 29-7, the teal Hb-O₂ dissociation curve represents pure or “stripped” Hb (i.e., in the absence of CO₂, 2,3-DPG, and other organic phosphates). The O₂ affinity of pure Hb is quite high, as evidenced by the left shift of the curve. Adding only CO₂ (orange curve) or only 2,3-DPG (green curve) to the solution shifts the curve somewhat to the right, and adding both yields the brown curve, which is indistinguishable from the red curve for intact RBCs under physiological conditions.

FIGURE 29-7 Effect of adding CO_2 or 2,3-DPG to stripped Hb. The teal, orange, green, and brown curves are Hb- O_2 dissociation curves for pure Hb (2 mM) in artificial solutions. “Stripped Hb” is devoid of both CO_2 and 2,3-DPG. When CO_2 or 2,3-DPG was present, P_{CO_2} was 40 mm Hg and [2,3-DPG] was 2.4 mM. The cytosol of erythrocytes in blood (red curve) had the same composition as the artificial solutions.

The **fetal hemoglobin (HbF)** in fetal erythrocytes (see p. 649) has a higher O_2 affinity than the Hb inside adult RBCs (HbA). This difference is crucial for the fetus, whose blood must extract O_2 from maternal blood in the placenta (see p. 1137). The difference in O_2 affinities does not, however, reflect differences in O_2 affinities of *stripped* HbA and HbF, which are nearly identical. The crucial difference is that the γ chains of HbF bind 2,3-DPG less avidly than do the β chains of HbA. With less 2,3-DPG bound, the dissociation curve of HbF is left-shifted, similar to the HbA curve labeled “Hb + CO_2 ” in Figure 29-7.

O_2 is not the only gas that can bind to the Fe^{2+} of Hb; carbon monoxide (CO), nitric oxide (NO), and H_2S can also bind to Hb and snap it into the R state. **N29-5 In CO poisoning** (see pp. 1224–1225), CO binds to Hb with an affinity that is ~ 200 -fold greater than that of O_2 . Thus, the maximal O_2 capacity falls to the extent that CO binds to Hb. However, the major reason that CO is toxic is that, as it snaps Hb into the R state, CO increases the O_2 affinity of Hb and shifts the Hb- O_2 dissociation curve far to the left. Thus, when Hb reaches the systemic capillaries in CO poisoning, its tenacity for O_2 is so high that the bright red blood cannot release enough O_2 to the tissues.

N29-5

Other Gases That Bind to Hemoglobin

Contributed by Arthur DuBois, Emile Boulpaep, Walter Boron

The text discusses in some detail the interaction of O_2 and CO_2 with Hb, briefly discusses the interaction of CO with Hb, and mentions the interactions of NO and H_2S with Hb.

Carbon Monoxide

As noted in the text, the affinity of Hb for CO is ~200-fold greater than for O₂. Thus, when a fully oxygenated Hb molecule—Hb(O₂)₄—is exposed to even a low level of CO, a CO molecule displaces one of the O₂ molecules from some of the Hb molecules, resulting in Hb(O₂)₃(CO). If the only effect of CO poisoning were to render ineffective one of the four O₂-binding sites, then the symptoms would be no worse than reducing the hematocrit by 25% (e.g., from 40% to 30%) or perfusing the arteries with mixed-venous blood (which also has an Hb-O₂ saturation of 75%). In fact, if a single CO molecule binds to 40% of the Hb molecules in the blood, the patient will experience symptoms, as outlined below. Why?

Basis of CO Toxicity

CO is toxic for two reasons. First, it reduces the number of binding sites available for O₂ carriage. Second, the binding of CO stabilizes the Hb molecule in its relaxed state, which shifts the Hb-O₂ dissociation curve far to the left and makes it more difficult for the Hb to release O₂ in the systemic capillaries.

Calculating the CO Saturation of Hb

To calculate the HbCO concentration, remember that when the Hb is exposed to CO, the [HbCO] will equal the [HbO₂] when the Hb is exposed to O₂ at 210 times the [CO] in question. For example, Hb is 50% saturated with O₂ (at equilibrium) when the P_{O_2} is 28 mm Hg. The 50% HbCO concentration will be reached at equilibrium with 28/210 mm Hg of CO, which would be only 0.133 mm Hg of CO. Because an atmosphere of pressure is 760 mm Hg, 0.133 mm Hg of CO is equivalent to 0.133/760 or 0.000175 atmosphere of CO, or 175 ppm of CO. This level of CO would severely incapacitate or kill a person exposed to it for a long time. However, because it takes 4 hours to reach half the final equilibrated level of HbCO, a 4-hour exposure to 175 ppm alveolar CO would lead to a HbCO level of 50%/2, or 25% HbCO. This level would give the person a headache and interfere with mental function. In 2 hours of exposure, the HbCO would be $\frac{1}{4}$ of 50% saturation, or 12.5% HbCO. This lower level would interfere with night vision and—because of some interference with O₂ transport—raise the risk of angina in a person with limited coronary blood flow.

Symptoms and Treatments

Symptoms of mild CO poisoning may begin when the CO saturation of Hb reaches 10%; that is, when 40% of the Hb molecules bind one CO (25% of sites on one Hb molecule × 40% of Hb molecules = 10% saturation). These symptoms—which are not very specific—may include headache, nausea, and vomiting.

For mild CO poisoning, the treatment is simply to remove the causative agent, which leaves the body with a half-time of ~4 hours (i.e., CO dissociates very, very slowly from Hb—it has a low off-rate).

For more severe CO poisoning, the recommended treatment is to have the patient breathe 100% O₂, which increases the probability that O₂ will displace CO from Hb (i.e., it increases the off-rate) and thereby speeds the washout of CO by about a factor of 4 (half-time \cong 60 minutes).

When the CO saturation of Hb reaches 20% to 25% (i.e., when, on average, 80% to 100% of Hb molecules each bind one CO molecule), the symptoms are severe and include confusion, chest pain, and unconsciousness. The treatment is hyperbaric 100% O₂—oxygen delivered at high pressure (OHP)—which has two positive effects. First, the hyperbaric O₂ (i.e., increased P_{O_2}) accelerates even further the

displacement of CO from Hb. Breathing hyperbaric 100% O₂ at 2.5 atmospheres of pressure reduces the half-time of washout to 20 minutes. Second, the hyperbaric-O₂ treatment can increase the concentration of dissolved O₂ to such an extent that this dissolved O₂ in the blood can deliver sufficient O₂ to satisfy the body's metabolic demands (see Equations 29-1 through 29-3).

CO reaches a lethal level at an Hb saturation of ~50%.

Interestingly, hyperventilation is *not* an effective treatment for CO poisoning. One reason for this lack of effect may be that hyperventilation blows off CO₂ and reduces the arterial P_{CO_2} (see pp. 679–680). According to the Bohr effect, low levels of CO₂ (e.g., caused by hyperventilation) would shift the Hb-O₂ dissociation curve to the left, exacerbating the effect of the CO poisoning. In fact, Yandell Henderson showed that use of 5% CO₂ in 95% O₂ decreased plasma pH, which *accelerated* the displacement of CO from HbCO as well as increasing the tissue P_{O_2} through the Bohr effect (communicated by Arthur DuBois).

Nitric Oxide

Hb also binds NO. This interaction may help ensure that the effects of NO are paracrine rather than endocrine—that is, that the effects of NO are restricted to the sites of release. The physiological target of NO is soluble guanylyl cyclase (see pp. 66–67), which binds NO through a *heme* group, just as does Hb!

Carriage of CO₂

Blood carries “total CO₂” mainly as HCO₃⁻

The blood carries CO₂ and related compounds in five forms: N29-6

N29-6

Total CO₂

Contributed by Walter Boron

eTable 29-1 below complements Figure 29-8.

eTABLE 29-1
Components of “Total CO₂”

COMPONENT		ARTERIAL BLOOD (P_{CO_2} = 40 mm Hg)			MIXED-VEINOUS BLOOD (P_{CO_2} = 46 mm Hg)		
		CONCENTRATION	CONTRIBUTION TO TOTAL CO ₂ (mL/dL)	FRACTION OF TOTAL CO ₂ (%)	CONCENTRATION	CONTRIBUTION TO TOTAL CO ₂ (mL/dL)	FRACTION OF TOTAL CO ₂ (%)
Physically dissolved carbon dioxide	CO ₂	1.2 mM	2.4	5	1.4 mM	2.8	5.3
Carbonic acid	H ₂ CO ₃	3 μM	~0	~0	~3.5 μM	~0	~0
Bicarbonate	HCO ₃ ⁻	24 mM	43.2	90	25.6 mM	46.0	88.5
Carbonate	CO ₃ ²⁻	30 μM	~0	~0	30 μM	~0	~0
Carbamino compounds	R-NH-COO ⁻	1.2 mM	2.4	5	1.6 mM	3.2	6.2
Total		26.4 mM	48	100	28.6 mM	52	100

1. **Dissolved carbon dioxide.** [CO₂]_{Dis} follows Henry's law (see [p. 593](#)), and it is in the millimolar range in both blood plasma and blood cells. It makes up only ~5% of the total CO₂ of arterial blood (gold portion of leftmost bar in [Fig. 29-8](#)).

FIGURE 29-8 Constituents of “total CO₂ in blood.” The left bar (a) represents arterial blood; the middle bar (\bar{v}), mixed-venous blood; and the right bar, the incremental CO₂ that the blood picks up in the systemic capillaries.

2. Carbonic acid. H₂CO₃ can form either from CO₂ and H₂O, or from H⁺ and HCO₃⁻ (see p. 630). Because the equilibrium constant governing the reaction $\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3$ is ~ 0.0025 , [H₂CO₃] is only 1/400th as large as [CO₂]. Thus, H₂CO₃ is not quantitatively important for CO₂ carriage.

3. Bicarbonate. HCO₃⁻ can form in three ways. First, H₂CO₃ can dissociate into HCO₃⁻ and H⁺. Second, CO₂ can combine directly with OH⁻ to form HCO₃⁻, the reaction catalyzed by carbonic anhydrase. **N18-3** Third, HCO₃⁻ forms when carbonate combines with H⁺. In arterial blood, HCO₃⁻ is ~ 24 mM, so that HCO₃⁻ represents $\sim 90\%$ of total CO₂ (purple portion of leftmost bar in Fig. 29-8).

4. Carbonate. CO₃²⁻ forms from the dissociation of bicarbonate: $\text{HCO}_3^- \rightarrow \text{CO}_3^{2-} + \text{H}^+$. Because the pK of this reaction is so high (~ 10.3), [CO₃²⁻] is only $\sim 1/1000$ th as high as HCO₃⁻ at pH 7.4. Thus, like H₂CO₃, CO₃²⁻ is not quantitatively important for CO₂ carriage.

5. Carbamino compounds. By far the most important carbamino compound is carbamino hemoglobin (Hb-NH-COO⁻), which forms rapidly and reversibly as CO₂ reacts with free amino groups on Hb (see p. 653). In arterial blood, carbamino compounds account for $\sim 5\%$ of total CO₂ (blue) portion of leftmost bar in Fig. 29-8).

The reason we group together the previously listed five CO₂-related compounds under the term **total CO₂** is that the method Van Slyke  **N29-7** introduced in the 1920s—which remains the basis for assaying blood HCO₃⁻ in modern clinical laboratories—cannot distinguish among the five.

N29-7

Van Slyke's Manometric Method for Determining Total CO₂

Contributed by Emile Boulpaep, Walter Boron

In 1924, Van Slyke and Neill introduced a technique for determining what is today known as the “total CO₂” of blood  **N29-6** and other solutions. This technique quickly became the standard for determining total CO₂ in clinical chemistry laboratories. Moreover, the Van Slyke approach is the foundation even for modern, automated approaches for determining total CO₂.

Although the original approach requires painstaking precision in the laboratory in order to obtain reliable results, the fundamental principle is a rather simple two-step process. First, one uses an acid (Van Slyke and Neill used 1 N lactic acid) to titrate virtually all of the carbamino Hb, carbonate (CO₃²⁻), and bicarbonate (HCO₃⁻) to carbon dioxide (CO₂), which enters the gaseous phase. Second, one uses a manometer to measure the pressure (*P*) of a known volume (*V*) of this CO₂ gas. The ideal gas law tells us that

$$PV = nRT \quad (\text{NE 29-2})$$

Here, *n* is the number of molecules, *R* is the universal gas constant, and *T* is the absolute temperature. Thus, with the proper corrections for nonideality, it is possible to compute the number of CO₂ molecules.

We will now examine the titration reactions in a little more detail. For the titration of carbamino Hb by the H⁺ in lactic acid, two reactions occur in series:

These reactions are the reverse of the ones shown in Equation 29-10.

The titration of CO₃²⁻ by the H⁺ in lactic acid yields HCO₃⁻:

Finally, the titration of this newly formed HCO₃⁻—as well as the pre-existing HCO₃⁻ (which is a far larger amount under physiological conditions)—by the H⁺ in lactic acid yields carbonic acid (H₂CO₃), which in turn yields CO₂ and H₂O:

(NE 29-5)

Because the pK governing the equilibrium $\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3$ is ~ 2.6 , $>99.7\%$ of the newly formed H_2CO_3 goes on to form CO_2 .

In practice, the technique used to generate the CO_2 gas also extracts a variable amount of O_2 from the solution. In other words, the CO_2 in the gas phase is mixed with an amount of O_2 that is difficult to predict. Therefore, Van Slyke and Neill introduced an additional step to their analysis: they added 1 N NaOH to convert all total CO_2 to CO_3^{2-} , thereby removing the CO_2 from the gas phase. This last step allowed them to obtain, with precision, the amount of CO_2 gas in the gas phase and thus to calculate the amount of total CO_2 that had been in their sample.

CO₂ transport depends critically on carbonic anhydrase, the Cl-HCO₃ exchanger, and Hb

The total CO_2 concentration of arterial blood is ~ 26 mM, or ~ 48 mL of CO_2 gas/dL (measured at STP).

HCO_3^- constitutes $\sim 90\%$ of this 48 mL/dL, with CO_2 and carbamino compounds contributing $\sim 5\%$ each (bar *a* in Fig. 29-8). As blood courses through the systemic capillary beds, it picks up ~ 4 mL/dL of CO_2 , so that the total CO_2 of mixed-venous blood is ~ 52 mL/dL (bar \bar{v} in Fig. 29-8). In what forms does blood carry this *incremental* 4 mL/dL of CO_2 to the lungs? About 10% of the incremental CO_2 moves as dissolved CO_2 , $\sim 69\%$ as HCO_3^- , and $\sim 21\%$ as carbamino compounds (rightmost two bars in Fig. 29-8). Therefore, dissolved CO_2 and carbamino CO_2 are far more important for carrying *incremental* CO_2 to the lungs than we might have surmised, given their contribution to *total* CO_2 in arterial blood.

Figure 29-9 summarizes the events that occur as incremental CO_2 enters systemic capillaries. As fast as biological oxidations in the mitochondria produce CO_2 , this gas diffuses out of cells, through the extracellular space, across the capillary endothelium, and into the blood plasma. Some of the incremental CO_2 ($\sim 11\%$) remains in blood plasma throughout its journey to the lungs, but most ($\sim 89\%$), at least initially, enters the RBCs.

FIGURE 29-9 Carriage of CO₂ from systemic capillaries to the lungs.

The ~11% of the incremental CO₂ in plasma travels in three forms:

- 1. Dissolved CO₂.** About 6% of incremental CO₂ remains dissolved in blood plasma (assuming a hematocrit of 40%).
- 2. Carbamino compounds.** An insignificant amount forms carbamino compounds with plasma proteins.
- 3. Bicarbonate.** About 5% of incremental CO₂ forms HCO₃⁻ in the plasma and remains in the plasma: CO₂ + H₂O → H₂CO₃ → H⁺ + HCO₃⁻. The amount of HCO₃⁻ that follows this path depends critically on non-HCO₃⁻ buffering power (see pp. 637–638), which is very low in plasma (~5 mM/pH unit).

The remaining ~89% of incremental CO₂ enters the RBCs, predominantly through two “gas channels,” **aquaporin 1 (AQP1)** and the **Rh complex**. **N29-8** This CO₂ also has three fates:

N29-8

Gas Channels

Contributed by Walter Boron

The traditional view had been that all gases cross all cell membranes by simply dissolving in the lipid phase of the membrane. The first evidence that the gas dogma was in need of refinement was the

observation that apical membranes of gastric gland cells are impermeable to CO_2 and NH_3 (Waisbren et al, 1994) and that apical membranes of colonic crypts are impermeable to NH_3 (Singh et al, 1995). Low permeabilities to gases and H_2O may be a general property of membranes facing inhospitable environments (Cooper et al, 2002), including the mechanical stresses experienced by RBCs and capillary endothelial cells. Cells exposed to such hostile environments may have evolved specialized, *robust membranes* with unique lipid composition or protein or oligosaccharide coatings at the membrane surface.

The second observation that upset the gas dogma was the discovery that CO_2 passes through the water channel AQP1 (Cooper et al, 1998; Nakhoul et al, 1998). Peter Agre shared the 2003 Nobel Prize in Chemistry for discovering AQPs and their H_2O permeability.  **N5-7** The physiological role of AQPs transcends water. For example, AQP7 and AQP9 transport glycerol. Might AQP1's CO_2 permeability be physiologically relevant? The first such evidence was the demonstration that an AQP plays a critical role in CO_2 uptake for photosynthesis by tobacco leaves (Uehlein et al, 2003). Endeward and colleagues (2008) demonstrated that approximately half of the CO_2 entering human RBCs passes through the AQP1 channel.

The AQPs form homotetramers, and each monomer has a pore for H_2O . Molecular dynamics simulations suggest that CO_2 could pass single file with H_2O through each of the four aquapores as well as through the central pore between the four monomers (Wang et al, 2007). Preliminary inhibitor studies from the Boron laboratory confirm this prediction, indicating that ~40% of the CO_2 that passes through AQP1 moves through the four aquapores, whereas the remaining 60% passes through the central pore. The molecular dynamics simulations suggest that virtually all of the O_2 passes through the central pore.

A second family of gas channels is the Rh proteins. The bacterial Rh homolog AmtB forms a homotrimer, and each monomer appears to have a pore for NH_3 . The RhAG protein from the human Rh complex in RBCs is permeable both to NH_3 and to CO_2 (Endeward et al, 2008). Preliminary work from the Boron laboratory indicates that NH_3 moves exclusively through one of the three ammonia pores, whereas CO_2 moves mainly through the central pore of both AmtB and RhAG.

Interestingly, gas channels exhibit selectivity for gas in much the same way as ion channels exhibit selectivity for ions. For example, AQP4 (heavily expressed at the blood-brain barrier) and AQP5 (heavily expressed in alveolar type I pneumocytes) are virtually totally selective for CO_2 over NH_3 . AQP1 (heavily expressed in RBCs) is intermediate in its CO_2/NH_3 selectivity, AmtB is shifted more toward NH_3 selectivity, and RhAG (heavily expressed in RBCs) is even more shifted toward selectivity for NH_3 over CO_2 . This work is the first evidence for gas selectivity by a protein channel (Musa-Aziz et al, 2009).

- 1. Dissolved CO₂.** About 4% of incremental CO₂ remains dissolved inside the RBC.
- 2. Carbamino compounds.** About 21% of incremental CO₂ forms carbamino compounds with Hb. Why does so much CO₂ travel as carbamino compounds inside the RBC, whereas so little does in the blood plasma? First, the Hb concentration inside RBCs (~33 g/dL) is far higher than that of albumin and globulins in plasma (~7 g/dL). Second, Hb forms carbamino compounds far more easily than do major plasma proteins. Moreover, Hb forms carbamino compounds even more easily as it loses O₂ in the systemic capillaries (reverse of CO₂-Bohr effect). Finally, Hb is a far better buffer than the plasma proteins for the H⁺ formed as a byproduct in carbamino formation, and becomes an even better buffer as it loses O₂ in the systemic capillaries (reverse of the pH-Bohr effect).
- 3. Bicarbonate.** About 64% of the incremental CO₂ forms HCO₃⁻. Why does so much more CO₂ form HCO₃⁻ in the erythrocyte than in plasma? First, erythrocytes contain a high level of **carbonic anhydrases** (see p. 434),  **N18-3** which greatly accelerates the conversion of CO₂ to HCO₃⁻. In the absence of enzyme, hardly any HCO₃⁻ would form inside erythrocytes during the brief time that the cells spend during their passage through a typical systemic capillary. Second, the **Cl-HCO₃ exchanger AE1** (see pp. 124–125 and 434–435) transports some of the newly formed HCO₃⁻ out of the cell, promoting formation of more HCO₃⁻. This uptake of Cl⁻ in exchange for HCO₃⁻ is known as the chloride or Hamburger shift. Third, the buffering of H⁺ by Hb (see point 2 above) also pulls the reaction to the right.

The combined effects of the described intracellular and extracellular events is that ~10% of incremental CO₂ formed in systemic tissues moves to the lungs as dissolved CO₂, 6% in plasma and 4% inside erythrocytes (gold portion of rightmost bar in Fig. 29-8). About 21% moves as carbamino compounds, almost exclusively inside erythrocytes as carbamino Hb (blue portion of rightmost bar in Fig. 29-8). Finally, ~69% of incremental CO₂ moves as HCO₃⁻, 5% that forms in plasma and 64% that forms inside the RBC (purple portion of rightmost bar in Fig. 29-8). Because H₂O enters the cell during HCO₃⁻

formation, erythrocytes swell as they pass through systemic capillaries.

When mixed-venous blood (with a P_{CO_2} of ~ 46 mm Hg) reaches the pulmonary capillaries (surrounded by alveoli with a P_{CO_2} of only ~ 40 mm Hg), CO_2 moves from the erythrocytes and blood plasma into the alveolar air space. All of the reactions discussed above reverse. In the process, Cl^- and H_2O leave the erythrocytes, and the cells shrink.

The high P_{O_2} in the lungs causes the blood to dump CO_2

The carriage of total CO_2 in the blood depends on the three blood-gas parameters— P_{CO_2} , plasma pH, and P_{O_2} . The three plots in the main portion of Figure 29-10 are **CO_2 dissociation curves**. Each plot shows how changes in P_{CO_2} affect the total- CO_2 content of blood. Although pH per se does not appear in this diagram, pH decreases as P_{CO_2} increases along the x-axis (i.e., respiratory acidosis; see p. 833). The blue plot is the CO_2 dissociation curve when P_{O_2} is zero ($S_{\text{O}_2} \cong 0\%$ Hb). The next two plots are CO_2 dissociation curves for P_{O_2} values of 40 mm Hg ($S_{\text{O}_2} \cong 75\%$; purple curve) and 100 mm Hg ($S_{\text{O}_2} \cong 97.5\%$; red curve). The green line at the bottom of Figure 29-10 shows that the *dissolved* component of total CO_2 rises only slightly with increases in P_{CO_2} .

Three features of the CO₂ dissociation curves in Figure 29-10 are noteworthy:

1. **Near-linear relationship in the physiological range of P_{CO₂} and P_{O₂} values** (see Fig. 29-10, inset). In contrast, the O₂ dissociation curve is highly nonlinear in its physiological range (i.e., 40 to 100 mm Hg).
2. **Up-shift of curve with decreasing P_{O₂}**. At any P_{CO₂}, total CO₂ content rises as P_{O₂} (or Hb saturation) falls—the **Haldane effect**.  **N29-9** Thus, as blood enters systemic capillaries and releases O₂, the CO₂-carrying capacity rises so that blood picks up extra CO₂. Conversely, as blood enters the pulmonary capillaries and binds O₂, the CO₂-carrying capacity falls so that blood dumps extra CO₂ (Table 29-4). The Haldane effect is the flip side of the coin from the pH-Bohr and CO₂-Bohr effects. First, just as H⁺ binding lowers the O₂ affinity of Hb (see Equation 29-9), O₂ binding destabilizes protonated hemoglobin (Hb-H⁺), promoting H⁺ release. By mass action, this H⁺ reduces CO₂-carrying capacity by favoring the formation of CO₂ from both carbamino Hb and HCO₃⁻ (see Fig. 29-9). Second, just as carbamino formation lowers the O₂ affinity of Hb (see Equation 29-11), O₂ binding destabilizes carbamino Hb (Hb-NH-COO⁻), promoting CO₂ release.

TABLE 29-4
Factors Affecting the Amount of Total CO₂ Carried by Blood

PARAMETER	EFFECTS OF INCREASING THE PARAMETER
P _{CO₂}	Increased [CO ₂] _{Dis} (Henry's law). Increased formation of HCO_3^- ($\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{HCO}_3^- + \text{H}^+$). Increased formation of carbamino ($\text{CO}_2 + \text{Hb-NH}_2 \rightarrow \text{Hb-NH-COO}^- + 2\text{H}^+$).
[Plasma protein]	Increased plasma buffering power. The increased capacity for consuming H ⁺ indirectly promotes formation of HCO_3^- .
Plasma pH	Increased formation of HCO_3^- in plasma (Henderson-Hasselbalch equation). Increased pH inside red cell, promoting formation of HCO_3^- and carbamino Hb.
[Hb]	Increased formation of carbamino Hb (<i>direct</i>). Increases buffering power inside erythrocyte. The increased capacity for consuming H ⁺ <i>indirectly</i> promotes formation of HCO_3^- and carbamino Hb.
P _{O₂}	Decreased buffering power of Hb (inverse of pH-Bohr effect). The decreased capacity for consuming H ⁺ indirectly restrains formation of HCO_3^- and carbamino Hb. Decreased formation of carbamino Hb (inverse of CO ₂ -Bohr effect).

3. **Steepness.** Because CO₂ dissociation curves (see Fig. 29-10) are much steeper than O₂ dissociation curves (see Fig. 29-3), P_{CO₂} must increase from 40 mm Hg in arterial blood to only 46 mm Hg in mixed-venous blood to increase the CO₂ content by the ~4 mL/dL of CO₂ required to remove CO₂ as fast as the mitochondria produce it. In contrast, P_{O₂} must decrease from 100 to 40 mm Hg to dump enough O₂ to meet metabolic demands.

John Scott Haldane (1860–1936) was born in Edinburgh, where he received his medical degree in 1884. He began his academic career at Queen's College, Dundee, before moving to Oxford. Haldane is credited with several notable discoveries:

- He showed that high blood levels of CO_2 are a more powerful stimulus for breathing than low levels of O_2 (1905).
- He developed a method for the staged decompression of deep-sea divers to avoid the bends on the return of the divers to the surface. He published the first diving decompression tables (1908).
- He—along with Christiansen and Douglas—showed that the CO_2 content of the blood decreases with increasing P_{O_2} , known as the *Haldane effect* (1914). This effect is responsible for about half of the CO_2 exchange in the blood.

Christiansen J, Douglas CG, Haldane JS. The absorption and dissociation of carbon dioxide by human blood. *J Physiol*. 1914;48:244–277.

In the inset to [Figure 29-10](#), point *a* on the red curve represents arterial blood, with a P_{CO_2} of 40 mm Hg and a P_{O_2} of 100 mm Hg ($S_{\text{O}_2} \cong 97.5\%$). Point \bar{v} on the purple curve represents mixed-venous blood, with a P_{CO_2} of 46 mm Hg but a P_{O_2} of only 40 mm Hg ($S_{\text{O}_2} \cong 75\%$). The difference between the total CO_2 contents represented by the two points (i.e., 52 versus 48 mL/dL) represents the 4 mL/dL of CO_2 the blood takes up as it passes through systemic capillaries. If it were not for the Haldane effect, the blood would remain on the red curve, and the P_{CO_2} increase would cause the CO_2 content to increase by only ~ 2.7 mL/dL. Thus, at a P_{CO_2} of 46 mm Hg, the fall in P_{O_2} that occurs as blood flows through systemic capillaries allows the blood to pick up $\sim 50\%$ more CO_2 (i.e., 4 versus 2.7 mL/dL). Viewed differently, if it were not for the Haldane effect, mixed-venous P_{CO_2} would have to increase to ~ 49 mm Hg for blood to carry 4 mL/dL of CO_2 . [Table 29-4](#) summarizes how changes in blood parameters can influence the amount of total CO_2 that the blood is able to carry.

The O_2 - CO_2 diagram describes the interaction of P_{O_2} and P_{CO_2} in the blood

We have seen that Hb plays a key role in transporting O_2 from the lungs to peripheral tissues, transporting

CO_2 in the opposite direction, and buffering H^+ . These functions are all intimately interrelated: P_{CO_2} and pH influence the O_2 -Hb dissociation curve (Bohr effects; see Fig. 29-5), and P_{O_2} influences the CO_2 dissociation curve (Haldane effect; see Fig. 29-10). A useful way of illustrating this mutual dependence is the **O_2 - CO_2 diagram**, which we will revisit on page 691 to understand regional differences between alveolar P_{O_2} and P_{CO_2} .

On a coordinate system with P_{CO_2} on the y-axis and P_{O_2} on the x-axis, each blue curve in Figure 29-11 represents an **isopleth of identical O_2 content** in whole blood (from the Greek *isos* [equal] + *plethein* [to be full]). For example, arterial blood (point *a*) lies on the isopleth for an O_2 content of 20.0 mL/dL, with coordinates of $P_{\text{O}_2} = 100$ mm Hg and $P_{\text{CO}_2} = 40$ mm Hg. Following this isopleth from a P_{CO_2} of 40 mm Hg (point *a*) to, say, 46 mm Hg, we see that the blood could carry the same 20.0 mL/dL of O_2 only if we increase P_{O_2} from 100 to nearly 105 mm Hg. Thus, as P_{CO_2} increases, the O_2 content of blood decreases (Bohr effect). If it were not for the Bohr effect, all the blue curves would be vertical lines. Mixed-venous blood (point \bar{v}) is on the O_2 -content isopleth for 15.3 mL/dL, at a P_{O_2} of 40 mm Hg and a P_{CO_2} of 46 mm Hg. If blood were equilibrated with inspired air (point *I*), it would have a P_{O_2} of 150 mm Hg and a P_{CO_2} of zero.

FIGURE 29-11 O_2 - CO_2 diagram.

Each red curve is an **isopleth of identical CO_2 content**. Arterial blood (point *a*) lies on the isopleth for 48 mL/dL. Similarly, mixed-venous blood (point \bar{v}) lies on the isopleth for 52 mL/dL. Following this 52-mL/dL isopleth from a P_{O_2} of 40 mm Hg (point \bar{v}) to, say, 100 mm Hg, we see that the blood could carry the same 52 mL/dL of CO_2 only if we increase P_{CO_2} from 46 to nearly 50 mm Hg. Thus, as the P_{O_2}

increases, the CO_2 content of blood decreases (*Haldane effect*). If it were not for the Haldane effect, all the red curves would be horizontal lines. Blood equilibrated with inspired air (point *I*) would have a CO_2 content of zero.

In [Figure 29-11](#), the green curve connecting the points \bar{v} , *a*, and *I* represents all possible combinations of P_{O_2} and P_{CO_2} in normal lungs.

CHAPTER 30

Gas Exchange in the Lungs

Walter F. Boron

The complex anatomy of the pulmonary tree, the mechanics of the respiratory system, and the sophisticated carriage mechanisms for O_2 and CO_2 combine to serve two essential purposes: the ready diffusion of O_2 from the alveoli to the pulmonary-capillary blood, and the movement of CO_2 in the opposite direction. In this chapter, we consider principles that govern these diffusive events and factors that, in certain diseases, can limit gas exchange.

Diffusion of Gases

Gas flow across a barrier is proportional to diffusing capacity and concentration gradient (Fick's law)

Although, early on, physiologists debated whether the lung actively secretes O_2 into the blood, we now know that the movements of both O_2 and CO_2 across the alveolar blood-gas barrier occur by simple **diffusion** (see [p. 108](#)). Random motion alone causes a net movement of molecules from areas of high concentration to areas of low concentration. Although diffusion per se involves no expenditure of energy, the body must do work—in the form of ventilation and circulation—to create the concentration gradients down which O_2 and CO_2 diffuse. Over short distances, diffusion can be highly effective.

Suppose that a barrier that is permeable to O_2 separates two air-filled compartments ([Fig. 30-1A](#)). The partial pressures (see [p. 593](#)) of O_2 on the two sides are P_1 and P_2 . The probability that an O_2 molecule on side 1 will collide with the barrier and move to the opposite side is proportional to P_1 :

$$\text{Flow}_{1 \rightarrow 2} \propto P_1$$

(30-1)

The **unidirectional movement** of O_2 in the opposite direction, from side 2 to side 1, is proportional to the partial pressure of O_2 on side 2:

$$\text{Flow}_{2 \rightarrow 1} \propto P_2$$

(30-2)

The **net movement** of O_2 from side 1 to side 2 is the difference between the two unidirectional flows:

$$\text{Flow}_{\text{net}} \propto (P_1 - P_2)$$

(30-3)

A DRY, HOMOGENEOUS BARRIER

B ALVEOLAR WALL

FIGURE 30-1 Diffusion of a gas across a barrier.

Note that net flow is proportional to the difference in partial pressures, not the ratio. Thus, when P_1 is 100 mm Hg (or torr) and P_2 is 95 mm Hg (ratio of 1.05), the net flow is 5-fold greater than when P_1 is 2 mm Hg and P_2 is 1 mm Hg (ratio of 2).

The term **flow** describes the number of O_2 molecules moving across the entire area of the barrier per unit time (*units*: moles/s). If we normalize flow for the area of the barrier, the result is a **flux** (*units*: moles/[cm² · s]). Respiratory physiologists usually measure the flow of a gas such as O_2 as the volume of gas (measured at standard temperature and pressure/dry; see [Box 26-3](#)) moving per unit time. V refers to the volume and \dot{V} is its time derivative (volume of gas moving per unit time), or flow.

The proportionality constant in [Equation 30-3](#) is the **diffusing capacity** for the lung, D_L (*units*: mL/[min · mm Hg]). Thus, the flow of gas becomes

$$\dot{V}_{\text{net}} = D_L \cdot (P_1 - P_2) \quad (30-4)$$

This equation is a simplified version of **Fick's law** (see [p. 108](#)), which states that net flow is proportional to the concentration gradient, expressed here as the partial-pressure gradient.

Applying Fick's law to the diffusion of gas across the alveolar wall requires that we extend our model somewhat. Rather than a simple barrier separating two compartments filled with dry gas, a wet barrier covered with a film of water on one side will separate a volume filled with moist air from a volume of blood plasma at 37°C (see [Fig. 30-1B](#)). Now we can examine how the physical characteristics of the gas and the barrier contribute to D_L .

Two *properties of the gas* contribute to D_L —molecular weight (MW) and solubility in water. First, the mobility of the gas should decrease as its molecular weight increases. Indeed, **Graham's law** states that diffusion is inversely proportional to the square root of molecular weight. Second, Fick's law states that the flow of the gas across the wet barrier is proportional to the *concentration* gradient of the gas dissolved in water. According to **Henry's law** (see [Box 26-2](#)), these concentrations are proportional to the respective partial pressures, and the proportionality constant is the solubility of the gas (s). Therefore,

poorly soluble gases (e.g., N₂, He) diffuse poorly across the alveolar wall.

Two *properties of the barrier* contribute to D_L —area and thickness. First, the net flow of O₂ is proportional to the **area (A)** of the barrier, describing the odds that an O₂ molecule will collide with the barrier. Second, the net flow is inversely proportional to the **thickness (a)** of the barrier, including the water layer. The thicker the barrier, the smaller the O₂ partial-pressure gradient ($\Delta P_{O_2}/a$) through the barrier ([Fig. 30-2](#)). An analogy is the slope of the trail that a skier takes from a mountain peak to the base. Whether the skier takes a steep “expert” trail or a shallow “beginner’s” trail, the end points of the journey are the same. However, the trip is much faster along the steeper trail!

FIGURE 30-2 Effect of barrier thickness.

Finally, a combined property of both the barrier and the gas also contributes to D_L , a proportionality constant k that describes the interaction of the gas with the barrier.

Replacing D_L in [Equation 30-4](#) with an area, solubility, thickness, molecular weight, and the proportionality constant yields

$$\dot{V}_{\text{net}} = \underbrace{\left[k \frac{A \cdot s}{a \sqrt{MW}} \right]}_{D_L} (P_1 - P_2)$$

(30-5)

Equations 30-4 and 30-5 are analogous to **Ohm's law** for electricity:

$$I = \left(\frac{1}{R} \right) \cdot \Delta V$$

(30-6)

Electrical current (I) in Ohm's law corresponds to the net flow of gas (\dot{V}_{net}); the reciprocal of resistance (i.e., conductance) corresponds to diffusing capacity (D_L); and the voltage difference (ΔV) that drives electrical current corresponds to the pressure difference ($P_1 - P_2$, or ΔP).

The total flux of a gas between alveolar air and blood is the summation of multiple diffusion events along each pulmonary capillary during the respiratory cycle

Equation 30-5 describes O_2 diffusion between two compartments whose properties are uniform both spatially and temporally. Does this equation work for the lungs? If we assume that the alveolar air, blood-gas barrier, and pulmonary-capillary blood are uniform in space and time, then the net diffusion of O_2 (\dot{V}_{O_2}) from alveolar air to pulmonary-capillary blood is

$$\dot{V}_{O_2} = \underbrace{\left[k \frac{A \cdot s}{a \sqrt{MW}} \right]}_{D_{L_{O_2}}} (P_{A_{O_2}} - P_{c_{O_2}})$$

(30-7)

$D_{L_{O_2}}$ is the diffusing capacity for O_2 , $P_{A_{O_2}}$ is the O_2 partial pressure in the alveolar air, and $P_{c_{O_2}}$ is the comparable parameter in pulmonary-capillary blood. Although Equation 30-7 may seem sophisticated enough, a closer examination reveals that $D_{L_{O_2}}$, $P_{A_{O_2}}$, and $P_{c_{O_2}}$ are each even more complicated than they at first appear.

$D_{L_{O_2}}$

Among the five terms that make up $D_{L_{O_2}}$, two vary both temporally (during the respiratory cycle) and spatially (from one piece of alveolar wall to another). During inspiration, lung expansion causes the surface area (A) available for diffusion to increase and the thickness of the barrier (a) to decrease (Fig. 30-3A). Because of these *temporal* differences, $D_{L_{O_2}}$ should be maximal at the end of inspiration. However, even at one instant in time, barrier thickness and the surface area of alveolar wall differ among pieces of alveolar wall. These *spatial* differences exist both at rest and during the respiratory cycle. 🍷

FIGURE 30-3 Complications of using Fick's law.

N30-1

Spatial Differences in Alveolar Dimensions

Contributed by Emile Boulpaep, Walter Boron

The total area of the lungs is not distributed evenly among all alveoli. First, all else being equal, some

alveoli are “naturally” larger than others. Thus, some have a greater area for diffusion than do others, and some have a thinner wall than do others.

Second, the position of an alveolus in the lung can affect its size. As we saw in Chapter 27, when a person is positioned vertically, the effects of gravity cause the intrapleural pressure to be more negative near the apex of the lung than near the base (see Fig. 27-2). Thus, other things being equal, alveoli near the apex of the lung tend to be more inflated, so that they have a greater area and smaller thickness compared to alveoli near the base of the lung.

Third, during inspiration, alveoli undergo an increase in volume that causes their surface area to increase and their wall thickness to decrease. However, these changes are not uniform among alveoli. Again, the differences can be purely anatomical: all other things being equal, some alveoli “naturally” have a greater static compliance (see p. 610) than others. Thus, during inspiration, their area will increase more, and their wall thickness will decrease more. However, other things being equal, the compliance of an alveolus also depends on its position in the lung. We will see in Chapter 31 that the relatively overinflated alveoli near the apex of the lung (in an upright individual) have a relatively low compliance. In other words, during inspiration these apical alveoli have a smaller volume increase (see Fig. 31-5D). Thus, their area for diffusion undergoes a relatively smaller increase, and their wall thickness undergoes a relatively smaller decrease, than alveoli near the base of the lung.

In summary, for all of the reasons we have discussed, the area and thickness parameters vary widely among alveoli at the end of a quiet inspiration, and the relation among these differences changes dynamically during a respiratory cycle.

$P_{A_{O_2}}$

Like area and thickness, alveolar P_{O_2} varies both temporally and spatially (see Fig. 30-3B). In any given alveolus, $P_{A_{O_2}}$ is greatest during inspiration (when O_2 -rich air enters the lungs) and least just before the initiation of the next inspiration (after perfusion has maximally drained O_2 from the alveoli), as discussed on page 676. These are *temporal* differences. We will see that when an individual is standing, $P_{A_{O_2}}$ is greatest near the lung apex and least near the base (see pp. 681–682). Moreover, mechanical variations in the resistance of conducting airways (see pp. 681–682) and the compliance of alveoli (see p. 597 or pp. 608–610) cause ventilation—and thus P_{O_2} (see p. 610)—to vary among alveoli. These are *spatial* differences.

$P_{c_{O_2}}$

As discussed below, as the blood flows down the capillary, capillary P_{O_2} rises to match $P_{A_{O_2}}$ (see Fig. 30-3C). Therefore, O_2 diffusion is maximal at the beginning of the pulmonary capillary and gradually falls to zero farther along the capillary. Moreover, this profile varies during the respiratory cycle.

The complications that we have raised for O_2 diffusion apply as well to CO_2 diffusion. Of these complications, by far the most serious is the change in $P_{c_{O_2}}$ with distance along the pulmonary capillary. How, then, can we use Fick's law to understand the diffusion of O_2 and CO_2 ? Clearly, we cannot insert a single set of fixed values for DL_{O_2} , $P_{A_{O_2}}$, and $P_{c_{O_2}}$ into Equation 30-7 and hope to describe the overall flow of O_2 between all alveoli and their pulmonary capillaries throughout the entire respiratory cycle. However, Fick's law does describe gas flow between air and blood for a *single piece of alveolar wall* (and its apposed capillary wall) at a *single time* during the respiratory cycle. For O_2 ,

$$\dot{V}_{O_2} \text{ for one piece of alveolar wall, at one time} = \underbrace{\left[k \frac{A \cdot s}{a \sqrt{MW}} \right]}_{D_{L_{O_2}}} (P_{A_{O_2}} - P_{c_{O_2}})$$

(30-8)

For one piece of alveolar wall and at one instant in time, A and a (and thus $D_{L_{O_2}}$) have well defined values, as do $P_{A_{O_2}}$ and $P_{c_{O_2}}$. The total amount of O_2 flowing from all alveoli to all pulmonary capillaries throughout the entire respiratory cycle is simply the sum of all individual diffusion events, added up over all pieces of alveolar wall (and their apposed pieces of capillary wall) and over all times in the respiratory cycle:

$$\text{Overall } \dot{V}_{O_2} = \sum_{\substack{\text{All pieces} \\ \text{of alveolar} \\ \text{wall}}} \sum_{\substack{\text{All times} \\ \text{in respiratory} \\ \text{cycle}}} \left(D_{L_{O_2}} (P_{A_{O_2}} - P_{c_{O_2}}) \right)$$

(30-9)

Here, $D_{L_{O_2}}$, $P_{A_{O_2}}$, and $P_{c_{O_2}}$ are the “microscopic” values for one piece of alveolar wall, at one instant in time.

Even though the version of Fick's law in [Equation 30-9](#) does indeed describe O_2 diffusion from alveolar air to pulmonary-capillary blood—and a comparable equation would do the same for CO_2 diffusion in the opposite direction—it is not of much practical value for *predicting* O_2 uptake. However, we can easily compute the uptake of O_2 *that has already taken place* by use of the **Fick principle** (see [p. 423](#)). The rate of O_2 uptake by the lungs is the difference between the rate at which O_2 leaves the lungs via the pulmonary veins and the rate at which O_2 enters the lungs via the pulmonary arteries. The rate of O_2 *departure from* the lungs is the product of blood flow (i.e., cardiac output, \dot{Q}) and the O_2 content of pulmonary venous blood, which is virtually the same as that of systemic arterial blood ($C_{a_{O_2}}$). Remember that “content” (see [p. 650](#)) is the sum of dissolved O_2 and O_2 bound to hemoglobin (Hb). Similarly, the rate of O_2 *delivery to* the lungs is the product of \dot{Q} and the O_2 content of pulmonary arterial blood, which is the same as that of the mixed-venous blood ($C_{\bar{v}_{O_2}}$). Thus, the difference between the rates of O_2 departure and O_2 delivery is

$$\begin{aligned} \overbrace{\text{Overall } \dot{V}_{O_2}}^{\text{Rate of } O_2 \text{ uptake by lungs}} &= \overbrace{\dot{Q} \cdot C_{a_{O_2}}}^{\text{Rate of } O_2 \text{ departure from lungs}} - \overbrace{\dot{Q} \cdot C_{\bar{v}_{O_2}}}^{\text{Rate of } O_2 \text{ delivery to lungs}} \\ &= \dot{Q} \cdot (C_{a_{O_2}} - C_{\bar{v}_{O_2}}) \end{aligned}$$

(30-10)

For a cardiac output of 5 L/min, a $C_{a_{O_2}}$ of 20 mL O_2 /dL blood, and a $C_{\bar{v}_{O_2}}$ of 15 mL O_2 /dL blood, the

rate of O₂ uptake by the pulmonary-capillary blood is

$$\begin{aligned} \overbrace{\text{Overall } \dot{V}_{O_2}}^{\text{Rate of O}_2 \text{ uptake by lungs}} &= \overbrace{\frac{5000 \text{ mL of blood}}{\text{min}}}^{\text{Cardiac output}} \times \overbrace{(20-15) \frac{\text{mL O}_2}{100 \text{ mL blood}}}^{\text{a-}\bar{v} \text{ difference of O}_2 \text{ content}} \\ &= 250 \text{ mL O}_2/\text{min} \end{aligned} \quad (30-11)$$

Obviously, the amount of O₂ that the lungs take up must be the same regardless of whether we *predict* it by repeated application of Fick's law of diffusion (see [Equation 30-9](#)) or *measure* it by use of the Fick principle (see [Equation 30-10](#)):

$$\overbrace{\sum_{\text{All pieces of alveolar wall}} \sum_{\text{All times in respiratory cycle}} (D_{L_{O_2}} (P_{A_{O_2}} - P_{c_{O_2}}))}^{\text{Fick's law}} = \overbrace{\dot{Q} \cdot (C_{a_{O_2}} - C_{\bar{v}_{O_2}})}^{\text{Fick principle}} \quad (30-12)$$

The flow of O₂, CO, and CO₂ between alveolar air and blood depends on the interaction of these gases with red blood cells

We have been treating O₂ transport as if it involved only the diffusion of the gas across a homogeneous barrier. In fact, the barrier is a three-ply structure  **N30-2** comprising an alveolar epithelial cell, a capillary endothelial cell, and the intervening interstitial space containing extracellular matrix. The barrier is remarkable not only for its impressive surface area (50 to 100 m²) and thinness (~0.6 μm) but also for its strength, which derives mainly from type IV collagen in the lamina densa of the basement membrane (often <50 nm) within the extracellular matrix.

N30-2

Three-Ply Structure of the Alveolar Barrier

See the following review:

Maina JN, West JB: Thin and strong! The bioengineering dilemma in the structural and functional design of the blood-gas barrier. *Physiol Rev* 85:811–844, 2005.

One could imagine that, as O₂ diffuses from the alveolar air to the Hb inside an erythrocyte (red blood cell, or RBC), the O₂ must cross 12 discrete mini-barriers ([Fig. 30-4](#)). A mini-diffusing capacity (D₁ to

D_{12}) governs each of the 12 steps and contributes to a so-called **membrane diffusing capacity (D_M)** because it primarily describes how O_2 diffuses through various membranes. How do these mini-diffusing capacities contribute to D_M ? Returning to our electrical model (see [Equation 30-6](#)), we recognize that D is analogous to the reciprocal of resistance. Therefore, we can represent the 12 diffusive steps by 12 resistors in series. Because the total resistance is the sum of the individual resistances, the reciprocal of D_M is the sum of the reciprocals of the mini-diffusing capacities:

$$\frac{1}{D_M} = \frac{1}{D_1} + \frac{1}{D_2} + \frac{1}{D_3} + \cdots + \frac{1}{D_{10}} + \frac{1}{D_{11}} + \frac{1}{D_{12}} \quad (30-13)$$

Of course, these parameters vary with location in the lung and position in the respiratory cycle.

FIGURE 30-4 Transport of O_2 from alveolar air to Hb. The 12 diffusion constants (D_1 to D_{12}) govern 12 diffusive steps across a series of 12 barriers: (1) the interface between the alveolar air and water layer, (2) the water layer itself, (3–5) the two membranes and cytoplasm of the type I alveolar pneumocyte (i.e., epithelial cell), (6) the interstitial space containing the extracellular matrix, (7–9) the two membranes and cytoplasm of the capillary endothelial cell, (10) a thin layer of blood plasma ($<0.2 \mu m$ in mammals), and (11, 12) the membrane and cytoplasm of the erythrocyte. $\theta \cdot V_c$ describes how fast O_2 binds to Hb.

For most of the O_2 entering the blood, the final step is binding to Hb (see [p. 647](#)), which occurs at a finite rate:

$$\text{Rate of O}_2 \text{ uptake by hemoglobin} = (\theta \cdot V_c) P_{O_2} \quad (30-14)$$

θ is a rate constant that describes how many milliliters of O_2 gas bind to the Hb in 1 mL of blood each minute, and for each millimeter of mercury (mm Hg) of partial pressure. V_c is the volume of blood in the pulmonary *capillaries*. The product $\theta \cdot V_c$ has the same dimensions as D_M (units: mL/[min · mm Hg]), and both contribute to the overall diffusing capacity:

$$\frac{1}{D_L} = \frac{1}{D_M} + \frac{1}{\theta \cdot V_c} \quad (30-15)$$

Because O_2 binds to Hb so rapidly, its “Hb” term $1/(\theta \cdot V_c)$ is probably only ~5% as large as its “membrane” term $1/D_M$.

For carbon monoxide (CO), which binds to Hb even more tightly than does O_2 (see pp. 654–655)—but far more slowly— $\theta \cdot V_c$ is quantitatively far more important. The overall uptake of CO, which pulmonary specialists use to compute D_L (see p. 670), depends about equally on the D_M and $\theta \cdot V_c$ terms.

As far as the movement of CO_2 is concerned, one might expect the D_L for CO_2 to be substantially higher than that for O_2 , inasmuch as the solubility of CO_2 in water is ~23-fold higher than that of O_2 (see p. 593). However, measurements show that $D_{L_{CO_2}}$ is only 3- to 5-fold greater than $D_{L_{O_2}}$. The likely explanation is that the interaction of CO_2 with the RBC is more complicated than that of O_2 , involving interactions with Hb, carbonic anhydrase, and the $Cl-HCO_3$ exchanger (see pp. 655–657).

In summary, the movement of O_2 , CO, and CO_2 between the alveolus and the pulmonary capillary involves not only diffusion but also interactions with Hb. Although these interactions have only a minor effect on the diffusing capacity for O_2 , they are extremely important for CO and CO_2 . Although we will generally refer to “diffusing capacity” as if it represented only the diffusion across a homogeneous barrier, one must keep in mind its more complex nature.

Diffusion and Perfusion Limitations on Gas Transport

The diffusing capacity normally limits the uptake of CO from alveolar air to blood

Imagine that a subject breathes air containing 0.1% CO for a brief period of time. Breathing somewhat higher levels of CO for many hours could be fatal (see pp. 1224–1225) because CO, which binds to Hb with an affinity that is 200 to 300 times higher than that of O₂, prevents Hb from releasing O₂ to the tissues (see pp. 655–657). If we assume that barometric pressure (P_B) is 760 mm Hg and that P_{H₂O} is 47 mm Hg at 37°C, then we can compute the P_{CO} of the wet inspired air entering the alveoli (see Box 26-1):

$$\begin{aligned} P_{\text{CO}} &= \overbrace{F_{\text{I,CO}}}^{\text{Fraction of inspired dry air that is CO}} \cdot (P_{\text{B}} - P_{\text{H}_2\text{O}}) \\ &= 0.1\% \cdot (760 - 47) \text{ mm Hg} \\ &= \sim 0.7 \text{ mm Hg} \end{aligned} \quad (30-16)$$

If the subject smokes cigarettes or lives in a polluted environment, CO will be present in the mixed-venous blood—and, therefore, the alveolar air—even before our test begins. If not, the initial P_{CO} of the mixed-venous blood entering the pulmonary capillaries will be ~0 mm Hg. Thus, a small gradient (~0.7 mm Hg) drives CO diffusion from alveolar air into blood plasma (Fig. 30-5A). As CO enters the blood plasma, it diffuses into the cytoplasm of RBCs, where Hb binds it avidly. The flow of CO from alveolus to RBC is so slow, and the affinity and capacity of Hb to bind CO is so great, that Hb binds almost all incoming CO. Because only a small fraction of the total CO in the pulmonary-capillary blood remains free in solution, the aqueous phase of the blood remains nearly a perfect sink for CO. That is, P_{CO} in the capillary (P_{c,CO}), which is proportional to *free* [CO] in the capillary, rises only slightly above 0 mm Hg as the blood courses down the capillary (see Fig. 30-5B). Thus, by the time the blood reaches the end of the capillary (~0.75 second later), P_{c,CO} is still far below alveolar P_{CO} (P_{A,CO}). In other words, CO fails to reach **diffusion equilibrium** N30-3 between the alveolus and the blood.

A CO DIFFUSION

B P_{CO} PROFILE

C VARY DIFFUSING CAPACITY (D_L)

D VARY BLOOD FLOW (\dot{Q})

FIGURE 30-5 Diffusion of CO. In **A**, ΔP_{CO} is the CO partial-pressure gradient from alveolar air to pulmonary-capillary blood. As the RBC enters the capillary, O_2 occupies three of the four sites on Hb. In **B**, $P_{A_{CO}}$ is alveolar P_{CO} . In **C**, the blood flow \dot{Q} has a relative value of 1. In **D**, the diffusing capacity D_L has a relative value of 1. Because P_{CO} is very low in **B** through **D**, we are on the linear portion of the Hb-CO dissociation curve. Thus, the CO content at the end of the capillary is approximately proportional to the capillary P_{CO} .

N30-3

An Analogy for the Diffusion-Limited Uptake of CO

Contributed by Emile Boulpaep, Walter Boron

The following may be a helpful analogy for how the partial pressure of CO (P_{CO}) changes with time as blood flows down a pulmonary capillary. Keep in mind that, if the linear velocity of the blood is constant, time corresponds to distance down the capillary as shown on the x-axis in Figure 30-5B. Imagine a basement that is somewhat leaky to water. The leakiness of the wall is analogous to the diffusing capacity (D_L) of the lung. After a severe rainstorm, the water outside the basement rises to a level that is 100 cm above the floor of the basement. This 100 cm of water is analogous to the alveolar P_{CO} . The combination of the hydrostatic pressure gradient of 100 cm and the leakiness of the wall allow water to leak in at the rate of 100 L/min. Thus, the influx of water is analogous to the uptake of CO by the

pulmonary-capillary blood (\dot{V}_{CO}). Fortunately, the basement is equipped with a sump pump—activated by the presence of water—that removes water at 99 L/min. The sump pump is analogous to Hb, and the pumping of the water is analogous to the binding of CO to Hb. Thus, under the conditions of this example, the pump can remove all but 1 L/min of the incoming water, so that water level (analogous to P_{CO}) will slowly rise. By how much will the water level rise within 5 hours, a period that is analogous to the time that an RBC spends in a pulmonary capillary?

If the leakiness of the basement wall is low (low D_L), then the water level may rise by only a few centimeters over the 5-hour period. Thus, even though a large amount of water may have entered during the 5 hours, the basement water level never rose enough to equilibrate with the outside water level, which was 100 cm above the floor. The reason for this failure of the water to equilibrate is that the pump was able to remove almost all the water. If the leakiness of the basement wall is higher (higher D_L), then the water level after 5 hours may be 50 cm—but still less than the water level outside the wall.

It is important to recognize that the failure of the water to equilibrate across the wall in our examples was not a function of the water per se but of three parameters: (1) the relatively low leakiness of the basement wall (low D_L), (2) the modest 100-cm pressure gradient driving water across the wall into the basement (low $P_{\text{A}_{\text{CO}}}$), and (3) the high capacity of the pump for removing water (CO binding capacity of Hb). Obviously if the wall were substantially leakier, if the pressure gradient were substantially higher, or if the pump were substantially slower, the water level in the basement could have risen to as much as 100 cm during the 5-hour period—but never more. However, given low driving pressure and the high pump capacity, the total amount of water that entered the basement during the 5-hour period was limited by the leakiness of the basement wall. If the leakiness had been twice as great, the amount of water entering the basement during the 5-hour period also would have been twice as great. Thus, the entry of water was leakiness limited.

There are two reasons that $P_{\text{C}_{\text{CO}}}$ rises so slowly as blood flows down the pulmonary capillary:

- 1. The CO flux (\dot{V}_{CO}) is low.** According to Fick's law, $\dot{V}_{\text{CO}} = D_{L_{\text{CO}}} (P_{\text{A}_{\text{CO}}} - P_{\text{C}_{\text{CO}}})$. Because we chose to use an extremely low inspired P_{CO} , the alveolar P_{CO} driving CO diffusion was likewise extremely low, causing $P_{\text{C}_{\text{CO}}}$ to rise slowly. In addition, the physiological $D_{L_{\text{CO}}}$ is moderate.
- 2. Hb continuously traps incoming CO.** Hb has a high affinity and high capacity for CO. Thus, for a low \dot{V}_{CO} , $P_{\text{C}_{\text{CO}}}$ —proportional to the free [CO]—rises very slowly.

We will now explore factors that influence how much CO the blood takes up as it flows down the capillary. The principles that we develop here apply equally well to O_2 and CO_2 . First, we use the Fick principle (see [Equation 30-10](#)) to quantitate, after the fact, how much CO has entered the blood:

$$\text{Overall } \dot{V}_{\text{CO}} = \dot{Q} \cdot (C_{\text{c}_{\text{CO}}} - C_{\text{v}_{\text{CO}}})$$

(30-17)

Overall \dot{V}_{CO} is the total flow of CO along the entire length of all capillaries throughout the lungs, \dot{Q} is

cardiac output, Cc'_{CO} is the CO content of blood at the end of the pulmonary capillary (dissolved and bound to Hb), and $C\bar{v}_{CO}$ is the CO content of mixed-venous blood at the *beginning* of the capillary. If we assume that $C\bar{v}_{CO}$ is zero, then [Equation 30-17](#) simplifies to

$$\text{Overall } \dot{V}_{CO} = \dot{Q} \cdot Cc'_{CO} \quad (30-18)$$

Of course, this overall \dot{V}_{CO} , computed from the Fick principle, must be the same as the sum of the individual diffusion events, computed from Fick's law (analogous to [Equation 30-12](#)):

$$\underbrace{\dot{Q} \cdot Cc'_{CO}}_{\text{Fick principle}} = \underbrace{\sum_{\text{All pieces of alveolar wall}} \sum_{\text{All times in respiratory cycle}} (D_{LCO} \cdot (P_{ACO} - P_{cCO}))}_{\text{Fick's law}} \quad (30-19)$$

How does CO uptake depend on D_{LCO} and \dot{Q} ? For basal conditions, we assume that D_{LCO} and \dot{Q} each have relative values of 1 and that the curve labeled “ $D_L = 1$ ” in [Figure 30-5C](#) describes the trajectory of P_{cCO} . As a result, Cc'_{CO} also has a relative value of 1. According to the Fick principle, the total amount of CO moving into the blood along the capillary is

$$\begin{aligned} \text{Overall } \dot{V}_{CO} &= \dot{Q} \cdot Cc'_{CO} \\ &= 1 \cdot 1 \\ &= 1 \end{aligned} \quad (30-20)$$

What would happen if we kept \dot{Q} constant, but doubled D_{LCO} ? Fick's law (see [Equation 30-19](#)) predicts that the flow of CO into the blood for each diffusion event along the capillary would double. Thus, along the entire capillary, P_{cCO} would rise twice as steeply (see [Fig. 30-5C](#), curve labeled “ $D_L = 2$ ”) as before. As a result, [N30-4](#) Cc'_{CO} and thus \dot{V}_{CO} would also double.

N30-4

Assumptions Underlying Figure 30-5C

Contributed by Emile Boulpaep, Walter Boron

In our analysis—in which we are halving or doubling D_L —we are assuming that D_L is strictly a reflection of Fick's law. That is, we are assuming that D_L equals D_M , and we are ignoring the buffering of CO by

Hb.

In our example in which we have doubled D_L (curve labeled “ $D_L = 2$ ” in Fig. 30-5C), we showed that the partial pressure of CO (P_{CO}) at the end of the pulmonary capillary has doubled. The CO content of the blood at the end of the pulmonary capillary (Cc'_{CO}) also very nearly doubles. Cc'_{CO} has two components, the CO freely dissolved in blood and the CO bound to Hb. The latter is by far the more important. At the low capillary P_{CO} values in our example, the relationship between capillary P_{CO} and the CO saturation of Hb is approximately linear. According to Henry's law, the relationship between P_{CO} and dissolved CO is also linear. Thus, the total CO content of blood at the end of the capillary is approximately proportional to P_{CO} at the end of the capillary in our example. Thus, when D_L doubles, both the P_{CO} and the total CO content of the blood also double at the end of the pulmonary capillary.

Reducing DL_{CO} by half would have the opposite effect: Cc'_{CO} and thus \dot{V}_{CO} would also halve (see Fig. 30-5C, bottom curve). Therefore, CO uptake is proportional to DL_{CO} over a wide range of DL_{CO} values (Table 30-1, upper half). Of course, if it were possible to make DL_{CO} extremely high, then capillary P_{CO} would rise so fast that CO would equilibrate with the Hb before the end of the capillary, and capillary P_{CO} would reach alveolar P_{CO} (see Fig. 30-5C, top curve). However, for realistic values of DL_{CO} —as well as low alveolar P_{CO} levels and normal Hb concentrations—CO would fail to reach equilibrium by the end of the capillary.

TABLE 30-1
Alveolar Transport of CO

	DL_{CO}	\dot{Q}	\times	Cc'_{CO}	$=$	\dot{V}_{CO}
Vary D_L (\dot{Q} constant)	2	1		2		2
	1	1		1		1
	$\frac{1}{2}$	1		$\frac{1}{2}$		$\frac{1}{2}$
Vary \dot{Q} (D_L constant)	1	$\frac{1}{2}$		2		1
	1	1		1		1
	1	2		$\frac{1}{2}$		1

The values in the table are all relative to “control” values of unity.
 Cc'_{CO} , CO content of the blood at the end of the capillary; D_L , diffusing capacity; DL_{CO} , diffusing capacity of the lungs for CO; \dot{Q} , cardiac output; \dot{V}_{CO} , overall rate of CO uptake by the pulmonary-capillary blood.

How would alteration of blood flow affect \dot{V}_{CO} ? If \dot{Q} were halved and the dimensions of the capillary remained constant, then the contact time of the blood with the alveolar capillary would double. Thus, at any distance down the capillary, twice as much cumulative time would be available for CO diffusion. The trajectory of capillary P_{CO} versus distance would be twice as steep (see Fig. 30-5D, curve labeled “ $\dot{Q} = 0.5$ ”) as in the basal state (curve labeled “ $\dot{Q} = 1$ ”), and Cc'_{CO} would also be twice as great. However, because we achieved this increase in Cc'_{CO} by cutting \dot{Q} in half, the product $\dot{Q} \cdot Cc'_{CO} = \dot{V}_{CO}$ would be the same as that in the basal state (see Table 30-1, lower half).

Doubling of blood flow would cause capillary P_{CO} to rise only half as steeply (see Fig. 30-5D, bottom curve) as in the basal state, but still would have no effect on \dot{V}_{CO} . Thus, for the range of D_L and \dot{Q} values

in this example, *CO uptake is unaffected by changes in blood flow*. Of course, if we were to reduce \dot{Q} to extremely low values, then capillary P_{CO} would reach alveolar P_{CO} by the end of the capillary (see Fig. 30-5D, top curve).

In our example, we have assumed that the P_{CO} profile along the capillary is linear and that changes in \dot{Q} do not affect capillary dimensions. **N30-5** In fact, these assumptions are not entirely valid. Nevertheless, the uptake of CO is more or less proportional to the D_L for CO, and rather insensitive to perfusion. Therefore, we say that the uptake of CO is **diffusion limited** because it is the diffusing capacity that predominantly limits CO transport. We can judge whether the transport of a gas is predominantly diffusion limited by comparing the partial pressure of the gas at the end of the pulmonary capillary with the alveolar partial pressure. *If the gas does not reach diffusion equilibrium (i.e., if the end-capillary partial pressure fails to reach the alveolar partial pressure), then transport is predominantly diffusion limited.* However, if the gas does reach diffusion equilibrium, then its transport is perfusion limited, as discussed next.

N30-5

Assumptions Underlying Figure 30-5D

Contributed by Emile Boulpaep, Walter Boron

In analyzing Figure 30-5D, we have assumed that the linear velocity of the pulmonary-capillary blood is proportional to the flow (\dot{Q}). Thus, when the flow doubles, we are assuming that the contact time of the blood with the alveolar capillary would fall by half.

This assumption requires that the dimensions of the vessel be fixed (i.e., that neither the diameter nor the length of the capillary increase) and that the increase in flow not recruit new blood vessels. In fact, as we shall see in Chapter 31, neither of these assumptions is correct. First, if we start from a low perfusion pressure, increasing the perfusion pressure causes the recruitment of pulmonary vessels that previously were not conducting blood. Second, pulmonary vessels are highly compliant, so that increases in perfusion pressure cause the vessels to dilate. For both reasons (i.e., recruitment and dilation), pulmonary vascular resistance falls as the perfusion pressure increases. Thus, if the flow doubles, the contact time of the blood with the alveolar capillary will fall, but by less than half.

Perfusion normally limits the uptake of N_2O from alveolar air to blood

Unlike CO, nitrous oxide (“laughing gas,” N_2O) does not bind to Hb. Therefore, when a subject inhales N_2O , the gas enters the blood plasma and the RBC cytoplasm but has nowhere else to go (Fig. 30-6A). Consequently, as blood courses down the pulmonary capillary, the concentration of free N_2O —and thus capillary P_{N_2O} (P_{CN_2O})—rises very rapidly (see Fig. 30-6B). By the time the blood is ~10% of the way along the capillary, P_{CN_2O} has reached alveolar P_{N_2O} (P_{AN_2O}), and N_2O is thus in diffusion equilibrium between alveolus and blood. The reason N_2O reaches diffusion equilibrium—whereas CO does not—is not that its D_{LN_2O} is particularly high, or that we chose a high inspired P_{N_2O} . The key difference is that Hb does not bind to N_2O .

A N₂O DIFFUSION

B P_{N₂O} PROFILE

C VARY DIFFUSING CAPACITY D_L

D VARY BLOOD FLOW (Q̇)

FIGURE 30-6 Diffusion of N₂O. In **B**, P_{AN_2O} is alveolar P_{N_2O} and P_{CN_2O} is capillary P_{N_2O} . In **C**, the blood flow \dot{Q} has a relative value of 1. In **D**, the diffusing capacity D_L has a relative value of 1. The N₂O content at the end of the capillary is proportional to P_{N_2O} .

How does N₂O uptake by the lungs depend on D_{LN_2O} and \dot{Q} ? If we assume that the N₂O content of the mixed-venous blood entering the pulmonary capillary ($C_{\bar{v}N_2O}$) is zero, then

$$\text{Overall } \dot{V}_{N_2O} = \dot{Q} \cdot Cc'_{N_2O} \quad (30-21)$$

Cc'_{N_2O} is the N₂O content of the blood at the end of the pulmonary capillary and represents entirely N₂O physically dissolved in blood, which according to Henry's law (see [Box 26-2](#)) is proportional to P_{CN_2O} . The overall \dot{V}_{N_2O} computed from the Fick principle in Equation 30-21 is the sum of individual diffusion events along the capillary:

$$\overbrace{\dot{Q} \cdot C_{cN_2O} = \sum_{\text{All pieces of alveolar wall}} \sum_{\text{All times in respiratory cycle}} (D_{LN_2O} \cdot (P_{AN_2O} - P_{cN_2O}))}^{\text{Fick's law}} \quad \text{Fick principle} \quad (30-22)$$

Because N₂O reached diffusion equilibrium at ~10% of the way down the capillary (i.e., $P_{cN_2O} = P_{AN_2O}$), the individual diffusion terms in Equation 30-22 equate to zero for the distal 90% of the capillary!

We can approach the uptake of N₂O in the same way we did the uptake of CO. We begin, under basal conditions, with relative values of 1 for D_{LN_2O} , \dot{Q} , and end-capillary N₂O content (C'_{cN_2O}). Thus, the initial \dot{V}_{N_2O} is $\dot{Q} \times C'_{cN_2O} = 1$.

Figure 30-6C shows that doubling of D_{LN_2O} doubles the flow of N₂O into the blood for each diffusion event, causing P_{cN_2O} to rise twice as steeply as before along the capillary. However, even though this doubling of D_{LN_2O} causes N₂O to come into diffusion equilibrium twice as fast as before, it has no effect either on the N₂O content of end-capillary blood or on \dot{V}_{N_2O} , both of which remain at 1. Cutting D_{LN_2O} in half also would have no effect on \dot{V}_{N_2O} . Thus, N₂O uptake is insensitive to changes in D_{LN_2O} at least over the range of values that we examined (Table 30-2, upper half). In other words, the uptake of N₂O is not diffusion limited.

TABLE 30-2
Alveolar Transport of N₂O

	D_{LN_2O}	\dot{Q}	\times	C'_{cN_2O}	$=$	\dot{V}_{N_2O}
Vary D_L (\dot{Q} constant)	2	1		1		1
	1	1		1		1
	1/2	1		1		1
Vary \dot{Q} (D_L constant)	1	1/2		1		1/2
	1	1		1		1
	1	2		1		2

What would be the effect of reducing \dot{Q} by half while holding D_{LN_2O} constant? If we assume that capillary dimensions remain constant, then halving of \dot{Q} would double the contact time of blood with the alveolus and make the P_{cN_2O} trajectory along the capillary twice as steep as before (see Fig. 30-6D). Nevertheless, C'_{cN_2O} remains unchanged at 1. However, because we reduced \dot{Q} by half, \dot{V}_{N_2O} also falls by half. Conversely, doubling of \dot{Q} causes \dot{V}_{N_2O} to double. Thus, N₂O uptake is more or less proportional to blood flow (i.e., perfusion) over a wide range of \dot{Q} values (see Table 30-2, lower half). For this reason, we say that N₂O transport is predominantly **perfusion limited**. *The transport of a gas is predominantly perfusion limited if the gas in the capillary comes into equilibrium with the gas in the alveolar air by the end of the capillary.*

In principle, CO transport could become perfusion limited and N₂O transport could become diffusion limited under special conditions

Although normally CO transport is diffusion limited and N₂O transport is perfusion limited, changes in certain parameters could, at least in theory, make CO uptake perfusion limited, or make N₂O uptake diffusion limited. To illustrate, we introduce an analogy ([Fig. 30-7](#)): workers at a railroad siding trying to load boxes (transport gas at a rate \dot{V}) onto the cars of a passing train. Each worker (the diffusive event) has a limited rate for putting boxes on the train, and the total rate is the sum for all the workers (D_L). Each railway car (the RBC) has a limited capacity for holding boxes, and the total capacity is the sum for all cars (Hb concentration). Finally, because the train is moving (the perfusion rate, \dot{Q}), a limited time is available to load each railway car.

FIGURE 30-7 Railway car analogy. Workers represent the diffusion of O_2 across the alveolar wall. Railway cars represent the capacity of the blood to carry O_2 . The speed of the train represents blood flow.

First imagine that the speed of the train perfectly matches the number of workers (see Fig. 30-7A). Thus, all workers are always fully occupied, and the railway cars depart the siding fully loaded; the last box is put on each car just as the car leaves the siding. Any decrease in worker number, any increase in the carrying capacity of each car, or any increase in train speed causes the railway cars to leave the siding at least partially empty. Thus, if we fix train speed at “normal,” *decreasing the number of workers* below “normal” (see Fig. 30-7B) would cause a proportional decrease in the shipping rate—the number of boxes the train carries away per hour. In other words, when the number of workers is between zero and normal, the shipping rate is worker (diffusion) limited.

Now return to the original “perfect-match” condition in which both worker number and train speed are normal. Increasing worker number at constant train speed has no effect on either the number of boxes loaded onto each railway car (which remain filled to capacity) or the shipping rate (see Fig. 30-7C). In this higher range of worker number, the shipping rate is no longer limited by the workers, but by the speed of the train or by the carrying capacity of the railway cars. Thus, we could say that the shipping rate is speed (perfusion) limited, although it would be equally true to say that it is carrying-capacity (Hb) limited.

Let us return again to the original condition in which worker number perfectly matches train speed. Increasing train speed while fixing worker number at the normal value causes railway cars to leave the siding partially empty (see Fig. 30-7D). However, shipping rate is unaffected because the normal number of boxes is simply distributed over a greater number of cars. Under these conditions, shipping rate is again worker (diffusion) limited because increasing the number of workers would proportionally increase shipping rate. In fact, whenever you see cars leaving the siding only partially filled, you can conclude that shipping rate is worker (diffusion) limited, regardless of whether this situation arose because of a decrease in worker number, an increase in train speed, or an increase in car carrying-capacity.

Finally, let us again return to the perfectly matched initial condition and now decrease train speed while holding worker number fixed at the normal value. As velocity decreases below normal, shipping rate decreases proportionally (see Fig. 30-7E), even though the railway cars leave the siding fully loaded. Thus, shipping rate is speed (perfusion) limited. It would be equally true to characterize the system as being limited by carrying capacity (Hb). In fact, whenever you see cars leaving the siding fully filled, you can conclude that shipping rate is speed (perfusion) limited, regardless of whether this situation arose because of an increase in worker number, a decrease in train speed, or a decrease in car carrying capacity.

The reader is now in a position to consider factors that could render CO transport predominantly *perfusion* limited or N₂O transport *diffusion* limited. Several changes to the system would cause CO transport to be no longer limited by DL_{CO} . **N30-6** Conversely, several other changes would cause the transport of N₂O to be no longer limited by \dot{Q} .

N30-6

Making CO Uptake Perfusion Limited or Making N₂O Uptake Diffusion Limited

Contributed by Emile Boulpaep, Walter Boron

After analyzing our railway car analogy, we are now in a position to consider factors that could—at least in principle—render the transport of CO predominantly *perfusion* limited, or that could—at least in

principle—render the transport of N_2O predominantly *diffusion* limited. Let us first consider CO uptake.

At least six changes to the system (eTable 30-1) could cause pulmonary capillary P_{CO} (P_{cCO}) to reach alveolar P_{CO} ($P_{A_{CO}}$) by the end of the capillary and thus cause CO transport no longer to be limited by DL_{CO} .

1. **Increase DL_{CO}** (i.e., increase the number of workers in the analogy of Fig. 30-7). This change would increase the flow of CO into the capillary for each diffusion event and thus increase both the rate at which the Hb would load up with CO and the rate at which free CO (proportional to P_{CO}) could accumulate in the capillary. Another way of increasing the flow of CO into the capillary would be to **increase P_{CO}** , which would increase the driving force for CO diffusion. Keep in mind that it is the product of P_{CO} and DL_{CO} that—according to Fick's law—determines diffusion.
2. **Decrease (or totally eliminate) Hb** (i.e., decrease the carrying capacity of each railway car). In the extreme, eliminating Hb would force all incoming CO to remain free in solution, so that free [CO] (i.e., P_{cCO}) would rapidly rise along the pulmonary capillary.
3. **Increase the CO content of mixed-venous blood** (partially preload railway cars with dummy boxes before the cars enter the dock area). By partially loading the Hb with CO before the blood even came into contact with the alveoli, we would reduce the amount of additional CO that could bind to Hb before the Hb-CO complex was in equilibrium with free CO. With fewer binding sites available for the CO diffusing in from the alveoli, the level of free CO would rise more rapidly. In the extreme, P_{cCO} would reach $P_{A_{CO}}$ by the end of the capillary.
4. **Decrease \dot{Q}** (decrease train speed). By increasing the contact time of capillary blood with the alveoli, we would allow each bolus of capillary blood to undergo more diffusion events as it moves a certain distance along the length of the capillary. Thus, for a given distance traveled along the capillary, the blood would take up more CO, more CO would bind to Hb, and more CO also would remain free—so that P_{cCO} would more closely approach $P_{A_{CO}}$.
5. **Lengthen the capillary** (increase the length of the loading dock, with a proportional increase in the number of workers). The effect of this maneuver is the same as for point 4 above in that it increases the contact time of the blood with the pulmonary capillary.
6. **Distend the capillary while keeping \dot{Q} constant** (decrease train speed). In this case, we would decrease the linear velocity of the blood, increasing the contact time with the capillary. The effect, however, would not be quite as dramatic as that in point 4 because the increase in diameter would decrease the surface-to-volume ratio so that each bolus of blood would be able to avail itself of a smaller surface area for diffusion. Keep in mind that linear velocity will decrease with the square of the radius, whereas surface area will increase only linearly with area.

At least four changes to the system would cause the transport of N_2O , normally perfusion limited, to become diffusion limited (eTable 30-2). In other words, capillary P_{N_2O} would fail to reach alveolar P_{N_2O} by the end of the pulmonary capillary.

1. The first is to greatly **decrease** DL_{N_2O} (i.e., decrease the number of workers). The result will be to slow diffusion. In the extreme, we could decrease the flow of N_2O so much that the N_2O fails to achieve equilibrium by the end of the capillary. Another way of decreasing the flow of N_2O into the capillary would be to **decrease** P_{N_2O} , which would decrease the driving force for N_2O diffusion. Keep in mind that it is the product of P_{N_2O} and DL_{N_2O} that—according to Fick's law—determines diffusion.
2. **Increase** \dot{Q} (increase train speed). An increase in \dot{Q} increases the linear velocity of the blood and thus decreases the time available for N_2O diffusion into a bolus of blood. If the increase in \dot{Q} is sufficiently large, then the amount of N_2O diffusing into the lumen will be so small that capillary P_{N_2O} will never reach alveolar P_{N_2O} . That is, the contact time will be insufficient for N_2O to achieve equilibrium.
3. **Shorten the capillary** (decrease the length of the loading dock). Like the increase in \dot{Q} , the decrease in capillary length will decrease the contact time for a bolus of blood with the pulmonary capillary.
4. **Decrease capillary diameter while keeping \dot{Q} constant** (increase train speed). This maneuver would increase the linear velocity of the blood, decreasing the contact time of a bolus of blood with the capillary. The effect might be even more dramatic than that in point 2 because the decrease in diameter would increase the surface-to-volume ratio so that each bolus of blood would be able to avail itself of a greater surface area for diffusion.

In case you are wondering why the N_2O analysis has two terms less than the CO analysis, one term is missing because N_2O does not interact with Hb (point 2 for CO), and a second term is missing because we cannot further decrease the mixed-venous N_2O content below zero (point 3 for CO).

eTABLE 30-1
Changes that Could Theoretically Make the Transport of a Diffusion-Limited Gas (CO) Become Perfusion Limited

Change*	Why Change Makes Transport Perfusion Limited
↑ D_L or ↑ PA_{CO} (↑ number of workers)	If CO could enter rapidly enough, it could load the Hb with CO and cause free [CO] to rise rapidly.
↓ [Hb] (↓ capacity of each car)	Because carrying capacity for CO is reduced, a given rate of CO transport causes the concentration of free CO to rise rapidly.
↑ \bar{C}_{vCO} (partially preload cars with dummy boxes)	If the Hb were sufficiently preloaded with CO, not much additional CO would need to enter to fully load the Hb.
↓ \dot{Q} (↓ train speed)	If the contact time of blood with alveolar air were sufficiently long, enough CO could enter to load the Hb, causing the concentration of free CO to rise rapidly.
↑ Capillary length (lengthen loading dock)	The contact time of blood with alveolar air would be increased, so that Hb would eventually become loaded, as described above.
↑ Capillary diameter at fixed \dot{Q} (↓ train speed)	As above, contact time would increase.

*Descriptions in parentheses refer to the railway car analogy in Figure 30-7.

eTABLE 30-2

Changes that Could Theoretically Make the Transport of a Perfusion-Limited Gas (N₂O) Become Diffusion Limited

Change*	Why Change Makes Transport Diffusion Limited
↓ D _L or ↓ P _A CO (↓ number of workers)	If N ₂ O entered slowly enough, P _C N ₂ O would fail to reach P _A N ₂ O by the end of the capillary.
↑ Q̇ (↑ train speed)	If the contact time of blood with alveolar air were sufficiently brief, not enough N ₂ O would enter the blood to cause P _C N ₂ O to reach P _A N ₂ O by the end of the capillary.
↓ Capillary length (shorten loading dock)	The contact time of blood with alveolar air would be decreased, so that N ₂ O would fail to reach diffusion equilibrium, as described above.
↓ Capillary diameter at constant Q̇ (↑ train speed)	As above, contact time would decrease.

*Descriptions in parentheses refer to the railway car analogy in Figure 30-7.

The uptake of CO provides an estimate of D_L

Because the **pulmonary diffusing capacity** plays such an important role in determining the partial-pressure profile of a gas along the pulmonary capillary, being able to measure D_L would be valuable. Moreover, an approach that is easily applicable to patients could be useful both as a diagnostic tool and as a means to follow the progression of diseases affecting D_L.

We have already observed (see [Equation 30-9](#)) that we can use Fick's law to compute the overall uptake of a gas if we summate many individual diffusion events for all pieces of alveolar wall and all times in the respiratory cycle:

All pieces
of alveolar
wall

Σ

(30-23)

All times
in respiratory
cycle

Σ

(D_Lgas · (P_Agas – P_cgas))

Overall V̇_{gas} =

If we could ignore spatial and temporal nonuniformities, then we could eliminate the two troublesome Σ symbols and compute an *overall* D_Lgas from the *overall* V̇_{gas}. We could accommodate modest spatial and temporal variations in P_Agas by computing an *average* alveolar partial pressure (P̄_Agas). Furthermore, if the partial-pressure profile of the gas along the capillary were linear, we could use an *average* capillary partial pressure (P̄_cgas) as well. If we could identify a gas for which these assumptions are reasonable, we could simplify [Equation 30-23](#) to an expression that is similar to the version of Fick's law with which we started this chapter (see [Equation 30-7](#)):

Overall V̇_{gas} = D_Lgas · (P̄_Agas – P̄_cgas)

(30-24)

Which gas could we use to estimate D_L ? We certainly do *not* want to use N_2O , whose uptake is *perfusion* limited. After all, \dot{V}_{N_2O} is more or less proportional to changes in \dot{Q} , but virtually insensitive to changes in D_L (see [Table 30-2](#)). Viewed differently, the driving pressure between alveolus and capillary ($P_{A_{N_2O}} - P_{c_{N_2O}}$) is high at the beginning of the capillary but soon falls to zero (see [Fig. 30-6B](#)). Thus, it would be very difficult to pick a reasonable value for the *average* capillary P_{N_2O} to insert into [Equation 30-24](#). However, CO is an excellent choice because its uptake is diffusion limited, so that changes in the parameter of interest (i.e., D_L) have nearly a proportionate effect on \dot{V}_{CO} . Viewed differently, the driving pressure between alveolus and capillary ($P_{A_{CO}} - P_{c_{CO}}$) is nearly ideal because it falls more or less linearly as blood courses down the pulmonary capillary (see [Fig. 30-5B](#)). Thus, we might solve [Equation 30-24](#) for DL_{CO} :

$$DL_{CO} = \frac{\dot{V}_{CO}}{(\bar{P}_{A_{CO}} - \bar{P}_{c_{CO}})} \quad (30-25)$$

Note that DL_{CO} and \dot{V}_{CO} are *average* values that reflect properties of all alveoli throughout both lungs at all times in the respiratory cycle. $\bar{P}_{A_{CO}}$ reflects minor changes during the respiratory cycle, as well as more substantial variations in $P_{A_{CO}}$ from alveolus to alveolus due to local differences in ventilation and perfusion (see [pp. 689–690](#)). Finally, $\bar{P}_{c_{CO}}$ reflects not only the small increase in $P_{c_{CO}}$ as blood flows down the capillary, but also any CO that may be present in the mixed-venous blood that enters the pulmonary capillary. For nonsmokers who live in a nonpolluted environment, $P_{\bar{v}_{CO}}$ is nearly zero, and thus we often can ignore $\bar{P}_{c_{CO}}$.

We will discuss two general methods for estimating DL_{CO} , the steady-state technique and the single-breath test. These tests, both using CO, are useful for estimation of pulmonary diffusing capacity in a clinical setting, even among very ill patients in the intensive care unit.

In the **steady-state technique** ([Fig. 30-8](#)), the subject breathes a low-CO air mixture (e.g., 0.1% to 0.2%) for approximately a dozen breaths to allow $P_{A_{CO}}$ to stabilize. Calculating DL_{CO} requires at least two measurements: \dot{V}_{CO} and $\bar{P}_{A_{CO}}$. We compute the rate of CO uptake from the difference between the amounts of CO in inspired air versus expired air over time. We can directly measure $\bar{P}_{A_{CO}}$ in an alveolar-air sample (see [pp. 676–677](#)). D_L is then $\dot{V}_{CO}/\bar{P}_{A_{CO}}$. If the subject happens to be a smoker or to live in a polluted environment, an accurate measurement of D_L requires a venous blood sample to estimate the $P_{\bar{v}_{CO}}$. In this case, we calculate D_L from the more complete expression in [Equation 30-25](#).

FIGURE 30-8 Steady-state method for estimating DL_{CO} .

In the **single-breath technique** (Fig. 30-9), the subject makes a maximal expiratory effort to residual volume (see p. 602) and then makes a maximal inspiration of air containing CO and holds the breath for 10 seconds. The inhaled air is a mixture of dilute CO (e.g., 0.3%) plus a gas such as helium, which has a low water solubility and thus a negligible transport across the blood-gas barrier (see Equation 30-5). We can use helium to compute the extent to which the inhaled CO/He mixture becomes diluted as it first enters the alveoli, and also to calculate the alveolar volume into which the CO/He mixture distributes (see p. 602). This information allows us to calculate two crucial parameters at the *beginning* of the breath-holding period: (1) P_{ACO} and (2) the amount of CO in the alveoli. During the 10 seconds of breath holding, some of the inhaled CO diffuses into the blood. The greater the DL_{CO} , the greater the diffusion of CO, and the more P_{ACO} falls. As the subject exhales, we obtain a sample of alveolar air and use it to determine two crucial parameters at the *end* of the breath-holding period: (1) P_{ACO} and (2) the amount of CO in the alveoli. The initial and final P_{ACO} values allow us to compute \bar{P}_{ACO} . The initial and final alveolar CO amounts allow us to compute \dot{V}_{CO} during the 10-second breath-holding period.

FIGURE 30-9 Single-breath method for estimating DL_{CO} .

Bear in mind that the value of DL_{CO} determined by use of either of these methods is an *average* pulmonary diffusing capacity. As discussed in [Chapter 31](#), pulmonary disease can cause ventilation to become nonuniform, making it difficult to obtain alveolar-air samples that are representative of the entire lung. **N30-7** A normal value for DL_{CO} is ~ 25 mL CO taken up per minute for each millimeter of mercury of partial pressure driving CO diffusion and for each milliliter of blood having a normal Hb content. This value of DL_{CO} depends not only on D_M (i.e., the “membrane” or truly diffusive component of D_L) in [Equation 30-15](#) but also on $\theta \cdot V_c$. For CO transport, D_M and $\theta \cdot V_c$ are each ~ 50 mL CO/(min \cdot mL blood):

N30-7

Effect of Nonuniformity of Ventilation on Alveolar-Air Samples

Contributed by Emile Boulpaep, Walter Boron

In [Chapter 31](#), we will introduce the **single-breath N_2 -washout technique** and Fowler method for measuring anatomical dead space (see pp. 676–677). In this approach, the subject inhales one breath of 100% O_2 , and we assume that the inspired 100% O_2 distributes evenly throughout all the alveoli of the lungs. If ventilation is indeed uniform, the inspired O_2 dilutes alveolar N_2 uniformly in all regions of the lung. Thus, when the subject exhales, the air emerging from the alveolar air spaces should have a uniform $[N_2]$, and the plateau of the single-breath N_2 washout should be flat, as shown by the part of the red curve in [Figure 31-2C](#) labeled “Pure alveolar air.”

However, if the alveoli are unevenly ventilated, the inhaled 100% O_2 will not distribute uniformly

throughout the lungs and therefore will not uniformly dilute the pre-existing alveolar N₂. Regions of the lung that are relatively *hypoventilated* will receive relatively less 100% O₂ during the single inspiration, so that they will be relatively poor in O₂ but rich in N₂. Conversely, hyperventilated regions will receive relatively more of the inhaled 100% O₂ and hence will be O₂ rich and N₂ poor. During the expiration, we no longer observe a plateau for [N₂]. Why? After exhalation of the anatomical dead space, the first alveolar air out of the lungs is dominated by the O₂-rich/N₂-*poor* gas coming from the relatively *hyperventilated* airways—which inflate and deflate relatively quickly. As the expiration continues, the alveolar air gradually becomes dominated more and more by the O₂-poor/N₂-*rich* gas from the *hypoventilated* airways, which inflate and deflate relatively slowly. Because of this shift from hyperventilated to hypoventilated regions, the [N₂] gradually creeps upward—that is, there is no clear plateau—in subjects with a sufficiently high nonuniformity of ventilation.

$$\frac{1}{D_L} = \frac{1}{50} + \frac{1}{50} = \frac{1}{25}$$

(30-26)

Thus, 1/(θ · V_c) makes a major contribution to the final DL_{CO}. Because V_c is proportional to the Hb content of the blood, and because Hb content is decreased in **anemia**, a subject can have a reduced DL_{CO} even though the diffusion pathways in the lung (i.e., D_M) are perfectly normal. Recall that 1/(θ · V_c) makes an insignificant contribution to the D_L for O₂. Nevertheless, it is the D_L for CO—and not that for O₂—that one uses for a clinical index of diffusing capacity. [Table 30-3](#) summarizes several factors that can affect the calculated DL_{CO}.

TABLE 30-3
Factors that Affect the Diffusing Capacity for CO

FACTOR	EFFECT	EXPLANATION
Body size	↑ Size → ↑ DL _{CO}	With ↑ in lung size, diffusion area (A) and volume of pulmonary-capillary blood (V _c) both ↑.
Age	↑ Age → ↓ DL _{CO}	DL _{CO} decreases by ~2% per year after age 20.
Sex	Male → ↑ DL _{CO}	Corrected for age and body size, DL _{CO} is about 10% greater in men than women.
Lung volume	↑ Volume → ↑ DL _{CO}	In an individual, ↑ in lung volume causes an ↑ in volume of pulmonary-capillary blood (V _c), an ↑ in diffusion area (A), and a ↓ in diffusion distance (a).
Exercise	Exercise → ↑ DL _{CO}	An ↑ in \dot{Q} causes dilation of pulmonary capillaries, which in turn causes an ↑ in area for diffusion (A) and volume of pulmonary-capillary blood (V _c).
Body position	DL _{CO} : supine > sitting > standing	Changes in posture presumably ↑ volume of pulmonary-capillary blood (V _c).
PA _{O2}	↑ PA _{O2} → ↓ D _{LCO}	O ₂ lowers the rate at which CO combines with Hb.
PA _{CO2}	↑ PA _{CO2} → ↑ D _{LCO}	CO ₂ causes an ↑ in volume of pulmonary-capillary blood (V _c).  N30-10

DL_{CO}, diffusion capacity of CO; ^{PA_{CO2}}, partial pressure of CO₂ in alveolar air; ^{PA_{O2}} partial pressure of O₂ in alveolar air; \dot{Q} , cardiac output.

N30-10

Effect of CO₂ on the Diffusing Capacity

Contributed by Emile Boulpaep, Walter Boron

An increase in arterial P_{CO_2} causes an increase in pulmonary-capillary blood (V_c) and thus an increase in the $(\theta \cdot V_c)$ term of D_L :

$$\frac{1}{D_L} = \frac{1}{D_M} + \frac{1}{\theta \cdot V_c}$$

The preceding equation is a repetition of Equation 30-15. We will see in Chapter 31 that a high P_{CO_2} causes pulmonary vasoconstriction (see p. 687). Evidently, the predominant effect of increasing P_{CO_2} (e.g., caused by breathing CO_2) is to constrict pulmonary venules more than arterioles, thereby distending the pulmonary capillaries and thus increasing V_c . Note that according to this scenario, CO_2 has no effect on D_M (i.e., it has no direct effect on diffusion per se).

For both O_2 and CO_2 , transport is normally perfusion limited

Uptake of O_2

Blood enters the pulmonary capillaries (Fig. 30-10A) with the P_{O_2} of mixed-venous blood, typically 40 mm Hg. Capillary P_{O_2} reaches the alveolar P_{O_2} of ~100 mm Hg about one third of the way along the capillary (see Fig. 30-10B, black curve). This P_{O_2} profile along the pulmonary capillary is intermediate between that of CO in Figure 30-5B (where CO fails to reach diffusion equilibrium) and N_2O in Figure 30-6B (where N_2O reaches diffusion equilibrium ~10% of the way along the capillary). The transport of O_2 is similar to that of CO in that both molecules bind to Hb. Why, then, does O_2 reach **diffusion equilibrium**, whereas CO does not?

A O₂ DIFFUSION

B AT REST

C EXERCISE

D HIGH ALTITUDE

FIGURE 30-10 Diffusion of O_2 . In **A**, as the RBC enters the capillary, O_2 occupies three of the four sites on Hb. In **B** through **D**, P_{AO_2} is alveolar P_{O_2} . In **B** and **D**, \dot{Q} is constant.

The uptake of O_2 differs from that of CO in three important respects. First, Hb that enters the pulmonary capillary is already heavily preloaded with O_2 . Because Hb in the mixed-venous blood is ~75% saturated with O_2 (see p. 650)—versus ~0% for CO—the available O_2 -binding capacity of Hb is relatively low. Second, because the alveolar P_{O_2} is rather high (i.e., ~100 mm Hg)—versus <1 mm Hg for CO—the alveolar-blood P_{O_2} gradient is large (i.e., ~60 mm Hg) and the initial rate of O_2 diffusion from the alveolus into pulmonary-capillary blood is immense. Third, D_L for O_2 is higher than that for CO, owing to a greater $\theta \cdot V_c$. As a result of these three factors, Hb in pulmonary-capillary blood rapidly approaches its equilibrium carrying capacity for O_2 along the first third of the capillary. Because capillary P_{O_2} reaches alveolar P_{O_2} , O_2 transport is **perfusion limited**, as is the case for N_2O . Because O_2 normally reaches diffusion equilibrium so soon along the capillary, the lung has a tremendous **D_L reserve** for O_2 uptake. **N30-8** Even if we reduce D_{LO_2} by half, O_2 still reaches diffusion equilibrium about two thirds of the way along the capillary (see Fig. 30-10B, blue curve). If we could double D_{LO_2} , O_2 would reach diffusion equilibrium much earlier than usual (see Fig. 30-10B, red curve). However, neither change in D_{LO_2} would affect O_2 uptake, which is *not* diffusion limited.

N30-8

Capillary Reserve in Renal Glomerulus

Contributed by Emile Boulpaep, Walter Boron

The D_L reserve for O_2 along the pulmonary capillaries is reminiscent of the filtration reserve that exists along the capillaries of the glomerulus in the kidney (see pp. 745–746). In both cases, the system is able to accommodate a substantial increase in blood flow before saturating.

The D_L reserve for O_2 uptake is extremely important during **exercise**, when cardiac output can increase by up to a factor of 5 (see p. 410), a change that substantially decreases the contact time of the blood with the pulmonary capillaries. The contact time appears not to decrease by more than a factor of ~3, probably because the slightly increased pressure recruits and distends the pulmonary vessels (see p. 687). As a result, even with vigorous exercise, P_{CO_2} reaches virtual equilibrium with the alveolar air by the end of the capillary (see Fig. 30-10C, green curve)—except in some elite athletes. **N30-9** Thus, the increase in \dot{Q} during exercise leads to a corresponding increase in \dot{V}_{O_2} , which carries obvious survival benefits. In patients with pulmonary disease, thickening of the alveolar blood-gas barrier can reduce D_{LO_2} sufficiently that equilibration of P_{O_2} fails to occur by capillary's end during exercise (see Fig. 30-10C, brown curve). In this case, O_2 transport becomes diffusion limited.

N30-9

Exercise-Induced Arterial Hypoxemia in Females

Contributed by Emile Boulpaep, Walter Boron

In elite male athletes—and thoroughbred race horses, which are bred to have an impressive cardiac output—maximal aerobic exercise may lead to **arterial hypoxemia**—a fall in the P_{O_2} of arterial blood. The reason for this hypoxemia is believed to be a cardiac output that outstrips the lung's diffusion reserve, leading to a failure to reach diffusion equilibrium in the pulmonary capillaries (i.e., diffusion-limited O_2 transport). Note that in most men—those with normal levels of maximal cardiac output—maximum exercise does not lead to arterial hypoxemia. Instead, the exercise-induced increase in ventilation maintains a near-normal arterial P_{O_2} and usually a lower-than-normal arterial P_{CO_2} .

In women, however, it is common for exercise to lead to arterial hypoxemia. This effect does not correlate with level of physical fitness but appears to be constitutional, possibly reflecting an exercise-induced increase in ventilation-perfusion mismatch.

Reference

Harms CA, McClaran SR, Nickele GA, et al. Exercise-induced arterial hypoxaemia in healthy young women. *J Physiol*. 1998;507:619–628.

Like exercise, **high altitude** stretches out the P_{O_2} profile along the capillary (see Fig. 30-10D, red curve). The reasons are two, both of which stem from the low barometric pressure at altitude, which leads to a proportional decrease in ambient P_{O_2} (see p. 1230) and thus to a fall in alveolar P_{O_2} . First, the low $P_{A_{O_2}}$ causes the alveolar-capillary P_{O_2} gradient at the beginning of the capillary to fall, reducing the absolute O_2 transport rate. It is true that continued O_2 extraction by the systemic tissues causes P_{O_2} to fall as well in the mixed-venous blood that enters the pulmonary capillaries. However, at altitude, the difference driving O_2 uptake, $P_{A_{O_2}} - P_{\bar{V}_{O_2}}$, is still smaller than normal. Second, because at altitude $P_{\bar{V}_{O_2}}$ is lower, we now operate on a steeper part of the Hb- O_2 dissociation curve (see Fig. 29-3). Thus, a given increment in the O_2 content of the pulmonary-capillary blood occurs with a smaller increase in P_{O_2} .

The combination of exercise and high altitude can cause O_2 transport to become diffusion limited even in healthy individuals (see Fig. 30-10D, green curve). If the subject also has a pathological condition that lowers DL_{O_2} , then transport may become diffusion limited even more readily at altitude. Obviously, any combination of exercise, high altitude, and reduced DL_{O_2} compounds the problems for O_2 transport.

Escape of CO_2

Mixed-venous blood entering the pulmonary capillary has a P_{CO_2} of ~46 mm Hg, whereas the alveolar P_{CO_2} is ~40 mm Hg (Fig. 30-11A). Thus, CO_2 diffuses in the opposite direction of O_2 —from blood to alveolus—and P_{CO_2} falls along the pulmonary capillary (see Fig. 30-11B, black curve), eventually reaching **diffusion equilibrium**. Compared with O_2 , one factor that tends to speed CO_2 equilibration is that the D_L for CO_2 is 3-fold to 5-fold greater than that for O_2 (see p. 664). However, two factors tend to slow the

equilibration of CO_2 . First, the initial P_{CO_2} gradient across the blood-gas barrier is only ~ 6 mm Hg at the beginning of the capillary, $\sim 10\%$ as large as the initial P_{O_2} gradient. Second, in their physiological ranges, the CO_2 -dissociation curve (see Fig. 29-10) is far steeper than the Hb- O_2 dissociation curve (see Fig. 29-3). Thus, a decrement in the CO_2 content of the pulmonary-capillary blood causes a relatively small decrease in P_{CO_2} . Thus, a smaller gradient and a steeper dissociation curve counteract the larger D_L . Many authors believe that, as indicated by the black curve in Figure 30-11B, capillary P_{CO_2} reaches alveolar P_{CO_2} about one third of the way along the pulmonary capillary (as is the case for O_2). Others have suggested that CO_2 equilibration is slower, occurring just before the end of the pulmonary capillary. In either case, *CO_2 excretion is perfusion limited*. The decrease in D_L that occurs in certain lung diseases (see next section) or heavy exercise (see Fig. 30-11B, red and blue curves) may cause the transport of CO_2 to become diffusion limited.

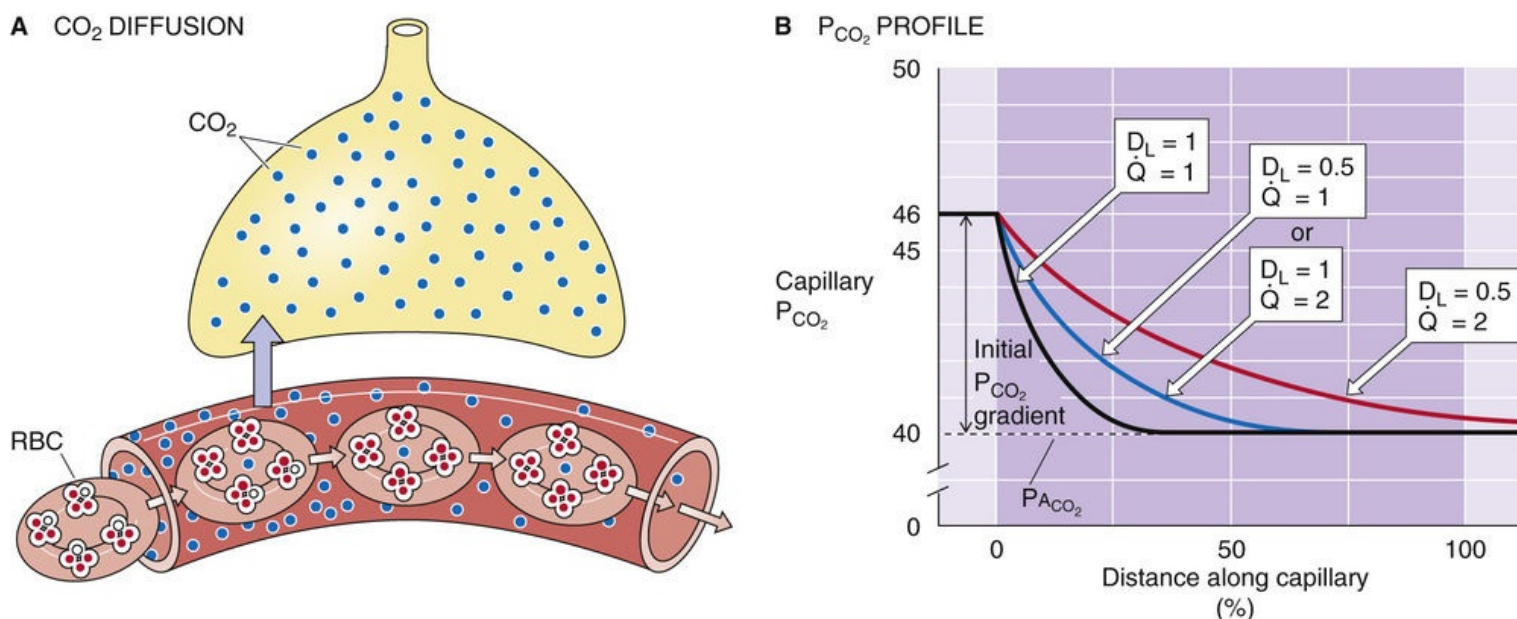

FIGURE 30-11 Diffusion of CO_2 . In B, $P_{\text{A}\text{CO}_2}$ is alveolar P_{CO_2} .

Pathological changes that reduce D_L do not necessarily produce hypoxia

The measured pulmonary diffusing capacity for CO falls in disease states accompanied by a thickening of the alveolar blood-gas barrier, a reduction in the surface area (i.e., capillaries) available for diffusion, or a decrease in the amount of Hb in the pulmonary capillaries. Examples of pathological processes accompanied by a decrease in D_L include the following:

Diffuse interstitial pulmonary fibrosis, a fibrotic process causing a thickening of the interstitium, thickening of alveolar walls, and destruction of capillaries—sometimes with marked decreases in D_L . In some cases, the cause is unknown (i.e., idiopathic); in others it is secondary to such disorders as sarcoidosis, scleroderma, and exposure to occupational agents (e.g., asbestos).

Chronic obstructive pulmonary disease (COPD), which not only increases the resistance of conducting airways (see [p. 597](#)) but can lead to a destruction of pulmonary capillaries and thus a reduction in both (1) surface area available for diffusion, and (2) total pulmonary-capillary Hb content (see [p. 619](#)).

Loss of functional lung tissue, as caused by surgical removal of lung tissue. D_L falls because of a decrease in both (1) surface area, and (2) total pulmonary-capillary Hb content.

Anemia, in which the fall in total Hb content decreases the $\theta \cdot V_c$ component of DL_{CO} .

Although pulmonary diseases can cause both a decrease in D_L and hypoxemia (i.e., a decrease in arterial P_{O_2}), it is not necessarily true that the decrease in D_L is the sole or even the major cause of the hypoxemia. The same diseases that lower D_L also upset the distribution of ventilation and perfusion throughout the lung. As discussed in [Chapter 31](#), mismatching of ventilation to perfusion among various regions of the lungs can be a powerful influence leading to hypoxemia. Furthermore, because the lung has a sizeable D_L reserve for O_2 (and perhaps for CO_2 as well), D_L would have to decrease to about one third of its normal value for O_2 transport to become diffusion limited. Thus, in a disease causing both a decrease in D_L and disturbances in the distribution of ventilation and perfusion, it is difficult to determine the extent to which an accompanying reduction of D_L is responsible for the resulting hypoxemia.

CHAPTER 31

Ventilation and Perfusion of the Lungs

Walter F. Boron

Although diffusion is at the very heart of the gas exchange, as we discussed in [Chapter 30](#), two other parameters are also extremely important. Ventilation and perfusion—both of which require energy—are critical because they set up the partial-pressure gradients along which O_2 and CO_2 diffuse. **Ventilation** is the convective movement of air that exchanges gases between the atmosphere and the alveoli. In [Chapter 27](#) we discussed the mechanics of ventilation. In the first part of the present chapter we consider the importance of ventilation for determining alveolar P_{O_2} and P_{CO_2} , and also see that ventilation varies from one group of alveoli to the next. **Perfusion** is the convective movement of blood that carries the dissolved gases to and from the lung. In [Chapters 17](#) through [25](#) we discussed the cardiovascular system. In the second part of the present chapter, we examine the special properties of the pulmonary circulation and see that, like ventilation, perfusion varies in different regions of the lung. Finally, in the third part of this chapter, we see that the ratio of ventilation to perfusion—and the distribution of ventilation-perfusion ratios among alveolar units—is critically important for gas exchange and thus for the composition of the arterial blood gases: P_{O_2} , P_{CO_2} , and pH.

Ventilation

About 30% of total ventilation in a respiratory cycle is wasted ventilating anatomical dead space (i.e., conducting airways)

Total ventilation (\dot{V}_T) is the volume of air moved out of the lungs per unit of time:

$$\dot{V}_T = \frac{V}{t}$$

(31-1)

Here V is the volume of air exiting the lungs during a *series of breaths*. Note that we are using \dot{V} differently than in [Chapter 27](#), where \dot{V} represented flow through an airway at a particular *instant* in time. A practical definition is that \dot{V}_T is the product of tidal volume (V_T or V_T) and the respiratory frequency (f). Thus, for someone with a tidal volume of 0.5 L, breathing 12 breaths/min,

$$\begin{aligned}\dot{V}_T &= V_T \cdot f \\ &= (0.5 \text{ L}) \cdot (12/\text{min}) \\ &= 6 \text{ L/min}\end{aligned}$$

(31-2)

Because total ventilation usually is reported in L/min, it is sometimes called **minute ventilation**.

Before an inspiration, the conducting airways are filled with “stale” air having the same composition as alveolar air ([Fig. 31-1](#), step 1); we will see why shortly. During inspiration, ~500 mL of “fresh” atmospheric air (high P_{O_2} /low P_{CO_2}) enters the body (step 2). However, only the first 350 mL reaches the alveoli; the final 150 mL remains in the conducting airways (i.e., nose, pharynx, larynx, trachea, and other airways without alveoli)—that is, the **anatomical dead space**. These figures are typical for a 70-kg person; V_T and V_D are roughly proportional to body size. During inspiration, ~500 mL of air also enters the alveoli. However, the first 150 mL is stale air previously in the conducting airways; only the final 350 mL is fresh air. By the end of inspiration, the 500 mL of air that entered the alveoli (150 mL of stale air plus 350 mL of fresh air) has mixed by diffusion with the pre-existing alveolar air (see [Fig. 31-1](#), step 3). During expiration (step 4), the first 150 mL of air emerging from the body is the fresh air left in the conducting airways from the previous inspiration. As the expiration continues, 350 mL of stale alveolar air sequentially moves into the conducting airways and then exits the body—for a total of 500 mL of air leaving the body. Simultaneously, 500 mL of air leaves the alveoli. The first 350 mL is the same 350 mL that exited the body. The final 150 mL of stale air to exit the alveoli remains in the conducting airways, as we are ready to begin the next inspiration.

FIGURE 31-1 Ventilation of dead space and alveolar space during a respiratory cycle.

Thus, with each 500-mL inspiration, only the *initial* 350 mL of fresh air entering the body reaches the alveoli. With each 500-mL expiration, only the *final* 350 mL of air exiting the body comes from the alveoli. One 150-mL bolus of *fresh air* shuttles back and forth between the atmosphere and conducting airways. Another 150-mL bolus of *stale air* shuttles back and forth between the conducting airways and alveoli. **Dead-space ventilation** (\dot{V}_D) is the volume of the stale air so shuttled per minute. **Alveolar ventilation** (\dot{V}_A) is the volume of fresh air per minute that actually reaches the alveoli, or the volume of stale alveolar air that reaches the atmosphere. **N31-1** Thus, total ventilation—a reflection of the work invested in breathing—is the sum of the wasted dead-space ventilation and the useful alveolar ventilation. In our example,

	liters	breaths	liters
	breath	minute	minute
$\dot{V}_D = V_D \cdot f$	$= 0.150 \cdot$	12	$= 1.8$
$\dot{V}_A = (V_T - V_D) \cdot f$	$= 0.350 \cdot$	12	$= 4.2$
$\dot{V}_T = V_T \cdot f$	$= 0.500 \cdot$	12	$= 6.0$

Inhaled Versus Exhaled Volume

Contributed by Emile Boulpaep, Walter Boron

The rate of O_2 consumption (e.g., 250 mL/min) is generally greater than the rate of CO_2 production (e.g., 200 mL/min) in individuals consuming a typical Western-pattern diet. That is, the **respiratory quotient**

(RQ) is generally less than unity (see p. 681). As a result, every minute we inhale slightly more air than we exhale (e.g., 250 mL/min – 200 mL/min = 50 mL/min). Because of this difference, in reporting ventilatory volumes, respiratory physiologists have standardized on the **volume of exhaled air (V_E)**, which as we have noted is slightly smaller than the **volume of inhaled air (V_I)**.

so that the dead-space ventilation is 30% of the total ventilation.

The inset of [Figure 31-1](#) illustrates how inspiration and expiration lead to small fluctuations in the alveolar partial pressures for O_2 and CO_2 , noted above in [Figure 30-3B](#). Throughout the respiratory cycle, blood flowing through the pulmonary capillaries continuously draws O_2 out of the alveolar air and adds CO_2 . Just before an inspiration, alveolar P_{O_2} has fallen to its lowest point, and alveolar P_{CO_2} has risen to its highest. During inspiration, a new bolus of inspired fresh air mixes with pre-existing alveolar air, which causes alveolar P_{O_2} to rise and alveolar P_{CO_2} to fall. During expiration and until the next inspiration, alveolar P_{O_2} and P_{CO_2} gradually drift to the values that we saw at the start of the respiratory cycle. Assuming that functional residual capacity (FRC) is 3 L and that each breath adds 350 mL of fresh air, one can calculate that alveolar P_{O_2} oscillates with an amplitude of ~5 mm Hg, whereas alveolar P_{CO_2} oscillates with an amplitude of ~4 mm Hg. [N31-2](#)

N31-2

Oscillations in P_{O_2} and P_{CO_2} During Breathing

Contributed by Emile Boulpaep, Walter Boron

We will assume that the volume of alveolar air after a quiet expiration is 3000 mL (the FRC), and that this air has a P_{O_2} of 98.4 mm Hg—the nadir of P_{O_2} during our hypothetical respiratory cycle. The subsequent inspiration delivers to the alveoli 350 mL of fresh air (at 500 mL tidal volume less 150 mL of anatomical dead space) that has a P_{O_2} of 149 mm Hg. Thus, after the 350 mL of fresh air mixes with the 3000 mL of pre-existing alveolar air, the alveolar P_{O_2} will be

$$P_{AO_2} = \frac{(3000 \times 98.4) + (350 \times 149)}{(3000 + 350)} = 103.6 \text{ mm Hg}$$

(NE 31-1)

This value is the zenith of P_{O_2} during our hypothetical respiratory cycle. During the ensuing several seconds, the alveolar P_{O_2} drifts back down to 98.4 mm Hg as O_2 diffuses from the alveolar air into the pulmonary-capillary blood. Thus, during a respiratory cycle, alveolar P_{O_2} oscillates from a low of 98.4 mm Hg to a high of 103.6 mm Hg, with a mean P_{O_2} of 101 mm Hg. In other words, alveolar P_{O_2} oscillates around a mean of 101 mm Hg, with the peak and nadir deviating from the mean by ~2.6 mm Hg—an amplitude of ~5 mm Hg.

In the case of CO_2 , the analysis is similar. After a quiet expiration, the 3000 mL of alveolar air has a P_{CO_2} of 42.2 mm Hg—the zenith of P_{CO_2} during our hypothetical respiratory cycle. The subsequent

inspiration delivers to the alveoli 350 mL of fresh air, which has a P_{CO_2} of ~0 mm Hg. Thus, after the 350 mL of fresh air mixes with the 3000 mL of pre-existing alveolar air, the alveolar P_{CO_2} will be

$$P_{\text{ACO}_2} = \frac{(3000 \times 42.2) + (350 \times 0)}{(3000 + 350)} = 37.8 \text{ mm Hg}$$

(NE 31-2)

This value is the nadir of P_{CO_2} during our hypothetical respiratory cycle. During the ensuing several seconds, the alveolar P_{CO_2} drifts back up to 42.2 mm Hg as CO_2 diffuses from the pulmonary-capillary blood to the alveolar air. Thus, during a respiratory cycle, alveolar P_{CO_2} oscillates from a high of 42.2 mm Hg to a low of 37.8 mm Hg, with a mean P_{CO_2} of 40 mm Hg. In other words, alveolar P_{CO_2} oscillates around a mean of 40 mm Hg, with the peak and nadir deviating from the mean by ~2.2 mm Hg—an amplitude of ~4 mm Hg.

The Fowler single-breath N_2 -washout technique estimates anatomical dead space

In 1948, Ward Fowler introduced an approach for estimating the anatomical dead space, based on the washout of N_2 from the lungs. The key concept is that N_2 is physiologically inert. After the subject has been breathing room air, the alveolar air is ~75% N_2 . After a quiet expiration, when lung volume is FRC (Fig. 31-2A, step 1), the subject takes a single normal-sized breath (~500 mL). The inspired air is 100% O_2 , although, in principle we could use any nontoxic gas mixture lacking N_2 . The *first portion* of inspired O_2 enters the alveolar spaces (step 2), where it rapidly mixes by diffusion and dilutes the N_2 and other gases remaining after the previous breaths of room air (step 3). The *last portion* of the inspired O_2 (~150 mL) remains in the conducting airways, which have a P_{N_2} of zero.

A DILUTION OF INSPIRED 100% O₂

B [N₂] PROFILE OF EXPIRED AIR WITH NO MIXING

C MEASURED [N₂] PROFILE

FIGURE 31-2 Fowler technique for measuring anatomical dead space.

The subject now exhales ~500 mL of air (see Fig. 31-2A, step 4). If no mixing occurred between the N₂-free air in the most distal conducting airways and the N₂-containing air in the most proximal alveolar spaces, then the first ~150 mL of air emerging from the body would have an [N₂] of zero (see Fig. 31-2B, red lines). After this would come a sharp transition to a much higher [N₂] for the final ~350 mL of expired air. Thus, the expired volume with an [N₂] of zero would represent air from the conducting airways (anatomical dead space), whereas the remainder would represent air from the alveoli.

In reality, some mixing occurs between the air in the conducting airways and alveoli, so that the transition is S-shaped (see Fig. 31-2C, red curve). A vertical line drawn through the S-shaped curve so that area *a* is the same as area *b* marks the idealized transition between air from conducting and alveolar airways—as in Figure 31-2B. The expired lung volume at the point of this vertical line is thus the anatomical dead space. In Figure 31-2C, the part of the S-shaped curve with an expired [N₂] of zero represents pure dead-space air, the part where [N₂] gradually rises represents a mixture of dead-space and alveolar air, and the part where [N₂] is high and flat represents pure alveolar air. This plateau is important, because it is during this plateau that one obtains an **alveolar gas sample**.

N31-3

Shape of the Single-Breath N₂-Washout Curve

Contributed by Emile Boulpaep, Walter Boron

Exhaling vigorously causes turbulence (see p. 617) in the larger airways, further blurring the boundary

between dead space and alveolar air. The greater the mixing, the more spread out is the S-shaped transition in Figure 31-2C.

Breath holding not only blurs the boundary (because more time is available for diffusional mixing of N_2 in the alveolar spaces with the O_2 in the dead space) but also moves the boundary to the left. In fact, if you were to hold your breath infinitely long, all the O_2 in your conducting airways would be contaminated with N_2 . As a result, the N_2 profile in Figure 31-2B or C would be a low, stable value from the very first milliliter of exhaled air. That is, there would be no gray area, and it would appear—according to the Fowler technique—as if you did not have any dead space.

Inhaling a large tidal volume of 100% O_2 increases the apparent anatomical dead space as measured by the Fowler technique. The reason is that the conducting airways have a finite compliance (see p. 610)—lower than the compliance of alveoli, but still greater than zero. Thus, with a large inhalation (and thus a rather negative intrapleural pressure), the conducting airways dilate somewhat, and this dilation is reflected in a larger-than-normal value for anatomical dead space.

N31-4

Obtaining a Sample of Alveolar Air

Contributed by Emile Boulpaep, Walter Boron

How do we obtain the alveolar air sample? As noted in our discussion of the Fowler single-breath N_2 -washout technique on pages 676–677, we ask the subject to make a prolonged expiratory effort. We discard the first several hundred milliliters of expired air—which contains pure dead-space air, a mixture of dead-space and alveolar air, and some pure alveolar air—to be certain that we do not contaminate our sample with air from the conducting airways. We then collect the **end-tidal** sample of air—pure alveolar air—and assay it for P_{CO_2} .

The Bohr expired-[CO_2] approach estimates physiological dead space

In principle, we could compute the dead space using *any* gas whose expiration profile looks like that of N_2 . Nitrogen is useful because we can easily create an artificial situation in which the subject makes a single inhalation of N_2 -free air (e.g., a single breath of 100% O_2). Another possibility is CO_2 . Its profile during expiration is similar to that of N_2 . Moreover, we do not need to use any special tricks to get it to work because room air has practically no CO_2 . Yet plenty of CO_2 is in the alveoli, where it evolves from the incoming mixed-venous blood. After a quiet expiration (Fig. 31-3A, step 1), the P_{CO_2} of the alveolar air is virtually the same as the P_{CO_2} of the arterial blood (see p. 673), ~40 mm Hg. The subject now inhales a normal tidal volume (~500 mL) of room air, although any CO_2 -free gas mixture would do. The first portion enters the alveoli (step 2), where it rapidly dilutes the CO_2 and other gases remaining after the previous breath (step 3). The rest (~150 mL) remains in the conducting airways, which now have a P_{CO_2} of ~0. When the subject now expires (step 4), the first air that exits the body is the CO_2 -free gas that had filled the conducting airways, followed by the CO_2 -containing alveolar air. Thus, the idealized profile of expired [CO_2] (see Fig. 31-3B, red lines) is similar to the idealized [N_2] profile (see Fig. 31-

2B). In particular, the volume of expired air at the vertical line in Figure 31-3B is the estimated *anatomical* dead space.

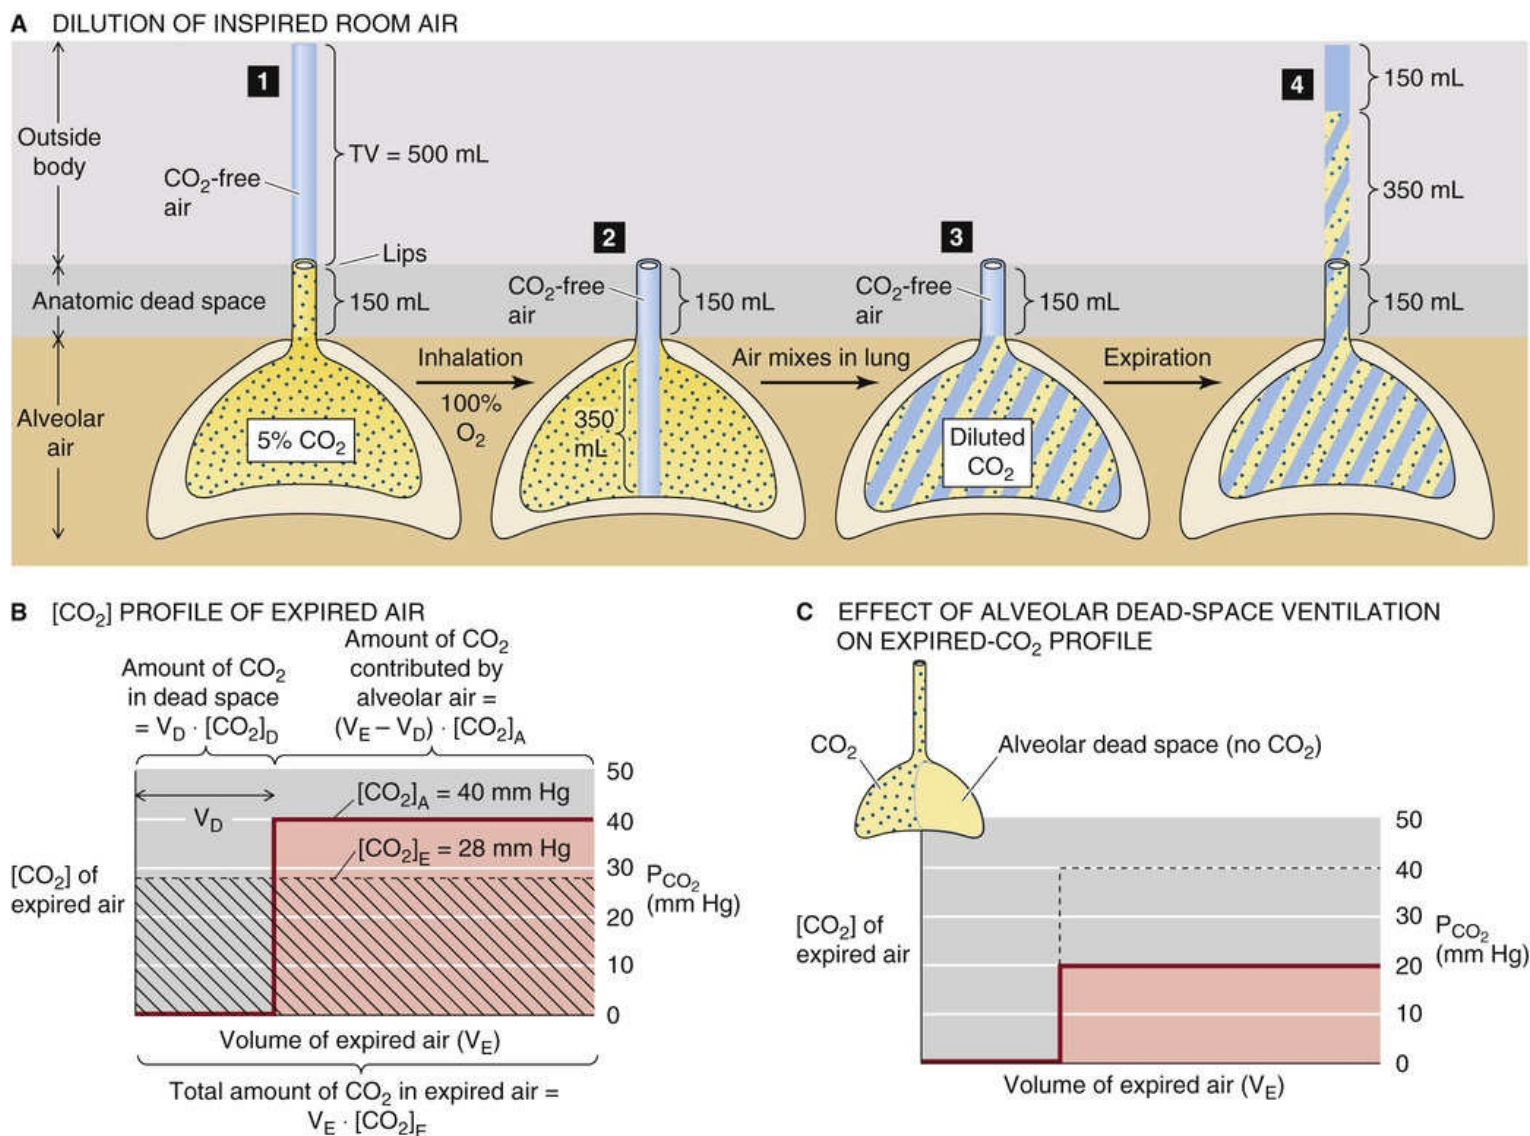

FIGURE 31-3 Bohr method for measuring physiological dead space.

One could use a CO₂ probe to record the expired [CO₂] profile during a single-breath CO₂ washout, rather than the [N₂] profile that Fowler used to measure anatomical dead space. However, because CO₂ probes did not exist in his day, Christian Bohr [N31-5](#) used a single-breath CO₂ washout but analyzed the *average* P_{CO_2} in the *mixed*-expired air (i.e., averaged over the dead space plus expired alveolar air).

N31-5

Christian Bohr

Contributed by Walter Boron

Christian Bohr (1855–1911), a native of Copenhagen, was an eminent physiologist and also the father of the physicist Niels Bohr. The major contributions of Christian Bohr were the first description of **dead space** (specifically the *physiological* dead space) and the description of the **Bohr effect**. Christian Bohr

was a proponent of the hypothesis that the lung actively secretes O_2 into the pulmonary-capillary blood. His trainee, future Nobelist August Krogh,  **N31-21** later disproved this hypothesis.

N31-21

August Krogh

For more information about Schack August Steenberg Krogh (1874–1949) and the work that led to his Nobel Prize, visit http://www.nobelprize.org/nobel_prizes/medicine/laureates/1920/ (accessed January 2015).

The principle of the Bohr approach is that the amount of CO_2 present in the volume of mixed-expired air (V_E) is the sum of the CO_2 contributed by the volume of air from the dead space (V_D) plus the CO_2 contributed by the volume of air coming from the *alveoli* ($V_E - V_D$). As summarized in [Figure 31-3B](#):

1. The amount of CO_2 coming from the **dead space** is the product of V_D and $[CO_2]$ in this dead-space air. Because $[CO_2]_D$ is zero, the area beneath V_D is also zero.
2. The amount of CO_2 coming from **alveolar air** is the product of $(V_E - V_D)$ and alveolar $[CO_2]$ and is represented by the rose area in [Figure 31-3B](#).
3. The total amount of CO_2 in the **mixed-expired air** is the product of V_E and the average $[CO_2]$ in this air and is represented by the hatched area in [Figure 31-3B](#).

Because the rose and hatched areas in [Figure 31-3B](#) must be equal, and because the alveolar and expired $[CO_2]$ values are proportional to their respective P_{CO_2} values, it is possible to show that  **N31-6**

$$\frac{V_D}{V_E} = \frac{P_{ACO_2} - P_{ECO_2}}{P_{ACO_2}}$$

(31-4)

This is the **Bohr equation**. Typically, V_D/V_E ranges between 0.20 and 0.35. For a V_D of 150 mL and a V_E of 500 mL, V_D/V_E would be 0.30. For example, if the alveolar P_{CO_2} is 40 mm Hg and the mixed-expired P_{CO_2} is 28 mm Hg, then

$$\frac{V_D}{V_E} = \frac{40 - 28}{40} = 30\%$$

(31-5)

[Equation 31-4](#) makes good intuitive sense. In an imaginary case in which we reduced V_D to zero, the expired air would be entirely from the alveoli, so that

$$\frac{V_D}{V_E} = \frac{40 - 40}{40} = 0\%$$

(31-6)

On the other hand, if we reduced the tidal volume to a value at or below the dead-space volume, then *all* of the expired air would be dead-space air. In this case, $P_{E\text{CO}_2}$ would be zero, and

$$\frac{V_D}{V_E} = \frac{40 - 0}{40} = 100\%$$

(31-7)

N31-6

The Bohr Equation

Contributed by Emile Boulpaep, Walter Boron

The principle of the Bohr approach is that the CO_2 concentration of the *expired air* is the CO_2 concentration of the *alveolar air*—as diluted by the CO_2 in the dead space, which contains no CO_2 . Imagine that we have a volume of expired air (V_E). The total amount of CO_2 present in this expired air is the sum of the CO_2 contributed by the volume of air from the *dead space* (V_D) and the CO_2 contributed by the volume of air coming from the *alveoli* ($V_E - V_D$):

$$\left[\begin{array}{l} \text{Amount of } \text{CO}_2 \\ \text{in expired air} \end{array} \right] = \left[\begin{array}{l} \text{Amount of } \text{CO}_2 \\ \text{contributed by} \\ \text{conducting airways} \end{array} \right] + \left[\begin{array}{l} \text{Amount of } \text{CO}_2 \\ \text{contributed by} \\ \text{alveolar air} \end{array} \right]$$

(NE 31-3)

Knowing that the amount of the gas is simply the product of the volume and the concentration of the gas in that volume, we can write

$$V_E \times [\text{CO}_2]_E = V_D \times [\text{CO}_2]_D + (V_E - V_D) \times [\text{CO}_2]_A$$

(NE 31-4)

Note that the volume of air coming from the alveoli is *not* the *total* volume of alveolar air, which might be a couple of liters, but rather that *part* of the expired volume that came from the alveoli. For example, if the expired volume were 500 mL and the dead space were 150 mL, the air coming from the alveoli ($V_E - V_D$) would be 350 mL.

Because $[\text{CO}_2]_D$ is virtually zero, we can drop the “conducting airway” term from Equation NE 31-4.

In other words, the hatched area beneath the dashed line in Figure 31-3B is equal to the red area under the solid red line. The simplified version of Equation NE 31-4 is thus

$$V_E \times [\text{CO}_2]_E = (V_E - V_D) \times [\text{CO}_2]_A$$

(NE 31-5)

Furthermore, because the CO₂ concentration is proportional to the CO₂ partial pressure, and because the proportionality constant is the same for the expired air and the alveolar air,

$$V_E \times P_{E\text{CO}_2} = (V_E - V_D) \times P_{A\text{CO}_2}$$

(NE 31-6)

We can rearrange this equation and solve for the ratio V_D/V_E , which is the fraction of the expired volume that came from the dead space:

$$\frac{V_D}{V_E} = \frac{P_{A\text{CO}_2} - P_{E\text{CO}_2}}{P_{A\text{CO}_2}}$$

(NE 31-7)

This is the Bohr equation. Typically, V_D/V_E ranges between 0.20 and 0.35. For a V_D of 150 mL and a V_E of 500 mL, V_D/V_E would be 0.30. Because the partial pressure of CO₂ in the dead-space air is virtually zero, $P_{E\text{CO}_2}$ must be less than $P_{A\text{CO}_2}$. For example, imagine that the alveolar P_{CO_2} were 40 mm Hg and the average P_{CO_2} in the expired air were 28 mm Hg:

$$\frac{V_D}{V_E} = \frac{40-28}{40} = 30\%$$

(NE 31-8)

Equation NE 31-7 makes good intuitive sense. In an extreme hypothetical case in which we reduced V_D to zero, the expired air would be entirely from the alveoli, so that

$$\frac{V_D}{V_E} = \frac{40-40}{40} = 0\%$$

(NE 31-9)

On the other hand, if the tidal volume and the dead space were both 150 mL, then *all* of the expired air would be dead-space air. Thus, the $P_{E\text{CO}_2}$ would have to be zero, and

$$\frac{V_D}{V_E} = \frac{40-0}{40} = 100\%$$

(NE 31-10)

If the tidal volume were increased from 500 mL to 600 mL and V_D remained at 150 mL, the ratio V_D/V_E would fall from 0.30 to 0.25. With a greater V_E , the alveolar air would make a greater contribution to the mixed expired air, so that the mean expired P_{CO_2} would be 30 mm Hg (i.e., closer to P_{ACO_2}) instead of only 28 mm Hg. Thus, if you wish to compute V_D using the Bohr approach, it is best to use an expired volume that is larger than V_D , but not too much larger.

Two examples of this principle are of practical importance. During **panting**, the respiratory frequency is very high, but the tidal volume is only slightly greater than the anatomical dead space. Thus, most of the total ventilation is wasted as dead-space ventilation. If we reduced tidal volume below V_D , then in principle there would be no alveolar ventilation at all! During **snorkeling**, a swimmer breathes through a tube that increases V_D . If the snorkeling tube had a volume of 350 mL and the dead space within the body of the swimmer were 150 mL, then a tidal volume of 500 mL would in principle produce no alveolar ventilation. Consequently, the swimmer would suffocate, even though total ventilation was normal! Thus, the fractional dead space (V_D/V_E) depends critically on tidal volume.

It is important to recognize that although the Fowler and Bohr methods yield about the same estimate for V_D in healthy individuals, the two techniques actually measure somewhat different things. The Fowler approach measures **anatomical dead space**—the volume of the conducting airways from the mouth/nose up to the point where N_2 in the alveolar gas rapidly dilutes inspired 100% O_2 . The Bohr approach, on the other hand, measures the **physiological dead space**—the volume of airways *not* receiving CO_2 from the pulmonary circulation, and, therefore, *not* engaging in gas exchange. In a healthy person, the anatomical and physiological dead spaces are identical—the volume of the conducting airways. However, if some alveoli are ventilated but not perfused by pulmonary-capillary blood, these unperfused alveoli, like conducting airways, do not contain CO_2 . The air in such unperfused alveoli, known as **alveolar dead space**, contributes to the physiological dead space:

$$\underbrace{\text{Physiological dead space}}_{\text{Bohr method}} = \underbrace{\text{Anatomical dead space}}_{\text{Fowler method}} + \text{Alveolar dead space}$$

(31-8)

The Fowler and Bohr methods could yield very different results in a patient with a **pulmonary embolism**, a condition in which a mass such as a blood clot wedges into and obstructs part or all of the pulmonary circulation. Alveoli downstream from the embolus are ventilated but not perfused; that is, they are alveolar dead space (see Fig. 31-3C). Thus, the Bohr method—but not the Fowler method—could detect an increase in the physiological dead space caused by a pulmonary embolism.

Alveolar ventilation is the ratio of CO_2 production rate to CO_2 mole fraction in alveolar air

One way of computing alveolar ventilation is to subtract the dead space from the tidal volume and multiply the difference by the respiratory frequency (see [Equation 31-3](#)). We can also calculate \dot{V}_A from alveolar P_{CO_2} . The body produces CO_2 via oxidative metabolism at a rate of ~ 200 mL/min. In the steady state, this rate of CO_2 production (\dot{V}_{CO_2}) must equal the rate at which the CO_2 enters the alveoli, and the rate at which we exhale the CO_2 . Of course, this 200 mL/min of exhaled CO_2 is part of the ~ 4200 mL of total alveolar air that we exhale each minute. Therefore, the exhaled 200 mL of CO_2 is $\sim 5\%$ of the exhaled 4200 mL of alveolar air:

$$\frac{\text{Volume of } CO_2 \text{ leaving alveoli in 1 min}}{\text{Volume of air leaving alveoli in 1 min}} = \left(\text{Volume fraction of } CO_2 \text{ in alveolar air} \right) = (CO_2 \text{ mole fraction})_A$$

$$\frac{\dot{V}_{CO_2}}{\dot{V}_A} = \frac{200 \text{ mL}}{4200 \text{ mL}} = 5\%$$

(31-9)

Rearranging the foregoing equation and solving for \dot{V}_A yields

$$\dot{V}_A = \underbrace{\frac{\dot{V}_{CO_2}}{(CO_2 \text{ mole fraction})_A}}_{\text{(31-10)}} = k \frac{\dot{V}_{CO_2}}{P_{ACO_2}}$$

The equation above the brace is true only when we *measure all parameters under the same conditions*. This obvious point would hardly be worth noting if respiratory physiologists had not managed, by historical accident, to measure the two volume terms under different conditions:

1. Body temperature and pressure, saturated with water vapor (BTPS; see [p. 594](#)) for \dot{V}_A .
2. Standard temperature and pressure/dry (STPD; see [p. 594](#)) for \dot{V}_{CO_2} .

Thus, in [Equation 31-10](#) we introduce a constant k that not only indicates that alveolar P_{CO_2} (P_{ACO_2} ; measured at $37^\circ C$) is proportional to the mole fraction of CO_2 in alveolar air, but also accounts for the different conditions for measuring the parameters. [N31-7](#)

$$\dot{V}_A = 0.863 \cdot \frac{\dot{V}_{\text{CO}_2}}{P_{\text{A}\text{CO}_2}}$$

(L/min, BTPS) (mm Hg · L/mL) (mm Hg)

(mL/min, STPD)

N31-7

The Conversion Factor 0.863

Contributed by Emile Boulpaep, Walter Boron

Unfortunately for the student of respiratory physiology, the way customs have evolved for measuring respiratory volumes and partial pressures is a case study in mixed conventions. In a rational world, all parameters would be measured under a consistent set of conditions. In the real world of respiratory science, however, the parameters you (and clinicians) will need to compute alveolar ventilation, alveolar P_{CO_2} , and alveolar P_{O_2} are measured under at least three very different sets of conditions. As a result, the student is faced with “correction factors” such as 0.863. Our advice to the student, when working numerical problems, is to insert the laboratory data directly into the correct equation—which you ought to intuitively understand—and use the proper correction factor. You will get the right answer. Before explaining the origin of 0.863 in Equation 31-11, we will examine the system of units in which clinical laboratories report each of the three terms in that equation.

First, \dot{V}_A , the alveolar ventilation, is reported in the same units as \dot{V}_E (the rate at which air is expired from the lungs). If you collect all the warm, moist air that a subject exhales over a period of 1 minute, the laboratory will report that volume BTPS (body temperature and pressure, saturated with water vapor), precisely the same volume that the sample of expired air would have occupied in the warm, moist confines of the lung (see Box 26-3).

Second, \dot{V}_{CO_2} , the rate at which the body produces CO_2 , is measured at STPD (standard temperature and pressure/dry). Thus, if you collect a sample of warm, moist air expired over a period of 1 minute and give it to a clinical laboratory for analysis, the laboratory will report the \dot{V}_{CO_2} value as the volume that the dry CO_2 in the sample *would* occupy at 0°C . The rationale is that this is the way chemists treat gases.

Third, $P_{\text{A}\text{CO}_2}$, the partial pressure of CO_2 in the alveoli, is reported in BTPD (body temperature and pressure/dry). If you obtain a sample of alveolar air and send it to a clinical laboratory, it will take the warm, moist air you send it and keep it at 37°C but remove the H_2O . Of course, if the sample is in a rigid container and if P_B is 760 mm Hg, this removal of water vapor will lower the total pressure of the sample by 47 mm Hg (i.e., the vapor pressure of water at 37°C) to 713 mm Hg. To keep the pressure constant, the laboratory will allow the sample volume to decrease to a volume that is 713/760 of the original volume. This, however, means that the mole fraction of CO_2 increases by the fraction 760/713. Thus, the P_{CO_2} in the warm, moist alveolar air is actually *lower* than the reported BTPD; the BTPS value of $P_{\text{A}\text{CO}_2}$ is the reported value multiplied by (713/760) or ~ 0.983 . The real tragedy of the convention for reporting $P_{\text{A}\text{CO}_2}$ at BTPD is that the same laboratory will report arterial P_{CO_2} as BTPS.

In deriving the factor 0.863, we begin with a rearrangement of Equation 31-9, using a consistent set of units (i.e., BTPS):

$$\dot{V}_A(\text{BTPS}) = \frac{\dot{V}_{\text{CO}_2}(\text{BTPS})}{(\% \text{CO}_2 \text{ BTPS})_A}$$

(NE 31-11)

Because \dot{V}_{CO_2} is actually *reported* in STPD, our first task is to convert \dot{V}_{CO_2} (STPD) to \dot{V}_{CO_2} (BTPS). Because standard temperature is 0°C and body temperature is 37°C, we must multiply \dot{V}_{CO_2} (STPD) by the ratio of temperatures in degrees Kelvin, the factor $[(273 + 37)/273]$. Furthermore, as noted in the previous paragraph, when we add water vapor to a dry sample of a gas and then expand the volume to keep the total pressure fixed at P_B , the partial pressure of that gas will decrease to (713/760) of its dry partial pressure. Thus,

$$\dot{V}_A(\text{BTPS}) = \frac{\dot{V}_{\text{CO}_2}(\text{STPD}) \left(\frac{310}{273} \right) \left(\frac{713}{760} \right)}{(\% \text{CO}_2 \text{ BTPS})_A}$$

(NE 31-12)

Our final task is to replace $(\% \text{CO}_2 \text{ BTPS})_A$ with P_{ACO_2} (BTPD). Because $P_{\text{ACO}_2}(\text{BTPS}) = (\% \text{CO}_2 \text{ BTPS})_A \times P_B$,

$$(\% \text{CO}_2 \text{ BTPS}) = \frac{P_{\text{ACO}_2}(\text{BTPS})}{P_B}$$

(NE 31-13)

Because P_{ACO_2} is reported in BTPD, we must multiply it by the factor (713/760). Thus,

$$(\% \text{CO}_2 \text{ BTPS}) = \frac{P_{\text{ACO}_2}(\text{BTPD}) \left(\frac{713}{760} \right)}{760}$$

(NE 31-14)

Substituting the expression for $(\% \text{CO}_2 \text{ BTPS})_A$ in Equation NE 31-14 into Equation NE 31-12, we have

$$\begin{aligned}
 \dot{V}_A (\text{BTPS}) &= \frac{\dot{V}_{\text{CO}_2} (\text{STPD}) \left(\frac{310}{273} \right) \left(\frac{713}{760} \right)}{\left(\frac{P_{\text{A}_{\text{CO}_2}} (\text{BTPD}) \left(\frac{713}{760} \right)}{760} \right)} \\
 &= \frac{\dot{V}_{\text{CO}_2} (\text{STPD}) \left(\frac{310}{273} \right) (760)}{P_{\text{A}_{\text{CO}_2}} (\text{BTPD})} \\
 &= 863 \times \frac{\dot{V}_{\text{CO}_2} (\text{STPD})}{P_{\text{A}_{\text{CO}_2}} (\text{BTPD})}
 \end{aligned}$$

(NE 31-15)

In the above equation, both \dot{V}_A and \dot{V}_{CO_2} are reported in mL/min. Because it is customary to report \dot{V}_A in L/min, the factor 863 becomes 0.863:

L/min	mL/min
$\dot{V}_A (\text{BTPS})$	$\dot{V}_{\text{CO}_2} (\text{STPD})$

$$\dot{V}_A (\text{BTPS}) = 0.863 \times \frac{\dot{V}_{\text{CO}_2} (\text{STPD})}{P_{\text{A}_{\text{CO}_2}} (\text{BTPD})}$$

(NE 31-16)

The above is the alveolar ventilation equation.

For example, if \dot{V}_{CO_2} is 200 mL/min and $P_{\text{A}_{\text{CO}_2}}$ is 40 mm Hg, then

$$\dot{V}_A (\text{BTPS}) = 0.863 \times \frac{200 \text{ mL/min}}{40 \text{ mm Hg}} = 4.315 \text{ L/min}$$

(NE 31-17)

This is the **alveolar ventilation equation**, which we can use to compute \dot{V}_A . We determine \dot{V}_{CO_2} by collecting a known volume of expired air over a fixed time period and analyzing its CO_2 content. For a 70-kg human, \dot{V}_{CO_2} is ~200 mL/min. We can determine $P_{\text{A}_{\text{CO}_2}}$ by sampling the expired air at the end of an expiration—an alveolar gas sample (see pp. 676–677). **N31-4** This **end-tidal** P_{CO_2} (see Fig. 31-2C) is ~40 mm Hg. In practice, clinicians generally measure *arterial* P_{CO_2} ($P_{\text{a}_{\text{CO}_2}}$), and assume that alveolar and arterial P_{CO_2} are identical (see p. 673). Inserting these values into the alveolar ventilation equation, we have

$$\begin{aligned}
 \dot{V}_A &= 0.863 \cdot \frac{\dot{V}_{\text{CO}_2}}{P_{\text{A}_{\text{CO}_2}}} = 0.863 \cdot \frac{200 \text{ mL/min}}{40 \text{ mm Hg}} \\
 &= 4.315 \text{ L/min}
 \end{aligned}$$

(31-12)

For the sake of simplicity—and consistency with our example in [Equation 31-3](#)—we round this figure to 4.2 L/min.

Although it is usually safe to regard \dot{V}_{CO_2} as being constant for a person at rest, a clinical example in which \dot{V}_{CO_2} can increase markedly is **malignant hyperthermia** (see [Box 9-2](#)), which is associated with increased oxidative metabolism. One hallmark of this clinical catastrophe is that the increase in \dot{V}_{CO_2} leads to an increase in P_{ACO_2} even though \dot{V}_A is normal.

Alveolar and arterial P_{CO_2} are inversely proportional to alveolar ventilation

Viewing [Equation 31-11](#) from a different perspective illustrates one of the most important concepts in respiratory physiology: Other things being equal, alveolar P_{CO_2} is inversely proportional to alveolar ventilation. This conclusion makes intuitive sense because the greater the \dot{V}_A , the more the fresh, inspired air dilutes the alveolar CO_2 . Rearranging [Equation 31-11](#) yields

$$P_{\text{ACO}_2} = 0.863 \cdot \frac{\dot{V}_{\text{CO}_2}}{\dot{V}_A}$$

(31-13)

In other words, if CO_2 production is fixed, then doubling \dot{V}_A causes P_{ACO_2} to fall to half of its initial value. Conversely, halving \dot{V}_A causes P_{ACO_2} to double. Because, *arterial* P_{CO_2} is virtually the same as *alveolar* P_{CO_2} (see [p. 673](#)), changes in \dot{V}_A affect both P_{ACO_2} and P_{aCO_2} .

The blue curve in [Figure 31-4](#) helps illustrate the principle. Imagine that your tissues are producing 200 mL/min of CO_2 . In a steady state, your lungs must blow off 200 mL of CO_2 each minute. Also, imagine that your lungs are exhaling 4200 mL/min of alveolar air. Because the 200 mL of expired CO_2 must dissolve in the 4200 mL of exhaled alveolar air (center red point in [Fig. 31-4](#)), [Equation 31-13](#) tells us that your P_{ACO_2} (and thus P_{aCO_2}) must be ~40 mm Hg.

FIGURE 31-4 Dependence of alveolar CO_2 and O_2 on alveolar ventilation. As alveolar ventilation increases, alveolar P_{O_2} and P_{CO_2} approach their values in inspired air. At extremely low or high \dot{V}_A , where O_2 consumption and CO_2 production do not remain constant, these idealized curves are no longer valid.

What would happen if the excitement of reading about respiratory physiology caused your alveolar ventilation to double, to 8400 mL/min? This is an example of **hyperventilation**. You could double \dot{V}_A either by doubling respiratory frequency or by doubling the difference between tidal volume and dead space, or a combination of the two (see Equation 31-3). Immediately on doubling \dot{V}_A , you would be blowing off at twice the previous rate not only alveolar air (i.e., 8400 mL/min) but also CO_2 (i.e., 400 mL/min). Because your body would continue to produce only 200 mL/min of CO_2 —assuming that doubling \dot{V}_A does not increase \dot{V}_{CO_2} —you would initially blow off CO_2 faster than you made it, causing CO_2 levels throughout your body to fall. However, the falling P_{CO_2} of mixed-venous blood would cause alveolar P_{CO_2} to fall as well, and thus the rate at which you blow off CO_2 would gradually fall. Eventually, you would reach a new steady state in which the rate at which you blow off CO_2 would exactly match the rate at which you produce CO_2 (i.e., 200 mL/min).

When you reach a new steady state, the P_{CO_2} values in your mixed-venous blood, arterial blood, and alveolar air would be stable. But what would be the P_{ACO_2} ? Because each minute you now are blowing off 8400 mL of alveolar air (i.e., twice normal) but still only 200 mL of CO_2 (right red point in Fig. 31-4), your P_{ACO_2} must be half normal, or ~20 mm Hg. Not only does the hyperventilation cause alveolar P_{CO_2} to fall by half, it also causes arterial P_{CO_2} to fall by half. Thus, hyperventilation leads to **respiratory alkalosis** (see p. 634). This respiratory alkalosis causes the arterioles in the brain to constrict (see p. 559), reducing blood flow to the brain, which causes dizziness.

What would happen if, instead of doubling alveolar ventilation, you halved it from 4200 to 2100 mL/min? This is an example of **hypoventilation**. At the instant you began hypoventilating, the volume of CO₂ expired per unit time would fall by half, to 100 mL/min, even though CO₂ production by the tissues would remain at 200 mL/min. Thus, CO₂ would build up throughout the body, causing $P_{A\text{CO}_2}$ to rise. To what value would $P_{A\text{CO}_2}$ have to increase before you would reach a new steady state? Because each minute you must exhale 200 mL of CO₂ but this can be diluted in only 2100 mL, or half the usual amount of alveolar air (left red point in Fig. 31-4), the alveolar [CO₂] must double from ~40 to 80 mm Hg. Of course, this doubling of *alveolar* P_{CO_2} is paralleled by a doubling of *arterial* P_{CO_2} , leading to a **respiratory acidosis** (see p. 633).

Therefore, the steady-state alveolar P_{CO_2} is inversely proportional to alveolar ventilation. The higher the \dot{V}_A , the lower the $P_{A\text{CO}_2}$. If \dot{V}_A were infinitely high, then $P_{A\text{CO}_2}$ would theoretically fall to zero, the P_{CO_2} of inspired air.

Alveolar and arterial P_{O_2} rise with increased alveolar ventilation

As illustrated by the red curve in Fig. 31-4, increases in alveolar ventilation cause alveolar P_{O_2} to rise and—at an infinite \dot{V}_A —approach the inspired P_{O_2} of ~149 mm Hg.

Although alveolar P_{O_2} obviously depends critically on \dot{V}_A , it is also influenced to a lesser extent by alveolar gases other than O₂—namely, H₂O, N₂, and CO₂. The partial pressure of **H₂O** at 37°C is 47 mm Hg, and $P_{\text{H}_2\text{O}}$ will not change unless body temperature changes. The partial pressures of all of the other gases “fit” into what remains of barometric pressure (P_B) after $P_{\text{H}_2\text{O}}$ has claimed its mandatory 47 mm Hg. We can think of N₂ as a “spectator molecule,” because it is not metabolized; P_{N_2} is whatever it has to be to keep the total pressure of the dry alveolar air at $760 - 47 = 713$ mm Hg. That leaves us to deal with **CO₂**.

Because inspired air contains virtually no CO₂, we can think of the alveolar CO₂ as coming exclusively from metabolism. However, \dot{V}_{CO_2} depends not only on how fast the tissues burn O₂ but also on the *kind of fuel* they burn. If the fuel is carbohydrate, then the tissues produce one molecule of CO₂ for each O₂ consumed (see p. 1188). This ratio is termed the **respiratory quotient (RQ)**:

$$\text{RQ} = \frac{\dot{V}_{\text{CO}_2}}{\dot{V}_{\text{O}_2}}$$

(31-14)

In this example the RQ is 1, which is a good place to start when considering how alveolar P_{CO_2} affects alveolar P_{O_2} . If we consider only the *dry* part of the inspired air that enters the alveoli (see Table 26-1), then $P_{\text{I N}_2}$ is $713 \times 0.78 = 557$, $P_{\text{I O}_2}$ is $713 \times 0.2095 = 149$ mm Hg, and $P_{\text{I CO}_2}$ is ~0. As pulmonary-capillary blood takes up incoming O₂, it replaces the O₂ with an equal number of CO₂ molecules in the steady state (RQ = 1). Because the exchange of O₂ for CO₂ is precisely 1 for 1, alveolar P_{O_2} is what is left

of the inspired P_{O_2} after metabolism replaces some alveolar O_2 with CO_2 ($P_{ACO_2} = 40$ mm Hg):

$$\begin{aligned} P_{AO_2} &= P_{IO_2} - P_{ACO_2} \\ &= 149 - 40 \\ &= 109 \text{ mm Hg} \\ &\textbf{(31-15)} \end{aligned}$$

A typical fat-containing Western-pattern diet produces an RQ of ~ 0.8 (see [p. 1188](#)), so that 8 molecules of CO_2 replace 10 molecules of O_2 in the alveolar air. This 8-for-10 replacement has two consequences. First, the volume of alveolar air falls slightly during gas exchange. Because the non- H_2O pressure remains at 713 mm Hg, this volume contraction concentrates the N_2 and dilutes the O_2 . Second, the volume of *expired* alveolar air is slightly less than the volume of *inspired* air.

The **alveolar gas equation** [N31-8](#) describes how alveolar P_{O_2} depends on RQ:

$$\begin{aligned} \textbf{RQ = 1: } P_{AO_2} &= P_{IO_2} - P_{ACO_2} \\ &\textbf{(31-16)} \end{aligned}$$

$$\begin{aligned} \textbf{General case: } P_{AO_2} &= P_{IO_2} - P_{ACO_2} \cdot \left(F_{IO_2} + \frac{1 - F_{IO_2}}{RQ} \right) \\ &\textbf{(31-17)} \end{aligned}$$

N31-8

The Alveolar Gas Equation

Contributed by Emile Boulpaep, Walter Boron

The alveolar gas equation allows one to compute the ideal alveolar P_{O_2} (P_{AO_2}) from one's knowledge of the alveolar P_{CO_2} (P_{ACO_2}) as well as two other parameters, the mole fraction of O_2 in the dry inspired air (F_{IO_2}) and the RQ. We begin by deriving an expression for RQ, which, as described on page 1188, is defined as the ratio of the rate of metabolic CO_2 production (\dot{V}_{CO_2}) to the rate of O_2 consumption (\dot{V}_{O_2}):

$$\begin{aligned} RQ &= \frac{\dot{V}_{CO_2}}{\dot{V}_{O_2}} \\ &\textbf{(NE 31-18)} \end{aligned}$$

For RQ values less than unity, the body consumes more O_2 than it produces CO_2 , so that the *inspired*

alveolar ventilation (\dot{V}_A) must be greater than the *expired* alveolar ventilation (\dot{V}_{AE}). Because the metabolically produced CO_2 must all appear in the expired alveolar gas, \dot{V}_{CO_2} is the fraction of the expired alveolar ventilation that is CO_2 gas (F_{ACO_2}):

$$\dot{V}_{\text{CO}_2} = F_{\text{ACO}_2} \times \dot{V}_{AE}$$

(NE 31-19)

Similarly, the consumed O_2 must all enter the body via the lungs; \dot{V}_{O_2} is the difference between (1) the amount of O_2 entering the alveoli during inspirations over a certain period of time, and (2) the amount of O_2 exiting the alveoli during expirations over that same time interval:

$$\dot{V}_{\text{O}_2} = \underbrace{(F_{\text{IO}_2} \times \dot{V}_{A_I})}_{\text{Rate of O}_2 \text{ entering the alveoli}} - \underbrace{(F_{\text{AO}_2} \times \dot{V}_{A_E})}_{\text{Rate of O}_2 \text{ leaving the alveoli}}$$

(NE 31-20)

Here, F_{IO_2} is the mole fraction of O_2 in the inspired air, and F_{AO_2} is the mole fraction of O_2 in the expired alveolar air. Substituting the expressions for \dot{V}_{CO_2} (see Equation NE 31-19) and \dot{V}_{O_2} (see Equation NE 31-20) into the definition of RQ (see Equation NE 31-18), we have

$$\text{RQ} = \frac{F_{\text{ACO}_2} \times \dot{V}_{A_E}}{(F_{\text{IO}_2} \times \dot{V}_{A_I}) - (F_{\text{AO}_2} \times \dot{V}_{A_E})} = \frac{F_{\text{ACO}_2}}{F_{\text{IO}_2} \times \left(\frac{\dot{V}_{A_I}}{\dot{V}_{A_E}} \right) - F_{\text{AO}_2}}$$

(NE 31-21)

We now need an expression for the ratio $\dot{V}_{A_I} / \dot{V}_{A_E}$. In the derivation of this expression, the fundamental assumption is that the N_2 gas in the lungs is not metabolized. Thus, in the steady state, the amount of N_2 entering the alveoli with inspirations over a certain period of time is the same as the amount of N_2 leaving the alveoli with the expirations over the same period. In other words,

$$\underbrace{\dot{V}_{A_I} \times F_{\text{IN}_2}}_{\text{Amount of N}_2 \text{ entering the alveoli}} = \underbrace{\dot{V}_{A_E} \times F_{\text{AN}_2}}_{\text{Amount of N}_2 \text{ leaving the alveoli}}$$

(NE 31-22)

Here, F_{IN_2} is the mole fraction of N_2 in this inspired gas, and F_{AN_2} is the mole fraction of N_2 in the expired alveolar air. For the rest of this derivation, we will consider only *dry* gases; the laboratory reports all partial pressure (P) and mole fraction (F) values in terms of the “dry” gas (see Box 26-1).

Thus, considering only the dry *inspired* air, the mole fractions of N₂, O₂, and CO₂ must sum to 1:

$$1 = F_{I_{N_2}} + F_{I_{O_2}} + F_{I_{CO_2}}$$

$$F_{I_{N_2}} = 1 - F_{I_{O_2}} - F_{I_{CO_2}}$$

(NE 31-23)

Because the inspired air contains virtually no CO₂ (i.e., $F_{I_{CO_2}} \cong 0$),

$$F_{I_{N_2}} = 1 - F_{I_{O_2}}$$

(NE 31-24)

Similarly, considering only the dry *expired* air, the mole fractions of N₂, O₂, and CO₂ must likewise sum to 1:

$$1 = F_{A_{N_2}} + F_{A_{O_2}} + F_{A_{CO_2}}$$

$$F_{A_{N_2}} = 1 - F_{A_{O_2}} - F_{A_{CO_2}}$$

(NE 31-25)

If we now substitute the expressions for $F_{I_{N_2}}$ (see Equation NE 31-24) and $F_{A_{N_2}}$ (see Equation NE 31-25) into Equation NE 31-22, we have

$$\dot{V}_{A_I} \times (1 - F_{I_{O_2}}) = \dot{V}_{A_E} \times (1 - F_{A_{O_2}} - F_{A_{CO_2}})$$

(NE 31-26)

Solving for the ratio of inspired to expired alveolar ventilation yields

$$\frac{\dot{V}_{A_I}}{\dot{V}_{A_E}} = \frac{1 - F_{A_{O_2}} - F_{A_{CO_2}}}{1 - F_{I_{O_2}}}$$

(NE 31-27)

We now have the ratio ($\dot{V}_{A_I} / \dot{V}_{A_E}$) that we needed for Equation NE 31-21. Substituting Equation NE 31-27 into Equation NE 31-21, we get

$$RQ = \frac{F_{A_{CO_2}}}{F_{I_{O_2}} \times \left(\frac{1 - F_{A_{O_2}} - F_{A_{CO_2}}}{1 - F_{I_{O_2}}} \right) - F_{A_{O_2}}}$$

(NE 31-28)

If we now solve Equation NE 31-28 for $F_{A_{O_2}}$, we have

$$F_{A_{O_2}} = F_{I_{O_2}} - F_{A_{CO_2}} \left[F_{I_{O_2}} + \frac{1 - F_{I_{O_2}}}{RQ} \right]$$

(NE 31-29)

Realizing that the “dry” partial pressure (P) is the product of mole fraction (the above F terms) and (PB – 47), we can multiply Equation NE 31-12 through by (PB – 47) to arrive at our final equation, which expresses quantities in terms of partial pressures:

$$P_{A_{O_2}} = P_{I_{O_2}} - P_{A_{CO_2}} \left[F_{I_{O_2}} + \frac{1 - F_{I_{O_2}}}{RQ} \right]$$

(NE 31-30)

Remember, all the partial-pressure and mole-fraction values in the above equation refer to dry *gases*. Thus, $P_{I_{O_2}}$ is $F_{I_{O_2}} \times (P_B - 47)$.

On page 681, we provide a simplified version of Equation NE 31-30:

$$P_{A_{O_2}} = P_{I_{O_2}} - \frac{P_{A_{CO_2}}}{RQ}$$

(NE 31-31)

Why is this equation a reasonable approximation? Examination of Equations NE 31-30 and NE 31-31 shows that they are identical except that the term in brackets in Equation NE 31-30 is replaced by $1/RQ$ in Equation NE 31-31. For Equation NE 31-30, we can rearrange the term in brackets as follows:

$$\begin{aligned} \left[F_{I_{O_2}} + \frac{1 - F_{I_{O_2}}}{RQ} \right] &= \left[F_{I_{O_2}} \frac{RQ}{RQ} + \frac{1 - F_{I_{O_2}}}{RQ} \right] \\ &= \left[\frac{F_{I_{O_2}} \cdot RQ + 1 - F_{I_{O_2}}}{RQ} \right] \\ &= \left[\frac{F_{I_{O_2}} (RQ - 1) + 1}{RQ} \right] \end{aligned}$$

(NE 31-32)

Under physiological conditions—when $F_{I_{O_2}}$ is 0.21 and RQ is 0.8—the above expression evaluates to

0.958/RQ, which is quite close to 1/RQ ... which is to say that Equation NE 31-31 is a reasonable approximation of Equation 31-30 under these conditions.

When RQ is unity, the term in brackets in Equation 31-30 evaluates to unity, and Equation NE 31-30 simplifies to Equation 31-16 in the text:

$$P_{A_{O_2}} = P_{I_{O_2}} - P_{A_{CO_2}} \quad \text{(NE 31-33)}$$

$F_{I_{O_2}}$ is the fraction of inspired *dry* air that is O_2 , which is 0.21 for room air (see Table 26-1). Note that when RQ is 1, the term in parentheses becomes unity, and Equation 31-17 reduces to Equation 31-16. The term in parentheses also becomes unity, regardless of RQ, if $F_{I_{O_2}}$ is 100% (i.e., the subject breathes pure O_2)—in this case, no N_2 is present to dilute the O_2 .

A simplified version of Equation 31-17 is nearly as accurate:

$$P_{A_{O_2}} = P_{I_{O_2}} - \frac{P_{A_{CO_2}}}{RQ} \quad \text{(31-18)}$$

The concepts developed in the last two sections allow us to compute both alveolar P_{CO_2} and alveolar P_{O_2} . The approach is first to use Equation 31-13 to calculate $P_{A_{CO_2}}$ from \dot{V}_{CO_2} and \dot{V}_A , and then use Equation 31-17 to calculate $P_{A_{O_2}}$ from $P_{A_{CO_2}}$ and RQ. Imagine that we first found that $P_{A_{CO_2}}$ is 40 mm Hg and that we know that RQ is 0.8. What is $P_{A_{O_2}}$?

$$\begin{aligned} P_{A_{O_2}} &= P_{I_{O_2}} - P_{A_{CO_2}} \cdot \left(F_{I_{O_2}} + \frac{1 - F_{I_{O_2}}}{RQ} \right) \\ P_{A_{O_2}} &= 149 - 40 \cdot \underbrace{\left(0.21 + \frac{1 - 0.21}{0.8} \right)}_{1.2} \\ &= 149 - 48 \\ &= 101 \text{ mmHg} \end{aligned} \quad \text{(31-19)}$$

By default, the partial pressure of N_2 and other gases (e.g., argon) is $P_B - P_{A_{CO_2}} - P_{A_{O_2}}$ or $713 - 40 - 101 = 572$ mm Hg. For simplicity, we round down this $P_{A_{O_2}}$ to 100 mm Hg in our examples.

Because of the action of gravity on the lung, regional ventilation in an upright subject is normally greater at the

base than the apex

Until now, we have assumed that all alveoli are ventilated to the same extent. We could test this hypothesis by using an imaging technique for assessing the uniformity of ventilation. Imagine that a subject who is standing up breathes air containing ^{133}Xe . Because Xe has very low water solubility, it (like He and N_2) has a very low diffusing capacity (see pp. 661–663) and—over a short period—remains almost entirely within the alveoli.

Imaging the ^{133}Xe radioactivity immediately after a single breath of ^{133}Xe provides an index of *absolute regional ventilation* (Fig. 31-5A). However, $[^{133}\text{Xe}]$ might be low in a particular region either because the alveoli truly receive little ventilation or because the region has relatively little tissue. Therefore, we normalize the *absolute* data to the maximal regional alveolar volume. The subject continues to breathe the ^{133}Xe until $[^{133}\text{Xe}]$ values stabilize throughout the lungs. When the subject now makes a maximal inspiratory effort (V_L = total lung capacity [TLC]), the level of radioactivity detected over any region reflects that region's maximal volume. Dividing the single-breath image by the steady-state image at TLC yields a ratio that describes *regional ventilation per unit volume*.

A DETECTION OF INSPIRED ^{133}Xe

B REGIONAL DISTRIBUTION OF VENTILATION

C INTRAPLEURAL PRESSURES

D STATIC PRESSURE-VOLUME DIAGRAM

FIGURE 31-5 Distribution of ventilation. (Data from West JB: Respiratory Physiology—The Essentials, 4th ed. Baltimore, Williams & Wilkins, 1990.)

This sort of analysis shows that alveolar ventilation in a standing person gradually falls from the base to the apex of the lung (see Fig. 31-5B). Why? The answers are **posture** and **gravity**. In Chapter 27 we saw that, because of the lung's weight, intrapleural pressure (P_{IP}) is more negative at the apex than at the base when the subject is upright (see Fig. 31-5C). The practical consequences of this P_{IP} gradient become clear when we examine a static pressure-volume diagram not for the lungs as a whole (see Fig. 27-5), but rather for a small piece of lung (see Fig. 31-5D). We assume that the intrinsic mechanical properties of the airways are the same, regardless of whether the tissue is at the base or at the apex. At the base, where P_{IP} might be only -2.5 cm H₂O at FRC, the alveoli are relatively underinflated compared to tissues at the

apex, where P_{IP} might be $-10\text{ cm H}_2\text{O}$ and the alveoli are relatively overinflated. However, because the base of the lung is underinflated at FRC, it is on a steeper part of the pressure-volume curve (i.e., it has a greater **static compliance**) than the overinflated apex. Thus, during an inspiration, the same ΔP_{IP} (e.g., $2.5\text{ cm H}_2\text{O}$) produces a larger ΔV_L near the base than near the apex. Keep in mind that it is the *change* in volume per unit time, not the initial volume, that defines ventilation.

The relationship between ventilation and basal versus apical location in the lung would be reversed if the subject hung by the knees from a trapeze. A person reclining on the right side would ventilate the dependent lung tissue on the right side better than the elevated lung tissue on the left. Of course, the right-to-left P_{IP} gradient in the reclining subject would be smaller than the apex-to-base P_{IP} gradient in the standing subject, reflecting the smaller distance (i.e., smaller hydrostatic pressure difference). Subjects under microgravity conditions (see [p. 1233](#)), such as astronauts aboard the International Space Station, experience no P_{IP} gradients, and thus no gravity-dependent regional differences in ventilation.

Restrictive and obstructive pulmonary diseases can exacerbate the nonuniformity of ventilation

Even in microgravity, where we would expect no regional differences in ventilation, ventilation would still be nonuniform at the *microscopic* or *local* level because of seemingly random differences in local static compliance (C) and airway resistance (R). In fact, such local differences in the ventilation of alveolar units are probably more impressive than gravity-dependent regional differences. Moreover, pathological changes in compliance and resistance can substantially increase the local differences and thus the nonuniformity of ventilation.  **N31-9**

N31-9

Detecting Nonuniformity of Ventilation

Contributed by Emile Boulpaep, Walter Boron

We have already seen how ^{133}Xe **scanning** can be useful in detecting the physiological nonuniformity of ventilation. Obviously, because of limitations in scanning technology, ^{133}Xe scans are helpful only if sufficiently large regions of the lung have sufficiently large differences in ventilation. However, a ^{133}Xe scan might not detect a nonuniformity of ventilation in which many small, well-ventilated airways are intermingled with many, small poorly ventilated airways. Two other approaches that we have mentioned in other contexts would detect such a nonuniformity of ventilation.

The first is the **single-breath N_2 -washout technique**, which we introduced in our discussion of the Fowler method for measuring anatomical dead space (see p. 675). In this approach, the subject inhales one breath of 100% O_2 , and we assume that the inspired 100% O_2 distributes evenly throughout all the alveoli of the lungs. If ventilation is indeed uniform, the inspired O_2 dilutes alveolar N_2 uniformly in all regions of the lung. Thus, when the subject exhales, the air emerging from the alveolar air spaces should have a uniform $[\text{N}_2]$, and the plateau of the single-breath N_2 washout should be flat, as shown by the red curve in Figure 31-2C labeled “Pure alveolar air.”

However, if the alveoli are unevenly ventilated, the inhaled 100% O_2 will not be distributed uniformly throughout the lungs and therefore will not uniformly dilute the pre-existing alveolar N_2 . Regions of the

lung that are relatively *hypoventilated* will receive relatively less 100% O_2 during the single inspiration, so that they will be relatively poor in O_2 but rich in N_2 . Conversely, *hyperventilated* regions will receive relatively more of the inhaled 100% O_2 and hence will be O_2 rich and N_2 poor. During the expiration, we no longer observe a plateau for $[N_2]$. Why? After exhalation of the anatomical dead space, the first alveolar air out of the lungs is dominated by the O_2 -rich/ N_2 -poor gas coming from the relatively *hyperventilated* airways—which inflate and deflate relatively quickly. As the expiration continues, the alveolar air gradually becomes dominated more and more by the O_2 -poor/ N_2 -rich gas from the *hypoventilated* airways, which inflate and deflate relatively slowly. Because of this shift from hyperventilated to hypoventilated regions, the $[N_2]$ gradually creeps upward—that is, there is no clear plateau—in subjects with a sufficiently high nonuniformity of ventilation.

A second test for unevenness of ventilation is the **7-minute N_2 washout**. We saw in Chapter 26 how to compute lung volume from the volume of distribution of N_2 (see p. 602). The general approach is for a subject to inhale 100% O_2 , allow that O_2 to dilute the pre-existing alveolar N_2 , and then exhale into a collection container. If this breathing pattern is continued for a standard period of 7 minutes, and if ventilation is evenly distributed, virtually all of the pre-existing N_2 washes out of the lungs (see Fig. 26-9B). We already learned that, from the amount of N_2 washed into the collection container, we can compute V_L . However, we can also use this experiment to assess the evenness of ventilation. In a normal individual, the mean alveolar $[N_2]$ in the expired air is $<2.5\%$ after 7 minutes of O_2 breathing. However, if some airways are poorly ventilated, their N_2 will not be washed out as well after 7 minutes of O_2 breathing, so that the $[N_2]$ in these hypoventilated airways may be substantially greater than 2.5%. Because these hypoventilated airways contribute to the total expired alveolar air, the mean expired alveolar $[N_2]$ after 7 minutes will be elevated. Obviously, the degree of elevation depends on the volume of hypoventilated airways and the extent of their hypoventilation.

Restrictive Pulmonary Disease

As discussed in [Box 27-1](#), restrictive pulmonary diseases include disorders that decrease the static compliance of alveoli (e.g., fibrosis) as well as disorders that limit the expansion of the lung (e.g., pulmonary effusion). [Figure 31-6A](#) shows a hypothetical example in which R is normal and disease has halved the static compliance of one lung but left the other unaffected.  **N31-10** Thus, for the usual change in P_{ip} , the final volume change (ΔV) of the diseased lung is only half normal, so that its ventilation is also halved. Because the ventilation of the other unit is normal, decreased local compliance has increased the nonuniformity of ventilation.

A REDUCE COMPLIANCE OF ONE LUNG TO HALF NORMAL

B INCREASE AIRWAY RESISTANCE OF ONE LUNG 5-FOLD

FIGURE 31-6 Pathological nonuniformity of ventilation.

N31-10

Effect of Changes in Compliance on the Time Constant Governing Changes in Lung Volume

Contributed by Emile Boulpaep, Walter Boron

On page 622, we saw that, during inspiration and expiration, the time course of lung volume (V_L) is approximately exponential. The **time constant** (τ) for the change in V_L (ΔV_L) is the time required for the change in V_L to be ~63% complete. Moreover, **N27-10** explains why τ is the product of airway resistance (R) and alveolar compliance (C):

$$\tau = R \times C$$

(NE 31-34)

Decreased Compliance

In the example discussed under restrictive pulmonary disease on page 683, we decreased the compliance of one lung by half. Of course, other things being equal, the ΔV of the affected lung will be half normal,

as illustrated in Figure 31-6A. What is not so obvious is that τ of the affected lung will also be half normal. In other words, the lung with half-normal compliance will achieve its final volume twice as fast as normal. The reason is that, with a normal airway resistance, the inhaled air—at any instant in time—will flow at a more-or-less normal rate, so that the affected lung achieves its half-normal ΔV earlier than the normal lung.

Although it might seem that the decreased τ in this example is a good thing, the problem is that the reduced ΔV translates to less ventilation, and that is not a good thing. As described in the text, this reduced ventilation increases the nonuniformity of ventilation, which in turn—as discussed below in this chapter—tends to lead to hypoxia and respiratory acidosis.

Increased Compliance

What would be the effect of increasing the static compliance of one lung? A disease that increases the static compliance is emphysema (see Fig. 27-5). Other things being equal, an increase in compliance will cause the ΔV of the affected lung to be greater than normal. At the same time, the τ of the affected lung will also be increased. The reason is that, with a normal airway resistance, the inhaled air—at any instant in time—will flow at a more-or-less normal rate, so that the affected lung achieves its greater-than-normal ΔV later than a normal lung. If τ is too large, then the time that the person allows for inspiration may not be long enough for the affected lung to increase its volume to the level that it could achieve if the inspiration were infinitely long. As a result, the inspiration will be truncated, and the true ΔV for the affected lung will be less than normal, thereby exacerbating the unevenness of ventilation. Moreover, the greater the respiratory frequency, the greater the truncation of the inspiration, and thus the greater the exacerbation of the unevenness of ventilation.

Figure 27-15A illustrates the effect of increased airway resistance on the time course of V_L , and Figure 27-15B illustrates the effect on the change in lung volume, which is proportional to **dynamic compliance**. In the example in Figure 27-15, the static compliance was normal and the final ΔV was the same for the normal and affected lung. The example we are discussing in this webnote is just the opposite (i.e., a normal airway resistance but altered compliance). Nevertheless, the principle of how increases in τ affect ventilation is the same: the greater the τ , the greater the chance that increased respiratory frequency will lead to a truncated inspiration and thus a greater unevenness of ventilation.

Although we have focused on inspiration in these examples, the same principles apply to *expiration*, namely, the greater the τ , the greater the chance of a truncated *expiration*.

Obstructive Pulmonary Disease

As discussed in Box 27-2, obstructive pulmonary diseases include disorders (e.g., asthma, chronic obstructive pulmonary disease [COPD]) that increase the resistance of conducting airways. Scar tissue or a local mass, such as a neoplasm, can also occlude a conducting airway or compress it from the outside. Even if the effect is not sufficiently severe to increase overall airway resistance, a local increase in R causes an increase in the time constant τ  **N31-10** for filling or emptying the affected alveoli (see Fig. 31-6B, lower curve). An isolated increase in R will not affect ΔV if sufficient time is available for the inspiration. However, if sufficient time is not available, then alveoli with an elevated τ will not completely fill or empty, and their ventilation will decrease. Of course, the mismatching of ventilation between the two units worsens as respiratory frequency increases, as we saw in our discussion of dynamic compliance (see p. 624).

Perfusion of the Lung

The pulmonary circulation has low pressure and resistance but high compliance

The pulmonary circulatory system handles the same cardiac output as the systemic circulation, but in a very different way. The systemic circulation is a *high-pressure* system. This high pressure is necessary to pump blood to the top of the brain while the individual is standing, or even to a maximally elevated fingertip. The systemic circulation also needs to be a high-pressure system because it is a *high-resistance* system. It uses this high resistance to control the distribution of blood flow. Thus, at rest, a substantial fraction of the systemic capillaries are closed, which gives the system the flexibility to redistribute large amounts of blood (e.g., to muscle during exercise). The mean pressure of the aorta is ~95 mm Hg (Table 31-1). At the opposite end of the circuit is the right atrium, which has a mean pressure of ~2 mm Hg. Thus, the driving pressure for blood flow through the systemic circulation is ~93 mm Hg. Given a cardiac output (\dot{Q}) of 5 L/min or 83 mL/s, we can compute the resistance of the systemic system using an equation like Ohm's law (see Equation 17-10):

$$\begin{aligned} R_{\text{systemic}} &= \frac{\Delta P}{\dot{Q}} = \frac{93 \text{ mm Hg}}{83 \text{ mL blood/s}} \\ &= 1.1 \text{ PRU} \end{aligned} \tag{31-20}$$

PRU is a peripheral resistance unit (see p. 415), which has the dimension mm Hg/(mL/s).

TABLE 31-1
Comparison of Pressures in the Pulmonary and Systemic Circulatory Systems*

PULMONARY CIRCULATION		SYSTEMIC CIRCULATION	
LOCATION	MEAN PRESSURE (mm Hg)	LOCATION	MEAN PRESSURE (mm Hg)
Pulmonary artery	15	Aorta	95
Beginning of capillary	12	Beginning of capillary	35
End of capillary	9	End of capillary	15
Left atrium	8	Right atrium	2
Net driving pressure	15 – 8 = 7	Net driving pressure	95 – 2 = 93

*The reference point for all pressures is the pressure outside the heart at the level of the left atrium.

In contrast, the pulmonary circulation is a *low-pressure* system. It can afford to be a low-pressure system because it needs to pump blood only to the top of the lung. Moreover, it *must* be a low-pressure system to avoid the consequences of Starling forces (see pp. 467–468), which would otherwise flood the lung with edema fluid. The mean pressure in the pulmonary artery is only ~15 mm Hg. Because the mean pressure of the left atrium, at the other end of the circuit, is ~8 mm Hg, and because the cardiac output of the right side of the heart is the same as for the left side, we have

$$R_{\text{pulmonary}} = \frac{\Delta P}{\dot{Q}} = \frac{7 \text{ mmHg}}{83 \text{ mL blood/s}} \\ = 0.08 \text{ PRU} \\ \textbf{(31-21)}$$

Thus, the total resistance of the pulmonary circulation is less than one tenth that of the systemic system, which explains how the pulmonary circulation accomplishes its mission at such low pressures. Unlike in the systemic circulation, where most of the pressure drop occurs in the arterioles (i.e., between the terminal arteries and beginning of the capillaries), in the pulmonary circulation almost the entire pressure drop occurs rather uniformly between the pulmonary artery and the end of the capillaries. In particular, the arterioles make a much smaller contribution to resistance in the pulmonary circulation than in the systemic circulation.

What are the properties of the pulmonary vasculature that give it such a low resistance? First, let us examine the complete circuit. The **pulmonary artery** arises from the right ventricle, bifurcates, and carries relatively deoxygenated blood to each lung. The two main branches of the pulmonary artery follow the two mainstem bronchi into the lungs and bifurcate along with the bronchi and bronchioles. A single pulmonary arteriole supplies all of the capillaries of a terminal respiratory unit (see [p. 597](#)). Together, the two lungs have ~300 *million* alveoli. However, they may have as many as 280 *billion* highly anastomosing capillary segments (each looking like the edge of a hexagon in a piece of chicken wire), or nearly 1000 such capillary segments per alveolus—creating a surface for gas exchange of ~100 m². It is easy to imagine why some have described the pulmonary capillary bed as a nearly continuous flowing sheet of blood surrounding the alveoli. At rest, the erythrocytes spend ~0.75 second navigating this capillary bed, which contains ~75 mL of blood. During exercise, capillary blood volume may increase to ~200 mL. Pulmonary venules collect the oxygenated blood from the capillary network, converge, course between the lobules, converge some more, and eventually enter the left atrium via the pulmonary veins. The total circulation time through the pulmonary system is 4 to 5 seconds.

Pulmonary blood vessels are generally shorter and wider than their counterparts on the systemic side. Arterioles are also present in much higher numbers in the pulmonary circulation. Although the pulmonary arterioles contain smooth muscle and can constrict, these vessels are far less muscular than their systemic counterparts, and their resting tone is low. These properties combine to produce a system with an unusually **low resistance**.

The walls of pulmonary vessels have another key property: thinness, like the walls of veins elsewhere in the body. The thin walls and paucity of smooth muscle give the pulmonary vessels a **high compliance**, which has three consequences. First, pulmonary vessels can accept the relatively large amounts of blood that shift from the legs to the lungs when a person changes from a standing to a recumbent position. Second, as we discuss below, the high compliance also allows the vessels to dilate in response to modest increases in pulmonary arterial pressure. Third, the pulse pressure in the pulmonary system is rather low (on an absolute scale). The systolic/diastolic pressures in the pulmonary artery are typically 25/8 mm Hg, yielding a **pulse pressure** of ~17 mm Hg. In contrast, the systolic/diastolic pressures in the aorta are ~120/80 mm Hg, for a pulse pressure of ~40 mm Hg. Nonetheless, relative to the *mean* pulmonary artery pressure of 15 mm Hg, the pulmonary pulse pressure of 17 mm Hg is quite high.

Overall pulmonary vascular resistance is minimal at FRC

Because pulmonary blood vessels are so compliant, they are especially susceptible to deformation by

external forces. These forces are very different for vessels that are surrounded by alveoli (i.e., “alveolar” vessels) compared with those that are not (i.e., “extra-alveolar” vessels). In both types, the key consideration is whether these external forces pull vessels open or crush them.

Alveolar Vessels

Alveolar vessels include the capillaries, as well as slightly larger vessels that are also surrounded on all sides by alveoli (Fig. 31-7A). The resistance of these alveolar vessels depends on both the transmural pressure gradient and lung volume.

FIGURE 31-7 Pulmonary vascular resistance. (B, Data from Murray JF: The Normal Lung, 2nd ed. Philadelphia, WB Saunders, 1986.)

We have already introduced the **transmural pressure gradient** (P_{TM}) in our discussions of systemic blood vessels (see p. 414) and conducting airways (see pp. 624–625). For alveolar vessels, P_{TM} is the difference between the pressure in the vessel *lumen* and that in the surrounding *alveoli* (P_A). For simplicity, we consider the factors affecting P_{TM} at a fixed lung volume.

The pressure inside these vessels varies with the *cardiac cycle*; indeed, the pulmonary capillary bed is one of the few in which flow is pulsatile (see p. 513). The pressure inside the alveolar vessels also depends greatly on their vertical position relative to the left atrium: the higher the vessel, the lower the pressure.

The pressure in the alveoli varies with the *respiratory cycle*. With no airflow and the glottis open, P_A is the same as P_B (i.e., 0 cm H₂O). On the other hand, P_A is negative during inspiration and positive during expiration. A combination of a high intravascular pressure and a negative P_A tends to dilate the compliant alveolar vessels, lowering their resistance. But a combination of a low intravascular pressure and a positive P_A crushes these vessels, raising their resistance.

Changes in *lung volume* (V_L) have characteristic effects on alveolar vessels. For simplicity, here we assume that each time we examine a new V_L , airflow has stopped, so that P_A is zero. As V_L increases, the alveolar walls become more stretched out. Consequently, the alveolar vessels become stretched along their longitudinal axis but crushed when viewed in cross section. Both of these effects tend to raise vessel

resistance. Thus, as V_L increases, the resistance of the alveolar vessels also increases (see Fig. 31-7B, red curve).

Extra-Alveolar Vessels

Because they are not surrounded by alveoli, the extra-alveolar vessels are sensitive to intrapleural pressure (see Fig. 31-7A). Again for simplicity, we examine the effect of changing V_L after airflow has already stopped. The increasingly negative values of P_{IP} needed to achieve increasingly higher lung volumes also increase the P_{TM} of the extra-alveolar vessels and tend to dilate them. Thus as V_L increases, the resistance of the extra-alveolar vessels decreases (see Fig. 31-7B, blue curve).

In summary, increases in V_L tend to crush alveolar vessels and thus increase their resistance, but to expand extra-alveolar vessels and thus decrease their resistance. The net effect on overall pulmonary vascular resistance of increasing V_L from residual volume (RV) to TLC is biphasic (see Fig. 31-7B, violet curve). Starting at RV, an increase in V_L first causes pulmonary vascular resistance to fall as the dilation of extra-alveolar vessels dominates. Pulmonary vascular resistance reaches its minimum value at about FRC. Further increases in V_L (as during a normal inspiration) increase overall resistance as the crushing of alveolar vessels dominates.  **N31-11**

N31-11

Additional Factors Affecting the Resistance of Pulmonary Vessels

Contributed by Emile Boulpaep, Walter Boron

Alveolar Vessels

On pages 684–685 we pointed out that two major factors affect the caliber of alveolar vessels (i.e., vessels surrounded by alveoli): (1) transmural pressure and (2) lung volume (V_L) per se. The cardiac cycle and the respiratory cycle are two factors that can affect the transmural pressure of alveolar vessels. A third factor is an indirect effect of increasing lung volume. (This indirect effect is in addition to the direct effect of increasing V_L , which stretches the vessels longitudinally and crushes them as they are viewed in cross section.) Let us compare two static conditions: resting at FRC, and holding lung volume at TLC. In order to achieve the higher lung volume, we needed to shift P_{IP} in the negative direction. As discussed on page 685, this decrease in P_{IP} dilates *extra*-alveolar vessels. Because the *volume* of these vessels increases, the *pressure* falls inside all the vessels in the thorax. This decrease in intravascular pressure at negative P_{IP} values accentuates the collapse of the alveolar vessels at high lung volumes.

Extra-Alveolar Vessels

On page 685, we considered only static conditions. What happens when—starting at TLC (where the P_{IP} at rest is very negative)—one makes a maximal *expiratory effort*? Instantly, P_{IP} becomes very positive, tending to collapse the extra-alveolar vessels, just as this maneuver tends to collapse conducting airways (see pp. 624–626). However, the mechanical tethering (or radial traction) of other structures on the extra-alveolar vessels tends to oppose their collapse, just as—at a high V_L —mechanical tethering tends to keep

conducting airways open during expiration. However, the effects of mechanical tethering decrease as V_L falls during expiration.

Increases in pulmonary arterial pressure reduce pulmonary vascular resistance by recruiting and distending pulmonary capillaries

Although the pulmonary circulation is normally a low-resistance system under resting conditions, it has a remarkable ability to lower its resistance even further. During exercise, 2-fold to 3-fold increases in cardiac output may elicit only a minor increase in mean pulmonary arterial pressure. In other words, a slight increase in pulmonary arterial pressure is somehow able to markedly *decrease* resistance ([Fig. 31-8A](#)) and thus markedly *increase* flow (see [Fig. 31-8B](#)). This behavior is a general property of a passive/elastic vascular bed (see [Fig. 19-7A](#), red curve). Two “passive” mechanisms—that is, mechanisms not related to “active” changes in the tone of vascular smooth muscle—are at work here: the recruitment and distention of pulmonary capillaries. However, before we can understand either change, we must more completely describe the pulmonary capillaries at “rest.”

A EFFECT OF PULMONARY ARTERIAL PRESSURE ON VASCULAR RESISTANCE

B EFFECT OF PULMONARY ARTERIAL PRESSURE ON BLOOD FLOW

C RECRUITMENT AND DISTENTION OF ALVEOLAR VESSELS

FIGURE 31-8 Effects of perfusion pressure on pulmonary hemodynamics.

Under “resting” conditions (i.e., at relatively low values of pulmonary arterial pressure), some pulmonary capillaries are open and conducting blood, others are open but not conducting substantial amounts of blood, and still others are closed (see Fig. 31-8C). Why should some capillaries be **open** but have no flow? In a highly anastomosing capillary network, tiny differences in driving pressure might exist. In addition, seemingly random differences in the dimensions of parallel capillaries may lead to differences in resistance. In low-pressure systems, such slight differences in absolute resistance allow pathways with relatively low resistances to steal flow from neighbors with slightly higher resistances, leaving some “open” pathways heavily underutilized. A familiar example is a type of garden hose used to drizzle water on a flower bed; this hose is closed at its distal end, but perforated with hundreds of tiny

holes. If water pressure is low, only some of the holes conduct water.

Why should some parallel vessels be **closed**? Popping open a previously closed vessel requires that the perfusion pressure overcome the tone of the vascular smooth muscle and reach that vessel's **critical closing pressure** (see [p. 454](#)), which varies from vessel to vessel. As we discuss below, alveolar vessels also may be closed because the alveolar pressure exceeds intravascular pressure, thereby crushing the vessel.

Recruitment

Imagine that the pressure inside a pulmonary arteriole starts out at a fairly low level. As pressure increases, some vessels that were completely *closed* may now open (see [Fig. 31-8C](#)). Similarly, capillaries that previously had been *open but not conducting* now begin to conduct blood. The greater the increase in perfusion pressure, the greater the number of open and conducting vessels. This recruitment of additional parallel capillary pathways reduces overall vascular resistance.

Distention

Once a vessel is open and conducting, further pressure increases will increase P_{TM} and thus cause the vessel to dilate (see [Fig. 31-8C](#)). The net effect is a reduction in overall pulmonary resistance. Although a pressure increase can simultaneously recruit and distend various vessels, distention probably tends to occur later; that is, distention is the primary mechanism for lowering resistance under conditions in which the initial pressure was already relatively high.

Hypoxia is a strong vasoconstrictor, opposite to its effect in the systemic circulation

In addition to lung volume and perfusion pressure, several other factors can modulate pulmonary vascular resistance.

Oxygen

The effects of changes in P_{O_2} , P_{CO_2} , and pH on pulmonary vascular resistance are opposite to those observed in the systemic circulation. Thus, hypoxia causes pulmonary vasoconstriction. What appears to be critical is not so much the P_{O_2} in the lumen of the arterioles and venules, but rather the P_{O_2} in the *alveolar air* adjacent to the vessel. Indeed, perfusing the pulmonary vasculature with a hypoxic solution is far less effective than ventilating the airways with a low- P_{O_2} air mixture.

Hypoxic vasoconstriction occurs in isolated lung tissue and thus does not rely on either the nervous system or systemic hormones. Rather, the low P_{O_2} is generally believed to act directly on the pulmonary vascular smooth-muscle cells. How this occurs is unknown, but hypothesized mechanisms include all those proposed for the sensing of hypoxia by the peripheral chemoreceptor, which we discuss on [page 712](#). Somehow, the hypoxia inhibits one or more K^+ channels, causing the membrane potential of vascular smooth-muscle cells to move away from the equilibrium potential for K^+ (E_K). This depolarization opens voltage-gated Ca^{2+} channels, leading to an influx of Ca^{2+} and smooth-muscle contraction (see [p. 247](#)).

Carbon Dioxide and Low pH

High P_{CO_2} or low interstitial pH promotes vasoconstriction, although with far less potency than hypoxia. Elevated P_{CO_2} may produce its effect by decreasing the pH of either the extracellular or intracellular fluid. Following a general pattern that is repeated in the control of ventilation (see p. 716), hypoxia makes the vascular smooth-muscle cells more sensitive to respiratory acidosis.

Autonomic Nervous System

The sympathetic and parasympathetic innervation of the pulmonary vasculature is far less impressive than that of the systemic circulation. Increased sympathetic tone seems to reduce the compliance of (i.e., stiffen) the pulmonary artery walls without increasing resistance per se. Increased parasympathetic tone causes a mild vasodilation, the relevance of which is unknown.

Hormones and Other Humoral Agents

The pulmonary blood vessels are relatively *unresponsive* to hormones and other signaling molecules. Table 31-2 summarizes the actions of some factors that modify pulmonary vascular resistance.

TABLE 31-2
Changes or Agents That Affect Pulmonary Vascular Resistance

DILATORS	CONSTRIC TORS
↑ PA_{O_2}	↓ PA_{O_2}
↓ PA_{CO_2}	↑ PA_{CO_2}
↑ pH	↓ pH
Histamine, H_2 agonists	Histamine, H_1 agonists
PGI_2 (prostacyclin), PGE_1	Thromboxane A_2 , $PGF_{2\alpha}$, PGE_2
β-adrenergic agonists (e.g., isoproterenol)	α-adrenergic agonists
Bradykinin	Serotonin
Theophylline	Angiotensin II
Acetylcholine	
NO	

PG, prostaglandin.

Because of gravity, regional perfusion in an upright subject is far greater near the base than the apex of the lung

When it comes to perfusion—as with ventilation—not all alveoli are created equal. First of all, *microscopic* or *local* differences in pulmonary vascular resistance lead to corresponding local differences in perfusion. Of course, pathological processes can exacerbate these differences. In addition, gravity causes large *regional* differences in perfusion that we can assess by using a ^{133}Xe imaging technique. In Figure 31-5A, we used the inhalation of ^{133}Xe gas to measure the uniformity of *ventilation*. In Figure 31-9A, we equilibrate a saline solution with a gas mixture containing ^{133}Xe and then inject the solution intravenously as the patient holds his or her breath. When the ^{133}Xe reaches the lungs, it rapidly enters the alveolar air, inasmuch as Xe is poorly soluble in water. A lung scan reveals the distribution of radioactivity, which now reflects the regional uniformity of *perfusion*. If we normalize the ^{133}Xe to account for differences in regional lung volume—as we did for the ventilation scan—then we can obtain a graph showing how blood flow varies from the bottom to the top of the lung of an upright subject.

A DETECTION OF INJECTED ^{133}Xe

B REGIONAL DISTRIBUTION OF PERFUSION

C LUNG ZONES

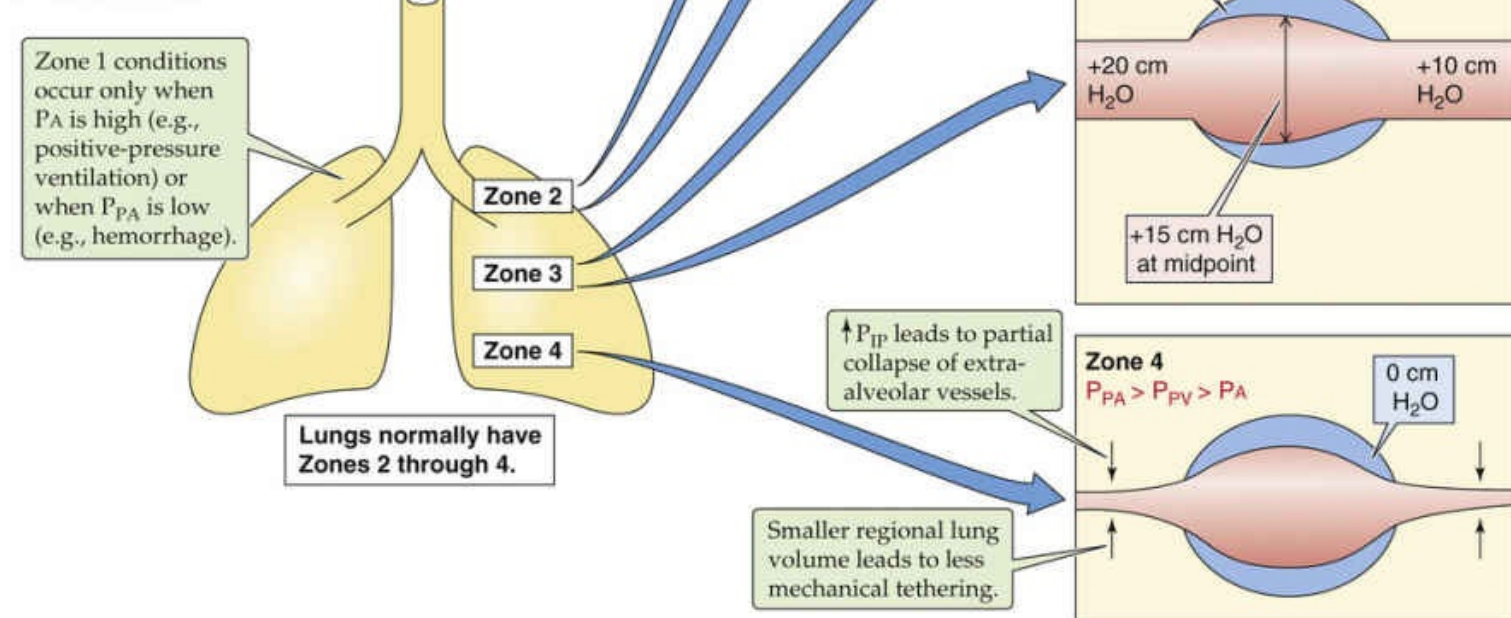

FIGURE 31-9 Physiological nonuniformity of pulmonary perfusion.

The results of such a ^{133}Xe perfusion study show that when the patient is upright, perfusion (\dot{Q}) is greatest near the base of the lungs and falls toward low levels near the apex (see Fig. 31-9B). Note that although regional \dot{Q} is highest *near* the base of the lung, \dot{Q} falls off somewhat from this peak as we approach the extreme base. With exercise, perfusion increases in all regions of the lung, but more so near the apex, so that the nonuniformity of perfusion is less.

Why should \dot{Q} have this peculiar height dependence? The basic answers are the same as those for the similar question we raised about the regional nonuniformity of *ventilation*: **posture** and **gravity**. Thus, standing on your head will reverse the flow-height relationship, and we would expect height-related differences in flow to be minimal in microgravity conditions.

Figure 31-9C shows how we can divide the upright lung into four zones based on the relationships among various pressures. We define the first three zones based on how *alveolar* blood vessels are affected by the relative values of three different pressures: alveolar pressure (P_A), the pressure inside pulmonary arterioles (P_{PA}), and the pressure inside pulmonary venules (P_{PV}). In the fourth zone, we instead focus on how extra-alveolar vessels are affected by intrapleural pressure (P_{IP}).

Zone 1: $P_A > P_{PA} > P_{PV}$

These conditions prevail at the apex of the lung under certain circumstances. The defining characteristic of a zone 1 alveolar vessel is that P_{PA} and P_{PV} are so low that they have fallen below P_A .

At the level of the left atrium (the reference point for the pressure measurements), the *mean* P_{PA} is ~ 15 mm Hg (see Table 31-1), which—because mercury is 13.6-fold more dense than water—corresponds to ~ 20 cm H_2O (see Fig. 31-9C, lower illustration for zone 3). Similarly, mean P_{PV} is ~ 8 mm Hg, or ~ 10 cm H_2O . As we move upward closer to the apex of an upright lung, the actual pressures in the lumens of pulmonary arterioles and venules fall by 1 cm H_2O for each 1 cm of vertical ascent. In the hypothetical case in which alveoli at the lung apex are 20 cm above the level of the left atrium, the mean P_{PA} of these alveoli would be 0 cm H_2O (see Fig. 31-9C, zone 1). The corresponding P_{PV} would be about -10 cm H_2O . The pressure inside the pulmonary capillary (P_c) would be intermediate, perhaps -5 cm H_2O . In principle, blood would still flow through this capillary—the driving pressure would be ~ 10 cm H_2O —were it not for the pressure inside the surrounding alveoli, which is 0 cm H_2O between breaths. Therefore, because P_A is much higher than P_c , the negative P_{TM} (see p. 414) would tend to crush the capillary and reduce blood flow.

Fortunately, zone 1 conditions do not exist for normal people at rest. However, they can arise if there is either a sufficient decrease in P_{PA} (e.g., in hemorrhage) or a sufficient increase in P_A (e.g., in **positive-pressure ventilation**).

Zone 2: $P_{PA} > P_A > P_{PV}$

These conditions normally prevail from the apex to the mid-lung. The defining characteristic of zone 2 is that mean P_{PA} and P_{PV} are high enough so that they sandwich P_A (see Fig. 31-9C, zone 2). Thus, at the arteriolar end, the positive P_{TM} causes the alveolar vessel to dilate. Further down the capillary, though, luminal pressure gradually falls below P_A , so that the negative P_{TM} squeezes the vessel, raising resistance and thus reducing flow. As we move downward in zone 2, the crushing force decreases because the hydrostatic pressures in the arteriole, capillary, and venule all rise in parallel by 1 cm H_2O for each 1 cm

of descent (see [Fig. 31-9C](#), upper → lower illustrations for zone 2). Simultaneously, resistance decreases. The conversion of a closed vessel (or one that is open but not conducting) to a conducting one by increased P_{PA} and P_{PV} is an example of **recruitment**.

Zone 3: $P_{PA} > P_{PV} > P_A$

These conditions prevail in the middle to lower lung. The defining characteristic of zone 3 is that mean P_{PA} and P_{PV} are so high that they both exceed P_A (see Fig. 31-9C, zone 3). Thus, P_{TM} is positive along the entire length of the alveolar vessel, tending to dilate it. As we move downward in zone 3, the hydrostatic pressures in the arteriole, capillary, and venule all continue to rise by 1 cm H₂O for each 1 cm of descent. Because P_A between breaths does not vary with height in the lung, the gradually increasing pressure of the alveolar vessel produces a greater and greater P_{TM} , causing the vessel to dilate more and more—an example of **distention** (see Fig. 31-9C, upper → lower illustrations for zone 3). This distention causes a gradual decrease in resistance of the capillaries as we move downward in zone 3. Hence, although the driving force ($P_{PA} - P_{PV}$) remains constant, perfusion increases toward the base of the lung.

The arrangement in which a variable P_{TM} controls flow is known as a **Starling resistor**. Keep in mind that the driving force ($P_{PA} - P_{PV}$) is constant in all of the zones.

Zone 4: $P_{PA} > P_{PV} > P_A$

These conditions prevail at the extreme base of the lungs. In zone 4, the *alveolar vessels* behave as in zone 3; they dilate more as we descend toward the base of the lung. However, the *extra-alveolar vessels* behave differently. At the base of the lung, P_{ip} is least negative (see Fig. 31-5C). Thus, as we approach the extreme base of the lung, the distending forces acting on the extra-alveolar blood vessels fade, and the resistance of these extra-alveolar vessels increases (see Fig. 31-9C, zone 4). Recall that we saw a similar effect—at the level of the whole lung (see Fig. 31-7B, blue curve)—where resistance of the extra-alveolar vessels increased as lung volume fell (i.e., as P_{ip} became less negative). Because these extra-alveolar vessels feed or drain the alveolar vessels, \dot{Q} begins to fall from its peak as we approach the extreme base of the lungs (see Fig. 31-9B).

These lung zones are *physiological*, not anatomical. The boundaries between the zones are neither fixed nor sharp. For example, the boundaries can move downward with positive-pressure ventilation (which increases P_A) and can move upward with exercise (which increases P_{PA}). In our discussion of lung zones, we have tacitly assumed that P_A is always zero and that the values of P_{PA} and P_{PV} are stable and depend only on height in the lung. In real life, of course, things are more complicated. During the respiratory cycle, P_A becomes negative during inspiration (promoting dilation of alveolar vessels) but positive during expiration. During the cardiac cycle, the pressure inside the arterioles and pulmonary capillaries is greatest during systole (promoting dilation of the vessel) and lowest during diastole. Thus, we would expect blood flow through an alveolar vessel to be greatest when inspiration coincides with systole.

Matching Ventilation and Perfusion

The greater the ventilation-perfusion ratio, the higher the P_{O_2} and the lower the P_{CO_2} in the alveolar air

In Figure 31-4 we saw that, all other factors being equal, alveolar ventilation determines alveolar P_{O_2} and P_{CO_2} . The greater the ventilation, the more closely P_{AO_2} and P_{ACO_2} approach their respective values in inspired air. However, in Figure 31-4 we were really focusing on *total* alveolar ventilation and how this influences the *average*, or idealized, alveolar P_{O_2} and P_{CO_2} . In fact, we have already learned that both ventilation and perfusion vary among alveoli. In any group of alveoli, the greater the local ventilation, the more closely the composition of local alveolar air approaches that of the inspired air. Similarly, because blood flow removes O_2 from the alveolar air and adds CO_2 , the greater the perfusion, the more closely the composition of local alveolar air approaches that of mixed-venous blood. Thus, the local **ventilation-perfusion ratio** (\dot{V}_A/\dot{Q}) determines the local P_{AO_2} and P_{ACO_2} .

You might view the alveoli as a sports venue where ventilation and perfusion are engaged in a continuous struggle over control of the composition of alveolar air. To the extent that ventilation gains the upper hand, P_{AO_2} rises and P_{ACO_2} falls. To the extent that perfusion holds sway, these parameters change in the opposite direction.

As a physical analog of this struggle over control of alveolar P_{O_2} , consider water flowing (analogous to \dot{V}_A) from a faucet into a sink (alveoli); the water exits (\dot{Q}) through a drain with an adjustable opening. If the drain opening is in midposition and we begin flowing water moderately fast, then the water level (P_{AO_2}) will gradually increase and reach a steady state. Increasing the inflow of water (\dot{V}_A) will cause the water level (P_{AO_2}) to rise until the product of pressure head and drain conductance is high enough to drive water down the drain as fast as the water flows in. If we increase the drain opening and thus the outflow of water (\dot{Q}), then the water level (P_{AO_2}) will fall until the decrease in the pressure head matches the increase in drain conductance, so that once again water inflow and outflow are balanced. Just as a high faucet-drain ratio will raise the water level, a high \dot{V}_A/\dot{Q} ratio will increase alveolar P_{O_2} .

Because of the action of gravity, the regional \dot{V}_A/\dot{Q} ratio in an upright subject is greater at the apex of the lung than at the base

We have already seen that when a subject is upright in a gravitational field, ventilation falls from the base to the apex of the lung (see Fig. 31-5B) and that perfusion also falls, but more steeply (see Fig. 31-9B). Thus, it is not surprising that the ratio \dot{V}_A/\dot{Q} itself varies with height in the lung (Fig. 31-10A). \dot{V}_A/\dot{Q} is lowest near the base, where \dot{Q} exceeds \dot{V}_A . The ratio gradually increases to 1 at about the level of the third rib and further increases toward the apex, where \dot{Q} falls more precipitously than \dot{V}_A .

FIGURE 31-10 Regional differences in \dot{V}_A/\dot{Q} ratio and alveolar gas composition. (Data from West JB: Ventilation/Blood Flow and Gas Exchange. Oxford, UK, Blackwell, 1985.)

Table 31-3 shows how differences in \dot{V}_A/\dot{Q} at the apex and base of the lungs influence the regional composition of alveolar air. At the apex (the most rostral 7% of lung volume in this example), where \dot{V}_A/\dot{Q} is highest, alveolar P_{O_2} and P_{CO_2} most closely approach their values in inspired air. Because both O_2 transport and CO_2 transport across the blood-gas barrier are **perfusion limited** (see pp. 671–673), O_2 and CO_2 have completely equilibrated between the alveolar air and the blood by the end of the pulmonary capillaries. Thus, blood leaving the apex has the same high P_{O_2} and low P_{CO_2} as the alveolar air. Of course, the relatively low P_{CO_2} produces a *respiratory alkalosis* (see p. 634) in the blood leaving the apex.

TABLE 31-3

Effect of Regional Differences in \dot{V}_A/\dot{Q} on the Composition of Alveolar Air and Pulmonary-Capillary Blood

LOCATION	FRACTION OF TOTAL LUNG VOLUME	\dot{V}_A/\dot{Q}	P_{O_2} (mm Hg)	P_{CO_2} (mm Hg)	pH	\dot{Q} (L/min)
Apex	7%	3.3	132	28	7.55	0.07
Base	13%	0.6	89	42	7.38	1.3
Overall	100%	0.84*	100	40	7.40	5.0

*Because the transport of both O_2 and CO_2 is perfusion limited, we assume that end-capillary values of P_{O_2} and P_{CO_2} are the same as their respective alveolar values. If the overall alveolar ventilation for the two lungs is 4.2 L/min, and if the cardiac output (i.e., perfusion) is 5 L/min, then the overall \dot{V}_A/\dot{Q} ratio for the two lungs is (4.2 L/min)/(5 L/min) = 0.84.

Modified from West JB: Ventilation/Blood Flow and Gas Exchange. Oxford, UK, Blackwell, 1989.

The situation is just the opposite near the base of the lung (the most caudal 13% of lung volume in this example). Because \dot{V}_A/\dot{Q} here is lowest, alveolar P_{O_2} and P_{CO_2} tend more toward their values in mixed-venous blood. What impact do these different regions of the lung, each with its own \dot{V}_A/\dot{Q} ratio, have on the composition of systemic arterial blood? Each region makes a contribution that is proportional to its blood flow (see the rightmost column in Table 31-3). Because the apex is poorly perfused, it makes only a small contribution to the overall composition of arterial blood. On the other hand, pulmonary tissue at the base of the lungs, which receives ~26% of total cardiac output, makes a major contribution. As a result,

the average composition of blood exiting the lung more closely reflects the composition of the blood that had equilibrated with the air in the base of the lung.

The **O₂-CO₂ diagram** introduced as [Figure 29-11](#) is a helpful tool for depicting how different \dot{V}_A/\dot{Q} ratios throughout the lung produce different blood-gas compositions. The curve in [Figure 31-10B](#) represents all possible combinations of P_{O_2} and P_{CO_2} in the alveolar air or end-pulmonary-capillary blood. The H₂O-saturated **inspired air** ($P_{O_2} = 149$, $P_{CO_2} = \sim 0$ mm Hg) represents the rightmost extreme of the diagram. By definition, the \dot{V}_A/\dot{Q} ratio of inspired air is ∞ , because it does not come into contact with pulmonary-capillary blood. The **mixed-venous blood** ($P_{O_2} = 40$, $P_{CO_2} = 46$ mm Hg) represents the other extreme. By definition, the \dot{V}_A/\dot{Q} ratio of mixed-venous blood is zero, because it has not yet come into contact with alveolar air. With the end points of the diagram established, we can now predict—with the help of the alveolar gas equation (see [Equation 31-17](#)), the Bohr effect (see [p. 652](#)), and the Haldane effect (see [p. 657](#))—all possible combinations of P_{O_2} and P_{CO_2} throughout the lung. As shown in [Figure 31-10B](#), the base, midportion, and apex of the lungs correspond to points along the O₂-CO₂ diagram between mixed-venous blood at one extreme and inspired air at the other.

The ventilation of unperfused alveoli (local $\dot{V}_A/\dot{Q} = \infty$) triggers compensatory bronchoconstriction and a fall in surfactant production

The effects of gravity on ventilation and perfusion cause regional \dot{V}_A/\dot{Q} to vary widely, even in idealized lungs (see [Fig. 31-10A](#)). However, microscopic or local physiological and pathological variations in ventilation and perfusion can cause even greater mismatches of \dot{V}_A/\dot{Q} , the extremes of which are alveolar dead-space ventilation (this section) and shunt (next section).

Alveolar Dead-Space Ventilation

At one end of the spectrum of \dot{V}_A/\dot{Q} mismatches is the elimination of blood flow to a group of alveoli. For example, if we ligated the pulmonary artery feeding one lung, the affected alveoli would receive no perfusion even though ventilation would initially continue normally ([Fig. 31-11A](#)). Above, we saw that such alveolar dead space together with the anatomical dead space constitute the physiological dead space (see [Equation 31-8](#)). The ventilation of the unperfused alveoli is called *alveolar dead-space ventilation* because it does not contribute to gas exchange. Thus, these alveoli behave like conducting airways. 🍷

[N31-12](#)

FIGURE 31-11 Extreme \dot{V}_A/\dot{Q} mismatch and compensatory response—alveolar dead-space ventilation.

N31-12

Notes on the Differences Between Anatomical and Physiological Dead Space

Contributed by Emile Boulpaep, Walter Boron

There is a fundamental difference between the anatomical and alveolar dead space. The **conducting airways** are in series with and upstream from (proximal to) the alveoli. The conducting airways have the composition of inspired air only after an *inspiration*; after an *expiration*, they have the composition of alveolar air. On the other hand, **unperfused alveoli** are in parallel with normal alveoli and have the composition of inspired air, regardless of the position in the respiratory cycle.

A natural cause of alveolar dead-space ventilation is a pulmonary embolism, which obstructs blood flow to a group of alveoli. Because one task of the lung is to filter small emboli from the blood (see p. 600), the lung must deal with small regions of alveolar dead-space ventilation on a recurring basis. At the instant the blood flow ceases, the alveoli supplied by the affected vessel(s) contain normal alveolar air. However, each cycle of inspiration and expiration replaces some stale alveolar air with fresh, inspired air. Because no exchange of O_2 and CO_2 occurs between these unperfused alveoli and pulmonary-capillary blood, the alveolar gas gradually achieves the composition of moist inspired air, with alveolar P_{O_2} rising to ~ 149 mm Hg and P_{CO_2} falling to ~ 0 mm Hg (see Fig. 31-11A, step 2). By definition, alveolar dead space has a \dot{V}_A/\dot{Q} ratio of ∞ , as described by the "Inspired air" point on the x-axis of an O_2 - CO_2 diagram (see Fig. 31-10B).

Redirection of Blood Flow

Blocking blood flow to one group of alveoli diverts blood to other "normal" alveoli, which then become

somewhat hyperperfused. Thus, the blockage not only increases \dot{V}_A/\dot{Q} in alveoli downstream from the blockage, but also decreases \dot{V}_A/\dot{Q} in other regions. Redirection of blood flow thus accentuates the nonuniformity of ventilation.

Regulation of Local Ventilation

Because alveolar dead-space ventilation causes alveolar P_{CO_2} to fall to ~ 0 mm Hg in downstream alveoli, it leads to a respiratory alkalosis (see p. 634) in the surrounding interstitial fluid. These local changes trigger a compensatory **bronchiolar constriction** in the adjacent tissues (see Fig. 31-11B), so that over a period of seconds to minutes, airflow partially diverts away from the unperfused alveoli and toward normal alveoli, to which blood flow is also being diverted. This compensation makes teleological sense, because it tends to correct the \dot{V}_A/\dot{Q} shift in both the unperfused and normal alveoli. The precise mechanism of bronchiolar constriction is unknown, although bronchiolar smooth muscle may contract—at least in part—in response to a high extracellular pH.  **N31-13**

N31-13

Bronchiolar Constriction during Alveolar Dead-Space Ventilation

Contributed by Emile Boulpaep, Walter Boron

The precise mechanism of bronchiolar constriction in response to alveolar dead-space ventilation is unknown. However, it is intriguing to speculate that, at least in part, the mechanism may parallel that for the autoregulation of blood flow in the brain. The vascular smooth-muscle cells (VSMCs) of the penetrating cerebral arterioles constrict in response to respiratory alkalosis—which is why one feels dizzy after hyperventilating. This constriction of the VSMCs occurs when one imposes an alkalosis in the complete absence of CO_2/HCO_3^- . Furthermore, the alkalosis-induced vasoconstriction is due entirely to a pH decrease on the *outside* of the VSMC. In other words, these cells have some sort of an extracellular pH sensor. A pH increase on the inside of the cell actually has the opposite effect: vasodilation. During extracellular acidosis, the vessels dilate.

In addition to a local respiratory alkalosis, the elimination of perfusion has a second consequence. Downstream from the blockage, alveolar type II pneumocytes become starved for various nutrients, including the lipids they need to make surfactant. (These cells never become starved for O_2 !) As a result of the decreased blood flow, **surfactant production falls** over a period of hours to days. The result is a local decrease in compliance, further reducing local ventilation.

These compensatory responses—bronchiolar constriction (i.e., increased resistance, a property of conducting airways) and reduced surfactant production (i.e., decreased compliance, a property of alveoli)—work well only if the alveolar dead space is relatively small, so that an ample volume of healthy tissue remains into which the airflow can divert.

The perfusion of unventilated alveoli (local $\dot{V}_A/\dot{Q} = 0$) triggers a compensatory hypoxic vasoconstriction

Shunt

Alveolar dead-space ventilation is at one end of the spectrum of \dot{V}_A/\dot{Q} mismatches. At the opposite end is shunt—the flow of blood past unventilated alveoli. For example, if we ligate a mainstem bronchus, then inspired air cannot refresh alveoli distal to the obstruction (see Fig. 31-12A). As a result, mixed-venous blood perfusing the unventilated alveoli “shunts” from the right side to the left side of the heart, without benefit of ventilation. When the low- O_2 shunted blood mixes with high- O_2 unshunted blood (which is ventilated), the result is that the mixture has a lower-than-normal P_{O_2} , causing hypoxia in the systemic arteries. It is possible to calculate the extent of the shunt from the degree of hypoxia. **N31-14**

FIGURE 31-12 Extreme \dot{V}_A/\dot{Q} mismatch and compensatory response—shunt.

N31-14

The Shunt Equation

Contributed by Emile Boulpaep, Walter Boron

A **shunt** is one extreme of a \dot{V}/\dot{Q} mismatch and arises when blood perfuses unventilated alveoli. Alveoli may be unventilated because they are downstream from an obstructed conducting airway. Regardless of the mechanism that prevents airflow to these alveoli, the resulting right-to-left shunt causes mixed-venous blood to remain relatively *unoxygenated* and to go directly to the left side of the heart, where it mixes with *oxygenated* “arterial” blood. This process is known as **venous admixture**.

Imagine that 80% of the blood flow to the lungs goes to alveoli that are appropriately ventilated but that 20% goes to alveoli that are downstream from completely obstructed conducting airways. The total perfusion of the lungs is \dot{Q}_T . The shunt perfusion of the unventilated alveoli is \dot{Q}_s , 20% in this example, and the shunted blood has an O_2 content (units: mL O_2 /dL) identical to that of mixed-venous blood (C_v). The difference ($\dot{Q}_T - \dot{Q}_s$) is the perfusion to the normally ventilated alveoli, 80% in our example, and

this unshunted blood has an O_2 content appropriate for the end of a pulmonary capillary (Cc').

The blood emerging from the lungs is a mixture of shunted and unshunted blood so that the O_2 emerging from the lung is partially O_2 carried by the shunted blood and partially O_2 carried by the unshunted blood:

$$\text{Total } O_2 \text{ leaving lungs} = \text{Shunted } O_2 + \text{Unshunted } O_2$$

(NE 31-35)

How much O_2 per minute emerges from the lungs in the systemic arterial blood? This amount is the product of the O_2 content of this arterial blood (C_a) and the total blood flow out the lungs (\dot{Q}_T):

$$\text{Total } O_2 \text{ leaving lungs} = C_a \times \dot{Q}_T$$

(NE 31-36)

Similarly, the O_2 contributed by the *shunted blood* is the product of the O_2 content and the flow of shunted blood:

$$\underbrace{O_2 \text{ contributed by shunted blood}}_{\text{mL } O_2 / \text{min}} = \underbrace{C_v}_{\substack{\text{mL } O_2 \\ 100 \text{ mL blood}}} \times \underbrace{\dot{Q}_S}_{\substack{\text{mL blood} \\ \text{min}}}$$

(NE 31-37)

Finally, the amount of O_2 contributed per minute by the unshunted blood is

$$O_2 \text{ contributed by unshunted blood} = Cc' \times (\dot{Q}_T - \dot{Q}_S)$$

(NE 31-38)

Inserting the expressions for each of the terms in Equations NE 31-36 through NE 31-38 into Equation NE 31-35, we have

$$\underbrace{C_a \times \dot{Q}_T}_{\substack{\text{Total } O_2 \\ \text{leaving lungs}}} = \underbrace{(C_v \times \dot{Q}_S)}_{\substack{O_2 \text{ carried by} \\ \text{shunted blood}}} + \underbrace{C_a \times (\dot{Q}_T - \dot{Q}_S)}_{\substack{O_2 \text{ carried by} \\ \text{unshunted blood}}}$$

(NE 31-39)

Rearranging this equation and solving for the fraction of total blood flow that is represented by the shunt (\dot{Q}_S / \dot{Q}_T), we have

$$\frac{\dot{Q}_S}{\dot{Q}_T} = \frac{C_{c'} - C_a}{C_{c'} - C_{\bar{v}}} \quad (\text{NE 31-40})$$

This expression is known as the **shunt equation**.

What does Equation NE 31-40 predict for \dot{Q}_S/\dot{Q}_T in our example? We will assume that the O_2 content of mixed-venous blood is 15 mL O_2 /dL blood, whereas that for blood at the end of the pulmonary capillaries is 20 mL O_2 /dL blood. These values are similar to those given in Table 29-3. If our hypothetical subject—who is affected by a 20% shunt—has systemic arterial blood with an O_2 content of 19 mL O_2 /dL blood, then the shunt equation predicts

$$\frac{\dot{Q}_S}{\dot{Q}_T} = \frac{C_{c'} - C_a}{C_{c'} - C_{\bar{v}}} = \frac{20-19}{20-15} = 20\% \quad (\text{NE 31-41})$$

Thus, the shunt equation predicts that the shunt is 20% of the total blood flow, which is reasonable, inasmuch as we started the example by assuming that 80% of the blood flowed through properly ventilated alveoli.

Natural causes of airway obstruction include aspiration of a **foreign body** or the presence of a **tumor** in the lumen of a conducting airway. The collapse of alveoli (**atelectasis**) also produces a right-to-left shunt, a pathological example of which is pneumothorax (see p. 608). Atelectasis also occurs naturally in dependent regions of the lungs, where P_{ip} is not so negative (see Fig. 31-5C) and surfactant levels gradually decline. Sighing or yawning stimulates surfactant release (see p. 615) and can reverse physiological atelectasis.

Imagine that an infant aspirates a peanut. Initially, the air trapped distal to the obstruction has the composition of normal alveolar air. However, pulmonary-capillary blood gradually extracts O_2 from the trapped air and adds CO_2 . Eventually, the P_{O_2} and P_{CO_2} of the trapped air drift to their values in **mixed-venous blood**. If the shunt is small, so that it does not materially affect the P_{O_2} or P_{CO_2} of the systemic arterial blood, then the alveoli will have a P_{O_2} of 40 mm Hg and a P_{CO_2} of 46 mm Hg. By definition, shunted alveoli have a \dot{V}_A/\dot{Q} of zero and are represented by the “Mixed-venous blood” point on an O_2 - CO_2 diagram (see Fig. 31-10B).

Redirection of Airflow

Blocking airflow to one group of alveoli simultaneously diverts air to normal parts of the lung, which then become somewhat hyperventilated. Thus, shunt not only decreases \dot{V}_A/\dot{Q} in unventilated alveoli, but also increases \dot{V}_A/\dot{Q} in other regions. The net effect is a widening of the nonuniformity of \dot{V}_A/\dot{Q} ratios.

Asthma

Although less dramatic than complete airway obstruction, an incomplete occlusion also decreases \dot{V}_A/\dot{Q} .

An example is asthma, in which hyperreactivity of airway smooth muscle increases local airway resistance and decreases ventilation of alveoli distal to the pathology.

Normal Anatomical Shunts

The **thebesian veins** drain some of the venous blood from the heart muscle, particularly the left ventricle, directly into the corresponding cardiac chamber. Thus, delivery of deoxygenated blood from thebesian veins into the left ventricle (<1% of cardiac output) represents a right-to-left shunt. The **bronchial arteries**, branches of the aorta that carry ~2% of the cardiac output, supply the *conducting* airways (see p. 597). After passing through capillaries, about half of the bronchial blood drains into a systemic vein—the azygos vein—and then to the right side of the heart. The other half (~1% of cardiac output) anastomoses with oxygenated blood in pulmonary venules and thus represents part of the anatomical right-to-left shunt (see p. 412).

Pathological Shunts

In Chapter 57, we discuss examples of right-to-left shunts.  **N31-15** Respiratory distress syndrome in the newborn (Box 57-2) can cause airway collapse. Generalized hypoxemia in the newborn can constrict the pulmonary vasculature, as we will see in the next paragraph, leading to pulmonary hypertension and the shunting of blood via the foramen ovale (see p. 1158) or a patent ductus arteriosus (see p. 1158).

N31-15

Right-to-Left Shunts

Contributed by Emile Boulpaep, Walter Boron

Two congenital anomalies of the great vessels in which there may be sizeable right-to-left shunts are **tetralogy of Fallot** and **transposition of the great vessels**. Both conditions can cause severe hypoxemia.

Regulation of Local Perfusion

The alveoli that derive from a single terminal bronchiole surround the pulmonary arteriole that supplies these alveoli. Thus, the vascular smooth-muscle cells of this pulmonary arteriole are bathed in an interstitial fluid whose composition reflects that of the local alveolar gas. In the case of shunt, the vascular smooth-muscle cells sense a decrease in P_{O_2} , an increase in P_{CO_2} , and a fall in pH. The decrease in local alveolar P_{O_2} triggers a compensatory **hypoxic pulmonary vasoconstriction** (see p. 687), which the accompanying respiratory acidosis augments (see Fig. 31-12B). Note that this response is just the opposite of that of *systemic* arterioles, which *dilate* in response to hypoxia (see pp. 477–478). Hypoxic pulmonary vasoconstriction makes teleological sense because it diverts blood flow away from unventilated alveoli toward normal alveoli, to which airflow is also being diverted. This compensation tends to correct the \dot{V}_A/\dot{Q} shift in both the unventilated and normal alveoli.

If the amount of pulmonary tissue involved is sufficiently small (<20%), then hypoxic vasoconstriction has a minimal effect on overall pulmonary vascular resistance. The vasoconstriction causes a slight increase in pulmonary arterial pressure, which recruits and distends pulmonary vessels outside of the shunt zone. In contrast, *global* alveolar hypoxia—caused by, for example, ascending to high altitude—

produces a generalized hypoxic vasoconstriction that may cause the resistance of the pulmonary vasculature to more than double. In susceptible individuals, the result can be acute mountain sickness (see [p. 1232](#)).

Even if whole-lung \dot{V}_A and \dot{Q} are normal, exaggerated local \dot{V}_A/\dot{Q} mismatches produce hypoxia and respiratory acidosis

As we saw in [Table 31-3](#), even a normal person has lung regions with \dot{V}_A/\dot{Q} values ranging from ~ 0.6 to 3.3 . In addition, even a normal person has local variations in \dot{V}_A/\dot{Q} due to alveolar dead-space ventilation as well as physiological and anatomical shunts. These physiological \dot{V}_A/\dot{Q} mismatches produces an arterial P_{CO_2} (i.e., ~ 40 mm Hg) that we regard as “normal” and an arterial P_{O_2} (i.e., ~ 100 mm Hg) that we also regard as “normal.” If pathological processes exaggerate this \dot{V}_A/\dot{Q} mismatch, the result is respiratory acidosis and hypoxia. The sophisticated compensatory responses to alveolar dead-space ventilation and shunt—discussed above—help to minimize these mismatches. Thus, uncompensated \dot{V}_A/\dot{Q} abnormalities lead to respiratory acidosis and hypoxia. To illustrate how \dot{V}_A/\dot{Q} mismatches produce these consequences, here we examine CO_2 and O_2 handling first in normal lungs and then in two extreme, idealized cases: alveolar dead-space ventilation and shunt—each in the absence of any local or system-wide compensation.

Normal Lungs

[Figure 31-13](#) shows how an individual with a normal \dot{V}_A/\dot{Q} distribution in each lung handles CO_2 and O_2 . We assume that total \dot{V}_A (4.2 L/min) and \dot{Q} (5 L/min) are normal and divided equally between the two lungs. Each lung eliminates half of the 200 mL/min of CO_2 produced by metabolism (see [Fig. 31-13A](#)), and each takes up half of the 250 mL/min of O_2 consumed by metabolism (see [Fig. 31-13B](#)). The physiological \dot{V}_A/\dot{Q} distribution, as discussed in the previous paragraph, yields a mean alveolar P_{CO_2} of ~ 40 mm Hg in each lung and a mean alveolar P_{O_2} of ~ 100 mm Hg. Because the fluxes of CO_2 and O_2 across the alveolar blood-gas barrier are each perfusion limited (see [pp. 671–673](#)), the CO_2 and O_2 partial pressures in the systemic arterial blood are the same as in the alveoli, and arterial pH is normal.

FIGURE 31-13 Normal distribution of \dot{V}_A and \dot{Q} . **N31-18** This is an idealized example. In the upper panels of **A** and **B**, the light beige boxes give the alveolar ventilation to each lung as well as the total alveolar ventilation (\dot{V}_A). The pink boxes give the blood flow to each lung as well as the total cardiac output (\dot{Q}). The white boxes give the rates of CO₂ or O₂ transport (in mL/min) at either the pulmonary or systemic capillaries. The blue boxes give the CO₂ and O₂ partial pressures (in mm Hg) in alveolar air. The lavender boxes give the CO₂ partial pressure (in mm Hg) and CO₂ content (in mL/dL) in the mixed-venous blood, in the blood leaving each of the lungs, and in the mixed-arterial blood. The dark beige boxes give the same information for O₂. The lower panel of **A** shows hypothetical plots of how total CO₂ content varies

with P_{CO_2} at the Hb-O₂ saturations typical of arterial blood (*red line*) and mixed-venous blood (*violet line*). The vertical arrow indicates the decrease in total CO₂ content between the mixed-venous and arterial blood (4 mL/dL). The lower panel of **B** shows comparable plots for how total O₂ content varies with P_{O_2} at the pH and P_{CO_2} values typical of mixed-venous blood (*violet curve*) and arterial blood (*red curve*). The vertical arrow indicates the increase in total O₂ content between the mixed-venous and arterial blood (5 mL/dL).

N31-18

Analysis of \dot{V}_A/\dot{Q} Patterns in Figure 31-13

Contributed by Emile Boulpaep, Walter Boron

The following is a discussion of Figure 31-13 that is more complete than the material presented in the subsection “Normal Lungs” (see p. 693).

Figure 31-13 is a highly simplified example illustrating the principles underlying how an individual with a *normal* \dot{V}_A/\dot{Q} in each lung handles CO₂ (Fig. 31-13A) and O₂ (Fig. 31-13B) as blood flows through the lungs, the systemic circulation, and then back to the lungs. We make the following assumptions:

- Total \dot{V}_A (4.2 L/min) and \dot{Q} (5 L/min) are normal.
- \dot{V}_A and \dot{Q} are evenly divided between the two lungs. Thus, the overall \dot{V}_A/\dot{Q} ratio is (4.2 L/min)/(5 L/min) or 0.84. Of course, the \dot{V}_A/\dot{Q} in each of the two lungs is also 0.84.
- \dot{V}_A and \dot{Q} are uniformly distributed within each lung. In other words, we are ignoring the usual apex-to-base inequalities of both \dot{V}_A and \dot{Q} (see Fig. 31-10). In addition, we assume that the lungs are free of pathological causes of either alveolar dead-space ventilation or shunt.
- The system has no physiological right-to-left shunts.
- The P_{ACO_2} in each lung will be 40 mm Hg; and the P_{AO_2} , 100 mm Hg.
- Total-body \dot{V}_{CO_2} will be 200 mL/min and total-body \dot{V}_{O_2} will be 250 mL/min.
- The entire system is in a steady state.

Predicting *precisely* how \dot{V}_A/\dot{Q} abnormalities affect the CO₂ and O₂ partial pressures in the three key compartments (alveoli, arterial blood, and mixed-venous blood) is extremely complicated, in part because changes in P_{CO_2} and pH affect O₂ carriage (the Bohr effect; see p. 652) and changes in P_{O_2} affect CO₂ carriage (the Haldane effect; see p. 657). Moreover, in reality, \dot{V}_A , \dot{Q} , and the \dot{V}_A/\dot{Q} ratio are *not* uniform throughout each lung. However, although the examples in the text are greatly simplified, they illustrate the principles of how \dot{V}_A/\dot{Q} mismatches lead to abnormalities in the arterial blood gases. We begin here with a discussion of the normal condition. We will consider alveolar dead-space ventilation

in **N31-19** and shunt in **N31-20**.

We will now follow the blood during one circuit through the circulation to see the relationship among the composition of the arterial blood, the CO₂ and O₂ transport rates in the lung, and the composition of the mixed-venous blood.

CO₂ Handling

First consider the fate of CO₂ in the following six steps (see Fig. 31-13A):

Step 1: Each lung must first receive and then exhale half of the total 200 mL/min of CO₂ that body metabolism produces. In other words, 100 mL of CO₂ enters each lung each minute, and because they are in a steady state, each lung exhales precisely this same amount each minute.

Step 2: In each lung, a \dot{V}_A of 2.1 L/min dilutes 100 mL of exhaled CO₂ (i.e., the exhaled 100 mL of CO₂ is contained within the 2100 mL of exhaled air). This combination of \dot{V}_A and \dot{V}_{CO_2} corresponds to a P_{ACO_2} of ~40 mm Hg.

Step 3: Because CO₂ transport is perfusion limited (see pp. 671–673), the blood that emerges from each lung has the same P_{CO_2} as the alveolar air, 40 mm Hg. According to the CO₂ dissociation curve, we see that this P_{CO_2} of 40 mm Hg corresponds to an arterial CO₂ content of 48 mL/dL (see lower panel of Fig. 31-13A, point *a*).

Step 4: As the blood flows through the systemic capillaries, it picks up the 200 mL/min of CO₂ produced by metabolism. Given a cardiac output of 5 L/min, we can use the Fick principle (see p. 423) to compute how much the CO₂ content must rise in the capillaries for each 100 mL of blood:

$$\Delta C_{CO_2} = \frac{\dot{V}_{CO_2}}{\dot{Q}} = \frac{200 \text{ mL CO}_2 / \text{min}}{5 \text{ L blood/min}} = 40 \text{ mL CO}_2 / \text{L} = 4 \text{ mL CO}_2 / \text{dL}$$

(NE 31-42)

Thus, the mixed-venous CO₂ content must be 48 + 4 = 52 mL/dL.

Step 5: According to the CO₂ dissociation curve, when the CO₂ content of the blood is 52 mL/dL, the mixed-venous P_{CO_2} must be 46 mm Hg (lower panel of Fig. 31-13A, point \bar{v}).

Step 6: As the blood completes the cycle and passes through the pulmonary capillaries, the P_{CO_2} falls from 46 mm Hg to its original value of 40 mm Hg as 100 mL of CO₂ diffuses from the pulmonary capillaries to the alveoli each minute in each lung. Simultaneously, the CO₂ content falls from 52 to 48 mL/dL as CO₂ evolves into the alveolar air at the rate of 100 mL/min in each lung (200 mL/min, total).

O₂ Handling

Now consider the fate of O₂, illustrated in six steps in Figure 31-13B. The situation for O₂ is comparable to that for CO₂, although the fluxes are all in a direction opposite to those for CO₂.

Step 1: Each lung must take up half of the 250 mL/min O₂ required by body metabolism, that is, 125 mL/min for each lung.

Step 2: For a $P_{A\text{CO}_2}$ of 40 mm Hg and an RQ (see Equation 31-14) of 0.8, the alveolar gas equation (see Equation 31-17) predicts a $P_{A\text{O}_2}$ of ~100 mm Hg for each lung.

Step 3: The transport of O₂, like that of CO₂, is perfusion limited (see pp. 671–673), so that the blood emerging from each lung has a P_{O_2} of ~100 mm Hg. According to the O₂ dissociation curve, a P_{O_2} of 100 mm Hg corresponds to an arterial O₂ content of 20 mL/dL (see lower panel of Fig. 31-13B, point *a*).

Step 4: As the blood flows through the systemic capillaries, it must give up 250 mL/min of O₂, which will be consumed by metabolism. According to the Fick principle, the decrease in O₂ content that occurs as the blood passes through the systemic capillaries is

$$\Delta C_{\text{O}_2} = \frac{\dot{V}_{\text{O}_2}}{\dot{Q}} = \frac{250 \text{ mL O}_2 / \text{min}}{5 \text{ L blood/min}} = 50 \text{ mL O}_2 / \text{L} = 5 \text{ mL O}_2 / \text{dL}$$

(NE 31-43)

Thus, the mixed-venous O₂ content must be 20 – 5 = 15 mL/dL.

Step 5: From the O₂ dissociation curve, we see that a mixed-venous O₂ content of 15 mL/dL corresponds to a mixed-venous O₂ of 40 mm Hg (see lower panel of Fig. 31-13B, point \bar{v}).

Step 6: As the blood completes the cycle and passes through the lungs, it must pick up 125 mL/min of O₂ in each lung. This influx of O₂ causes the O₂ content to increase from 15 to 20 mL/dL, as the blood P_{O_2} increases from 40 to 100 mm Hg.

Alveolar Dead-Space Ventilation Affecting One Lung

To simulate alveolar dead-space ventilation (Fig. 31-14) in the laboratory, we can surgically ligate the left pulmonary artery, thereby eliminating all *perfusion to the left lung*. Total \dot{Q} remains at its normal 5 L/min, but all blood goes to the right lung. \dot{V}_A remains at its normal 4.2 L/min and is evenly distributed between the two lungs. Thus, the \dot{V}_A/\dot{Q} to the left lung is 2.1/0 or ∞ , whereas the \dot{V}_A/\dot{Q} to the right lung is

2.1/5 or 0.42. The overall \dot{V}_A/\dot{Q} is normal, 0.84. The key question is whether a combination of a high \dot{V}_A/\dot{Q} in the abnormal lung and a low \dot{V}_A/\dot{Q} in the normal lung can yield normal blood-gas levels.

A ALVEOLAR DEAD-SPACE VENTILATION: CO₂ HANDLING

B ALVEOLAR DEAD-SPACE VENTILATION: O₂ HANDLING

FIGURE 31-14 Alveolar dead-space ventilation. **N31-19** The numbers in this idealized example refer to a time after the individual has achieved a new steady state. In the upper panels of **A** and **B**, the light beige boxes give the alveolar ventilation to each lung as well as the total alveolar ventilation (\dot{V}_A). The pink boxes give the blood flow to each lung as well as the total cardiac output (\dot{Q}). The white boxes give the rates of CO₂ or O₂ transport (in mL/min) at either the pulmonary or systemic capillaries. The blue boxes give the CO₂ and O₂ partial pressures (in mm Hg) in alveolar air. The lavender boxes give the CO₂ partial pressure (in mm Hg) and CO₂ content (in mL/dL) in the mixed-venous blood, in the blood leaving each of the lungs, and in the mixed-arterial blood. The dark beige boxes give the same information for O₂. The

lower panel of **A** shows plots of how total CO₂ content in this example varies with P_{CO_2} at the Hb-O₂ saturations of arterial blood (*red line*) and mixed-venous blood (*violet line*). Despite the severe respiratory acidosis, the decrease in total CO₂ content between the mixed-venous and arterial blood is normal (4 mL/dL). The lower panel of **B** shows comparable plots for how total O₂ content varies with P_{O_2} at the pH and P_{CO_2} values of mixed-venous blood (*violet curve*) and arterial blood (*red curve*). Despite the severe hypoxia, the increase in total O₂ content between the mixed-venous and arterial blood is normal (5 mL/dL).

N31-19

Analysis of \dot{V}/\dot{Q} Patterns in Figure 31-14

Contributed by Emile Boulpaep, Walter Boron

The following is a discussion of Figure 31-14 that is more complete than the material presented in the subsection “Alveolar Dead-Space Ventilation Affecting One Lung” (see pp. 693–696).

Figure 31-14 is a highly simplified example that illustrates the principles underlying how alveolar dead-space ventilation affects the handling of CO₂ and O₂. Except as noted below in this paragraph, all assumptions and parameter values for this example are the same as for the normal case in Figure 31-13.

N31-18 The key difference in the example in Figure 31-14 is that *the left lung receives no perfusion—alveolar dead-space ventilation*. The total \dot{Q} remains at 5 L/min, but all of this perfusion goes to the right lung. Notice that the \dot{V}_A of 4.2 L/min is evenly distributed between the two lungs. Thus, the \dot{V}_A/\dot{Q} of the left lung is 2.1/0 or ∞ , whereas the \dot{V}_A/\dot{Q} of the right lung is 2.1/5 or 0.42. The overall \dot{V}_A/\dot{Q} remains 0.84. Can the *low* \dot{V}_A/\dot{Q} of the normal lung make up for the *high* \dot{V}_A/\dot{Q} of the abnormal lung?

CO₂ Handling

First consider the fate of CO₂ in the following seven steps (see Fig. 31-14):

Step 1: In the steady state, the normal right lung must eliminate the entire complement of metabolically produced CO₂ production, which is 200 mL/min. This rate of CO₂ delivery to the right lung is twice its normal level.

Step 2: In the right lung, the normal \dot{V}_A of 2.1 L/min must now dilute twice the normal amount of CO₂. Thus, alveolar P_{CO_2} in this right lung must be twice normal (i.e., ~80 mm Hg).

Step 3: Because no blood is flowing to the left lung, its alveolar P_{CO_2} is the same as the P_{CO_2} of inspired air (i.e., ~0 mm Hg). Half of the alveolar air that the subject expires comes from the right lung, and half comes from the left lung. Thus, the **mean** P_{ACO_2} is $(80 + 0)/2 = 40$ mm Hg, which is normal! As we will see below, this mean alveolar P_{CO_2} is important for computing the **alveolar-arterial (A-a) difference** (see Box 31-1).

Step 4: Because the transport of CO₂ across the blood-gas barrier is perfusion limited (see pp. 671–673), the blood leaving the *right* lung has a P_{CO_2} that is the same as the alveolar P_{CO_2} of the right lung, 80 mm Hg. Because no blood exits from the *left* lung, the systemic arterial blood also has a P_{CO_2} of

80 mm Hg. According to the CO₂ dissociation curve, a P_{CO_2} of 80 mm Hg (which represents a substantial degree of respiratory acidosis) corresponds to a CO₂ content of ~67 mL/dL (see lower panel of Fig. 31-14A, point *a*).

Step 5: In the systemic capillaries, metabolically produced CO₂ enters the blood at the rate of 200 mL/min. As we already know from our analysis of the normal condition in Figure 31-13A, adding 200 mL CO₂ to 5 liters of blood increases the CO₂ content by 4 mL/dL:

$$\Delta C_{\text{CO}_2} = \frac{\dot{V}_{\text{CO}_2}}{\dot{Q}} = \frac{200 \text{ mL CO}_2 / \text{min}}{5 \text{ L blood/min}} = 40 \text{ mL CO}_2 / \text{L} = 4 \text{ mL CO}_2 / \text{dL}$$

(NE 31-44)

Thus, the CO₂ content of the blood at the end of the systemic capillaries will be 67 + 4 = 71 mL/dL.

Step 6: According to the CO₂ dissociation curve, when the CO₂ content of the blood is 71 mL/dL, the mixed-venous P_{CO_2} must be 87 mm Hg (see lower panel of Fig. 31-14A, point \bar{v}).

Step 7: As the blood completes the cycle and passes through the pulmonary capillaries of the right lung, the P_{CO_2} falls from 87 mm Hg back to its original value of 80 mm Hg. Simultaneously, the CO₂ content falls from 71 mL/dL to its original value of 67 mL/dL as CO₂ evolves into the alveolar air at the rate of 200 mL/min.

Thus, even with a severe \dot{V}_A/\dot{Q} abnormality, the lung is able to expel the usual 200 mL/min of CO₂, but at a tremendous price: a very high arterial P_{CO_2} and thus respiratory acidosis (see p. 633).

O₂ Handling

Now consider the fate of O₂ (see Fig. 31-14B):

Step 1: The normal right lung must deliver all the O₂ required by the body, 250 mL/min. This rate of O₂ abstraction from the right lung is twice normal.

Step 2: Because the \dot{V}_A/\dot{Q} ratio of the normal right lung is so low (i.e., half normal), the alveolar P_{O_2} in the right lung must be far lower than the usual value of ~100 mm Hg. Because the P_{ACO_2} in this lung is 80 mm Hg and RQ is 0.8, we use the alveolar gas equation (see Equation 31-17) to compute a P_{ACO_2} of 51 mm Hg.

Step 3: Because no blood flow goes to the left lung, its \dot{V}_A/\dot{Q} is ∞ , and thus its alveolar P_{O_2} is the same as the P_{O_2} of inspired air (i.e., 149 mm Hg). The **mean** P_{AO_2} of air expired from the two lungs is (51 + 149)/2 = 100 mm Hg and thus is normal—just as the mean P_{ACO_2} was normal.

Step 4: Because the transport of O₂ across the blood-gas barrier is perfusion limited (see pp. 671–673), the P_{O_2} of the blood leaving the right lung is the same as the alveolar P_{O_2} of the right lung, 51 mm Hg. Because no blood exits from the *left* lung, the systemic arterial blood has the same P_{O_2} as the blood leaving the right lung, namely 51 mm Hg. From the O₂ dissociation curve, we see that a P_{O_2} of 51 mm Hg dictates an O₂ content of only 14 mL/dL (see lower panel of Fig. 31-14B, point *a*).

Step 5: In the systemic capillaries, O₂ leaves the blood at the rate of 250 mL/min. As we already know from our analysis of Figure 31-13B, removing 250 mL of O₂ from 5 L of blood decreases the O₂ content by 5 mL/dL:

$$\Delta C_{O_2} = \frac{\dot{V}_{O_2}}{\dot{Q}} = \frac{250 \text{ mL O}_2 / \text{min}}{5 \text{ L blood/min}} = 50 \text{ mL O}_2 / \text{L} = 5 \text{ mL O}_2 / \text{dL}$$

(NE 31-45)

Thus, the O₂ content of the blood at the end of the systemic capillaries will be 14 – 5 = 9 mL/dL.

Step 6: According to the O₂ dissociation curve, when the O₂ content is 9 mL/dL, the mixed-venous P_{O_2} must be 37 mm Hg (see lower panel of Fig. 31-14B, point \bar{v}).

Step 7: As the blood completes the cycle and passes through the pulmonary capillaries of the right lung, the P_{O_2} rises from 37 to 51 mm Hg, and the O₂ content rise from 9 to 14 mL/dL as O₂ enters from the alveolar air at the rate of 250 mL/min.

Thus, even with a severe \dot{V}_A/\dot{Q} abnormality, the lung is able to import the usual 250 mL/min of O₂, but at a tremendous price: a very low arterial P_{O_2} (hypoxia).

Beware that this analysis, as complicated as it may seem, is highly oversimplified. For example, in step 4 and step 6 of the CO₂ analysis, we used a standard CO₂ dissociation curve. However, we know that hypoxia will increase the CO₂-carrying capacity of blood (Haldane effect; see p. 657). Similarly, in step 4 and step 6 of the O₂ analysis, we used a standard O₂ dissociation curve. However, we know that respiratory acidosis will decrease the O₂-carrying capacity of blood (the Bohr effect; see p. 652).

Nevertheless, the take-home message is clear. Even if overall \dot{V}_A and \dot{Q} are normal, an uneven distribution of perfusion leads to respiratory acidosis and hypoxia. Thus, the hyperperfused “good” lung cannot make up for the deficit incurred by the hypoperfused “bad” lung. In our example, *the fundamental problem is that ventilating unperfused alveoli in the left lung reduces the effective alveolar ventilation by half.*

The normal right lung must now eliminate all of the CO₂ that the body produces—that is, the right lung

must eliminate CO_2 at twice the rate that it normally does. However, the right lung has its usual \dot{V}_A of 2.1 L/min. Because a normal amount of alveolar air must carry away twice as much CO_2 in the new steady state, the right lung's alveolar P_{CO_2} doubles to ~ 80 mm Hg (see Fig. 31-14A). Because the entire cardiac output perfuses the normal right lung, arterial P_{CO_2} is also ~ 80 mm Hg. *Thus, even with the severe \dot{V}_A/\dot{Q} abnormality produced by alveolar dead-space ventilation, the lung is able to expel the usual 200 mL/min of CO_2 , but at a tremendous price: a very high arterial P_{CO_2} and thus respiratory acidosis.*

The normal right lung must also supply all of the body's O_2 —delivering O_2 to the blood at twice its normal rate. However, because the right lung still has its normal \dot{V}_A of 2.1 L/min, its alveolar P_{O_2} falls to ~ 51 mm Hg in the new steady state. The blood leaving the right lung, which is identical to systemic arterial blood, also has a P_{O_2} of ~ 51 mm Hg. *Thus, even with a severe \dot{V}_A/\dot{Q} abnormality, the lung is able to import the usual 250 mL/min of O_2 , but at a tremendous price: a very low arterial P_{O_2} (hypoxia).*

We can now answer the question that we posed above. The hyperperfused “good” lung cannot make up for the deficit incurred by the hypoperfused “bad” lung. In our example, the fundamental problem was that the ventilation of unperfused alveoli in the left lung effectively reduced the alveolar ventilation by half. In real life, the body would have compensated both locally and systemically. Locally, bronchiolar constriction and decreased surfactant production in the abnormal left lung (see Fig. 31-11B) would diminish alveolar dead-space ventilation and increase the effective alveolar ventilation to the normal right lung. Systemically, as we discuss in the next chapter, the respiratory acidosis and hypoxia would stimulate chemoreceptors to increase ventilation. If the body could double \dot{V}_A to the right lung—and if this right lung has a normal diffusing capacity—then it would be matching the doubled perfusion of the right lung with a doubled ventilation, and all resting blood-gas parameters would return to normal. 📌

N31-16

Surgical Removal of One Lung

Contributed by Walter Boron

As we saw in Figure 30-10, O_2 reaches diffusion equilibrium about one third of the way down the pulmonary capillary of a healthy young adult at rest. If one of the two lungs were removed surgically, the remaining lung would receive twice its normal complement of blood flow. However, provided that alveolar ventilation, $F_{\text{I}\text{O}_2}$, P_{B} , and D_{L} were normal, diffusion equilibrium for O_2 would still occur before the end of the pulmonary capillary. If the ventilation-perfusion relationship were also normal for this subject, then arterial P_{O_2} would be normal—at least at rest. However, during exercise, O_2 transport could well become diffusion limited. Moreover, if D_{L} were substantially below normal, or if \dot{V}_A/\dot{Q} relationships were problematic, then the subject could exhibit arterial hypoxemia even at rest. Therefore, in patients considered for total pneumonectomy, it is critical to evaluate pulmonary function preoperatively to confirm that the patient would be able to survive postoperatively with the remaining lung.

A massive pulmonary embolism that obstructs the left pulmonary artery is superficially similar to the

example that we have just discussed. However, other associated problems (e.g., right heart failure secondary to an increase in pulmonary vascular resistance, release of vasoactive agents) make the pulmonary embolism potentially fatal.

Shunt Affecting One Lung

Imagine that an object occludes the left mainstem bronchus, *eliminating all ventilation to the left lung*.

Total \dot{V}_A remains at 4.2 L/min, but all ventilation goes to the right lung. Thus, the \dot{V}_A/\dot{Q} to the left lung is 0/2.5 or 0, whereas the \dot{V}_A/\dot{Q} to the right lung is 4.2/2.5 or 1.68. The overall \dot{V}_A/\dot{Q} is normal, 0.84.

Again, the key question is whether a combination of a low \dot{V}_A/\dot{Q} in the abnormal lung and a high \dot{V}_A/\dot{Q} in the normal lung can yield normal blood-gas levels.

The normal right lung must now eliminate CO_2 at twice its normal rate. However, the right lung also has twice its normal \dot{V}_A . Because twice the normal amount of alveolar air carries away twice the normal amount of CO_2 , the right lung's new steady-state alveolar P_{CO_2} is normal, ~40 mm Hg (Fig. 31-15A). The blood leaving the normal lung also has a P_{CO_2} of ~40 mm Hg. However, the unventilated lung has the P_{CO_2} of *mixed-venous blood*, ~51 mm Hg in this example. After the two streams of blood mix—known as **venous admixture**, because venous blood combines with blood from ventilated alveoli—arterial blood in the left ventricle has a CO_2 content that is midway between the CO_2 contents of the two streams of blood, corresponding to an arterial P_{CO_2} of ~46 mm Hg. *Thus, even with the severe \dot{V}_A/\dot{Q} abnormality produced by shunt, the lung is once again able to expel the usual 200 mL/min of CO_2 , but once again at a price: a high arterial P_{CO_2} (respiratory acidosis).*

A SHUNT: CO₂ HANDLING

B SHUNT: O₂ HANDLING

FIGURE 31-15 Shunt. **N31-20** The numbers in this idealized example refer to a time after the individual has achieved a new steady state. In the upper panels of **A** and **B**, the light beige boxes give the alveolar ventilation to each lung as well as the total alveolar ventilation (\dot{V}_A). The pink boxes give the blood flow to each lung as well as the total cardiac output (\dot{Q}). The white boxes give the rates of CO₂ or O₂ transport (in mL/min) at either the pulmonary or systemic capillaries. The blue boxes give the CO₂ and O₂ partial pressures (in mm Hg) in alveolar air. The lavender boxes give the CO₂ partial pressure (in mm Hg) and CO₂ content (in mL/dL) in the mixed-venous blood, in the blood leaving each of the lungs, and in the mixed-arterial blood. The dark beige boxes give the same information for O₂. The lower panel of **A** shows

plots of how total CO_2 content in this example varies with P_{CO_2} at the Hb-O_2 saturations for unshunted blood at the end of the pulmonary capillary (*red line*), for shunted/mixed-venous blood (*violet line*), and for mixed-arterial blood (*green line*). Because of the 50% shunt, the decrease in total CO_2 content between mixed-venous blood (point \bar{v}) and unshunted blood (point c) must be twice normal (8 mL/dL) to produce a normal decrease (4 mL/dL) between mixed-venous blood (point \bar{v}) and mixed-arterial blood (point a). The

lower panel of **B** shows comparable plots for how total O_2 content varies with P_{O_2} at the pH and P_{CO_2} values of mixed-venous blood (*violet curve*), arterial blood (*red curve*), and for mixed-arterial blood (*green curve*). Because of the 50% shunt, the increase in total O_2 content between mixed-venous blood (point \bar{v}) and unshunted blood (point c) must be twice normal (10 mL/dL) to produce a normal increase (5 mL/dL) between mixed-venous blood (point \bar{v}) and mixed-arterial blood (point a).

N31-20

Analysis of \dot{V}_A/\dot{Q} Patterns in Figure 31-15

Contributed by Emile Boulpaep, Walter Boron

The following is a discussion of Figure 31-15 that is more complete than the material presented in the subsection “Shunt Affecting One Lung” (see pp. 696–698).

Figure 31-15 is a highly simplified example that illustrates the principles underlying how a shunt affects the handling of CO_2 and O_2 . Except as noted below in this paragraph, all assumptions and parameter values for this example are the same as for the normal case in Figure 31-13. **N31-18** The key difference in the example in Figure 31-15 is that the left lung receives no ventilation—**shunt**. The total \dot{V}_A remains 4.2 L/min, but all of this ventilation goes to the right lung. Notice that the \dot{Q} of 5 L/min is evenly distributed between the two lungs. Thus, the \dot{V}_A/\dot{Q} of the left lung is 0/2.5 or 0, whereas the \dot{V}_A/\dot{Q} of the right lung is 4.2/2.5 or 1.68. Can the *high* \dot{V}_A/\dot{Q} of the hyperventilated right lung make up for the *low* \dot{V}_A/\dot{Q} of the unventilated left lung?

CO_2 Handling

First, we will consider the fate of CO_2 in the following nine steps (see Fig. 31-15A):

Step 1: In the steady state, the normal right lung must eliminate the entire metabolic production of CO_2 , 200 mL/min. This rate of CO_2 delivery to the right lung is twice normal.

Step 2: The twice-normal amount of CO_2 is diluted into a twice-normal \dot{V}_A of 4.2 L/min, so that the alveolar P_{CO_2} in this right lung must be normal (i.e., 40 mm Hg).

Step 3: Because no air flow goes to the left lung, the air distal to the obstruction in the left lung will have the same P_{CO_2} and the same P_{O_2} as mixed-venous blood. However, because this air is not in direct communication with atmosphere, it does not contribute to the mean alveolar P_{CO_2} of the expired air. Thus, the mean P_{ACO_2} is simply the P_{CO_2} of the alveolar air in the right lung, 40 mm Hg, which is normal!

Step 4: Because the transport of CO_2 across the blood-gas barrier is perfusion limited (see pp. 671–673), the blood leaving the *right* lung has a P_{CO_2} that is the same as the alveolar P_{CO_2} on the right, 40 mm Hg.

According to the CO₂ dissociation curve, when the blood has a P_{CO_2} of 40 mm Hg, it must have a CO₂ content of 48 mL/dL (see lower panel of Fig. 31-15A, point c). This is the CO₂ content *after* the right lung has extracted CO₂ at the rate of 200 mL/min.

Step 5: What was the CO₂ content of the blood *before* the CO₂ was extracted? That is, what was the mixed-venous P_{CO_2} ? According to the Fick principle, the change in CO₂ content as the blood passes through the right lung is simply the rate of CO₂ extraction divided by the blood flow:

$$\Delta C_{\text{CO}_2} = \frac{\dot{V}_{\text{CO}_2}}{\dot{Q}} = \frac{200 \text{ mL CO}_2 / \text{min}}{2.5 \text{ L blood/min}} = 80 \text{ mL CO}_2 / \text{L} = 8 \text{ mL CO}_2 / \text{dL}$$

(NE 31-46)

Normally (see Fig. 31-13A), the CO₂ content of the pulmonary-capillary blood would fall by only 4 mL/dL as it equilibrated with the alveolar air. However, because the rate of CO₂ extraction is twice normal, the decrease in CO₂ content is also twice normal. Thus, the mixed-venous CO₂ content must be 48 + 8 = 56 mL/dL. From the CO₂ dissociation curve, we see that this CO₂ content corresponds to a mixed-venous P_{CO_2} of 51 mm Hg (see lower panel of Fig. 31-15A, point \bar{v}). Notice that the alveolar air in the obstructed left lung has a P_{CO_2} of 51 mm Hg, the same as that of the mixed-venous blood.

Step 6: What happens when the blood from the hyperventilated right lung mixes with the shunted blood from the unventilated left lung? Although one might be tempted to average the two P_{CO_2} values (i.e., 40 and 51 mm Hg), this is a mistaken instinct. Instead, one must average the two CO₂ contents. As we noted above, the CO₂ content of blood emerging from the right lung is 48 mL/dL. The CO₂ content of blood emerging from the left lung is the same as for the mixed-venous blood we examined in the previous step, 56 mL/dL. Thus, the **mixed arterial CO₂ content** is (48 + 56)/2 = 52 mL/dL (see lower panel of Fig. 31-15A, point a).

Step 7: According to the CO₂ dissociation curve, a CO₂ content of 52 mL/dL corresponds to an arterial P_{CO_2} of 46 mm Hg (see lower panel of Fig. 31-15A, point a).

Step 8: In the systemic capillaries, adding 200 mL/min of CO₂ to 5 L of blood increases the CO₂ content by 4 mL/dL, raising the CO₂ content from 52 mL/dL (lower panel of Fig. 31-15A, point a) to 56 mL/dL (see lower panel of Fig. 31-15A, point \bar{v}). Notice that 56 mL/dL is the mixed-venous value we arrived at above in step 5.

Step 9: According to the CO₂ dissociation curve, a CO₂ content of 56 mL/dL corresponds to a mixed-venous P_{CO_2} of 51 mm Hg (see lower panel of Fig. 31-15A, point \bar{v}). This is the same value that we arrived at above in step 5.

Thus, even with the severe \dot{V}_A/\dot{Q} abnormality represented by shunt, the lung is once again able to expel the usual 200 mL/min of CO₂, but once again at a price: a high arterial P_{CO_2} (respiratory acidosis). Because there is a \dot{V}_A/\dot{Q} mismatch in this example, we expect there to be an **alveolar-arterial (A-a) difference for P_{CO_2}** . **N31-17** Because the mean alveolar P_{CO_2} is 40 mm Hg, and the arterial P_{CO_2} is 46 mm Hg in our example, the A-a difference is 40 – 46 or –6 mm Hg.

O₂ Handling

The changes in O₂ handling are more extreme (see Fig. 31-15B).

Step 1: The normal right lung must deliver all the O₂ required by the body, 250 mL/min. This rate of O₂ abstraction from the right lung is twice normal.

Step 2: Because the \dot{V}_A/\dot{Q} ratio of the normal right lung is twice normal, and the O₂ extraction rate is twice normal, we would expect the alveolar P_{O_2} in the right lung to be the normal value of ~100 mm Hg. Put differently, because the inspired P_{O_2} (i.e., 149 mm Hg), the alveolar P_{CO_2} of the right lung (i.e., 40 mm Hg), and the RQ (i.e., 0.8) are all normal, the alveolar gas equation (see Equation 31-17) yields a normal P_{O_2} for the right lung, ~100 mm Hg.

Step 3: Of course, the P_{O_2} in the unventilated left lung ($\dot{V}_A/\dot{Q} = 0$) is the same as the P_{O_2} of mixed-venous blood. However, because this air is not in direct communication with atmosphere, it does not contribute to the mean alveolar P_{O_2} of the expired air. Thus, the **mean $P_{A_{O_2}}$** is simply the P_{O_2} of the alveolar air in the right lung, ~100 mm Hg, which is normal!

Step 4: Because the transport of O₂ across the blood-gas barrier is perfusion limited (see pp. 671–673), the P_{O_2} of the blood leaving the right lung is the same as the P_{O_2} in the right lung, ~100 mm Hg. Thus, according to the O₂ dissociation curve, the O₂ content of this blood must be 20 mL/dL (see lower panel of Fig. 31-15B, point c). This value is the O₂ content *after* the right lung has added O₂ at the rate of 250 mL/min.

Step 5: What was the O₂ content of the mixed-venous blood? According to the Fick principle, the increase in O₂ content as the blood passes through the right lung is simply the rate of O₂ extraction divided by the blood flow. Normally (see Fig. 31-15B), the O₂ content would rise by only 5 mL/dL as the blood equilibrated with the alveolar air. However, because the rate of O₂ extraction from the lung is twice normal, the increase in O₂ content is also twice normal:

$$\Delta C_{O_2} = \frac{\dot{V}_{O_2}}{\dot{Q}} = \frac{250 \text{ mL } O_2 / \text{min}}{2.5 \text{ L blood/min}} = 100 \text{ mL } O_2 / \text{L} = 10 \text{ mL } O_2 / \text{dL}$$

(NE 31-47)

Thus, the mixed-venous O_2 content must be 10 mL/dL less than the O_2 content of the end-capillary blood (i.e., 20 mL/dL). The mixed-venous O_2 content is thus $20 - 10 = 10$ mL/dL. From the O_2 dissociation curve, we see that this O_2 content corresponds to a mixed-venous P_{O_2} of 29 mm Hg (see lower panel of Fig. 31-15B, point \bar{v}). The alveolar air in the obstructed left lung has a P_{O_2} of 29 mm Hg, the same as that of the mixed-venous blood.

Step 6: What happens when the blood from the hyperventilated right lung mixes with the shunted blood from the unventilated left lung? One must average the O_2 contents of the blood emerging from the right and left lungs. As we noted above, the O_2 content of blood emerging from the right lung is 20 mL/dL. The O_2 content of blood emerging from the left lung is the same as for the mixed-venous blood we examined in the previous step, 10 mL/dL. Thus, the **mixed arterial O_2 content** is $(20 + 10)/2 = 15$ mL/dL (see lower panel of Fig. 31-15B, point a).

Step 7: From the O_2 dissociation curve, we see that a mixed-arterial O_2 content of 15 mL/dL corresponds to a P_{O_2} of ~40 mm Hg (see lower panel of Fig. 31-15B, point a).

Step 8: In the systemic capillaries, the tissues extract 250 mL/min of O_2 . Removing 250 mL of O_2 from 5 L of blood decreases the O_2 content by 5 mL/dL. Thus, the O_2 content of the blood at the end of the systemic capillaries will be $15 - 5 = 10$ mL/dL. This is the same value we arrived at in step 5 (see lower panel of Fig. 31-15B, point \bar{v}).

Step 9: According to the O_2 dissociation curve, an O_2 content of 10 mL/dL corresponds to a mixed-venous P_{O_2} of 29 mm Hg (see lower panel of Fig. 31-15B, point \bar{v}). This is the same figure we arrived at in step 5.

Thus, even with the severe \dot{V}_A/\dot{Q} abnormality represented by shunt, the lung is able to import the usual 250 mL/min of O_2 , but at a price: an extremely low arterial P_{O_2} (hypoxia).

The **A-a difference for P_{O_2}** in this example is $100 - 40 = 60$ mm Hg, which indicates a \dot{V}_A/\dot{Q} mismatch of considerable magnitude. In this extreme example, we entirely eliminated airflow to one lung. Less extreme instances of uneven distribution of airflow will lead to less severe degrees of respiratory acidosis and hypoxia.

Again, beware that this example, like the ones in Figure 31-13 and Figure 31-14, is highly oversimplified. Nevertheless, it is clear that even if overall \dot{V}_A/\dot{Q} is normal, and even if the distribution of perfusion is normal, an uneven distribution of ventilation leads to respiratory acidosis and hypoxia. Thus, the overventilated “good” lung cannot make up for the deficit incurred by the underventilated “bad” lung. One fundamental problem is that blood with a normal gas composition from the hyperventilated good lung mixes with shunted blood with a high P_{CO_2} and low P_{O_2} . The consequences are perhaps easiest to grasp for O_2 transport. The blood leaving the normal right lung has a normal O_2 content. The shunted blood leaving the unventilated left lung has a very low O_2 content, which is the same as that of mixed-venous blood. Thus, the mixed-arterial blood must have a low O_2 content and must be hypoxic.

A second fundamental problem is that—because of the shape of the Hb- O_2 dissociation curve—

hyperventilating a good lung cannot proportionally increase the O_2 content of the blood leaving that lung. What would happen if the subject were to hyperventilate? Not much. It is true that increasing alveolar ventilation might increase the right alveolar P_{O_2} above its starting value of 100 mm Hg. However, because the Hb is already 97.5% saturated with O_2 at a P_{O_2} of 100 mm Hg, the added ventilation would do little good. The subject would remain hypoxic.

The normal right lung must also deliver O_2 to the blood at twice the normal rate. However, because the right lung's \dot{V}_A is also twice its usual value, its new steady-state alveolar P_{O_2} is normal, ~ 100 mm Hg. The blood leaving the right lung also has a P_{O_2} of ~ 100 mm Hg, a hemoglobin (Hb) saturation (S_{O_2}) of $\sim 97.5\%$, and an O_2 content of ~ 20 mL/dL. However, the unventilated lung has a P_{O_2} of mixed-venous blood, ~ 29 mm Hg in this example. Thus, the blood leaving the shunted lung has an S_{O_2} of $\sim 49\%$ and an O_2 content of ~ 10 mL/dL. After venous admixture, arterial O_2 content is $(20 + 10)/2$ or 15 mL/dL, which corresponds to an arterial S_{O_2} (S_{aO_2}) of 73 and a P_{O_2} of ~ 40 mm Hg. *Thus, even with the severe \dot{V}_A/\dot{Q} abnormality caused by shunt, the lung is able to import the usual 250 mL/min of O_2 , but at the price of an extremely low arterial P_{O_2} (hypoxia).*

Why did the \dot{V}_A/\dot{Q} mismatch caused by shunt lead to only a mild respiratory acidosis but a severe hypoxia? The fundamental problem is that the Hb- O_2 dissociation curve (see Fig. 29-3) is nearly saturated at the normal arterial P_{O_2} . If O_2 content were proportional to P_{O_2} , then mixing unshunted blood ($P_{O_2} = 100$ mm Hg) with shunted blood ($P_{O_2} = 29$ mm Hg) would have yielded arterial blood with a P_{O_2} of $(100 + 29)/2 = \sim 65$ mm Hg, which is far higher than the arterial P_{O_2} of ~ 40 mm Hg in our example.

In our example, shunt would trigger compensation at two levels. Locally, hypoxic vasoconstriction would divert blood to well-ventilated alveoli. Systemically, an increase in \dot{V}_A would lower P_{CO_2} and raise P_{O_2} in the normal right lung. In fact, even a modest increase in \dot{V}_A would be sufficient to lower arterial P_{CO_2} to 40 mm Hg. However, even if \dot{V}_A approached infinity (raising the right lung's alveolar P_{O_2} to the inspired P_{O_2} of ~ 149 mm Hg), arterial P_{O_2} would still be well under 100 mm Hg. In fact, even if the inspired air were 100% O_2 , the arterial P_{O_2} would still fail to reach 100 mm Hg; because of the shape of the Hb- O_2 dissociation curve, an increased alveolar P_{O_2} can increase the O_2 content of arterial blood only marginally (Box 31-1).

Box 31-1

Clinical Approaches for Diagnosing a \dot{V}_A/\dot{Q} Mismatch

Rather simple diagnostic methods are available for detecting the presence of a \dot{V}_A/\dot{Q} mismatch, assessing its severity, and identifying a shunt.

Diagnosis of Exclusion

The physician can often diagnose a pathological nonuniformity of \dot{V}_A/\dot{Q} by excluding other possibilities. In general, low arterial P_{O_2} —under basal metabolic conditions—could be due to a reduced inspired P_{O_2}

(e.g., high altitude), reduced alveolar ventilation, decreased diffusing capacity (D_L), or \dot{V}_A/\dot{Q} mismatch. Let us assume that arterial P_{O_2} is appropriate for the altitude (see p. 681) and that results of simple spirometric tests indicate that respiratory mechanics are normal. Because D_L is normally about 3-fold greater than necessary for achieving diffusion equilibrium for O_2 and CO_2 (see pp. 671–672), a problem with D_L is unlikely in the absence of a positive history. By default, the most likely cause is a \dot{V}_A/\dot{Q} defect.

Alveolar-Arterial Gradient for O_2

The difference between the *mean* alveolar P_{O_2} and the systemic arterial P_{O_2} is known as the **alveolar-arterial (A-a) gradient for P_{O_2}** . In our “normal” example in Figure 31-13B, both mean alveolar P_{O_2} and arterial P_{O_2} were 100 mm Hg. In real life, however, physiological \dot{V}_A/\dot{Q} mismatches cause arterial P_{O_2} to be 5 to 15 mm Hg below the mean alveolar value.

A defining characteristic of \dot{V}_A/\dot{Q} mismatches is that they widen the A-a P_{O_2} gradient. In our example of alveolar dead space in Figure 31-14B, the mean alveolar P_{O_2} was $(51 + 149)/2 = 100$ mm Hg, whereas the systemic arterial P_{O_2} was 51 mm Hg, for an A-a gradient of 49 mm Hg. In our example of shunt in Figure 31-15B, the mean alveolar P_{O_2} was 100 mm Hg, whereas the arterial P_{O_2} was only 40 mm Hg—an A-a gradient of 60 mm Hg.

Because the A-a gradient for P_{O_2} is an index of the severity of the \dot{V}_A/\dot{Q} mismatch, physicians routinely estimate the A-a gradient in the intensive care unit. The approach is to (1) obtain the arterial blood-gas levels, which include P_{aO_2} and P_{aCO_2} ; (2) assume that the mean P_{aCO_2} is the same as the measured P_{aCO_2} ; (3) use the alveolar gas equation (see Equation 31-17) to compute the mean P_{AO_2} from mean P_{aCO_2} ; and (4) compute the difference $P_{AO_2} - P_{aO_2}$. However, the assumption in point 2 is not entirely true because \dot{V}_A/\dot{Q} mismatches cause an A-a gradient for CO_2 just as they do for O_2 . **N31-17**

N31-17

Alveolar-Arterial Differences for CO_2 (Robin Test)

Contributed by Emile Boulpaep, Walter Boron

\dot{V}_A/\dot{Q} mismatches lead not only to an alveolar-arterial (A-a) difference in P_{O_2} , but also to an A-a difference in the CO_2 partial pressure (Robin test). In our example of alveolar dead space (see Fig. 31-14A), the A-a difference for CO_2 was $40 - 80$ or -40 mm Hg, and in our example of shunt (see Fig. 31-15A), it was $40 - 46$ or -6 mm Hg. A-a differences for CO_2 are smaller than those for O_2 both because alveolar P_{CO_2} values are lower and because the CO_2 dissociation curve is more linear. Clinicians generally do not use the P_{CO_2} A-a difference as an index of a \dot{V}_A/\dot{Q} mismatch. In fact, they generally assume that the mean *alveolar* P_{CO_2} is identical to the *arterial* P_{CO_2} , and they use this value in the alveolar gas equation (see Equation 31-17) for computing the mean alveolar P_{O_2} needed to determine the A-a difference for P_{O_2} .

Effect of Breathing 100% O_2

Once a \dot{V}_A/\dot{Q} mismatch has been identified, it is important to distinguish between a shunt, which might be

corrected surgically, and other causes. Imagine two patients with similar degrees of hypoxia. In the first patient, one lung is relatively hypoventilated (low \dot{V}_A/\dot{Q}) and the other lung is relatively hyperventilated (high \dot{V}_A/\dot{Q}). However, no alveoli are shunted. In the second patient, a complete shunting of blood makes one lung totally unventilated (a \dot{V}_A/\dot{Q} of zero, as in Figure 31-15). The normal lung has a high \dot{V}_A/\dot{Q} . We can distinguish between the two cases by having both subjects inspire 100% O₂.

When the patient without predominant shunt breathes 100% O₂, the P_{O_2} of the blood leaving both lungs will be far higher than normal (Fig. 31-16A). Blood leaving the hypoventilated lung has a P_{O_2} somewhat lower than that of the blood leaving the hyperventilated lung. However, because the P_{O_2} is on the flat part of the Hb-O₂ dissociation curve in both cases, the S_{O_2} values are virtually identical. The miniscule difference in O₂ contents between the two streams of blood is due to a difference in dissolved O₂. Thus, the mixed systemic arterial blood will have a slightly elevated O₂ content, an S_{aO_2} of ~100%, and a markedly elevated P_{O_2} .

A \dot{V}_A/\dot{Q} MISMATCH WITHOUT PREDOMINANT SHUNT

B \dot{V}_A/\dot{Q} MISMATCH CAUSED BY SHUNT

FIGURE 31-16 Analyzing \dot{V}_A/\dot{Q} mismatch by administering 100% O₂. Sat, saturation. The P_{O_2} values are in mm Hg, and the C_{O_2} values are in mL/dL.

The situation is very different in the patient with a severe shunt (see Fig. 31-16B). Because blood leaving the shunted lung does not equilibrate with the alveoli ventilated with 100% O₂, it has the low P_{O_2} , S_{O_2} , and O₂ content characteristic of mixed-venous blood. Although blood leaving the normal lung will have an extremely high P_{O_2} , both the S_{O_2} and O₂ content will be only slightly above normal—like the hyperventilated lung in Figure 31-16A. Thus, when one stream of blood with a slightly increased O₂ content (“normal” lung) mixes with another stream with a markedly decreased O₂ content (“shunted” lung), the mixed-systemic arterial blood has a lower-than-normal O₂ content. This low O₂ content translates to a low S_{aO_2} and thus to a low systemic arterial P_{O_2} . Thus, unlike subjects with other kinds of \dot{V}_A/\dot{Q} mismatches that do not include substantial shunt (e.g., alveolar dead-space ventilation in Fig. 31-14), those with substantial shunt have low arterial P_{O_2} values, even while breathing 100% O₂. Because breathing 100% O₂ greatly increases mean alveolar P_{O_2} without substantially increasing arterial P_{O_2} , this maneuver greatly exaggerates the A-a difference for P_{O_2} .

Mixed \dot{V}_A/\dot{Q} Mismatches

Pathological \dot{V}_A/\dot{Q} mismatches cause the range of \dot{V}_A/\dot{Q} ratios to broaden beyond the physiological range. Some alveoli may be true alveolar dead space (i.e., perfusion absent, $\dot{V}_A/\dot{Q} = \infty$), but others may be more modestly underperfused. Some alveoli may be totally shunted (i.e., ventilation absent, $\dot{V}_A/\dot{Q} = 0$), but others may be more modestly underventilated. Thus, the left ventricle receives a mixture of blood from alveoli with \dot{V}_A/\dot{Q} ratios from ∞ to zero, corresponding to all of the points along the O₂-CO₂ diagram in Figure 31-10B. What is the composition of this mixed blood? The principles that we developed in our simplified examples of alveolar dead-space ventilation and shunt still hold. Even if total \dot{V}_A and total \dot{Q} remain normal, pathologically high \dot{V}_A/\dot{Q} ratios in some alveoli cannot make up for pathologically low ratios in others, and vice versa. The result of uncompensated pathological \dot{V}_A/\dot{Q} mismatching is always respiratory acidosis and hypoxia.

Control of Ventilation

George B. Richerson, Walter F. Boron

Overview of the Respiratory Control System

Breathing is one of those things in life that you almost never think about until something goes wrong with it. However, those with pulmonary disease become intensely aware of breathing, as do people who overexert themselves, especially at high altitude. The feeling of dyspnea that they experience (see [p. 701](#)) is one of the most unpleasant sensations in life ([Box 32-1](#)). Swimmers and SCUBA divers, musicians who sing or play wind instruments, Lamaze practitioners, and anyone with a bed partner who snores also focus intensely on breathing. It is common for respiratory output to be the last brain function to be lost in comatose patients, in which case its cessation marks the onset of brain death.  **N32-1** Thus, despite our common tendency to ignore breathing, control of ventilation is one of the most important of all brain functions.

Box 32-1

Dyspnea

Dyspnea is the feeling of being short of breath, or the unpleasant conscious awareness of difficulty in breathing. In some cases, dyspnea is an adaptive response. For example, when arterial P_{O_2} falls or P_{CO_2} rises from breath holding, asphyxia, or pulmonary disease, dyspnea leads to efforts to increase ventilation and thus to restore arterial blood gas levels to normal. However, dyspnea can occur even with a normal arterial P_{O_2} and P_{CO_2} . For example, increased airway resistance can cause dyspnea, even if arterial blood gas levels do not change. Exercise also causes dyspnea, even though P_{O_2} is usually normal and P_{CO_2} falls. Other causes of dyspnea seem maladaptive. For example, claustrophobia and panic attacks can induce the feeling of suffocation—that is, dyspnea—despite normal ventilatory parameters or even a drop in P_{CO_2} . The central neural mechanisms and pathways responsible for dyspnea are unknown, although many of the forebrain regions involved have been identified.

N32-1

Brain Death

Contributed by George Richerson

As stated in the text, respiratory output is often the last brain function to be lost in comatose patients, in which case its cessation marks the onset of brain death. In the United States, the legal definition of “brain death” is the irreversible loss of clinical function of the entire brain—which does not include the spinal cord. Brain death is legally equivalent to other forms of death. The declaration of brain death requires a careful neurological examination testing all reflexes mediated by cranial nerves, evaluating the patient for evidence of behaviors that require brain function, and ruling out any reversible cause such as hypothermia or drug overdose.

The ventilatory control mechanism must accomplish two tasks. First, it must establish the *automatic rhythm* for contraction of respiratory muscles. Second, it must adjust this rhythm to accommodate changing *metabolic* demands (as reflected by changes in blood P_{O_2} , P_{CO_2} , and pH), varying *mechanical*

conditions (e.g., changing posture), and a range of episodic *nonventilatory* behaviors (e.g., speaking, sniffing, eating).

Automatic centers in the brainstem activate the respiratory muscles rhythmically and subconsciously

The rhythmic output of the central nervous system (CNS) to muscles of ventilation normally occurs automatically, without any conscious effort. This output depends upon a vast array of interconnected neurons—located primarily in the medulla oblongata, but also in the pons and other brainstem regions. These neurons are called **respiratory-related neurons (RRNs)** because they fire more action potentials during specific parts of the respiratory cycle. For example, some neurons have peak activity during inspiration, and others, during expiration. Some RRNs are **interneurons** (i.e., they make local connections), others are **premotor neurons** (i.e., they innervate motor neurons), and still others are **motor neurons** (i.e., they innervate muscles of respiration). A subset of these neurons, thought to be in the medulla oblongata, is able to independently generate a respiratory rhythm—and is known as the **central pattern generator (CPG)**; see [p. 396](#)). Together the neurons of the respiratory network distribute signals appropriately to various pools of cranial and spinal motor neurons (see [pp. 241–242](#)), which directly innervate the respiratory muscles ([Fig. 32-1](#)).

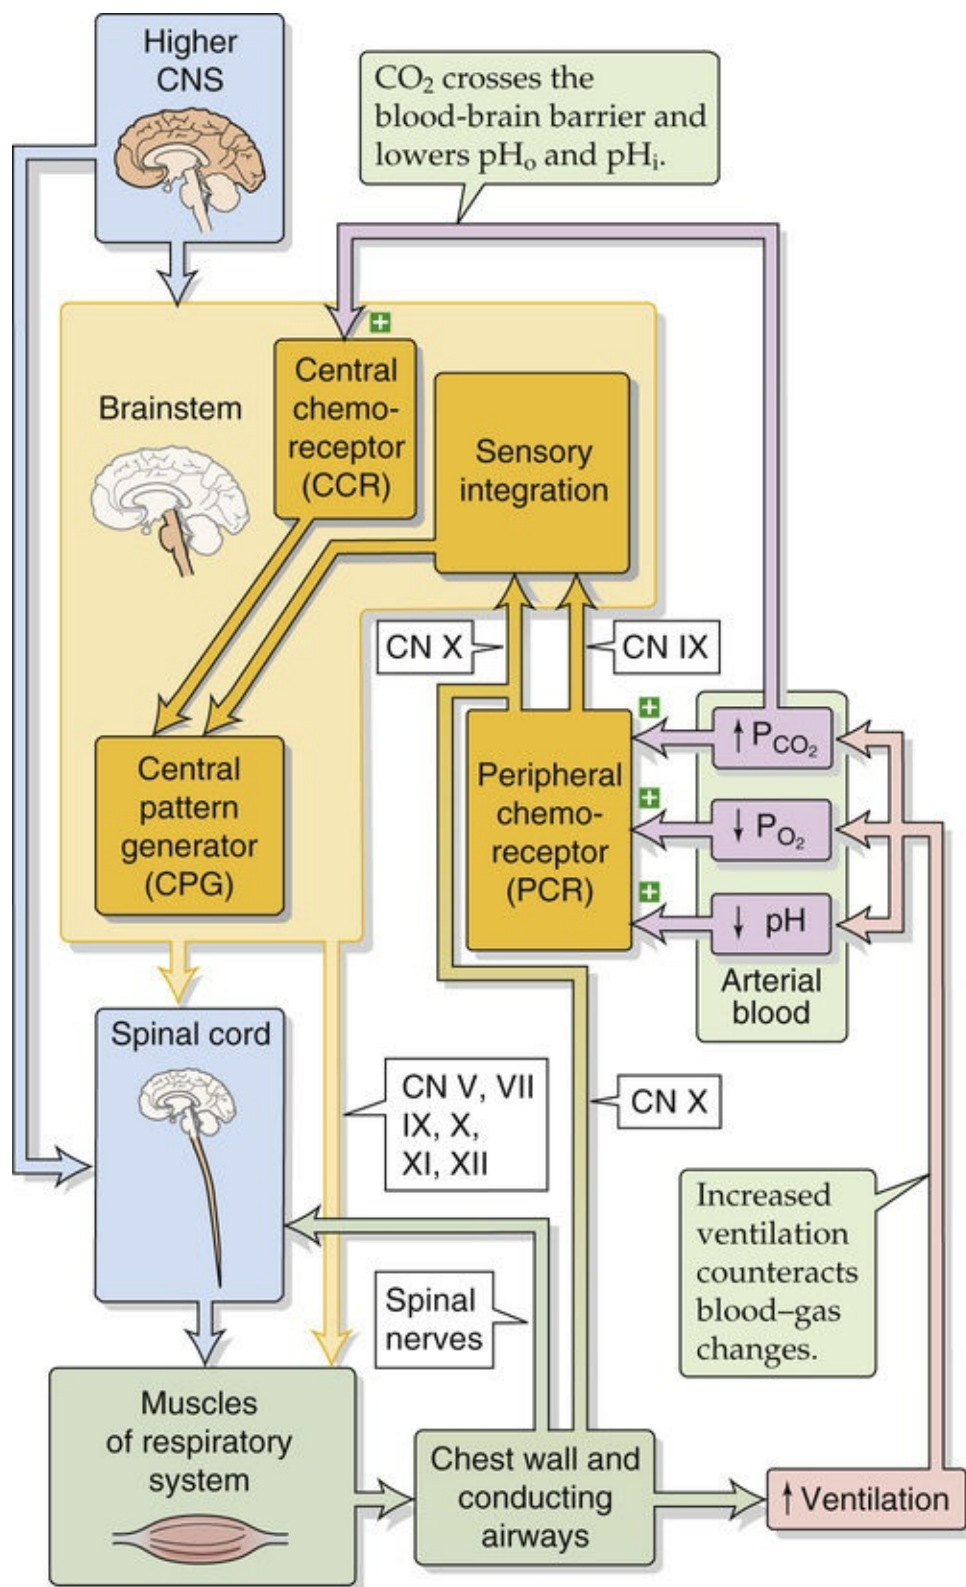

FIGURE 32-1 Control of ventilation.

The most important respiratory motor neurons are those that send axons via the phrenic nerve to innervate the diaphragm (Table 32-1), one of the *primary muscles of inspiration* (see p. 607). When respiratory output increases (e.g., during exercise), activity also appears in motor neurons that innervate a wide variety of *accessory* muscles of inspiration and expiration (see p. 607).

TABLE 32-1

Innervation of the Primary and Some Secondary Muscles of Respiration

MUSCLES	NERVE	LOCATION OF CELL BODY OF MOTOR NEURON
Primary Muscles of Inspiration		
Diaphragm	Phrenic nerve	Phrenic motor nuclei in ventral horn of spinal cord, C3–C5
External intercostal muscles	Intercostal nerves	Ventral horn of thoracic spinal cord
Secondary Muscles of Inspiration		
Larynx and pharynx	Vagus (CN X) and glossopharyngeal (CN IX) nerves	Primarily within the nucleus ambiguus
Tongue	Hypoglossal nerve (CN XII)	Hypoglossal motor nucleus
Sternocleidomastoid and trapezius muscles	Accessory nerve (CN XI)	Spinal accessory nucleus, C1–C5
Nares	Facial nerve (CN VII)	Facial motor nucleus
Secondary Muscles of Expiration		
Internal intercostal muscles	Intercostal nerves	Ventral horn of thoracic spinal cord
Abdominal muscles	Spinal nerves	Ventral horn of lumbar spinal cord

Each of these muscles is active at different times within the respiratory cycle, and the brain can alter this timing depending on prevailing conditions. It is the job of the premotor neurons to orchestrate the appropriate patterns of activity among the different pools of motor neurons. The pattern of alternating inspiratory and expiratory activity that occurs under normal conditions during non-rapid eye movement (NREM) sleep, at rest, and during mild exercise is called **eupnea**. During eupnea, neural output to respiratory muscles is highly regular, with rhythmic bursts of activity during inspiration only to the diaphragm and certain intercostal muscles. Expiration occurs purely as a result of cessation of inspiration and passive elastic recoil (see p. 606) of the chest wall and lungs. During more intense exercise, the amplitude and frequency of phrenic nerve activity increase, and additional activity appears in nerves that supply accessory muscles of inspiration. With this increased effort, the accessory muscles of expiration also become active (see p. 608), thereby producing more rapid exhalation and permitting the next inspiration to begin sooner (i.e., increasing respiratory frequency).

Peripheral and central chemoreceptors—which sense P_{O_2} , P_{CO_2} , and pH—drive the CPG

The CPG for breathing is the clock that times the automatic cycling of inspiration and expiration. In some cases, the CPG stops “ticking” in the absence of **tonic drive** inputs, which results in the absence of ventilation, or **apnea**. Although this tonic drive comes from many sources, the most important are the central and peripheral chemoreceptors, which monitor the **arterial blood gas** parameters— O_2 , CO_2 , and pH levels. Unlike the frequency of a clock, that of the respiratory CPG changes with the strength of the drive from the chemoreceptors, resulting in changes in both depth and frequency of ventilation.

The **peripheral chemoreceptors**, located in the carotid bodies in the neck and aortic bodies in the thorax, are primarily sensitive to decreases in arterial P_{O_2} , although high P_{CO_2} and low pH also stimulate them and enhance their sensitivity to hypoxia. They convey their sensory information to the medulla via the glossopharyngeal nerve (cranial nerve [CN] IX) and vagus nerve (CN X). The **central chemoreceptors**, located on the brain side of the blood-brain barrier (see pp. 284–287), sense increases in arterial P_{CO_2} and—much more slowly—decreases in arterial pH, but not arterial P_{O_2} . All three signals trigger an increase in alveolar ventilation that tends to return these arterial blood-gas parameters to normal. Thus, the chemoreceptors, in addition to supplying tonic drive to the CPG, form the critical sensory end of a **negative-feedback system** that uses respiratory output to stabilize arterial P_{O_2} , P_{CO_2} , and pH (see Fig. 32-1).

Other receptors as well as higher brain centers also modulate ventilation

Left alone, the respiratory CPG would tick regularly for an indefinite period. However, many inputs to the CPG cause the clock to speed up or slow down. For example, respiratory output is often highly irregular during many behaviors that use the respiratory muscles (e.g., eating, talking, and yawning). During NREM sleep or quiet wakefulness, and with anesthesia, the CPG is unperturbed and *does* run regularly; it is under these conditions that neuroscientists usually study mechanisms of respiratory control.

A variety of receptors in the lungs and airways provide sensory feedback that the medulla integrates and uses to alter respiratory output. Stretch receptors monitor pulmonary mechanics (e.g., lung volume, muscle length) and may help optimize breathing parameters during changes in posture or activity.

Activation of pulmonary stretch receptors also can terminate inspiratory efforts, thereby preventing overinflation. Other sensors that detect the presence of foreign bodies or chemicals in the airways are important for protecting the lungs by triggering a cough or a sneeze. Still others detect the movement of joints, which may be important for raising ventilation with exercise. The mechanoreceptors and chemoreceptors in the lungs and lower (i.e., distal) airways send their sensory information to the respiratory neurons of the medulla via CN X, and those in the upper airways send information via CN IX.

Nonrespiratory brainstem nuclei and higher centers in the CNS also interact with respiratory control centers, which allows the ventilatory system to accommodate such activities as speaking, playing a musical instrument, swallowing, and vomiting. These interconnections also allow respiratory control to be highly integrated with the autonomic nervous system, the sleep-wake cycle, emotions, and other aspects of brain function.

In the remainder of this chapter, we examine (1) respiratory neurons, (2) how these neurons generate the automatic rhythm of ventilation, (3) the control of ventilation by arterial blood-gas levels, and (4) how afferent feedback and higher CNS centers modulate ventilation.

Neurons That Control Ventilation

The neurons that generate the respiratory rhythm are located in the medulla

A classical method for determining which parts of the CNS [N32-2](#) are responsible for controlling respiratory output is to transect the neuraxis at different levels and to observe changes in breathing. Using this approach in the second century, Galen was the first to determine the location of the respiratory controller. As a physician for gladiators in the Greek city of Pergamon, he observed that breathing stopped after a sword blow to the high cervical spine. A similar blow to the lower cervical spine paralyzed the arms and legs, but allowed respiration to continue. He reproduced these lesions in live animals and correctly concluded that the brain sends information via the midcervical spinal cord to the diaphragm.

N32-2

Experimental Preparations for Studying the Neural Control of Ventilation

Contributed by George Richerson

One of the most difficult challenges in neurobiology today is to understand how neurons function within neural networks to generate normal behaviors. Although it is one of the most primitive in the mammalian brain, the neural network controlling respiration is still highly complex. The experimental preparations and techniques used to study respiration are also shared by neuroscientists studying other neural networks and include the following:

Intact, awake, behaving animals and humans are used to permit direct correlation of results with behavior. Investigators primarily use this approach to measure body movements, lung volume changes, or electrical activity in muscles or peripheral nerves.

Anesthetized, paralyzed, mechanically ventilated animals are used to permit better control of experimental variables and more intensive surgical techniques. Paralysis reduces movement of the brain so that individual neurons can be studied using extracellular recordings of single neurons.

The whole brain or large portions of the brain can be isolated in vitro by perfusing the brain via the arterial system, or by removing the spinal cord and lower brainstem of a neonatal rat from the body and keeping them alive submerged in artificial CSF. Because the brainstem circuitry is intact, a respiratory rhythm may still be produced. Elimination of the lungs and heart results in reduction of movement, which makes intracellular recording easier.

Brain slices are prepared by cutting the medulla into thin slices and are kept alive in artificial CSF. These slices can be used to study individual neurons in relative isolation; for example, with intracellular microelectrodes or patch-clamp recordings. Simple synaptic connections, limited to a restricted subset of those present in vivo, can also be studied.

Dissociated neurons can be studied immediately or after days or weeks in tissue culture. These approaches isolate neurons from synaptic input and permit highly stable recordings so that their biophysical properties can be studied with a high degree of precision and control.

These approaches to studying neural networks are at the same time very powerful and very limited. Results can vary depending on the species studied, on age, and on whether the subject is awake or anesthetized. Each experimental preparation has advantages for answering specific questions, as well as disadvantages. For example, it is not possible to define the properties of individual neurons while they are still part of a complex neural network. On the other hand, the respiratory rhythm is usually no longer present in “reduced” preparations, which makes it difficult to know if a given neuron is actually involved in respiratory control. All of these approaches suffer, more or less, from effects due to measurement of the responses—the biological equivalent of the Heisenberg uncertainty principle. There is ischemia in the center of en-bloc tissue, traumatic damage of neurons in brain slices, dedifferentiation of some neuronal properties in culture, and effects of anesthetics and prolonged surgery in vivo. For this reason, it is important that each result be verified and each theory be tested using many of these approaches, instead of relying on only one.

Eighteen centuries later, Lumsden used a similar approach in cats. He found that transection of the CNS between the medulla and spinal cord ([Fig. 32-2](#), spinomedullary transection) causes ventilation to cease as a result of loss of the descending input to phrenic and intercostal motor neurons in the spinal cord. However, even after a spinomedullary transection, respiratory activity continues in muscles innervated by motor neurons whose cell bodies reside in the brainstem. During the period that would have been an inspiration, the nostrils continue to flare, and the muscles of the tongue, pharynx, and larynx continue to maximize airway caliber—although this respiratory activity cannot sustain life. Thus, spinomedullary transection blocks ventilation by interrupting output to the diaphragm, not by eliminating the respiratory rhythm. We can conclude that the neural machinery driving ventilation lies above the spinal cord.

FIGURE 32-2 Effect of brainstem transections. A dorsal view of the brainstem and spinal cord, with the cerebellum removed, and records of integrated nerve activity during one respiratory cycle following the indicated transection. During inspiration, *integrated nerve activity* (a moving average of the amplitude and frequency of action potentials) increases in the nerves to the tongue (e.g., CN XII) and the diaphragm (phrenic nerve).

When Lumsden, in the 1940s, made a transection between the pons and the medulla (see Fig. 32-2, pontomedullary transection), he noticed that breathing continued, but with an abnormal “gasp” pattern. Others have since observed relatively normal breathing after a transection at this level, and concluded that the gasping seen by Lumsden was due to surgical damage to the respiratory CPG in the rostral medulla. Today, most respiratory neurophysiologists believe that the respiratory CPG is located in the medulla and that other sites, including the pons, only *shape* the respiratory output to produce the normal pattern. [N32-3](#)

N32-3

Evolution of the Respiratory Central Pattern Generator

Contributed by George Richerson

The medulla actually has two identical respiratory CPGs—one on each side. All of the elements of the respiratory controller—drive inputs, sensory feedback, RRNs, and motor neurons—are bilateral. Thus, after a midsagittal transection, each side of the medulla generates an independent respiratory rhythm. As noted in the textbook, the location of the respiratory CPG is not universally agreed upon.

The respiratory CPG probably evolved in fish, where blood-gas exchange across the gills requires pumping by *branchial* structures; this necessity explains why the CPG is located in the medulla. CPGs generate all repetitive motor activities (see pp. 396–397). In invertebrates, these include swimming in sea slugs and movements of the stomach in lobsters. The mechanisms of rhythm generation discovered in these systems have led to establishment of general principles that have been valuable in promoting understanding of CPGs in mammals.

The pons modulates—but is not essential for—respiratory output

Although the medulla alone can generate a basic respiratory rhythm, both higher CNS centers and sensory inputs fine-tune this rhythm. For example, the pons contains neurons that affect respiratory output.

Lumsden found that a *midpons transection* has only a modest effect: an increase in tidal volume and a slight decrease in respiratory rate. A *bilateral vagotomy*—interrupting the two vagus nerves, which carry sensory information from pulmonary stretch receptors—has a similar but smaller effect. However, combining a *midpons transection* with a *bilateral vagotomy* causes the animal to make a prolonged inspiratory effort—**inspiratory apneusis**—that is terminated by a brief expiration. A brainstem *transection above the pons* does not alter the basic respiratory pattern of eupnea. These observations led Lumsden to propose that (1) the caudal pons contains an **apneustic center** (i.e., it can cause apneusis), and (2) the rostral pons contains a **pneumotaxic center** that prevents apneusis (i.e., it promotes coordinated respirations). He believed that these two regions and the medulla are required for normal breathing.  **N32-4** Although this viewpoint is common in current literature, it is held by only a minority of respiratory physiologists.

N32-4

Role of the Pons in the Control of Ventilation

Contributed by George Richerson

See the special issue of *Respiratory Physiology and Neurobiology* dealing with pontine influences in breathing. The following is the lead/introductory article:

McCrimmon DR, Milsom WK, Alheid GF: The rhombencephalon and breathing: A view from the pons. *Respir Physiol Neurobiol* 143:103–104, 2004.

What is the modern view? We now appreciate that the apneustic center is not a specific nucleus but is distributed diffusely throughout the caudal pons. The pneumotaxic center is located in the **nucleus parabrachialis medialis** and adjacent **Kölliker-Fuse nucleus** in the rostral pons. However, the pneumotaxic center is not unique in preventing apneusis because simply increasing the temperature of the animal can reverse apneusis induced by lesions in the pneumotaxic center. Moreover, lesions in many locations *outside* the pneumotaxic center can also induce apneusis. Today we still do not understand the role of the apneustic center, and the consensus is that the pneumotaxic center plays a general role in a variety of brainstem functions—including breathing—but is not required for eupnea ([Box 32-2](#)). Thus, the terms *apneustic center* and *pneumotaxic center* are generally of only historical significance.

Box 32-2

Normal and Abnormal Respiratory Patterns

Respiratory output can change for a variety of reasons. Many patterns, both normal and abnormal, have recognizable characteristics summarized below. Figure 32-3 illustrates some of these.

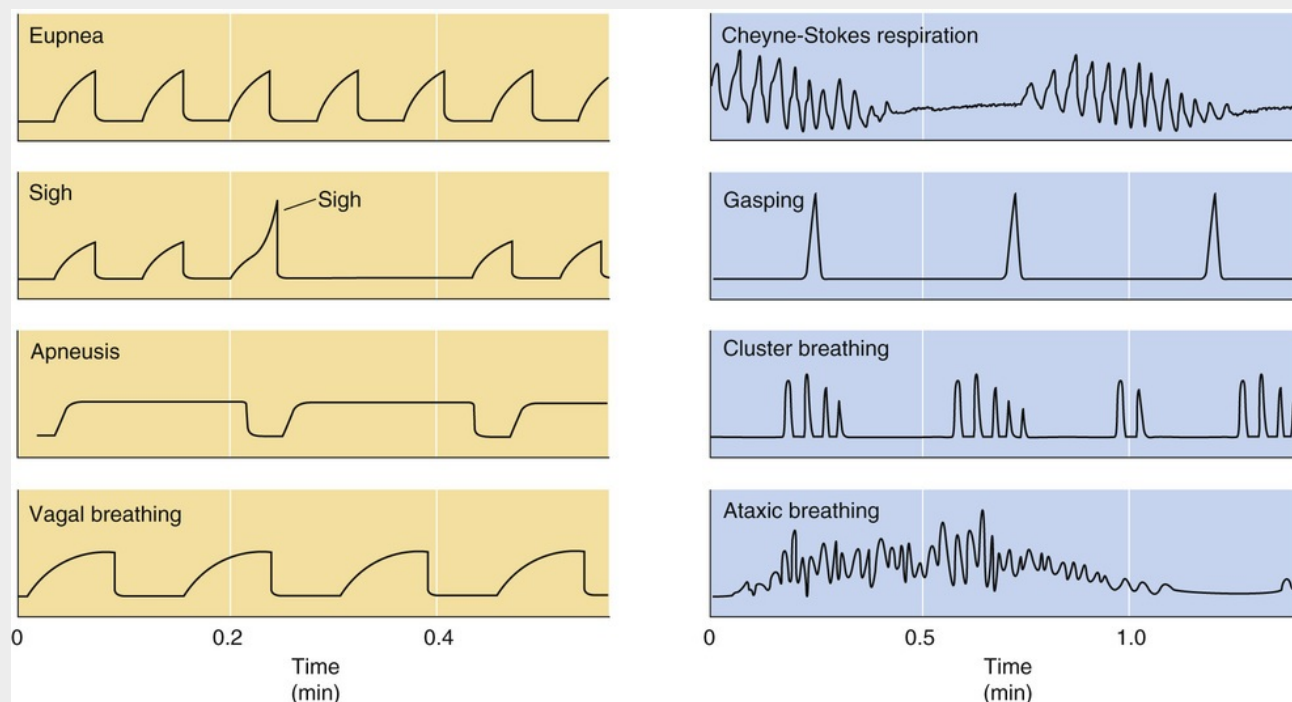

FIGURE 32-3 Respiratory patterns. These records are typical of either phrenic nerve activity or lung volume. Those on the left come from experimental animals, and those on the right, from humans. All of the patterns theoretically could occur in experimental animals or humans, and many occur in clinical settings.

Eupnea

Normal breathing.

Sighs

Larger than normal breaths (see Box 32-4) that occur automatically at regular intervals in normal subjects, possibly to counteract collapse of alveoli (atelectasis).

Yawn

An exaggerated sigh (see Box 32-4).

Tachypnea

An increase in respiratory rate.

Hyperventilation

An increase in alveolar ventilation (see pp. 675–676)—caused by an increase in respiratory frequency or an increase in tidal volume—that decreases arterial P_{CO_2} . Seen in pregnancy and liver cirrhosis (due to increased progesterone), in panic attacks, and as a compensation to metabolic acidosis (see p. 642).

Kussmaul Breathing

Extremely deep, rapid breathing seen with metabolic acidosis, such as in diabetic ketoacidosis (see p. 1185).

Central Neurogenic Hyperventilation

Rapid, deep breathing causing a decrease in arterial P_{CO_2} . Although first described in a small number of patients with focal brain lesions, it is now believed that this pattern reflected coexisting lung disease or

other systemic illness in the majority of these patients.

Cheyne-Stokes Respiration

A benign respiratory pattern. Cycles of a gradual increase in tidal volume, followed by a gradual decrease in tidal volume, and then a period of apnea. Seen with bilateral cortical disease or congestive heart failure, or in healthy people during sleep at high altitude.

Gasping

Maximal, brief inspiratory efforts separated by long periods of expiration. Seen in severe anoxia, as well as in terminal, agonal breathing exhibited by patients with brainstem lesions or cardiac arrest.

Apneusis (Inspiratory)

Prolonged inspirations separated by brief expirations, typically seen in animals with lesions of the rostral pons plus bilateral vagotomy. Rarely seen in humans.

Apnea

Cessation of respiration.

Vagal Breathing

Slow, deep inspirations caused by interruption of vagus nerve input to the brainstem. Rarely seen in humans.

Ataxic Breathing

Highly irregular inspirations, often separated by long periods of apnea. Seen mainly with medullary lesions.

Cluster Breathing

Similar to ataxic breathing, with groups of breaths, often of differing amplitude, separated by long periods of apnea. Seen with medullary or pontine lesions.

Biot Breathing

First described in patients with meningitis by Biot (in 1876), with breaths of nearly equal volume separated by periods of apnea. Biot breathing is also considered to be a variant of ataxic or cluster breathing.

The dorsal and ventral respiratory groups contain many neurons that fire in phase with respiratory motor output

In the 1930s, Gesell  **N32-5** and colleagues used extracellular microelectrode recordings to monitor single neurons, finding that many neurons within the medulla increase their firing rate during one of the phases of the respiratory cycle. Some of these neurons fire more frequently during inspiration—**inspiratory neurons**—whereas others fire more often during expiration—**expiratory neurons**.

N32-5

Robert Gesell

See the following reference:

Gesell R: Respiration and its adjustments. Annu Rev Physiol 1:185–216, 1939.

Not all neurons that fire in phase with the respiratory cycle are involved in control of breathing. For

example, because they are located within the chest cavity, aortic baroreceptors (see p. 534) produce an output that varies with lung inflation, but they are primarily involved in the control of cardiovascular—not respiratory—function. Conversely, some neurons whose firing does not correlate with the respiratory cycle may be essential for respiratory control. For example, central chemoreceptors may fire tonically (i.e., they do not burst during inspiration) and yet are critical for maintaining respiratory output by providing tonic drive (see pp. 700–701). Thus, not all RRNs (e.g., those stimulated by the aortic baroreceptors) play a *direct* role in respiration, and respiratory control involves more than just RRNs (e.g., chemoreceptor neurons).

Although electrical recordings from RRNs cannot identify *all* neurons necessary for producing respiratory output, this mapping has proved very useful in defining neurons that are candidates for *controlling* ventilation. On each side of the medulla, two large concentrations of RRNs—the dorsal and ventral respiratory groups—are grossly organized into sausage-shaped columns, oriented along the long axis of the medulla (Fig. 32-4). Many neurons of these two regions tend to fire exclusively during either inspiration or expiration.

FIGURE 32-4 Dorsal and ventral respiratory groups and their motor output. **A**, Inspiratory output. **B**, Expiratory output. These are dorsal views of the brainstem and spinal cord, with the cerebellum removed. The dorsal respiratory group (DRG) includes the nucleus tractus solitarius (NTS). The ventral respiratory group (VRG) includes the Bötzinger complex (BötC), pre-Bötzinger complex (preBötC), nucleus ambiguus (NA), nucleus para-ambigualis (NPA), and nucleus retroambigualis (NRA). The color coding indicates whether the neurons are primarily inspiratory (*red*) or primarily expiratory (*green*).

The pons also contains RRNs. **N32-4** Although, as discussed above, pontine neurons may not be needed to *produce* a normal respiratory rhythm, they can influence respiratory output.

The dorsal respiratory group processes sensory input and contains primarily inspiratory neurons

The **dorsal respiratory group (DRG)** primarily contains inspiratory neurons ([Table 32-2](#)). It extends for about one third of the length of the medulla and is located bilaterally in and around the **nucleus tractus solitarii (NTS)**, which receives *sensory* input from all viscera of the thorax and abdomen and plays an important role in control of the autonomic nervous system (see [p. 348](#)). The NTS is viscerotopically organized, with the respiratory portion of the NTS ventrolateral to the **tractus solitarius**, just beneath the floor of the caudal end of the fourth ventricle (see [Fig. 32-4](#)). These NTS neurons, as well as some immediately adjacent neurons in the dorsal medulla, make up the DRG.

	(b) Interneurons → VRG		(b) Premotor neurons → spinal cord → primary and accessory muscles of inspiration	

As might be surmised from the sensory role of the NTS, one of the major functions of the DRG is the *integration* of sensory information from the respiratory system. Indeed, some of the DRG neurons receive sensory input—via the glossopharyngeal (CN IX) and vagus (CN X) nerves—from peripheral chemoreceptors, as well as from receptors in the lungs and airways (see above). Some of the RRNs in the DRG are local *interneurons*. Others are *premotor neurons*, projecting directly to various pools of motor neurons—primarily inspiratory—in the spinal cord and ventral respiratory group (see [Fig. 32-4](#)).  **N32-6**

N32-6

Dorsal Respiratory Group Neurons

Contributed by George Richerson

For example, an interneuron in the DRG may synapse on a DRG premotor neuron, which, in turn, may descend into the spinal cord and reach one of the paired phrenic motor nuclei in the ventral horn of the spinal cord. There, the premotor neuron synapses on the cell bodies of phrenic motor neurons, whose axons follow the phrenic nerve to the diaphragm.

The ventral respiratory group is primarily motor and contains both inspiratory and expiratory neurons

The **ventral respiratory group (VRG)**  **N32-7** contains both inspiratory and expiratory neurons (see [Table 32-2](#)). It is ventral to the DRG, about midway between the dorsal and ventral surfaces of the medulla. The VRG lies within and around a series of nuclei that form a column of neurons extending from the pons nearly to the spinal cord and is thus considerably longer than the DRG (see [Fig. 32-4](#)). Like the DRG, the VRG contains local *interneurons* and *premotor* neurons. In contrast to the DRG, the VRG also contains *motor* neurons that innervate muscles of the pharynx and larynx, as well as viscera of the thorax and abdomen. Sensory information related to pulmonary function comes indirectly via the DRG. Thus, the VRG plays more of an efferent role, whereas the DRG primarily plays an afferent role.

N32-7

Ventral Respiratory Group

Contributed by George Richerson

Aside from input from muscle spindle fibers (see p. 388), which provide feedback to pharyngeal and laryngeal motor neurons, the VRG does not receive any monosynaptic sensory input.

Rostral VRG

Within the nucleus retrofacialis is a region known as the **Bötzinger complex**. This region is the rostral VRG, which contains primarily *expiratory* interneurons projecting to other respiratory nuclei, including the caudal VRG.

Intermediate VRG

Within and near the nucleus ambiguus and the nucleus para-ambigualis is the intermediate VRG. The majority of RRNs in the intermediate VRG are *inspiratory*. The **nucleus ambiguus** contains *somatic motor neurons* that leave the medulla via CN IX and X to supply the larynx and pharynx and prevent collapse of the upper airways during inspiration. In addition, this nucleus contains *parasympathetic preganglionic neurons* that supply airways in the lung and other structures via CN X. Finally, the nucleus ambiguus contains some motor neurons with respiration-related activity that send axons out the trigeminal nerve (CN V), presumably for opening the mouth; the facial nerve (CN VII), for flaring the nostrils; and the accessory nerve (CN XI), for activating other accessory muscles of respiration during strong inspirations.

The **nucleus para-ambigualis** surrounds the nucleus ambiguus and contains *premotor neurons* that

project to inspiratory motor neurons in the spinal cord and *interneurons* that have local connections to other neurons of the medulla. Like some neurons in the DRG, the inspiratory premotor neurons in the nucleus para-ambigualis drive *primary* muscles of inspiration. However, unlike neurons in the DRG, the inspiratory premotor neurons in the nucleus para-ambigualis also drive *accessory* muscles.

The pre-Bötzinger complex (see p. 706) is in the rostral portion of the intermediate VRG. It is not yet well defined anatomically, but instead is defined by the electrophysiological properties of its component neurons, which continue to produce bursts of respiratory activity in brain slices. The anatomical location roughly corresponds to a region slightly ventral and lateral to the nucleus ambiguus just caudal to the Böttinger complex. The pre-Böttinger complex contains inspiratory neurons that include local interneurons and premotor neurons. There is evidence that this region may be the respiratory CPG.

Caudal VRG

Within the **nucleus retroambigualis** is the caudal portion of the VRG, which contains mostly *expiratory* premotor neurons. Many of these travel down the spinal cord to synapse on motor neurons that innervate muscles of expiration, such as the internal intercostal and abdominal muscles. Because a quiet expiration is a passive event, these are *accessory* muscles of expiration. Thus, the premotor neurons in the caudal VRG are normally silent and become active only during forced expirations. These premotor neurons appear to receive their stimulatory drive from neurons in the rostral VRG.

The VRG consists of three regions that perform specific functions. (1) The **rostral VRG** or **Böttinger complex (BötC)**  **N32-8** contains *interneurons* that drive the expiratory activity of the caudal region. (2) The **intermediate VRG**  **N32-7** contains somatic *motor* neurons whose axons leave the medulla via CN IX and CN X. These fibers supply the pharynx, larynx, and other structures, thus maximizing the caliber of the upper airways during inspiration. The intermediate VRG also contains *premotor* neurons that project to inspiratory motor neurons in the spinal cord and medulla. Within the rostral pole of the intermediate VRG is a group of inspiratory neurons defined as the **pre-Böttinger complex (preBötC)**, which, as we will see below, may be part of the respiratory CPG, contributing to generation of the respiratory rhythm. (3) The **caudal VRG** contains expiratory *premotor* neurons that travel down the spinal cord to synapse on motor neurons that innervate accessory muscles of expiration, such as abdominal and certain intercostal muscles (see p. 608).

N32-8

Origin of the Terms Böttinger Complex and Pre-Böttinger Complex

Contributed by Emile Boulpaep, Walter Boron

The Böttinger complex—the most rostral portion of the VRG—is not named after a scientist or even a grateful patient. Rather, the Böttinger complex received its name from Professor Jack Feldman (currently of the University of California, Los Angeles) while he was at a banquet for a scientific meeting in Hirschhorn, Germany, in 1978.

Feldman had discovered this region and reported on it at a meeting in Stockholm the previous year, but had not published the work. At the Hirschhorn meeting, a colleague who had been at the Stockholm meeting presented some new data based on Feldman's previous presentation. Worrying that this forgotten corner of the medulla would go unnamed—or, worse yet, be named after the wrong person—Feldman

proposed a toast in which he suggested that this anatomical area be named after some aspect of the Hirschhorn meeting. So Professor Feldman picked up the bottle of wine that happened to be at the table—Bötzinger (a rather unremarkable white wine)—and the rest is neurophysiological history ... the **Bötzinger complex**.

Twelve years later, Feldman and his colleagues identified an area slightly *caudal* to the Bötzinger complex. This area appeared to be the source of the respiratory rhythm in the preparation with which they were working. The group thought that the logical name—the *post*-Bötzinger complex—would connote less importance than the authors thought the region deserved. So they chose the anatomically incorrect **pre-Bötzinger complex**. The reviewers of the subsequent paper seemed not to notice, and the name stuck.

Generation of the Respiratory Rhythm

Different RRNs fire at different times during inspiration and expiration

Eupneic breathing is highly stereotyped and consists of two major phases—inspiration and expiration (Fig. 32-5A, B). During the **inspiratory phase**, phrenic nerve output to the diaphragm gradually increases in activity during 0.5 to 2 seconds and then declines precipitously at the onset of expiration (see Fig. 32-5C). The ramp increase in activity helps to ensure a smooth increase in lung volume. During the **expiratory phase**, the phrenic nerve is inactive, except—in some cases—for a brief burst at the onset. Some physiologists consider this “postinspiratory” burst to represent its own phase.

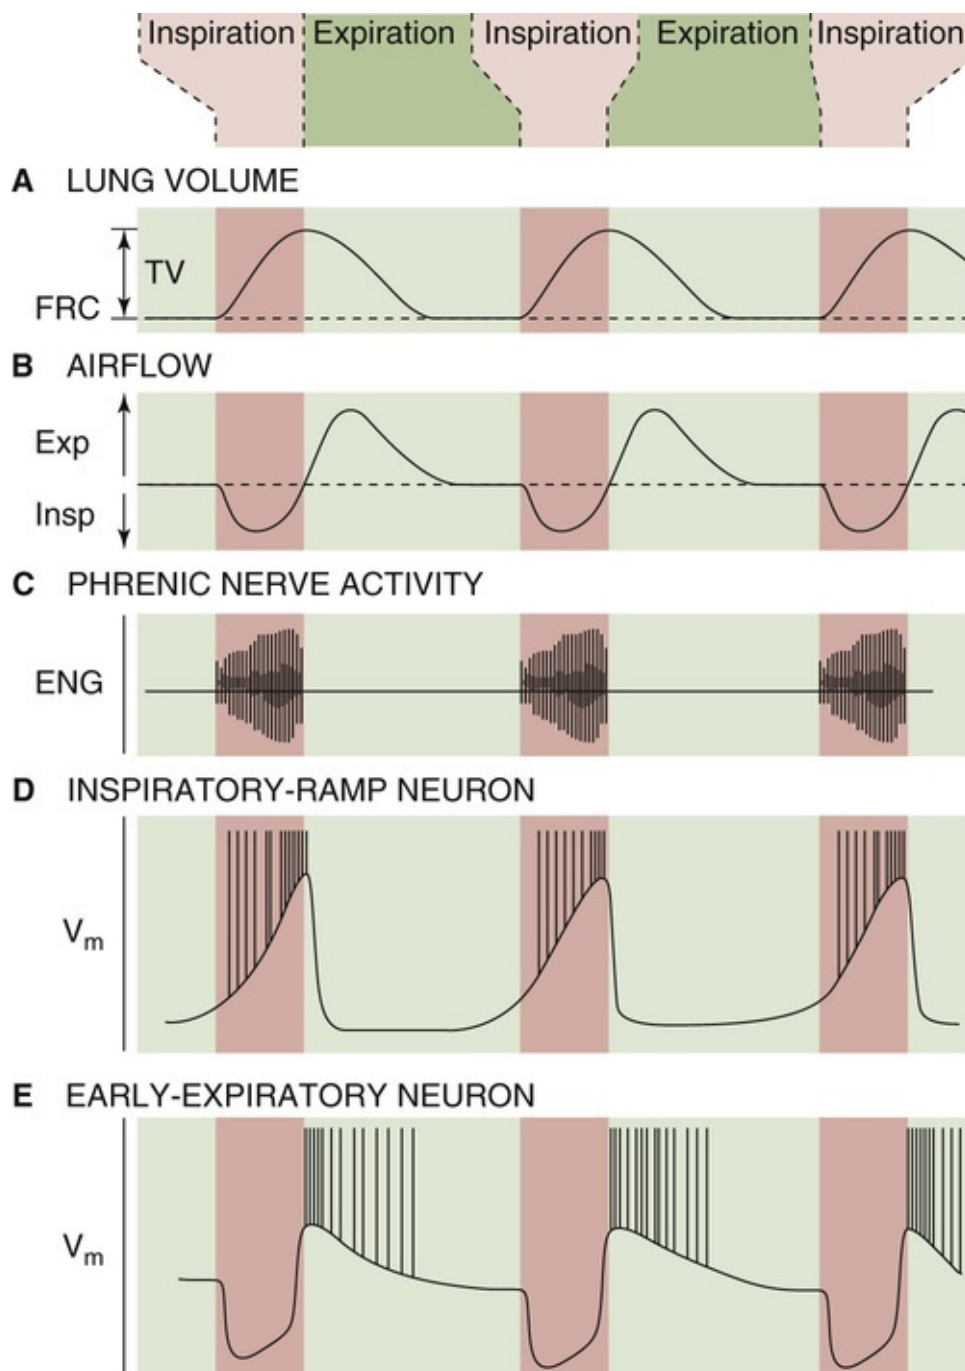

FIGURE 32-5 Neural activity during the respiratory cycle. The activity of RRNs in the medulla (examples of which are shown in **D** and **E**) leads to the phasic activity of the phrenic nerve (**C**) and other respiratory nerves, which produces airflow (**B**), causing lung volume to change (**A**). ENG, electroneurogram; Exp, expiration; FRC, functional residual capacity; Insp, inspiration; TV, tidal volume; V_m , membrane potential.

N32-9

Underlying the activity of the phrenic nerve—and the other motor nerves supplying the muscles of inspiration and expiration—is a spectrum of firing patterns of RRNs located within the DRG and VRG (see above). RRNs can be broadly classified as inspiratory or expiratory, but each class includes many subtypes, based on how their firing patterns correlate with the respiratory cycle. **Figure 32-5D and E** shows two such patterns. **N32-9** Each subtype presumably plays a unique role in generating and shaping respiratory output—that is, the activity of the nerves to each respiratory muscle. RRNs may be further subclassified on the basis of their responses to afferent inputs, such as lung inflation and changes in arterial P_{CO_2} .

Neural Activity During the Respiratory Cycle

Contributed by George Richerson, Emile Boulpaep, Walter Boron

Some RRNs fire mostly during early inspiration, others evenly throughout in inspiration, and still others during late expiration or evenly throughout expiration. Some fire during both inspiration and expiration, but with a peak of activity during one of the two phases of ventilation.

eFigure 32-1 is an expansion of Figure 32-5. eFigure 32-1 includes four additional panels: E, F, G, and I. Panel E in Figure 32-5 is the same as panel H in eFigure 32-1.

A LUNG VOLUME

B AIR FLOW

C PHRENIC NERVE ACTIVITY

D INSPIRATORY-RAMP NEURON

E EARLY-INSPIRATORY NEURON

F CONSTANT-INSPIRATORY NEURON

G LATE-ONSET INSPIRATORY NEURON

H EARLY-EXPIRATORY NEURON

I EXPIRATORY-RAMP NEURON

EFigure 32-1 Neural activity during the respiratory cycle. The activity of RRNs in the medulla (examples of which are shown in **D** to **I**) leads to the phasic activity of the phrenic nerve (**C**) and other respiratory nerves, which produces airflow (**B**), causing lung volume to change (**A**). ENG, electroneurogram; Exp, expiration; FRC, functional residual capacity; Insp, inspiration; TV, tidal volume; V_m , membrane potential.

As shown in Figure 32-5C—as well as eFigure 32-1C—the activity of the phrenic nerve varies in a characteristic way during the phases of the respiratory cycle. During the **inspiratory phase**, phrenic nerve output to the diaphragm gradually increases in activity over 0.5 to 2 seconds, followed by a precipitous decline at the onset of expiration. The ramp increase in activity helps to ensure a smooth increase in lung volume. Although not evident in eFigure 32-1C, during the **first expiratory phase** (E_1 , or the postinspiratory phase), there may be a paradoxical burst of activity in the phrenic nerve. This burst offsets the large elastic recoil of the lungs at the end of inspiration. This elastic recoil would tend to collapse the lungs rapidly if the tone of the inspiratory muscles decreased too abruptly.

During the **second expiratory phase** (E_2), the phrenic nerve is inactive. During a quiet expiration, which is normally a passive event, the accessory muscles of expiration are also inactive. However, during a forced expiration, the accessory muscles of expiration (e.g., internal intercostals, abdominal muscles) become active during E_2 .

Underlying the activity of the phrenic nerve—and the other motor nerves supplying the muscles of inspiration and expiration—is a spectrum of firing patterns of different RRNs throughout the medulla, some of which are shown in eFigure 32-1D–I. RRNs can be broadly classified as inspiratory or expiratory, but for each class there are many subtypes of RRNs, each presumably with different functions in generating and shaping the “respiratory output”—that is, the activity of the nerves to each of the respiratory muscles.

The tracings in eFigure 32-1 are idealized drawings. These recordings would have been made in a preparation such as the brain of a cat with an extracellular electrode recording the activity of a particular RRN. A cuff electrode on the phrenic nerve would have simultaneously recorded the activity of the phrenic nerve. All the panels in eFigure 32-1 relate to the condition of *eupnea*. In the following descriptions, the letters refer to the panel designations:

- A. Lung volume. Note that inspiration is shorter than expiration.
- B. Airflow. Airflow into the lung is represented by a downward deflection in the record. Note that the air flow is zero when lung volume is not changing (e.g., at the transition from inspiration to expiration).
- C. Phrenic-nerve activity. The panel shows a typical waveform of phrenic nerve output during eupnea.
- D. An RRN with inspiratory-ramp activity. Note that the neuron fires during inspiration with a gradually increasing firing rate.
- E. An RRN with early-burst activity. The neuron fires during early inspiration and then with a decrementing firing rate.
- F. An RRN with constant inspiratory activity. The neuron fires with a relatively constant rate during inspiration.
- G. An RRN with late-onset inspiratory activity. The neuron is silent except for a short burst late in

inspiration. This neuron could be part of an “off-switch” that terminates inspiration.

H. An RRN with early-expiratory activity. The neuron fires during E_1 , immediately after inspiration (postinspiratory), and then the firing rate decrements.

I. An RRN with expiratory-ramp activity. The firing rate gradually increases during E_2 .

The various groups of respiratory neurons in the brainstem consist of networks of neurons with firing patterns such as those outlined in the previous passage. Although the precise role each type of RRN plays in generating and shaping the respiratory motor output is unknown, it is instructive to consider some of the neurons that make up, for example, the DRG. In the DRG, most RRNs (>90%) are inspiratory, and three of the most common of these are known as $I\alpha$, $I\beta$, and P neurons.

$I\beta$ neurons (the I stands for “inspiratory”) fire with a ramp pattern (see eFig. 32-1D), presumably because they are driven by the **central inspiratory activity** that drives inspiration. In addition, they receive sensory input directly from pulmonary stretch receptors; lung inflation stimulates $I\beta$ neurons. Many $I\beta$ neurons do not send their axons to the spinal cord, but instead are interneurons whose axons synapse locally within the DRG. Thus, $I\beta$ neurons probably *integrate* sensory information from pulmonary stretch receptors and may play a key role in some respiratory reflexes, such as the Hering-Breuer reflex (see p. 706).

P neurons, unlike the $I\beta$ neurons, are not driven by the central inspiratory activity. However, they do receive direct input from pulmonary stretch receptors, so that their activity simply tracks changes in lung volume. Thus, like the $I\beta$ neurons, the P neurons presumably are important for sensory integration.

$I\alpha$ neurons, like $I\beta$ neurons, fire with a ramp pattern (see eFig. 32-1D). Input from other DRG neurons tends to inhibit $I\alpha$ neurons with increases in lung inflation. $I\alpha$ neurons are *premotor neurons*; their axons synapse on phrenic motor neurons and external intercostal motor neurons. That is, the firing of an $I\alpha$ neuron indirectly tends to cause a muscle of inspiration to contract. Thus, it is not surprising that the firing pattern of the $I\alpha$ neurons is similar to that of the phrenic nerve. Collaterals of $I\alpha$ neurons also branch off and synapse on neurons in the VRG.

The firing patterns of RRNs depend on the ion channels in their membranes and the synaptic inputs they receive

What are the mechanisms for generating so many types of activity in RRNs? For example, if the RRN is a premotor neuron, its firing pattern must be appropriate for driving a motor neuron, such as one in the phrenic nerve nucleus. Two complementary mechanisms appear to contribute to the firing patterns necessary for the neuron to do its job. (1) The intrinsic membrane properties of RRNs—the complement and distribution of ion channels present in a neuron—influence the firing pattern of that neuron. (2) The synaptic input—excitatory postsynaptic potentials (EPSPs) and inhibitory postsynaptic potentials (IPSPs)—changes with an appropriate pattern during the respiratory cycle and thereby generates a specific firing pattern.

Intrinsic Membrane Properties

Many neurons in respiratory nuclei have intrinsic membrane properties that influence the types of firing patterns they are able to produce. For example, many DRG neurons have a K^+ current called a **transient A-type current** (see p. 193). If we first hyperpolarize and then depolarize such a neuron, it begins firing

action potentials, but only after a delay. The hyperpolarization removes the inactivation of the A-type current, and the subsequent depolarization transiently activates the A-type K^+ current and transiently slows depolarization of the membrane and inhibits generation of action potentials (see [Fig. 7-18C](#)). If the A-type current is large, the neuron cannot begin to fire until after the A-type current sufficiently inactivates (see [Fig. 7-18D](#)). The delay in firing of a neuron with A-type current can explain why some RRNs fire only late during inspiration, even though they receive EPSPs continuously during inspiration. As we will see, other neurons have pacemaker properties due to their complement of ion channels, which allows them to fire action bursts of potentials spontaneously without synaptic input. 🧠N32-10

N32-10

Dorsal Respiratory Group Neuron with Ca^{2+} -Activated K^+ Current

Contributed by George Richerson, Emile Boulpaep, Walter Boron

A second type of neuron in the DRG has a large amount of Ca^{2+} -activated K^+ current (see p. 196). After the neuron fires several action potentials, the accumulation of Ca^{2+} inside the cell slowly activates this K_{Ca} channel, hyperpolarizing the cell and limiting the firing rate. Thus, suddenly depolarizing such a neuron triggers a burst of firing that tapers off as K_{Ca} channels activate. The decrease in firing rate, called *spike-frequency adaptation*, mimics the early-burst activity of some RRNs. 🧠N32-9 Like the A-type current, K_{Ca} channels could cause these neurons to have an appropriate firing pattern, even in the absence of rigidly patterned synaptic input.

Synaptic Input

The most obvious explanation for a neuron's having a specific firing pattern is that it receives excitatory synaptic input when it is supposed to fire action potentials and receives inhibitory synaptic input when it is quiet. Indeed, some RRNs fire only during early inspiration (see [Fig. 32-5E](#)), when they receive strong excitatory synaptic input. These early inspiratory neurons also inhibit late-onset inspiratory neurons, and vice versa ([Fig. 32-6](#)). 🧠N32-11 As a result of this reciprocal inhibition, only one of the two subtypes of inspiratory neurons can be maximally active at a time.

FIGURE 32-6 Patterned synaptic input: reciprocal inhibition. Because of reciprocal inhibition between the early-burst neuron and the late-onset inspiratory neuron, only one can be maximally active at a time. V_m , membrane potential.

N32-11

Patterned Input

Contributed by George Richerson

Independent of intrinsic membrane properties, the patterned synaptic input that many RRNs receive from other respiratory neurons can also influence the firing pattern. For example, the early-burst activity of the neuron whose firing pattern is shown in the upper panel of Figure 32-6 parallels the strong excitatory synaptic input that the neuron receives during the early part of inspiration as well as the inhibitory synaptic input that it receives during expiration.

Some firing patterns of RRNs result in part from inhibitory connections between neurons. For example, the early-burst inspiratory neurons described in the preceding paragraph appear to inhibit late-onset inspiratory neurons (N32-9, specifically eFig. 32-1G), and vice versa. As a result of this reciprocal inhibition, only one of the two subtypes of inspiratory neurons can be maximally active at any one time.

In addition to patterned synaptic input from RRNs, respiratory neurons also receive input from other

neuronal systems, which allows the respiratory system to respond appropriately to challenges and to be integrated with many different brain functions. Some of the neurotransmitters released onto respiratory neurons—both by RRNs and by neurons from other regions of the CNS—are listed in eTable 32-1.

eTABLE 32-1
Neurotransmitters Released onto Respiratory Neurons

Glutamate
Gamma aminobutyric acid (GABA)
Serotonin (5-hydroxytryptamine, 5-HT)
Norepinephrine
Dopamine
Acetylcholine
Thyrotropin-releasing hormone (TRH)
Substance P
Corticotropin-releasing hormone (CRH)
Endorphins
Enkephalins

In summary, both intrinsic membrane properties and patterned synaptic input can cause RRNs to fire in their characteristic patterns. In theory, either of these properties might be sufficient to ensure that these neurons have the right firing pattern. The presence of both properties illustrates a general concept that appears to be important in critical biologic systems: redundancy. For those body systems critical for life support, use of multiple mechanisms may ensure that normal functioning will occur despite severe perturbations.

In addition to receiving synaptic input from RRNs that occurs rhythmically, in phase with breathing, respiratory neurons also receive input from other neuronal systems. This input can either interrupt regular breathing or control the level of ventilation, allowing the respiratory system to respond appropriately to challenges and to be integrated with many different brain functions.

Pacemaker properties and synaptic interactions may both contribute to the generation of the respiratory rhythm

Perhaps the most important questions that still need to be answered about the neural control of breathing revolve around the mechanism and identity (or location) of the respiratory CPG. We address the mechanism in this section, and which cells are involved in the next.

Two general theories have evolved for the mechanism of the respiratory CPG. The first posits that subsets of neurons have pacemaker activity; the second, that synaptic interactions create the rhythm.

Pacemaker Activity

Some cells have ion channels that endow them with pacemaker properties (see pp. 397–398). For example, isolated cardiac myocytes produce rhythmic activity via “pacemaker currents” (see p. 489). Some neurons have similar pacemaker activity and repeatedly fire one spike at a time (i.e., beating pacemakers). Other pacemaker neurons repeatedly generate bursts of spikes (i.e., bursting pacemakers). The first evidence for pacemaker activity in a mammalian respiratory nucleus came from the laboratory of Peter Getting. In brain slices from the guinea pig, putative premotor respiratory neurons in the NTS fire erratically at a low rate, with no apparent respiratory rhythm. However, adding **thyrotropin-releasing hormone** (TRH; see p. 1014) to the bathing medium causes these neurons to generate bursts of action potentials (Fig. 32-7A), similar to inspiratory bursts in RRNs of the DRG during eupnea in an intact animal (see Fig. 32-7B). Indeed, axons from the medullary raphe nuclei (see pp. 312–313) project to the NTS, where they release TRH (as well as serotonin and substance P) and thereby could induce bursting pacemaker activity in NTS neurons. This pacemaker activity might contribute to generation of the respiratory rhythm or augment respiratory output generated within another site. Pacemaker activity is also present in neurons within the preBötC (see p. 708), where serotonin (see Fig. 13-8B)—the main neurotransmitter released by the medullary raphe neurons noted above—can induce pacemaker activity. 🧠

Ability of Serotonin to Induce Pacemaker Activity in the Pre-Böttinger Complex

Contributed by George Richerson, Walter Boron

eFigure 32-2 from an article by Ptak and colleagues shows the results of an experiment on an inspiratory preBötC neuron (see p. 708). This neuron has no *intrinsic* bursting activity. The bursting that we see in panel A is due to synaptic inputs.

FIGURE 32-2 Serotonin converts some non-intrinsically bursting inspiratory preBötC neurons into intrinsically bursting cells. (From Ptak K, Yamanishi T, Aungst J, et al: Raphé neurons stimulate respiratory circuit activity by multiple mechanisms via endogenously released serotonin and substance P. *J Neurosci* 29:3720–3737, 2009, with permission.)

As seen in the left half of panel B, blocking these synaptic inputs with extracellular Cd²⁺ ions eliminates all activity. In the right half of panel B—still in the presence of Cd²⁺—we see that graded depolarizing currents of 15 pA and then 20 pA produce tonic spiking, but not rhythmic bursting.

In panel C, the addition of serotonin (5-HT) to the Cd²⁺ now causes rhythmic bursting during depolarization. Note that an increased level of depolarizing current (from 15 pA to 20 pA) in the right

portion of this panel increases the frequency of this bursting.

In panel D, washing out the serotonin eliminates the bursting activity.

Synaptic Interactions

Neural circuits without pacemaker neurons also can generate rhythmic output (see pp. 397–398). Indeed, synaptic connections within and between the DRG and VRG establish neural circuits and generate EPSPs and IPSPs onto each other with a timing that could explain the oscillatory behavior during the respiratory cycle (see Fig. 32-6). Computational neurobiologists have proposed a variety of pure **network models**  **N32-13** of respiratory rhythm generation. According to these models, the CPG that produces the respiratory rhythm depends solely on synaptic connections between subtypes of RRNs and not at all on the pacemaker activity of individual neurons. Thus, the rhythm would be an emergent property of the network.

N32-13

The Central Pattern Generator as an “Emergent Property”

Contributed by George Richerson, Emile Boulpaep, Walter Boron

One of the network models of respiratory rhythm generation includes three key elements for generating normal inspiratory output: (1) “central inspiratory activity,” (2) an integrator, and (3) an inspiratory off-switch. A group of neurons in the DRG would generate central inspiratory activity that would in turn cause a steady increase in firing of premotor neurons (such as the $I\alpha$ neurons discussed in  **N32-9**) that drive inspiratory motor neurons and the $I\beta$ interneurons (also discussed in  **N32-9**). The $I\beta$ interneurons also receive input from the pulmonary stretch receptors. Thus, the $I\beta$ interneurons “integrate” information from both the command to the inspiratory muscles and the resultant lung inflation. When the integrator determines that the inspiration has proceeded far enough, it triggers the inspiratory “off-switch” neurons, the late-onset inspiratory neurons in eFigure 32-1G. According to the model, the activated inspiratory off-switch neurons cause inspiration to stop by resetting central inspiratory activity, which allows expiration to take over. Expiration is passive and ends when central inspiratory activity builds up enough to initiate firing of inspiratory neurons again.

According to the model, neurons of the so-called pneumotaxic center in the pons can also trigger the inspiratory off-switch. This hypothesis fits with experimental data, because interrupting input from both the pneumotaxic center and the pulmonary stretch receptors (i.e., input carried by vagal afferents) results in loss of the off-switch and thus in **apneusis** (see p. 702).

One of the difficulties with network models is that the exact identity of each of the components of the model is not certain.

One of the difficulties with network models of breathing is that not all of the neurons within the respiratory network are known. Network models also must take into account the presence of the rich complement of intrinsic membrane properties that exist in the component neurons, but not all of these are fully characterized either. As a result, *pure* network models must be very complex to explain all aspects of the normal respiratory rhythm. Supplementing network models with intrinsic membrane properties (e.g., pacemaker activity) allows the models to be simpler. Moreover, from an evolutionary perspective, it is reasonable to infer that pacemaker cells may have driven primitive respiratory systems. In higher

organisms, both pacemaker activity and synaptic interactions appear to be involved in generating the normal respiratory rhythm.

The respiratory CPG for eupnea could reside in a single site or in multiple sites, or could emerge from a complex network

Where is the respiratory CPG for eupnea? In 1851, Flourens proposed a *noeud vital* [vital node] in the medulla, a small region that is the sole site producing respiratory output. In 1909, the neuroanatomist Santiago Ramón y Cajal reported that neurons in the NTS receive afferents from pulmonary stretch receptors and that NTS neurons project directly to the phrenic motor nucleus. He concluded that the NTS is the site of respiratory rhythm generation. However, today—in spite of considerable progress—the question of where in the medulla the CPG is located remains controversial. Here we discuss three major proposals for the location of the respiratory CPG.

Restricted-Site Model

Toshihiko Suzue first introduced the in vitro brainstem/spinal cord preparation from the neonatal rat, and Jeffrey Smith and Jack Feldman further developed this preparation to study the generation of respiratory output. In this preparation, a small region in the rostral VRG—the preBötC (see [Fig. 32-4](#))—generates rhythmic motor output in the phrenic nerve and hypoglossal nerve (CN XII, which innervates the tongue, an accessory muscle of inspiration). Destroying the preBötC in the isolated brainstem causes respiratory output to cease. In a slice preparation, the preBötC generates rhythmic bursts of activity that one can record from the hypoglossal nerve rootlets ([Fig. 32-8](#)). These bursts require the continuous release of serotonin from raphé neurons onto neurons of the preBötC. These experiments have led to the hypothesis that the preBötC is the site of the respiratory CPG. 🍷[N32-14](#)

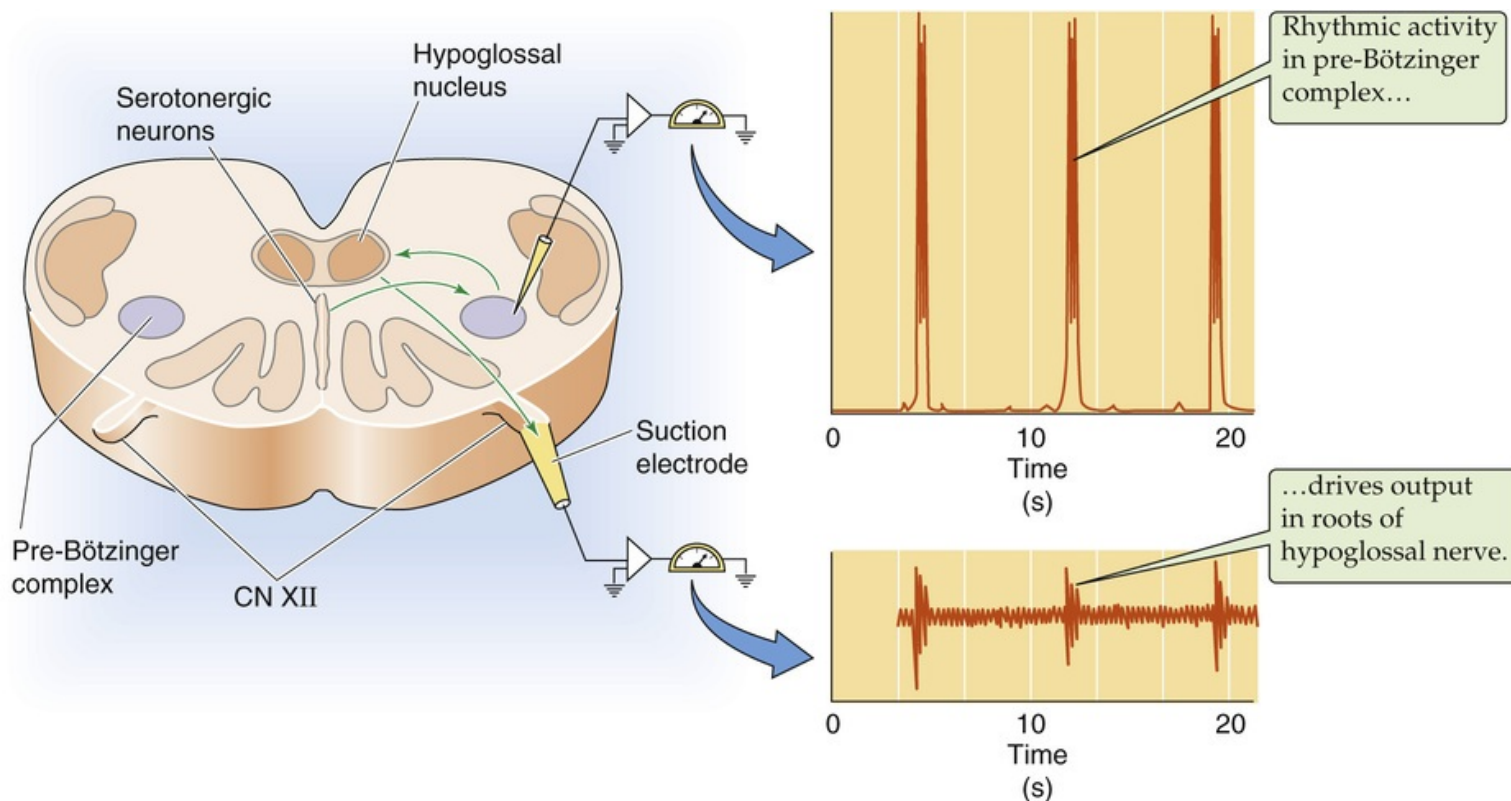

FIGURE 32-8 Possible role of preBötC as the respiratory CPG. The recordings were made in a brain slice containing the preBötC, a piece of the hypoglossal nucleus, some rootlets of the hypoglossal nerve, and serotonergic neurons. (Data from Smith JC, Ellenberger HH, Ballanyi K, et al: Pre-Bötzinger complex: A brainstem region that may generate respiratory rhythm in mammals. *Science* 254:726, 1991.)

N32-14

Site of the Respiratory Central Pattern Generator

Contributed by George Richerson, Emile Boulpaep, Walter Boron

Given the long history of the field and the many investigators working on different aspects of the problem, any conclusion about the precise location of a respiratory CPG is bound to be controversial.

In the case of the **preBötC** (see p. 706), some critics believe that the pattern of respiratory output generated resembles gasping. In addition, the conditions normally used to study the activity are artificial. In addition, destroying the preBötC in adult rats leads to ataxic breathing, and yet the animals survive. However, most investigators agree that the preBötC plays an important role in breathing, and defining the mechanisms of rhythm generation in the preBötC will be important for understanding normal breathing. For example, it is now clear that there are pacemaker neurons within the preBötC. Some of these pacemaker neurons are inhibited by hypoxia, whereas others are unaffected. This observation provides a possible explanation for why the pattern of breathing can change from eupnea to gasping when the oxygen levels in the brain become low, such as from cardiac arrest.

Distributed Oscillator Models

A different theory is that there is more than one CPG, any one of which could take over the job of generating the respiratory rhythm, depending on the conditions. As already noted, TRH can induce bursting pacemaker activity in DRG neurons. Moreover, a group of neurons in the parafacial respiratory group near the ventral surface of the medulla can also produce rhythmic activity. One interpretation is that

various groups of respiratory neurons are latent CPGs and that the location of the dominant CPG can shift during different behaviors. A second interpretation is that the presence of rhythmicity in multiple areas represents redundancy, ensuring that respiratory output does not fail. This design would be analogous to initiation of the heartbeat, in which many cells within the sinoatrial node can be the first to fire, and cells in other parts of the heart can take over if the sinoatrial node fails (see [p. 489](#)). In this model, some respiratory neurons with intrinsic oscillatory behavior would contribute to rhythm generation only under unusual conditions (e.g., hypoxia, anesthesia, early in development); under these conditions, the neurons might generate abnormal or pathological respiratory output (e.g., gasping). A third interpretation is that only one CPG exists for eupnea, and that other regions augment the rhythm (and make it more robust) but are unable to generate a rhythm on their own.

Emergent Property Model

The most common early explanation for generation of the respiratory rhythm (e.g., that proposed by Lumsden; see [p. 702](#)) is that no individual region of the DRG or VRG is *sufficient* to generate the rhythm but that many of them are *necessary*. A normal rhythm would require the component neurons in multiple brainstem regions to be “wired up” in a specific way. Some still believe that this view is essentially correct, arguing that none of the individual regions proposed to contain *the* CPG can produce a pattern of activity with all of the features described during eupnea.

None of the models we have discussed is universally accepted, and some of their elements are not mutually exclusive. The challenges in testing these hypotheses include the complexity of the CNS even at the level of the medulla, the technical difficulty in studying neurons of the mammalian brainstem under conditions that replicate exactly those present in vivo, and the large number of nonrespiratory neurons in the medulla. Yet, because it is primitive both ontogenetically and phylogenetically, the respiratory CPG will probably prove to be far easier to define than most other mammalian neural networks, such as those responsible for consciousness or memory.

Chemical Control of Ventilation

In fulfilling its mission to exchange O_2 and CO_2 between the atmosphere and the capillaries of the systemic circulation, the respiratory system attempts to regulate the blood-gas parameters, that is, the arterial levels of O_2 , CO_2 , and pH. These are overwhelmingly the most important influences on breathing. The body senses these parameters via two sets of chemoreceptors—the peripheral chemoreceptors and the central chemoreceptors. Hypoxia, hypercapnia, and acidosis all cause an increase in ventilation, which tends to raise P_{O_2} , to lower P_{CO_2} , and to raise pH, thereby correcting deviations in the three blood-gas parameters. Although small variations in arterial P_{CO_2} and P_{O_2} occur with activities such as sleep, exercise, talking, and panting, the control of arterial blood gases is so tight in normal individuals that it is rare for arterial P_{CO_2} to change from the normal 40 mm Hg by more than a few mm Hg. Thus, the peripheral and central chemoreceptors form the vital sensory arm of a negative-feedback mechanism that stabilizes arterial P_{O_2} , P_{CO_2} , and pH.

Peripheral Chemoreceptors

Peripheral chemoreceptors (carotid and aortic bodies) respond to hypoxia, hypercapnia, and acidosis

A decrease in arterial P_{O_2} is the primary stimulus for the peripheral chemoreceptors. Increases in P_{CO_2} and decreases in pH also stimulate these receptors and make them more responsive to hypoxia.

Sensitivity to Decreased Arterial P_{O_2}

Perfusion of the carotid body with blood having a low P_{O_2} —but a normal P_{CO_2} and pH—causes a prompt and reversible increase in the firing rate of axons in the carotid sinus nerve. [Figure 32-9A](#) shows an illustrative experiment on an isolated chemoreceptor cell of the carotid body. Under normal acid-base conditions, increasing P_{O_2} above the normal value of ~100 mm Hg has only trivial effects on the firing rate of the nerve. However, at normal values of P_{CO_2} and pH (see [Fig. 32-9B](#), blue curve), decreasing P_{O_2} to values <100 mm Hg causes a progressive increase in the firing rate.

Sensitivity to Increased Arterial P_{CO_2}

The carotid body can sense hypercapnia in the absence of hypoxia or acidosis. During in vitro experiments, it is possible to maintain a constant extracellular pH (pH_o) while increasing P_{CO_2} by keeping the ratio $[HCO_3^-]/P_{CO_2}$ constant (see p. 641). The maroon curve in Figure 32-9C shows the results of experiments in which graded increases in P_{CO_2} —at a fixed blood pH of 7.45 and a fixed P_{O_2} of 80 mm Hg—produced graded increases in the firing rate of the carotid sinus nerve.

Sensitivity to Decreased Arterial pH

The carotid body also can sense acidosis in the absence of hypoxia or hypercapnia. The green curve in Figure 32-9C shows the results of experiments that are the same as those represented by the maroon curve, except that blood pH was fixed at 7.25 rather than at 7.45. Over the entire range of P_{CO_2} values, the firing rate of the carotid sinus nerve is greater at a pH of 7.25 than at 7.45. Thus, metabolic acidosis (see p. 635) stimulates the carotid body.

In summary, besides being sensitive to hypoxia, the carotid body is sensitive to *both* components of respiratory acidosis (see p. 633)—high P_{CO_2} and low pH. In fact, respiratory acidosis makes the carotid body more sensitive to hypoxia (see Fig. 32-9B, orange curve), whereas respiratory alkalosis has the opposite effect (see Fig. 32-9B, red curve).

The glomus cell is the chemosensor in the carotid and aortic bodies

The body has two sets of peripheral chemoreceptors: the **carotid bodies**, one located at the bifurcation of each of the common carotid arteries, and the **aortic bodies**, scattered along the underside of the arch of the aorta (Fig. 32-10A). The carotid *bodies* should not be confused with the carotid *sinus* (see pp. 534–535), which is the bulbous initial portion of the internal carotid artery that serves as a *baroreceptor*. Similarly, the aortic *bodies* should not be confused with baroreceptors of the aortic arch.

A LOCATION OF CAROTID AND AORTIC BODIES**B MICROSCOPIC ANATOMY OF CAROTID BODY**

FIGURE 32-10 Anatomy of the peripheral chemoreceptors. (B, Data from Williams PL, Warwick R [eds]: Splanchnology. In Gray's Anatomy. Philadelphia, WB Saunders, 1980.)

The major function of the carotid and aortic bodies is to sense hypoxia in the arterial blood and signal cells in the medulla to increase ventilation. This signaling occurs via afferents of the glossopharyngeal nerve (CN IX) for the carotid bodies and of the vagus nerve (CN X) for the aortic bodies. The carotid bodies have been more extensively studied than the aortic bodies, which are smaller and less accessible. For the first description of their function as chemoreceptors, Corneille Heymans was awarded the 1938 Nobel Prize for Physiology or Medicine. 🏆N32-15

Corneille Jean François Heymans

Contributed by Walter Boron

Corneille Jean François Heymans (1892–1968) was born in Ghent, Belgium. He obtained his doctorate in medicine at the University of Ghent in 1920. Afterward, he worked with E. Gley at the Collège de France in Paris, M. Arthus in Lausanne, H. Meyer in Vienna, E.H. Starling in University College London, and Carl Wiggers 🏆N22-1 at Western Reserve University in Cleveland. In 1922, Heymans returned to Ghent to become a lecturer in pharmacodynamics, and in 1930 succeeded his father as professor of pharmacology.

For his work on the carotid and aortic bodies and their role in the regulation of respiration, he received the 1938 Nobel Prize in Physiology or Medicine.

Reference

Aside from their chemosensitivity, three features characterize the carotid bodies. First, they are extremely small: each weighs only ~2 mg. Second, for their size, they receive an extraordinarily high blood flow—the greatest of any tissue in the body. Their blood flow, normalized for weight, is ~40-fold higher than that of the brain. Third, they have a very high metabolic rate, 2- to 3-fold greater than that of the brain. Thus, even though the metabolic rate is high, the blood flow is so much higher that the composition of blood (e.g., P_{O_2} , P_{CO_2} , and pH) in carotid body capillaries approaches that of systemic arteries.

The chemosensitive cells of the carotid body are the type I or **glomus cells**. They are ~10 μm in diameter, are roughly spherical, and occur in clusters (see [Fig. 32-10B](#)). Adjacent glomus cells may communicate with each other via gap junctions. Glomus cells are neuroectodermal in origin and share many characteristics with neurons of the peripheral nervous system as well as with adrenal chromaffin cells (see [p. 1030](#)). Indeed, glomus cells have four neuron-like characteristics:

1. Some are innervated by *preganglionic* sympathetic neurons.
2. They have a variety of voltage-gated ion channels.
3. Depolarization triggers action potentials.
4. They have numerous intracellular vesicles containing a variety of neurotransmitters—acetylcholine, dopamine, norepinephrine, substance P, and met-enkephalin—that are released upon depolarization. These neurotransmitters control firing of the sensory nerve endings.

Sensory endings of the carotid sinus nerve (a branch of CN IX) impinge on carotid body glomus cells. Neurotransmitter release from the glomus cells triggers action potentials in the carotid sinus nerve, which makes its first synapse on neurons of the NTS (part of the DRG) and thereby signals the medulla that the systemic arterial blood has a low P_{O_2} , a high P_{CO_2} , or a low pH. 🟡[N32-16](#)

N32-16

The Glomus Cell

Contributed by George Richerson, Emile Boulpaep, Walter Boron

Curiously, the sensory endings of the carotid sinus nerve also contain vesicles, so the synapse formed with glomus cells may be bidirectional. The function of this synapse from the carotid sinus nerve onto the glomus cells is unknown.

Surrounding individual clusters of glomus cells are the type II or **sustentacular cells** (see [Fig. 32-10B](#)), which are supporting cells similar to glia. Also close to the glomus cells is a dense network of **fenestrated capillaries**. This vascular anatomy as well as the exceptionally high blood flow puts the glomus cells in an ideal position to monitor the arterial blood gases with fidelity.

Both the sympathetic and parasympathetic divisions of the autonomic nervous system innervate the carotid body. As already noted, preganglionic sympathetic neurons synapse on glomus cells and presumably can alter their function. Autonomic fibers also contact blood vessels; increased sympathetic tone decreases local blood flow. Because the metabolic rate of the carotid body is high, a large decrease in blood flow produces a local fall in P_{O_2} near the glomus cells, even when systemic arterial P_{O_2} remains constant. Increased sympathetic tone thus “fools” the carotid body into behaving as if a hypoxic state existed. Hence, by modulating blood flow to the carotid body, the autonomic nervous system can fine-tune the response of the peripheral chemoreceptors.

The aortic bodies also include scattered glomus cells that presumably have functions similar to those of glomus cells in the carotid bodies. However, aortic and carotid bodies exhibit distinct differences in their responses to stimuli and the effects they have on ventilation. For the purposes of this section, we focus our discussion here on the carotid bodies, about which more is known.

Hypoxia, hypercapnia, and acidosis inhibit K^+ channels, raise glomus cell $[Ca^{2+}]_i$, and release neurotransmitters

The sensitivity of the glomus cell to hypoxia, hypercapnia, and acidosis is a special case of chemoreception that we discussed in connection with sensory transduction (see [p. 354](#)). It is interesting that one cell type—the glomus cell—is able to sense all three blood-gas parameters. The final common pathway for the response to all three stimuli ([Fig. 32-11](#)) is an inhibition of BK K^+ channels (see [p. 196](#)), depolarization of the glomus cell, possible firing of action potentials, opening of voltage-gated Ca^{2+} channels, an increase in $[Ca^{2+}]_i$, secretion of neurotransmitters, and stimulation of the afferent nerve fiber. What differs among the three pathways is how the stimulus inhibits K^+ channels.

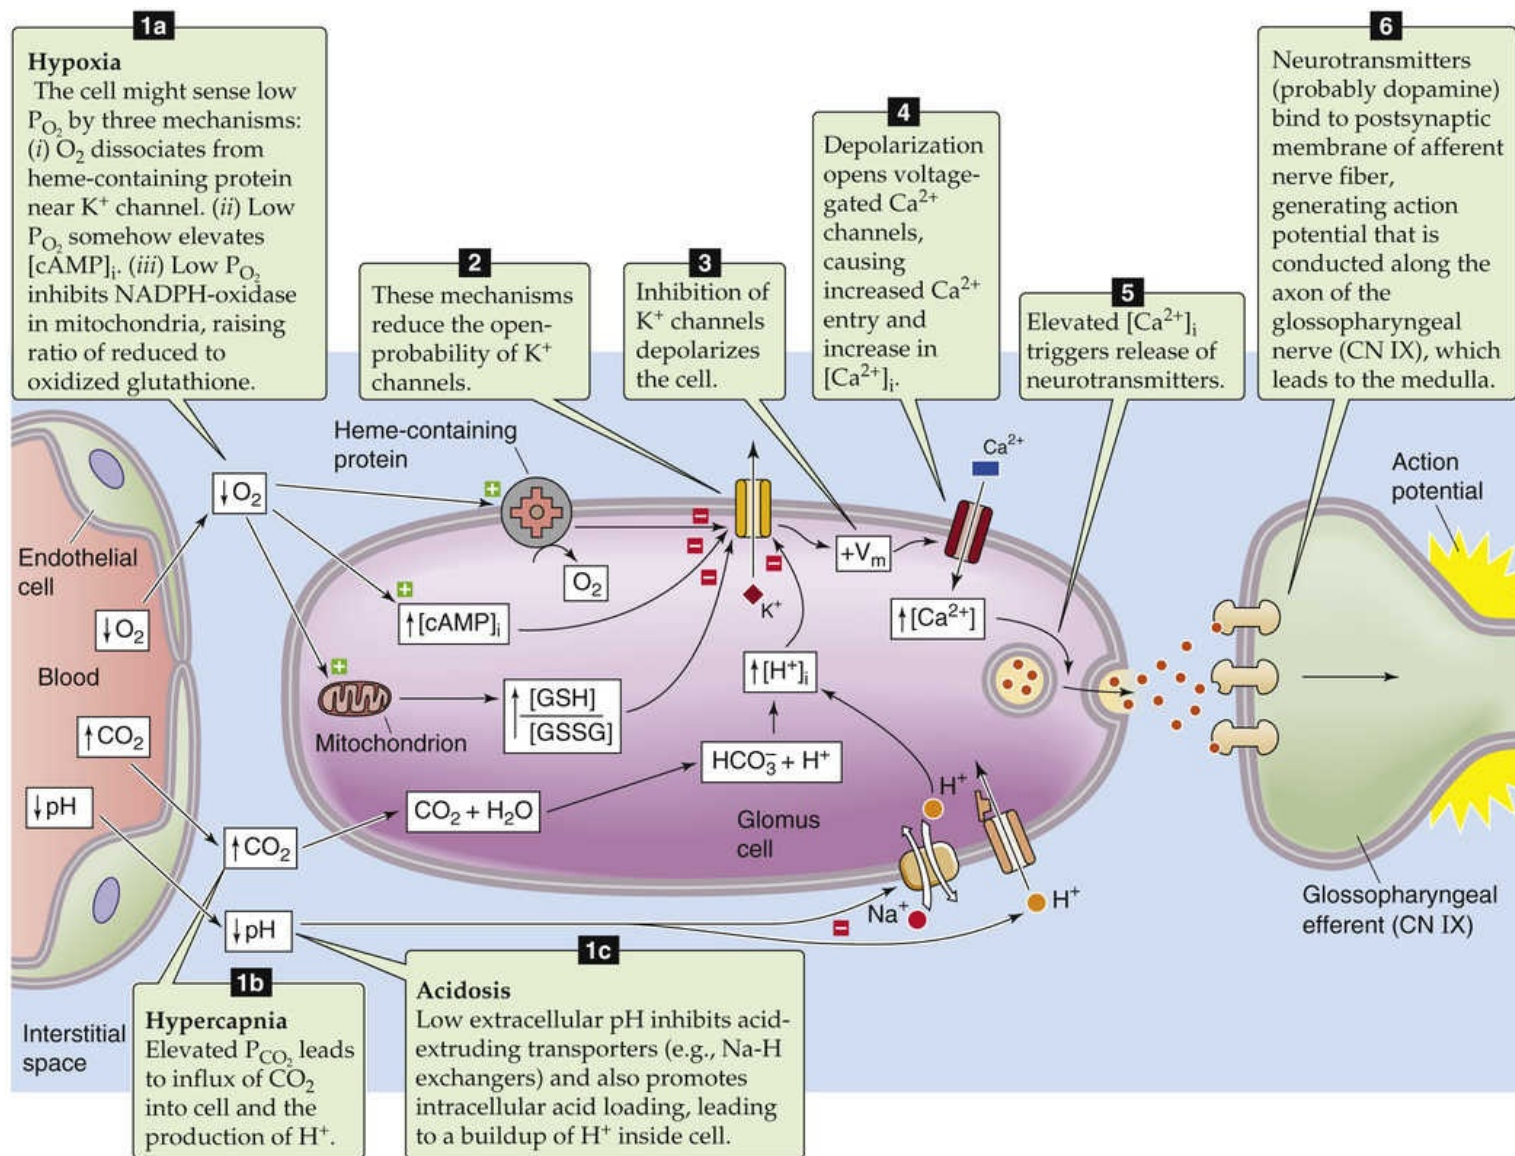

FIGURE 32-11 Response of glomus cell to hypoxia, hypercapnia, and acidosis. V_m , membrane potential.

Hypoxia **N32-17**

N32-17

Peripheral Chemoreceptors

Contributed by George Richerson, Emile Boulpaep, Walter Boron

Recent progress on the physiology of glomus cells has largely been a result of the ability to study glomus cells in culture and in the isolated carotid body in vitro.

Regarding the model in Figure 32-11, some controversy—which may reflect species differences—exists about which K^+ channel is the target of hypoxia. Some evidence favors the charybdotoxin-sensitive Ca^{2+} -activated K^+ channel. Other data point to a Ca^{2+} -insensitive voltage-gated K^+ channel and a voltage-insensitive “resting” K^+ channel.

Although one report (Williams et al, 2004) suggested that hemoxygenase-2 (HO-2) is a universal O_2 sensor, the results of a later study (Ortega-Sáenz et al, 2006) showed that mice deficient in HO-2 have a normal ability to sense a decrease in $[O_2]$.

Investigators have proposed three mechanisms by which low P_{O_2} might inhibit K^+ channels. First, some evidence suggests that a heme-containing protein responds to a decrease in P_{O_2} by lowering the open probability of closely associated K^+ channels. Second, in rabbit glomus cells, hypoxia raises $[cAMP]_i$, which inhibits a cAMP-sensitive K^+ current. Third, small decreases in P_{O_2} inhibit reduced nicotinamide adenine dinucleotide phosphate oxidase (NADPH oxidase) in mitochondria, thus increasing the ratio of reduced glutathione (GSH) to oxidized glutathione (GSSG; see [p. 955](#)), which directly inhibits certain K^+ channels. The relative roles of the three pathways may depend on the species. Regardless of how hypoxia inhibits which K^+ channels, the resulting depolarization activates voltage-gated Ca^{2+} channels.

Hypercapnia

An increase in P_{CO_2} causes CO_2 to move into the glomus cell, thereby generating H^+ (see [p. 646](#)) and leading to a virtually instantaneous fall of intracellular pH (pH_i). As pH_i decreases, the protons appear to inhibit high-conductance BK K^+ channels (see [Table 6-2](#), family No. 2) by displacing Ca^{2+} from their binding sites. The result is a depolarization, a rise in $[Ca^{2+}]_i$, and the release of neurotransmitter.

Extracellular Acidosis

A decrease in pH_o inhibits acid-base transporters (e.g., Na/HCO_3 cotransporters) that elevate pH_i and stimulates acid-base transporters (e.g., $Cl-HCO_3$ exchangers) that lower pH_i , thereby leading to a slow fall in pH_i (see [pp. 645–646](#)). Thus, even at a constant P_{CO_2} , extracellular acidosis (i.e., metabolic acidosis) triggers the same cascade of events as was outlined above for hypercapnia, albeit more slowly.

Central Chemoreceptors

When the blood-gas parameters are nearly normal, the central chemoreceptors are the primary source of feedback for assessing the effectiveness of ventilation and also the major source of tonic drive for breathing. Just as the peripheral chemoreceptors are primarily sensitive to arterial hypoxia, the neurons that act as central chemoreceptors are primarily sensitive to arterial *hypercapnia*, which generally presents itself as respiratory acidosis (i.e., a decrease in pH_o brought about by a rise in P_{CO_2} ; see [p. 633](#)). However, the actual parameter sensed appears to be a low pH in or around the chemoreceptor neurons.

The blood-brain barrier separates the central chemoreceptors in the medulla from arterial blood

In the 1950s, Isidore Leusen—working on dogs with denervated peripheral chemoreceptors—found that

ventilation increased when he perfused the cerebral ventricles with an acidic solution having a high P_{CO_2} . Because the resultant hyperventilation caused a respiratory *alkalosis* in the blood, it must have been the *local acidosis* in the brain that raised ventilation. From this and later experiments, we now believe that the primary stimulus driving respiration during respiratory acidosis is not actually an increase in arterial P_{CO_2} but probably the ensuing pH decrease within brain tissue. Most evidence indicates that the central chemoreceptors are at a site within the brain parenchyma that responds to changes both in arterial P_{CO_2} and cerebrospinal fluid (CSF) pH.

Starting from normal blood-gas parameters, an increase in the arterial P_{CO_2} from 40 to ~45 mm Hg (an increase of only ~12.5%) doubles ventilation. By contrast, hypoxia doubles ventilation only if P_{O_2} falls by ~50%. If P_{CO_2} increases suddenly, the increase in ventilation begins rapidly, augmenting first the *depth* and later the *frequency* of inspirations. However, the response may take as long as 10 minutes to develop fully ([Fig. 32-12A](#)). If, instead, the acid-base disturbance in arterial blood is a *metabolic* acidosis of comparable magnitude (i.e., a decrease in pH_o and $[\text{HCO}_3^-]_o$ at a fixed P_{CO_2} ; see [p. 635](#)), ventilation increases much more slowly and the steady-state increase is substantially less.

A EFFECT OF BREATHING CO₂ ON VENTILATION

B LOCATION OF CENTRAL CHEMORECEPTOR NEURONS

C DEPENDENCE OF CSF pH ON BLOOD pH

D DEPENDENCE OF VENTILATION ON CSF pH

FIGURE 32-12 Effect of arterial hypercapnia on brain pH and ventilation. (A, Data from Padgett P: The respiratory response to carbon dioxide. *Am J Physiol* 83:384–389, 1928; B, data from Fencik V: Acid-base balance in cerebral fluids. In Cherniack NS, Widdicombe J [eds]: *Handbook of Physiology, Section 3: The Respiratory System*, vol 2, part 1. Bethesda, MD, American Physiological Society, 1986, pp 115–140; C, data from Fencik V, Miller TB, Pappenheimer JR: Studies on the respiratory response to disturbances of acid-base balance, with deductions concerning the ionic composition of cerebral interstitial fluid. *Am J Physiol* 210:459–472, 1966.)

The reason for these observations is that the central chemoreceptors are located within the brain parenchyma (see Fig. 32-12B) and are bathed in **brain extracellular fluid (BECF)**, which is separated from arterial blood by the **blood-brain barrier (BBB)**. The BBB has a high permeability to small neutral molecules such as O₂ and CO₂ but a low permeability to ions such as Na⁺, Cl[−], H⁺, and [HCO₃[−]]_o (see p. 286). An increase in arterial P_{CO₂} rapidly leads to a P_{CO₂} increase of similar magnitude in the BECF, in the CSF, and inside brain cells. The result is an acidosis in each of these compartments. In fact, because the protein concentration of CSF or BECF is lower than that of blood plasma (see Table 11-1), the non-HCO₃[−] buffering power (see p. 629) of CSF and BECF is also substantially less. Thus, at least initially, raising P_{CO₂} produces a larger signal (i.e., pH decrease) in the CSF and BECF than in the blood. **N32-18**

N32-18

CO₂-Induced pH Changes in CSF and Brain Extracellular Fluid

Contributed by George Richerson, Emile Boulpaep, Walter Boron

As noted in the text, because the CSF and BECF have a lower protein content than either blood plasma or whole blood, the buffering power of the CSF and BECF is much lower than that of blood. Thus, increases in P_{CO_2} —initially at least—cause larger pH decreases in the CSF and BECF than in blood. Over time, as summarized on page 713, the choroid plexus and perhaps the BBB itself increase the active transport of HCO_3^- into the CSF and BECF. This transport represents a metabolic compensation to respiratory acidosis (see p. 641). During this compensation, the pH values of the CSF and BECF gradually rise, and thus the size of the net CO_2 -induced acidification gradually becomes smaller.

Although raising arterial P_{CO_2} causes the pH of the BECF and CSF to fall rapidly, the choroid plexus (see pp. 279–282) and perhaps the BBB partially restore the pH of these compartments by actively transporting HCO_3^- from the blood into the CSF. Thus, after many hours or days of respiratory acidosis in the arterial blood, the low-pH signal in the BECF and CSF gradually wanes. Even so, respiratory acid-base disturbances lead to substantial changes in the steady-state pH of the BECF and CSF (see Fig. 32-12C, purple curve).

In contrast to its high CO_2 permeability, the BBB's permeability to ions such as H^+ and HCO_3^- is low. For this reason, and because the BBB actively regulates the pH of the BECF and CSF, *metabolic* acid-base disturbances alter steady-state brain pH only 10% to 35% as much as identical blood pH changes during *respiratory* acid-base disturbances (see Fig. 32-12C, red curve). Therefore, ventilation is much less sensitive to changes in arterial pH and $[\text{HCO}_3^-]$ at constant arterial P_{CO_2} . Ventilation correlates uniquely with the pH of the BECF (see Fig. 32-12D), regardless of whether respiratory or metabolic acid-base disturbances produce the pH changes.

Central chemoreceptors are located in the ventrolateral medulla and other brainstem regions

Early work on central chemoreceptors by Hans Loeschcke, Marianne Schläpke, and Robert Mitchell identified candidate regions near the surface of the **ventrolateral medulla (VLM; Fig. 32-13A)**. The application of acidic solutions to the rostral or caudal VLM leads to a prompt increase in ventilation. Moreover, focal cooling of these areas to 20°C to reversibly inhibit neurons—or placement of lesions to permanently destroy the neurons—blunts the ventilatory response to respiratory acidosis. This and other work led to the conclusion that *the* central chemoreceptors are located near the surface of the VLM.

More recent work with brain slices and cultured cells show that acidosis stimulates neurons in many brainstem nuclei, including the medullary raphe (see Fig. 32-13A, inset) and the NTS—both in the

medulla—as well as the locus coeruleus and hypothalamus. Experiments in the laboratory of Eugene Nattie show that focal acidosis within many of these areas stimulates breathing in intact animals. **N32-19** It is not clear how important each of these chemosensitive areas is in the control of ventilation under normal conditions. One possibility is that multiple sensors are another example of redundancy in a critical system. Alternatively, some may come into play only under special circumstances, such as during severe acid-base disturbances or during sleep, when airway obstruction leads to arousal.

N32-19

Central Chemoreceptor

Contributed by George Richerson, Emile Boulpaep, Walter Boron

If the BBB is so permeable to CO_2 —and if the pH change in the BECF is so large and so fast—why does it take 5 to 10 minutes to produce a maximal ventilatory response to hypercapnia? The delay may be due to (1) a slower change in pH at the actual (i.e., unknown) location of chemosensation, (2) a delay in the chemotransduction events, or (3) a delay in the response of the CPG or respiratory motor neurons to input from the central chemoreceptor neurons.

More recent studies on brain slices and cultured cells show that acidosis stimulates neurons in many brainstem nuclei. These include the VLM discussed in the text, the medullary raphé (see Fig. 32-13B), the nucleus ambiguus, and the NTS—all in the medulla—as well as the locus coeruleus and the hypothalamus. Experiments in the laboratory of Eugene Nattie have provided evidence that at least some of these acidosis-stimulated neurons are in fact respiratory chemoreceptors. In intact animals, microinjecting acetazolamide into these regions increases ventilation. Acetazolamide blocks carbonic anhydrase, the enzyme that catalyzes the hydration of CO_2 to H^+ and HCO_3^- . **N18-3** Presumably, this blockade produces a localized region of acidosis that activates nearby chemosensitive neurons. Indeed, the effects of acetazolamide microinjections suggest that chemosensitive areas include the VLM, medullary raphé, the nucleus ambiguus, the NTS, and the locus coeruleus.

It remains unclear how important the aforementioned regions are to normal respiratory chemoreception. If they all are central chemoreceptors, then these multiple sensors may be another example of redundancy in a critical system. Alternatively, instead of all being involved in the response to CO_2 under normal conditions in adults, some of these neurons may come into play only under special circumstances, such as during severe acid-base disturbances, when one is asleep, or during a particular time in the development of an infant.

Some neurons of the medullary raphé and VLM are unusually pH sensitive

Certain medullary raphé neurons are unusually pH sensitive. In brain slices and in tissue culture, small decreases in extracellular pH raise the firing rate of one subset of medullary raphé neurons (see Fig. 32-13B) and lower the firing rate of another. **N32-20** In both types of chemosensitive neurons, metabolic and respiratory disturbances have similar effects on firing, which indicates that the primary stimulus is a decrease in either extracellular or intracellular pH, rather than an increase in P_{CO_2} .

N32-20

Medullary Raphé Neurons

Contributed by George Richerson

A NEURONS STIMULATED BY ACIDOSIS

B NEURONS INHIBITED BY ACIDOSIS

EFigure 32-3 **A**, An increase in P_{CO_2} (respiratory acidosis) raises the firing rate of a serotonergic neuron. **B**, The same increase in P_{CO_2} lowers the firing rate of a GABAergic neuron. The figure shows the results of patch-pipette recordings from neurons cultured from the medullary raphe of rats. Those that are stimulated by acidosis are serotonergic, and those that are inhibited are GABAergic. V_m , membrane potential. (Data from Wang W, Pizzonia JH, Richerson GB: Chemosensitivity of rat medullary raphe neurones in primary tissue culture. *J Physiol* 511:433–450, 1998.)

The two types of chemosensitive neurons have other distinguishing properties, including different shapes, basal firing patterns, and neurotransmitter content. For example, the neurons *stimulated* by acidosis contain the neurotransmitter **serotonin**, which induces pacemaker activity in preBötC neurons (see p. 707). These serotonergic neurons are also known to stimulate breathing in vivo. Serotonergic neurons are also present in the VLM. Those that are *inhibited* by acidosis may contain the inhibitory neurotransmitter **gamma-aminobutyric acid (GABA)**. When arterial P_{CO_2} rises, acidosis-stimulated neurons may stimulate breathing as an accelerator does on a car, whereas acidosis-inhibited neurons may decrease the inhibition of breathing, as when one is letting off on the brake (see Fig. 32-13C).

The serotonergic neurons in the medullary raphe are located in close apposition to large branches of the basilar artery (see Fig. 32-13D), so that—like the glomus cells of the peripheral chemoreceptors—they can sense arterial P_{CO_2} with fidelity. Thus, serotonergic neurons of the raphe and VLM have many properties that would be expected of central respiratory chemoreceptors. Many infants who have died of **sudden infant death syndrome (SIDS)** have a deficit of serotonergic neurons, which is consistent with a prevailing theory that a subset of SIDS infants have a defect in central respiratory chemoreception. 🧠
N32-21

N32-21

Sudden Infant Death Syndrome

Contributed by George Richerson

SIDS is defined as the sudden death of an infant younger than 1 year of age that remains unexplained after a complete clinical review, autopsy, and death-scene investigation. SIDS is the leading cause of postneonatal infant death in developed countries, causing six deaths each day in the United States alone. SIDS usually occurs during sleep in infants that were previously thought to be healthy. The consensus is that the majority of SIDS cases are due to abnormalities of breathing and arousal in response to high CO_2 or low O_2 . When a vulnerable infant is exposed to an exogenous stressor—such as covering of the mouth by a blanket—it is unable to respond appropriately. Consistent with this explanation, the incidence of SIDS has decreased by 50% since the recommendation was made for mothers to put babies to sleep on their backs (the “Back to Sleep” campaign). Although the pathophysiology of SIDS remains unknown, recent work has revealed a number of abnormalities of serotonin neurons in the medulla (Paterson et al, 2006) that may cause an infant to be vulnerable. These abnormalities seem to involve a delay in maturation of these neurons due to environmental or genetic factors. Because serotonin neurons are central respiratory chemoreceptors (Richerson, 2004) and are also involved in cardiovascular and thermoregulatory control, as well as regulation of sleep and arousal, a delay in their normal maturation could explain SIDS. Ongoing work is now aimed at identifying those infants with serotonin-neuron defects before they die and finding a treatment to prevent SIDS in those infants.

A second proposed set of central chemoreceptor neurons is located in a part of the rostral VLM called the **retrotrapezoid nucleus (RTN)**.  **N32-22** These neurons express the transcription factor Phox2b (see [p. 340](#)), mutations in which occur in the majority of cases of Ondine's curse (see [Box 32-5](#)).

N32-22

Neurons in the Retrotrapezoid Nucleus

Contributed by George Richerson

As discussed in the main text, central respiratory chemoreceptor neurons are present in several locations in the brain. One of these areas appears to be the RTN, located in the rostral VLM.

Properties of these neurons include the following:

- The RTN contains serotonergic neurons as well as glutamatergic neurons. Both are candidates for central chemoreceptors.
- These neurons might be intrinsically pH sensitive, or may be stimulated by serotonergic neurons or by astrocytes that release ATP in response to respiratory acidosis.
- The glutamatergic neurons in this region project to the preBötC and other respiratory nuclei.
- These neurons stimulate the respiratory network.
- These neurons respond to respiratory acidosis with an increase in firing rate in brain slices and in vivo.
- These neurons express the transcription factor Phox2b (see [Box 14-1](#)). Mutations in Phox2b occur in the majority of cases of Ondine's curse (see [Box 32-5](#)).

Integrated Responses to Hypoxia, Hypercapnia, and Acidosis

In real life, it is rare for arterial P_{O_2} to fall without accompanying changes in P_{CO_2} and pH. In addition, changes in individual blood-gas parameters may independently affect both the peripheral and the central chemoreceptors. How does the respiratory system as a whole respond to changes in multiple blood-gas parameters?

Hypoxia accentuates the acute response to respiratory acidosis

Respiratory Acidosis

When the blood-gas parameters are nearly normal, respiratory acidosis (increased P_{CO_2} /decreased pH) stimulates ventilation more than does hypoxia. If an animal breathes an air mixture containing CO_2 , the resultant respiratory acidosis causes ventilation to increase rapidly. Because both peripheral and central chemoreceptors respond to respiratory acidosis, both could contribute to the response. It is possible to isolate the function of the two sets of chemoreceptors by (1) denervating the peripheral chemoreceptors to study the response of the central chemoreceptors alone, or (2) perfusing the carotid bodies to study the response of the peripheral chemoreceptors alone. On the basis of approaches such as these, it appears that the central chemoreceptors account for 65% to 80% of the integrated response to respiratory acidosis under normoxic conditions. However, the response of the peripheral chemoreceptors is considerably more rapid than that of the central chemoreceptors, which require several minutes to develop a maximal response.

At an alveolar P_{O_2} that is somewhat higher than normal, raising the alveolar P_{CO_2} causes a linear increase in steady-state ventilation (Fig. 32-14A, red curve). Lowering the alveolar P_{O_2} has two effects (see Fig. 32-14A, other two curves). First, at a given P_{CO_2} , hypoxia increases ventilation, which reflects the response of the peripheral chemoreceptors to hypoxia. Second, hypoxia increases the *sensitivity* of the integrated response to respiratory acidosis. That is, the slopes of the curves increase. At least part of the explanation for this increase in slopes is that the peripheral chemoreceptor itself—as judged by the activity of the carotid sinus nerve—becomes more sensitive to respiratory acidosis with coexisting hypoxia.

A DEPENDENCE ON P_{CO_2}

B DEPENDENCE ON P_{O_2}

FIGURE 32-14 Integrated ventilatory response to changes in P_{CO_2} (A) and P_{O_2} (B). The shaded triangles indicate the slopes. (A, Data from Nielsen M, Smith H: Studies on the regulation of respiration in acute hypoxia. *Acta Physiol Scand* 24:293–313, 1952; B, data from Loeschcke HH, Gertz KH: Einfluss des O_2 -Druckes in der Einatemungsluft auf die Atemtätigkeit der Menschen, geprüft unter Konstanzhaltung des alveolaren CO_2 -Druckes. *Pflugers Arch Ges Physiol* 267:460–477, 1958.)

Metabolic Acidosis

Severe metabolic acidosis (e.g., diabetic ketoacidosis) leads to profound hyperventilation, known as **Kussmaul breathing** (see [Box 32-2](#)). This hyperventilation can drive arterial P_{CO_2} down to low levels in an attempt to compensate for the metabolic acidosis. Acutely, the main stimulus for hyperventilation comes from peripheral chemoreceptors. Because a severe decrease in arterial pH does produce a small fall in CSF pH, central chemoreceptors also participate in this response. If the insult persists for many hours, CSF pH falls even farther, and central chemoreceptor drive becomes more prominent ([Box 32-3](#)).

Box 32-3

Chronic Hypercapnia in Pulmonary Disease

Chronic hypercapnia occurs in many people with diseases that affect the lungs (e.g., emphysema—destruction of alveoli and loss of proper gas exchange) or respiratory muscles (e.g., amyotrophic lateral sclerosis, neuropathies, and myopathies). An increase in P_{CO_2} leads to an immediate respiratory acidosis in the arterial blood and brain. If CO_2 remains elevated, the pH of the CSF/BECF slowly recovers (i.e., increases) over the following 8 to 24 hours. The mechanism of this pH_{CSF} increase is probably an increase in HCO_3^- flux into the CSF/BECF across the choroid plexus (see Fig. 11-4) and BBB, representing a metabolic compensation to the respiratory acidosis (see p. 633). The increased CSF pH shifts the CO_2 response curves in Figure 32-14A to the right because, compared with reference conditions, a higher P_{CO_2} is needed to produce a given degree of CSF acidity (i.e., ventilatory drive). Such a resetting of the central chemoreceptors may be important clinically for patients who chronically retain CO_2 . Even though P_{CO_2} may be quite high, adaptation of the CSF/BECF restores pH_{CSF} toward normal. With central chemoreceptor drive for ventilation now decreased, the main drive for ventilation may become hypoxia via peripheral chemoreceptors. Administration of supplemental O_2 to such a patient may remove the hypoxic drive as well, causing ventilation to decrease and P_{CO_2} to rise to very high levels (e.g., $P_{\text{CO}_2} > 100$ mm Hg). At such high levels, CO_2 acts like a narcotic. This “ CO_2 narcosis” then directly inhibits ventilation and can cause death from hypoventilation—a classic example of “too much of a good thing.”

Respiratory acidosis accentuates the acute response to hypoxia

If an animal breathes an O_2 -deficient gas mixture, the resulting hypoxia causes ventilation to increase rapidly. As already discussed, the peripheral chemoreceptors respond primarily to hypoxia. To what extent do central mechanisms contribute to the integrated response to acute hypoxia? In an animal with denervated peripheral chemoreceptors, hypoxia actually *depresses* respiratory output. Thus, the integrated response actually underestimates the stimulatory contribution of the peripheral chemoreceptors.

At an arterial P_{CO_2} that is slightly lower than normal, lowering alveolar P_{O_2} has very little effect on ventilation until P_{O_2} falls below 50 mm Hg (see [Fig. 32-14B](#), red curve). The eventual response at very low P_{O_2} values indicates that the peripheral chemoreceptors play a vital, fail-safe role in responding to extreme hypoxia, as at high altitudes (see [p. 1231](#)). Raising the arterial P_{CO_2} (i.e., respiratory acidosis) has two effects (see [Fig. 32-14B](#), other two curves). First, at a given P_{O_2} , respiratory acidosis increases

ventilation, which reflects the dual contributions of the peripheral and central chemoreceptors to hypercapnia and acidosis. Second, respiratory acidosis increases the *sensitivity* of the integrated response to hypoxia. That is, the curves become steeper. These effects on the integrated response (see [Fig. 32-14B](#)) are similar to—although more exaggerated than—the effects of respiratory acidosis on the response of the peripheral chemoreceptor to hypoxia (see [Fig. 32-9B](#)).

Modulation of Ventilatory Control

The major parameters that feed back on the respiratory control system are the arterial blood-gas parameters— P_{O_2} , P_{CO_2} , and pH. In addition, the respiratory system receives input from two other major sources: (1) a variety of stretch and chemical/irritant receptors that monitor the size of the airways and the presence of noxious agents, and (2) higher CNS centers that modulate respiration during nonrespiratory activities.

Stretch and chemical/irritant receptors in the airways and lung parenchyma provide feedback about lung volume and the presence of irritants

Sensors within the lungs and upper airways detect foreign bodies, chemical irritants, or immunological challenges and help protect the lungs—one of the few organs that have direct access to the outside world. Sensors also detect changes in lung volume as part of a feedback mechanism that helps control output to respiratory muscles. Respiratory afferent fibers from sensors in the thorax travel with CN X, and those from sensors in the upper airways travel with CN IX. Both synapse within the DRG in the medulla (see [p. 705](#)).

Slowly Adapting Pulmonary Stretch Receptors

Mechanoreceptors within the tracheobronchial tree detect changes in lung volume by sensing stretch of the airway walls. One type of **pulmonary stretch receptor (PSR)**, the slowly adapting PSR, [N32-23](#) responds to stretch with an increase in firing that then decays very slowly over time. One of the functions of these receptors may be to inform the brain about lung volume to optimize respiratory output.

N32-23

Slowly Adapting PSRs

Contributed by George Richerson, Emile Boulpaep, Walter Boron

Within the tracheobronchial tree are mechanoreceptors that detect changes in lung volume by sensing stretch of the airway walls. These are **PSRs**. One type of PSR responds to stretch with a sudden increase in firing that then decays (i.e., “adapts”) very slowly over time. These **slowly adapting PSRs** are located from the extrathoracic trachea down through the intrapulmonary bronchi; their afferent axons are myelinated. Except for hypocapnia, chemical stimuli do not selectively excite these receptors, whose function may be partly to inform the brain about lung volume to optimize respiratory output.

A reflex that involves slowly adapting PSRs is the **Hering-Breuer reflex**, one of the first examples in physiology of *negative feedback*. In 1868, Hering and Breuer found that lung inflation inhibits the output of phrenic motor neurons ([Fig. 32-15](#)), which protects the lungs from overinflation. Because the reflex also increases respiratory frequency, it maintains a constant alveolar ventilation. This reflex may be important in controlling tidal volume during eupnea in human infants. In adults, this reflex does not occur until lung volume is greater than during a normal inspiration. However, the sensor may provide feedback that the medulla uses to choose a combination of tidal volume and respiratory frequency that minimizes

the work of breathing.

FIGURE 32-15 Hering-Breuer reflex. In a paralyzed and artificially ventilated animal, prevention of lung inflation during inspiratory activity (*blue curves*) leads to prolonged phrenic nerve output (i.e., if the animal were not paralyzed, then tidal volume would be large). Inflation of the lungs during inspiratory activity (*red curves*) produces feedback that shortens the duration of inspiratory activity (i.e., if the animal were not paralyzed, then the tidal volume would be smaller) and also causes the next breath to occur earlier (respiratory frequency would increase). (Data from von Euler C: Brainstem mechanisms for generation and control of breathing pattern. In Cherniack NS, Widdicombe J [eds]: Handbook of Physiology, Section 3: The Respiratory System, vol 2, part 1. Bethesda, MD, American Physiological Society, 1986, pp 1–67).

Rapidly Adapting Pulmonary Stretch (Irritant) Receptors

The rapidly adapting PSRs [N32-24](#) respond to a sudden, maintained inflation with a rapid increase in firing rate, which then decreases by 80% or more within 1 second. Unlike slowly adapting PSRs, rapidly adapting PSRs are very sensitive to a variety of chemical stimuli, hence the term irritant receptors. These stimuli include serotonin, prostaglandins, bradykinin, ammonia, cigarette smoke, and ether. An important function of these receptors may be to detect pathophysiological processes in the airway, such as chemical irritation, congestion, and inflammation. These receptors also detect histamine (see [p. 620](#) and [Fig. 13-8B](#)), which produces bronchoconstriction in asthma.

N32-24

Rapidly Adapting PSRs

In addition to the slowly adapting PSRs discussed in [Box 32-23](#), the lung has PSRs that respond to inflation at a higher volume. A sudden, maintained inflation causes their firing rate to increase suddenly and then to decrease (i.e., “adapt”) within 1 second to 20% or less of the initial rate. Rapid deflation also stimulates them. The distribution of these receptors is not as well characterized as that of the slowly adapting PSRs, but they seem to be located throughout the tracheobronchial tree. Their afferent axons are myelinated.

Unlike the slowly adapting PSRs, the rapidly adapting PSRs are also very sensitive to a variety of chemical stimuli, hence the term **irritant receptors**. These stimuli include histamine, serotonin, prostaglandins, bradykinin, ammonia, cigarette smoke, and ether. In some cases, the chemical directly stimulates the receptor. In others, the chemical first triggers a bronchoconstriction, and this volume change then activates the stretch receptor. An important function of these receptors may be to detect pathophysiological processes in the airway, such as chemical irritation, congestion, and inflammation. The response to histamine produces bronchoconstriction in asthma.

C-Fiber Receptors

A rich network of small, *unmyelinated* axons (C fibers; see [p. 302](#)) have nerve endings—**juxtacapillary** or **J receptors**—in alveoli and conducting airways. Like slowly adapting PSRs, which are extensions of myelinated axons, these C-fiber receptors respond to both chemical and mechanical stimuli. Stimulation of C-fiber receptors elicits a triad of rapid and shallow breathing, bronchoconstriction, and increased secretion of mucus into airways—all of which may be defense mechanisms. Bronchoconstriction and rapid, shallow breathing enhance turbulence (see [p. 617](#)), which favors the deposition of foreign substances in mucus higher up in the bronchial tree, where mucus-secreting cells are located ([Box 32-4](#)).

Box 32-4

Sighs, Yawns, Coughs, and Sneezes

The respiratory apparatus engages in a variety of motor behaviors that help maintain normal lung function and gas exchange by protecting the alveoli from collapse or preventing obstruction of the upper airways.

Sigh or “Augmented Breath”

A sigh is a slow and deep inspiration, held for just a moment, followed by a longer-than-normal expiratory period (see [Fig. 32-3](#)). A normal person sighs ~6 times per hour. Local collapse of alveoli (atelectasis) may initiate a sigh, which is an important mechanism for stimulating release of surfactant (see pp. 613–614) and thus reopening these alveoli. Hypoxia and respiratory acidosis increase sigh frequency, consistent with the idea that sighs counteract decreased alveolar ventilation.

Yawn

An exaggerated sigh, a yawn takes lung volume to total lung capacity for several seconds. The mouth is fully open. In the extreme case, the arms are stretched upward, the neck is extended to elevate the pectoral girdle, and the back is extended—maneuvers that maximize lung volume (see [p. 602](#)). Yawning is even more effective than sighing in opening up the most resistant atelectatic alveoli. Everyone “knows” that yawns are contagious, and some evidence suggests that this is actually true. Yawns may (1) minimize atelectasis as one prepares for sleep (as during a boring lecture), and (2) reverse—on arousal—the atelectasis that has accumulated during sleep. Interestingly, many trained athletes yawn just before a big

event, presumably preparing the lungs for enhanced gas exchange.

Cough Reflex

Coughing is important for ridding the tracheobronchial tree of inhaled foreign substances. There is probably no single class of “cough receptors.” 🟡N32-25 The tickling sensation that is relieved by a cough is analogous to the cutaneous itch and is probably mediated by C-fiber receptors. *Thus, a cough is a respiratory scratch.*

When *lower airway* receptors trigger a cough, it begins with a small inspiration that increases the coughing force. Mechanosensitive and irritant receptors in the *larynx* can trigger either coughing or apnea. When they trigger a cough, the inspiration is absent, which minimizes the chances that the offending foreign body will be pulled deeper into the lungs. In either case, a forced expiratory effort against a closed glottis raises intrathoracic and intra-abdominal pressures to very high levels. The glottis then opens suddenly, and the pressure inside the larynx falls almost instantaneously to near-atmospheric levels. This sudden drop in luminal pressure produces dramatic increases in the *axial* (alveolus to trachea) pressure gradient that drives air low (see pp. 616–617). In the trachea, this pressure drop also decreases the *radial* transmural pressure difference across the tracheal wall, thereby collapsing the trachea (see p. 626), especially the membranous (i.e., noncartilaginous) part of the trachea. As a result, tracheal cross-sectional area may fall to as little as one sixth of its original value. The net effect is a brief but violent rush of air out of the trachea at velocities near 800 km/hr (~65% of the speed of sound) that loosens mucus or foreign bodies and moves them upward. Protracted bouts of severe coughing can lead to lightheadedness or even syncope because the high intrathoracic pressure decreases venous return and reduces cardiac output (see pp. 548–551). 🟡N32-26

Sneeze

Sensors in the nose detect irritants and can evoke a sneeze. Curiously, these same receptors are probably also responsible for apnea in response to water applied to the face or nose, which is part of the **diving reflex** that evolved in diving mammals such as the seal to prevent aspiration during submersion. A sneeze differs from a cough in that a sneeze is almost always preceded by a deep inspiration. Like a cough, a sneeze involves an initial buildup of intrathoracic pressure behind a closed glottis. Unlike a cough, a sneeze involves pharyngeal constriction during the buildup phase and an explosive forced expiration through the nose as well as the mouth. This expiration is accompanied by contraction of facial and nasal muscles, so that the effect is to dislodge foreign bodies from the nasal mucosa.

N32-25

C Fibers

Contributed by George Richerson, Emile Boulpaep, Walter Boron

A rich network of extremely thin, unmyelinated axons—C fibers—innervates receptors in the alveoli and conducting airways. Like the slowly adapting PSRs, 🟡N32-23 which are innervated by *myelinated* nerve fibers, C-fiber receptors respond to both chemical and mechanical stimuli. *Alveolar* C-fiber receptors become active very soon (i.e., 1 to 2 seconds) after the injection of certain chemicals into the blood of the right atrium of the heart,* which suggests that the receptors may be very near pulmonary capillaries. Hence the name juxta-capillary or J receptors. The J receptors respond “chemically” to inflammatory agents released in the airway wall: histamine, serotonin, bradykinin, and prostaglandins. They also respond to mechanical stimuli, including lung or vascular congestion.

The C-fiber receptors in *conducting airways* are less sensitive to lung inflation than their alveolar

counterparts, but are more sensitive to chemical mediators of inflammation. Stimulating C-fiber receptors elicits a triad of rapid and shallow breathing, bronchoconstriction, and increased secretion of mucus into airways—all of which may be defense mechanisms. Bronchoconstriction and rapid, shallow breathing would enhance turbulence (see Fig. 27-12C), favoring the deposition of foreign substances in mucus higher up in the bronchial tree, where mucus-secreting cells are located.

The afferent nerve fibers for all sensors located in the tracheobronchial tree and lung parenchyma travel to the medulla in the vagus nerve (CN X) via either myelinated or unmyelinated fibers. The *myelinated* fibers *rapidly* transmit impulses from PSRs and are readily blocked by cooling ($\sim 8^{\circ}\text{C}$ to 10°C). Unmyelinated nerve fibers—the C fibers discussed above—*slowly* transmit impulses from J receptors near alveoli, as well as other receptors in conducting airways, and conduct impulses even at 4°C . This differential temperature sensitivity is a useful tool for studying respiratory reflexes. For a discussion of the effects of myelination and axon diameter on axon conduction velocity, see the passage in the text that begins on page 302.

* After entering the ventricle and being injected into the pulmonary veins, this blood rapidly reaches the alveolar capillaries, very near where the alveolar C-fiber receptors are thought to be.

N32-26

External Compression of Thoracic Vessels

Contributed by George Richerson, Emile Boulpaep, Walter Boron

The example of severe coughing leading to syncope is a special case in which the external compression of the vessels in the thorax causes an increase in their resistance and thus a decrease in venous return. Keep in mind that not only does the inferior vena cava have a rather low pressure, but *all* pulmonary vessels (i.e., arteries, capillaries, and veins) also have a low pressure. Thus, all of these vessels are particularly susceptible to collapse by an increase in the surrounding pressure.

Higher brain centers coordinate ventilation with other behaviors and can override the brainstem's control of breathing

The role of the CNS in controlling ventilation is far more complex than generating a regular pattern of inspirations and expirations, and then modifying this pattern in response to input from mechanical and chemical sensors. The CNS also must balance the need to control P_{O_2} , P_{CO_2} , and pH with the need to control ventilation for nonrespiratory purposes, such as speaking, sniffing, and regulating temperature (e.g., panting in dogs). In addition, the CNS must coordinate breathing with behaviors that require the *absence* of airflow, such as chewing, swallowing, and vomiting.

Many nonrespiratory regions of the CNS tonically stimulate or inhibit respiration. For example, the **reticular activating system** (see [p. 270](#)) in the brainstem is one of the sources of tonic drive to the respiratory CPG. An increase in this drive occurs during arousal from sleep, when a *general alerting reaction* increases ventilation and heart rate and activates the brain as evidenced on an electroencephalogram.

Coordination with Voluntary Behaviors That Use Respiratory Muscles

Numerous voluntary actions initiated in the cerebral cortex involve a change in airflow—voluntarily hyperventilating, breath holding, speaking, singing, whistling, and playing musical wind instruments. Although voluntary control over muscles of respiration can be exquisitely precise, this control is not absolute. For example, voluntary breath holding can last only so long before being overwhelmed by ventilatory drive from chemoreceptors. The cerebral cortex controls the respiratory system by at least two major mechanisms. First, some cortical neurons send axons to respiratory centers in the medulla. Second, some cortical premotor neurons send axons to motor neurons that control muscles of respiration. One consequence of this dual control mechanism is that lesions in specific areas of the cerebral cortex can abolish voluntary breath holding, a condition known as **respiratory apraxia**. Another consequence is that small CNS lesions may specifically knock out one set of connections. For example, patients with intractable pain are sometimes treated with partial transection of the upper cervical ventrolateral spinal cord to cut axons carrying pain sensation to the thalamus (spinothalamic tract). When this procedure inadvertently damages respiratory projections within the reticulospinal tract, patients breathe properly while awake but experience respiratory failure while asleep—**Ondine's curse** (Box 32-5). The lesion may cut automatic premotor neurons descending to the spinal cord from respiratory centers in the medulla, but not voluntary ones from the cortex.

Box 32-5

Ondine's Curse, Sleep, and Sleep Apnea

Ondine's Curse

Ondine, a water nymph in a German legend, was immortalized in the 1811 fairy tale by Friedrich Heinrich Karl, Baron de la Motte-Fouqué. In the play *Ondine* by Jean Giraudoux in 1939, Ondine married a mortal man, Hans, with the understanding that Hans would never marry a mortal woman. However, when Ondine later returned to the sea, her husband did remarry. Ondine's father punished Hans by requiring him to make a continuous conscious effort to maintain lung ventilation (and all other automatic body functions). If he fell asleep, he would stop breathing and die. Hans explained to Ondine how hard it is to live with his curse: “One moment of inattention and I shall forget to hear, to breathe. They will say he died because breathing bored him.” Some patients have the same disorder—minus the relationship with a water nymph. The majority of these patients have **congenital central hypoventilation syndrome (CCHS)** due to mutations in *PHOX2B* (see p. 340), which encodes a transcription factor required for development of the autonomic nervous system and a limited number of other neurons, including a subset in the RTN (see p. 714). These patients can be treated by providing mechanical ventilation when they sleep; they can maintain normal ventilation on their own while awake.

Sleep

Sleep, or even closing one's eyes, has powerful effects on the breathing pattern and CO₂ responsiveness. During non-rapid eye movement (NREM) sleep, the regularity of eupneic breathing increases; also, the sensitivity of the respiratory system to CO₂ decreases compared with wakefulness, and the outflow to the muscles of the pharynx decreases. During rapid eye movement (REM) sleep, the pattern of breathing becomes markedly irregular, sometimes with no discernible rhythm, and the sensitivity of the respiratory system to CO₂ decreases further. Thus, P_{CO_2} often increases during NREM sleep, and usually even more so during REM sleep. **Barbiturates** at low doses depress drive to the respiratory system and, if superimposed on normal sleep, can halt ventilation altogether.

Sleep Apnea

The collection of disorders in which ventilation ceases during deeper stages of sleep, particularly during REM sleep, is known as sleep apnea. Some cases of sleep apnea are related to Ondine's curse and are due to a lack of central drive—**central sleep apnea**. However, most cases are due to collapse of the airway with sleep—**obstructive sleep apnea**—usually in obese people. The airway collapse is due to an exaggeration of the normal decrease in airway tone during sleep, superimposed on the structural problem of reduced airway diameter due to obesity. This is a common disorder associated with severe and excessive snoring, poor and interrupted sleep, daytime somnolence, and behavioral changes, possibly leading ultimately to hypertension and cardiac arrhythmias.

Coordination with Complex Nonventilatory Behaviors

One of the jobs of the brain is to coordinate complex behaviors such as yawning, chewing, swallowing, sucking, defecating, grunting, and vomiting. During yawning and vomiting, for example, groups of neurons orchestrate an array of simultaneous actions, only some involving the respiratory system. The premotor neurons that project from medullary respiratory centers to respiratory motor neurons are probably distinct from descending pathways involved in these complex nonventilatory behaviors.

Modification by Affective States

Fear, horror, rage, and passion can be associated with major and highly characteristic changes in the respiratory pattern. For example, if a child runs in front of the car you are driving, the sudden application of the brakes is almost always accompanied by an equally sudden and rapid inspiration, with mouth open widely, increasing lung volume to nearly total lung capacity. The tendency of prevarications to be associated with changes in the breathing pattern is the basis for one part of the polygraph test used as a **lie detector**. Descending pathways from the limbic system (see [p. 349](#)) of the forebrain may mediate these emotional effects on breathing.

Balancing Conflicting Demands of Gas Exchange and Other Behaviors

Ventilation, or lack thereof, is involved in a wide variety of behaviors, many of which have nothing to do with alveolar gas exchange per se. How is it that the brain is able to weigh the need for alveolar gas exchange against these competing demands on the respiratory system? Playing a musical wind instrument is an example of a situation in which respiratory and nonrespiratory needs are reconciled. Musicians must make rapid and deep inspirations, followed by slow and prolonged expirations that can lead to considerable breath-to-breath variations in alveolar P_{CO_2} . Nevertheless, these variations balance out, so that professionals can follow a musical score for prolonged periods without significant changes in average alveolar ventilation.

In other cases, conflicting demands are not so easily resolved. In infants, suckling relegates alveolar ventilation to a lower priority, and P_{CO_2} rises. Subjects reading aloud tend to increase their alveolar ventilation by ~25%, and P_{CO_2} falls. Thus, during speech, chemical drive is overwhelmed by voluntary behavior. On the other hand, when strenuous exercise increases the need for alveolar ventilation, the CNS permits only brief gasps for speech—the ability of voluntary behavior to subvert body homeostasis can go only so far.

Organization of the Urinary System

Gerhard Giebisch, Erich E. Windhager, Peter S. Aronson

The kidneys serve three essential functions. First, they act as filters, removing metabolic products and toxins from the blood and excreting them through the urine. Second, they regulate the body's fluid status, electrolyte balance, and acid-base balance. Third, the kidneys produce or activate hormones that are involved in erythropoiesis, Ca^{2+} metabolism, and the regulation of blood pressure and blood flow.

Functional Anatomy of the Kidney

We begin this discussion with a macroscopic view and progress to the microscopic level as we describe the **nephron**, the functional unit of the kidney that is repeated approximately 1 million times within each kidney.

The kidneys are paired, retroperitoneal organs with vascular and epithelial elements

The human kidneys are paired, bean-shaped structures that lie behind the peritoneum on each side of the vertebral column ([Fig. 33-1A](#)). They extend from the twelfth thoracic vertebra to the third lumbar vertebra. The two kidneys together comprise somewhat less than 0.5% of the total body weight; in men, each kidney weighs 125 to 170 g, whereas in women, each kidney weighs 115 to 155 g.

A URINARY SYSTEM

C MAJOR BLOOD VESSELS IN KIDNEY

B KIDNEY

FIGURE 33-1 Structure of the urinary system. **B**, Posterior view of the right kidney.

A fibrous, almost nondistensible capsule covers each kidney (see [Fig. 33-1B](#)). In the middle of the concave surface, a slit in the capsule—the **hilus**—serves as the port of entry for the renal artery and nerves and as the site of exit for the renal vein, the lymphatics, and the ureter. The hilus opens into a shallow space called the **renal sinus**, which is completely surrounded by renal parenchyma except where it connects with the upper end of the ureter. The renal sinus includes the urine-filled spaces: the **renal pelvis** proper and its extensions, the **major** and the **minor calyces**. Blood vessels and nerves also pass through the sinus. The renal capsule reflects into the sinus at the hilus so that its inner layers line the sinus, and the outer layers anchor to the blood vessels and renal pelvis.

A section of the kidney (see [Fig. 33-1B](#)) reveals two basic layers, the cortex (granular outer region) and the medulla (darker inner region). The granularity of the **cortex** results from the presence of glomeruli, microscopic tufts of capillaries, and a large number of highly convoluted epithelial structures

in the form of tubules. The **medulla** lacks glomeruli and consists of a parallel arrangement of tubules and small blood vessels.

The medulla is subdivided into 8 to 18 conical **renal pyramids**, whose bases face the cortical-medullary border; the tip of each pyramid terminates in the renal pelvis. At the tip of each pyramid are perforations, almost invisible to the naked eye, through which urine flows into the minor calyces of the renal sinus.

The kidneys have a very high blood flow and glomerular capillaries flanked by afferent and efferent arterioles

Although the kidneys comprise <0.5% of total body weight, they receive ~20% of the cardiac output. This high blood flow provides the blood plasma necessary for forming an ultrafiltrate in the glomeruli. The renal circulation has a unique sequence of vascular elements: a high-resistance arteriole (the efferent arteriole), followed by a high-pressure glomerular capillary network for filtration, followed by a second high-resistance arteriole (the afferent arteriole), followed by a low-pressure capillary network that surrounds the renal tubules (peritubular capillaries) and takes up the fluid absorbed by these tubules.

The main features of the renal vascular system are illustrated in [Figure 33-1B and C](#). A single **renal artery** enters the hilus and divides into anterior and posterior branches, which give rise to interlobar and then arcuate arteries. The latter arteries skirt the corticomedullary junction, where they branch into ascending interlobular arteries that enter the cortex and give rise to numerous **afferent arterioles**. These give rise to glomerular capillaries that rejoin to form **efferent arterioles**. For nephrons in the *superficial* portion of the cortex, the efferent arterioles are the origin of a dense peritubular capillary network that supplies oxygen and nutrients to the tubules in the cortex. The afferent and efferent arterioles determine the hydrostatic pressure in the interposed glomerular capillaries. The tone of both arterioles is under the control of a rich sympathetic innervation, as well as a wide variety of chemical mediators.

Very small branches of the arcuate artery, or the proximal portion of the interlobular artery, supply a subpopulation of “juxtamedullary” glomeruli that are located at or near the junction of cortex and medulla. The efferent arterioles of these nephrons descend into the renal papillae to form hairpin-shaped vessels called the **vasa recta**, which provide capillary networks for tubules in the medulla. Some 90% of the blood entering the kidney perfuses superficial glomeruli and cortex; only ~10% perfuses juxtamedullary glomeruli and medulla.

Lymph vessels, which drain the interstitial fluid of the cortex and may contain high concentrations of renal hormones such as erythropoietin, leave the kidney by following arteries toward the hilus. Lymphatics are absent from the renal medulla, where they would otherwise tend to drain the high-osmolality interstitial fluid, which is necessary for producing a concentrated urine (see [pp. 809–817](#)).

The functional unit of the kidney is the nephron

Each kidney consists of 800,000 to 1,200,000 nephrons. Each nephron is an independent entity until the point at which its initial collecting tubule merges with another tubule ([Fig. 33-2](#)).

FIGURE 33-2 Structure of the nephron.

A nephron consists of a glomerulus and a tubule. The **glomerulus** is a cluster of blood vessels from which the plasma filtrate originates. The **tubule** is an epithelial structure consisting of many subdivisions, designed to convert the filtrate into urine. These two entities—vascular and epithelial—meet at the blind end of the tubule epithelium, which is called **Bowman's capsule** or the **glomerular capsule**. This capsule surrounds the glomerulus and contains **Bowman's space**, which is contiguous with the lumen of the tubule. It is here that filtrate passes from the vascular system into the tubule system.

The remainder of the nephron consists of subdivisions of the tubule (see Fig. 33-2). The epithelial elements of the nephron include Bowman's capsule, the proximal tubule, thin descending and thin ascending limbs of the loop of Henle, thick ascending limb of the loop of Henle, distal convoluted tubule, and connecting tubule. The connecting tubule [N33-1](#) leads further into the initial collecting tubule, the cortical collecting tubule, and medullary collecting ducts.

N33-1

Definition of a Nephron

Contributed by Erich Windhager, Gerhard Giebisch

The connecting tubule, initial collecting tubule, cortical collecting tubule, and medullary collecting duct all derive embryologically from the **ureteric bud**. Because the more proximal elements all derive embryologically from the **metanephric blastema**, the segments from the connecting tubule through the medullary collecting duct were treated in the past as an entity separate from the other components of the nephron. Today, the term *nephron* usually includes *both* the proximal segments and the collecting-duct system.

Within the renal cortex, as noted above, one can distinguish two populations of nephrons (see [Fig. 33-2](#)). **Superficial nephrons** have short loops extending to the boundary between outer and inner medulla. **Juxtamedullary nephrons**, which play a special role in the production of a concentrated urine, have long loops that extend as far as the tip of the medulla.

The renal corpuscle has three components: vascular elements, the mesangium, and Bowman's capsule and space

The **renal corpuscle**, the site of formation of the glomerular filtrate, comprises a glomerulus, Bowman's space, and Bowman's capsule.

During the development of the kidney, the interaction between the ureteric bud—which gives rise to the urinary system from the collecting duct to the ureters—and the surrounding loose mesenchyme ([Fig. 33-3A](#)) leads to the branching of the ureteric bud and condensation of the mesenchyme (see [Fig. 33-3B](#)). These condensed cells differentiate into an epithelium that forms a hollow, S-shaped tubular structure (see [Fig. 33-3C](#)) that gives rise to the nephron's tubular elements between Bowman's capsule and the connecting segment. The distal portion of the S-shaped tubular structure elongates and connects with branches of the developing ureteric bud (see [Fig. 33-3D](#)). At the same time, the blind proximal end of this S-shaped tubule closely attaches to the arterial vascular bundle that develops into the glomerular capillary tuft. Thinning of the epithelium on one circumference of the blind end of the S-shaped tubule leads to the emergence of the future parietal layer of Bowman's capsule. In contrast, the opposite visceral layer thickens and attaches to the glomerular capillaries (see [Fig. 33-3D](#)). These visceral epithelial cells later fold and develop into podocytes (see [Fig. 33-3E](#)).

FIGURE 33-3 Development of the glomerulus and Bowman's capsule. **G** and **H**, The four major layers of the glomerular filtration barrier. **I**, Model of podocyte foot processes and slit membrane. The diagram shows nephrin and other proteins of the slit diaphragm. Akt, protein kinase B; CD2AP, CD2-associated protein; DAG, diacylglycerol; Fyn, a Src kinase; IP₃, inositol 1,4,5-trisphosphate; IQGAP, IQ motif containing GTPase activating protein; PI3K, phosphatidylinositol 3-kinase; PLC, phospholipase C; Rac, a GTPase; SYNJ, synaptojanin; TRPC6, transient receptor potential cation channel, subfamily C, member

In the mature kidney (see [Fig. 33-3F](#)), foot processes of the podocytes cover the glomerular capillaries. These podocytes, modified epithelial cells, thus represent the *visceral* layer of Bowman's capsule. Beginning at the vascular pole, the podocytes are continuous with the *parietal* layer of Bowman's capsule. Glomerular filtrate drains into the space between these two layers (Bowman's space) and flows into the proximal tubule at the urinary pole of the renal corpuscle.

The **glomerular filtration barrier** between the glomerular capillary lumen and Bowman's space comprises four elements with different functional properties (see [Fig. 33-3G](#)): (1) a glycocalyx covering the luminal surface of endothelial cells, (2) the endothelial cells, (3) the glomerular basement membrane, and (4) epithelial podocytes.

The **glycocalyx** consists of negatively charged glycosaminoglycans (GAGs; see [p. 39](#)) that may play a role in preventing leakage of large negatively charged macromolecules.

Endothelial cells of the glomerular capillaries are almost completely surrounded by the glomerular basement membrane and a layer of podocyte foot processes ([Fig. 33-4](#)). The exception is a small region toward the center of the glomerulus, where the endothelial cells have neither basement membrane nor podocytes and come into direct contact with mesangial cells, which resemble smooth muscle. Filtration occurs away from the mesangial cells, at the peripheral portion of the capillary wall, which is covered with basement membrane and podocytes. The endothelial cells contain large **fenestrations**, 70-nm holes that provide no restriction to the movement of water and small solutes—including proteins or other large molecules—out of the lumen of the capillary ([Fig. 33-5](#)). Thus, the endothelial cells probably serve only to limit the filtration of cellular elements (e.g., erythrocytes).

FIGURE 33-4 Glomerular capillary covered by the foot processes of podocytes. This scanning electron micrograph shows a view of glomerular capillary from the vantage point of Bowman's space. The outer surfaces of the capillary endothelial cells are covered by a layer of interdigitating foot processes of the podocytes. The podocyte cell body links to the foot processes by leg-like primary and secondary processes.

FIGURE 33-5 Inner aspect of glomerular capillary, showing fenestrations of endothelial cells. This scanning electron micrograph shows a view of the glomerular capillary wall from the vantage point of the capillary lumen. Multiple fenestrations, each ~70 nm in diameter, perforate the endothelial cells.

The **basement membrane**, located between endothelial cells and podocyte foot processes (see [Fig. 33-3G](#)), separates the endothelial layer from the epithelial layer in all parts of the glomerular tuft. The basement membrane itself has three layers (see [Fig. 33-3H](#)): (1) an inner thin layer (*lamina rara interna*); (2) a thick layer (*lamina densa*), and (3) an outer thin layer (*lamina rara externa*). The basement membrane makes an important contribution to the permeability characteristics of the filtration barrier by restricting intermediate-sized to large solutes (molecular weight > 1 kDa). Because the basement membrane contains **heparan sulfate proteoglycans (HSPGs)**, it especially restricts large, negatively charged solutes (see [Fig. 34-4A](#)).

Podocytes have foot interdigitating processes that cover the basement membrane (see [Fig. 33-4](#)). Between these interdigitations (the nose-like structures in [Fig. 33-3H](#)) are **filtration slits** (see [Fig. 33-3H](#)); the interdigitations are connected by thin diaphragmatic structures—the **slit diaphragms**—with pores ranging in size from 4 to 14 nm. Glycoproteins with negative charges cover the podocyte bodies, the interdigitations, and the slit diaphragms. These negative charges contribute to the restriction of filtration of large anions ([Fig. 34-4A](#)). The extracellular domains of the integral membrane proteins **nephrin** and **NEPH1** from adjacent podocytes appear to zip together to help form the slit diaphragm. **Podocin** and other proteins also contribute to the slit diaphragm (see [Fig. 33-3I](#)). Phosphotyrosine motifs on the intracellular domains of some of these proteins may recruit other molecules involved in signaling events that control slit permeability. Genetic defects in any of several of these protein can make the filtration barrier leaky, leading to the appearance of large proteins (e.g., albumin) in the urine—**nephrotic syndrome**. For example, the genetic absence of nephrin leads to congenital nephrotic syndrome of the Finnish type, characterized by severe proteinuria. 🟡N33-2

Finnish-Type Nephrosis

Contributed by Gerhard Giebisch, Erich Windhager

A critical protein in slit diaphragm is **nephrin**, a protein specifically located at the **slit diaphragm** of glomerular podocytes. Nephrin plays an essential role in the maintenance of normal glomerular permeability because its absence leads to severe proteinuria. Thus, a rare human autosomal disease characterized by absence of nephrin (Finnish-type nephrosis with massive albuminuria) further supports the critical role of slit-diaphragm proteins in defining glomerular permeability to macromolecules. Figure 33-3 provides a view of glomerular filtration slits and includes slit-diaphragm proteins of functional importance. It is likely that changes in phosphorylation of podocyte proteins modulate the permeability properties of the slit membrane to proteins.

Supporting the glomerular capillary loops is a network of contractile **mesangial cells**, which secrete the extracellular matrix. This network is continuous with the smooth-muscle cells of the afferent and efferent arterioles. The matrix extends to the “extraglomerular” mesangial cells (see [Fig. 33-3F](#)). The **juxtaglomerular apparatus (JGA)** includes the extraglomerular mesangial cells, the macula densa, and the granular cells. The **macula densa** (from the Latin *macula* [spot] + *densa* [dense]) is a patch of specialized tubule epithelial cells—at the transition between the TAL and the distal tubule—that contacts its own glomerulus (see [Fig. 33-3F](#)). These cells have strikingly large nuclei and are closely packed, and thus they have a plaque-like appearance. The **granular cells** in the wall of afferent arterioles, also called juxtaglomerular or epithelioid cells, are specialized smooth-muscle cells that produce, store, and release the enzyme renin (see [p. 841](#)). The JGA is part of a complex feedback mechanism that regulates renal blood flow and filtration rate (see [pp. 750–751](#)), and it also indirectly modulates Na⁺ balance (see [pp. 841–842](#)) and systemic blood pressure (see [pp. 554–555](#)).

The tubule components of the nephron include the proximal tubule, loop of Henle, distal tubule, and collecting duct

[Figure 33-6](#) illustrates the ultrastructure of the cells of the different tubule segments. [Table 33-1](#) lists these segments and their abbreviations. **N33-3** Based on its appearance at low magnification, the **proximal tubule** can be divided into the proximal convoluted tubule (PCT; [Fig. 33-6A](#)), and the proximal straight tubule (PST; see [Fig. 33-6B](#)). However, based on ultrastructure, the proximal tubule can alternatively be subdivided into three segments: S1, S2, and S3. The S1 segment starts at the glomerulus and includes the first portion of the PCT. The S2 segment starts in the second half of the PCT and continues into the first half of the PST. Finally, the S3 segment includes the distal half of the PST that extends into the medulla.

FIGURE 33-6 Structure of tubule cells along the nephron. Because of the wide range of tubule diameters along the nephron, the scaling factors for tubule cross sections differ for panels **A** to **K**. However, the individual cells next to the tubule cross sections are drawn to the same scale.

TABLE 33-1

Tubule Segments of the Nephron

TUBULE SEGMENT	ABBREVIATION
Proximal convoluted tubule	PCT
Proximal straight tubule	PST
Thin descending limb of loop of Henle	tDLH
Thin ascending limb of loop of Henle	tALH
Thick ascending limb of loop of Henle	TAL
Distal convoluted tubule	DCT
Connecting tubule	CNT
Initial collecting tubule	ICT
Cortical collecting tubule	CCT
Outer medullary collecting duct	OMCD
Inner medullary collecting duct	IMCD

N33-3

Tubule Segments of the Nephron

Contributed by Erich Windhager, Gerhard Giebisch

In Figure 33-6, we identified 11 distinct segments (lettered A through K) in the nephron. The following is a description of the cells that make up each of these segments.

- A. Proximal convoluted tubule (PCT).** The first portion of the PCT consists of S1 cells, and the latter portion of S2 cells. Both cells have abundant apical microvilli and a deeply infolded basolateral membrane. They also have a rich supply of mitochondria, which lie between the infoldings. These complexities diminish from the S1 to the S2 segments.
- B. Proximal straight tubule (PST).** The first portion of the PST consists of S2 cells, and the latter portion of S3 cells. The ultrastructural complexity diminishes from the S2 to the S3 segments.
- C. Thin descending limb (tDLH).** The cells are less complex and flatter than those of the S3 segment of the proximal tubule.
- D. Thin ascending limb (tALH).** Away from the nucleus, the cells are even thinner than those of the descending limb.
- E. Thick ascending limb (TAL).** The cells, which lack microvilli, are substantially taller and more complex than those of the thin limbs.
- F. Distal convoluted tubule (DCT).** The cells are very similar to those of the TAL.
- G. Connecting tubule (CNT).** This segment consists of both connecting-tubule cells, which secrete kallikrein, and intercalated cells, which are rich in mitochondria.

- H. **Initial collecting tubule (ICT).** The ICT is defined as the segment just before the first confluence of tubules. About one third of the cells in this segment are intercalated cells, and the rest are principal cells.
- I. **Cortical collecting tubule (CCT).** The CCT is defined as the segment after the first confluence of tubules. The cells in this segment are very similar to those in the ICT.
- J. **Outer medullary collecting duct (OMCD).** The principal cells in this nephron segment have a modest cell height. The number of intercalated cells progressively decreases along the length of this segment.
- K. **Inner medullary collecting duct (IMCD).** This segment consists only of principal cells. Even at the beginning of the IMCD, the principal cells are taller than in the OMCD. At the end of the IMCD, the “papillary” collecting-duct cells are extremely tall.

Both the apical (luminal) and basolateral (peritubular) membranes of proximal-tubule cells are extensively amplified (see [Fig. 33-6A, B](#)). The apical membrane has infoldings in the form of a well-developed *brush border*. This enlargement of the apical surface area correlates with the main function of this nephron segment; namely, to reabsorb the bulk of the filtered fluid back into the circulation. A central cilium, which may play a role in sensing fluid flow, protrudes from the apical pole of proximal-tubule cells and nearly all the other types of tubule cells.

The *basolateral membranes* of adjacent proximal-tubule cells form numerous interdigitations, bringing abundant mitochondria in close contact with the plasma membrane. The interdigitations of the lateral membranes also form an extensive extracellular compartment bounded by the tight junctions at one end and by the basement membrane of the epithelium at the other end. Proximal-tubule cells contain lysosomes, endocytic vacuoles, and a well-developed endoplasmic reticulum. Proximal-tubule cells also have a prominent Golgi apparatus (see [p. 21](#)), which is important for synthesizing many membrane components, sorting them, and targeting them to specific surface sites. From the S1 to the S3 segments, cell complexity progressively declines, correlating with a gradual decrease of reabsorptive rates along the tubule. Thus, the cells exhibit a progressively less developed brush border, diminished complexity of lateral cell interdigitations, a lower basolateral cell membrane area, and a decrease in the number of mitochondria.

In comparison with the S3 segment of the proximal tubule, the cells lining the **thin descending limb (tDLH)** and **thin ascending limb (tALH)** of the loop of Henle are far less complex (see [Fig. 33-6C, D](#)), with few mitochondria and little cell membrane amplification. In superficial nephrons, the *thin ascending limbs* are extremely abbreviated (see [Fig. 33-2](#)). However, they form a major part of the long loops of the juxtamedullary nephrons.

Epithelial cells lining the **thick ascending limb** of the loop of Henle (TAL), which terminates at the macula densa, are characterized by tall interdigitations and numerous mitochondria within extensively invaginated basolateral membranes (see [Fig. 33-6E](#)). This complex cell machinery correlates with the key role these cells play in making the medullary interstitium hyperosmotic.

Until the latter part of the 20th century, morphologists defined the **classic distal tubule**—on the basis of light microscopic studies—as the nephron segment stretching from the macula densa to the first confluence of two nephrons in the collecting-duct system. Today, we subdivide the classic distal tubule into three segments, based on ultrastructural studies: the distal convoluted tubule (starting at the macula densa), the connecting tubule, and the initial collecting tubule. What was classically termed the early distal tubule is

mainly the distal convoluted tubule, whereas the classically termed late distal tubule is mainly the initial collecting tubule.

The **distal convoluted tubule (DCT)** begins at the macula densa and ends at the transition to the connecting tubule (see Fig. 33-6F). The cells of the DCT are similar in structure to those of the thick ascending limb. However, significant cell heterogeneity characterizes the tubule segments that follow.

The **connecting tubule (CNT)**, which ends at the transition to the initial collecting tubule, consists of two cell types: CNT cells and intercalated cells. CNT cells (see Fig. 33-6G) are unique in that they produce and release renal **kallikrein**, a serine protease—attached to the apical membrane—that modulates apical membrane channels and transporters. We discuss intercalated cells below.

The two segments following the CNT, the **initial collecting tubule (ICT, up to the first confluence)** and the **cortical collecting tubule (CCT, after the confluence)**, are identical. They are composed of intercalated and principal cells, which exhibit striking morphological and functional differences.

Intercalated cells, similar in structure to the intercalated cells of the CNT, make up about one third of the lining of these collecting-tubule segments (see Fig. 33-6H, I). They are unusual among tubule cells in that they lack a central cilium. One subpopulation of these cells (A- or α -intercalated cells) secretes H^+ and reabsorbs K^+ , whereas another (B- or β -intercalated cells) secretes HCO_3^- . **Principal cells** make up about two thirds of the cells of the ICT and CCT (see Fig. 33-6H, I). Compared with intercalated cells, principal cells have fewer mitochondria, only modestly developed invaginations of the basolateral membrane, and a central *cilium* on the apical membrane. Principal cells reabsorb Na^+ and Cl^- and secrete K^+ .

The **medullary collecting duct** is lined mostly by one cell type that increases in cell height toward the papilla (see Fig. 33-6J, K). The number of intercalated cells diminishes beginning at the outer medullary collecting duct. Cells in this segment continue the transport of electrolytes and participate in the hormonally regulated transport of water and of urea. At the extreme end of the medullary collecting duct (i.e., the “papillary” collecting duct or duct of Bellini), the cells are extremely tall.

The tightness of tubule epithelia increases from the proximal to the medullary collecting tubule

Epithelia may be either “tight” or “leaky,” depending on the permeability of their **tight junctions** (see pp. 136–137). In general, the tightness of the tubule epithelium increases from the proximal tubule to the collecting duct. In the leaky *proximal tubule*, junctional complexes are shallow and, in freeze-fracture studies, show only a few strands of membrane proteins (see pp. 43–44). In contrast, in the relatively tight *collecting tubule*, tight junctions extend deep into the intercellular space and consist of multiple strands of membrane proteins. Tubule segments with tight junctions consisting of only one strand have low electrical resistance and high solute permeability, whereas tubules with several strands tend to have high electrical resistance and low permeability.

Gap junctions (see pp. 158–161) provide low-resistance pathways between some, but not all, neighboring tubule cells. These gap junctions are located at various sites along the lateral cell membranes. Electrical coupling exists among proximal-tubule cells, but not among heterogenous cell types, such as those found in the connecting and collecting tubules.

Main Elements of Renal Function

The nephron forms an ultrafiltrate of the blood plasma and then selectively reabsorbs the tubule fluid or secretes solutes into it

As they do for capillaries elsewhere in the body, Starling forces (see pp. 467–468) govern the flow of fluid across the capillary walls in the **glomerulus** and result in net filtration. However, in the case of the glomerular capillaries, the filtrate flows not into the interstitium, but into Bowman's space, which is contiguous with the lumen of the proximal tubule.

The main function of renal tubules is to recover most of the fluid and solutes filtered at the glomerulus. If the fluid were not recovered, the kidney would excrete the volume of the entire blood plasma in less than half an hour. The retrieval of the largest fraction of glomerular filtrate occurs in the **proximal tubule**, which *reabsorbs* NaCl, NaHCO₃, filtered nutrients (e.g., glucose and amino acids), divalent ions (e.g., Ca²⁺, HPO₄²⁻, and SO₄²⁻), and water. Finally, the proximal tubule *secretes* NH₄⁺ and a variety of endogenous and exogenous solutes into the lumen.

The main function of the **loop of Henle**—tDLH, tALH, and TAL—is to participate in forming concentrated or dilute urine. The loop does this by pumping NaCl into the interstitium of the medulla without appreciable water flow, thus making the interstitium hypertonic. Downstream, the medullary collecting duct exploits this hypertonicity by either permitting or not permitting water to flow by osmosis into the hypertonic interstitium. In humans, only ~15% of the nephrons, the juxtamedullary nephrons, have long loops that descend to the tip of the papilla. Nevertheless, this *subpopulation* of nephrons (see Fig. 33-2) is extremely important for creating the osmotic gradients within the papilla that allow water movement out of the lumen of the *entire population* of medullary collecting ducts. As a result of this water movement, urine osmolality in the collecting ducts can far exceed that in the plasma.

TAL cells secrete the Tamm-Horsfall glycoprotein (THP), also known as uromodulin.  **N33-4** Normal subjects excrete 30 to 50 mg/day into the urine, which—along with albumin (<20 mg/day)—accounts for most of the protein normally present in urine. THP adheres to certain strains of *Escherichia coli* and may be part of the innate defense against urinary tract infections. This protein may also have a role in reducing aggregation of calcium crystals and thereby preventing formation of kidney stones. THP also constitutes the matrix of urinary casts. A cast is cylindrical debris in the urine that has taken the shape of the tubule lumen in which it was formed.

N33-4

Tamm-Horsfall Protein

Contributed by Walter Boron

The Tamm-Horsfall protein (THP)—also known as **uromodulin**—is the soluble cleavage product of an abundant glycosylphosphatidylinositol (GPI)–linked protein (see p. 13) on the apical membrane of the TAL cells. THP, normally the most abundant protein in the urine, may play a role in the defense against pathogenic bacteria in the genitourinary system.

Serafini-Cessi F, Malagolini N, Cavallone D. Tamm-Horsfall glycoprotein: Biology and clinical relevance. *Am J Kidney Dis.* 2003;42:658–676.

The classic **distal tubule** and the **collecting-duct system** perform the fine control of salt and water excretion. Although only small fractions of the glomerular filtrate reach these most distally located nephron sites, these tubule segments are where several hormones (e.g., aldosterone, arginine vasopressin) exert their main effects on electrolyte and water excretion.

The JGA is a region where each thick ascending limb contacts its glomerulus

Elements of the JGA play two important regulatory roles. First, if the amount of fluid and NaCl reaching a nephron's **macula densa** (see [Fig. 33-3F](#)) increases, the glomerular filtration rate (see [p. 732](#)) of *that nephron* falls. We discuss this phenomenon of **tubuloglomerular feedback** on [pages 750–751](#).

The second regulatory mechanism comes into play during a decrease in the pressure of the renal artery feeding the various afferent arterioles. When the baroreceptor (see [p. 841](#)) in the afferent arteriole senses decreased stretch in the arteriole wall, it directs neighboring granular cells to increase their release of **renin** into the general circulation. We discuss the renin-angiotensin-aldosterone axis, which is important in the long-term control of **systemic arterial blood pressure**, on [pages 841–842](#).

Sympathetic nerve fibers to the kidney regulate renal blood flow, glomerular filtration, and tubule reabsorption

The autonomic innervation to the kidneys is entirely **sympathetic**; the kidneys lack parasympathetic nerve fibers. The sympathetic supply to the kidneys originates from the celiac plexus (see [Fig. 14-3](#)) and generally follows the arterial vessels into the kidney. The varicosities of the sympathetic fibers release norepinephrine and dopamine into the loose connective tissue near the smooth-muscle cells of the vasculature (i.e., renal artery as well as afferent and efferent arterioles) and near the proximal tubules. Sympathetic stimulation to the kidneys has three major effects. First, the catecholamines cause vasoconstriction. Second, the catecholamines strongly enhance Na⁺ reabsorption by proximal-tubule cells. Third, as a result of the dense accumulation of sympathetic fibers near the granular cells of the JGA, increased sympathetic nerve activity dramatically stimulates renin secretion.

Renal nerves also include afferent (i.e., sensory) fibers. A few myelinated nerve fibers conduct baroreceptor and chemoreceptor impulses that originate in the kidney. Increased perfusion pressure stimulates renal **baroreceptors** in the interlobular arteries and afferent arterioles. Renal ischemia and abnormal ion composition of the interstitial fluid stimulate **chemoreceptors** located in the renal pelvis. These pelvic chemoreceptors probably respond to high extracellular levels of K⁺ and H⁺ and may elicit changes in capillary blood flow.

The kidneys, as endocrine organs, produce renin, 1,25-dihydroxyvitamin D, erythropoietin, prostaglandins, and

bradykinin

Besides **renin** production by the JGA granular cells (see [p. 841](#)), the kidneys play several other endocrine roles. Proximal-tubule cells convert circulating 25-hydroxyvitamin D to the active metabolite, **1,25-dihydroxyvitamin D**. This hormone controls Ca^{2+} and phosphorus metabolism by acting on the intestines, kidneys, and bone (see [p. 1064](#)), and is important for developing and maintaining bone structure.

Fibroblast-like cells in the interstitium of the cortex and outer medulla secrete **erythropoietin (EPO)** in response to a fall in the local tissue P_{O_2} (see [pp. 431–433](#)). EPO stimulates the development of red blood cells by action on hematopoietic stem cells in bone marrow. 🍷**N18-2** In chronic renal failure, the deficiency of EPO leads to severe anemia that can be treated with recombinant EPO.

The kidney releases **prostaglandins** and several **kinins**, paracrine agents that control circulation within the kidney. These substances are generally vasodilators and may play a protective role when renal blood flow is compromised. Tubule cells also secrete angiotensin, bradykinin, cAMP, and ATP into the lumen, which can modulate downstream nephron function.

Measuring Renal Clearance and Transport

Numerous tests can assess renal function. Some are applicable only in animal experiments. **N33-5** Others are useful in clinical settings and fall into two general categories:

1. Modern imaging techniques provide outstanding macroscopic views of renal blood flow, filtration, and excretory function.
2. Measurements of so-called renal clearance of various substances evaluate the ability of the kidneys to handle solutes and water.

N33-5

In Vitro Preparations for Studying Renal Function in the Research Laboratory

Contributed by Gerhard Giebisch, Erich Windhager

Clearance methods treat the whole kidney as a “black box.” Thus, using clearance methods, it is very difficult to determine which nephron segments are responsible for which transport processes. It is also impossible to determine which nephrons are responsible for overall urinary excretion. To learn how single nephrons function, and also to understand how individual segments of the nephron contribute to overall nephron function, renal physiologists have developed a series of invasive techniques for studying the function of renal cells in the research laboratory.

Free-Flow Micropuncture

It is possible, under microscopic observation, to insert a sharpened micropipette into tubule segments at or near the surface of the kidney or into exposed parts of the renal papilla. In these cases, one can collect fluid from identified tubule segments, as illustrated in Figure 33-9A for a superficially located proximal tubule. The investigator collects tubule fluid at a rate that is comparable to the flow rate in the undisturbed nephron and then analyzes this fluid for the solute of interest.

Stationary or Stopped-Flow Microperfusion

In the stationary or stopped-flow microperfusion approach, the investigator deposits an aqueous solution between two oil columns inside the tubule lumen and periodically withdraws samples for analysis (see Fig. 33-9B). An advantage of this technique is that one can choose the initial composition of the fluid deposited in the lumen.

Continuous Microperfusion

The continuous microperfusion approach is similar to the stationary approach described above in that a pair of oil blocks isolate the artificial perfusion fluid from the tubule fluid normally present (see Fig. 33-9C). A difference is that one continuously infuses fluid by means of a carefully calibrated microperfusion pump and then collects the perfusate in a micropipette located at the distal end of the perfused tubule segment. In addition, it is possible to perfuse the peritubular capillary network by means of separate micropipettes. This approach permits one to evaluate the effects of changes in the peritubular

environment on tubule transport. The simultaneous perfusion of the lumen and peritubular capillaries affords excellent control over the environment of the tubule cells at both the apical and basolateral surfaces.

Perfusion of Isolated Tubules

It is possible to microdissect a single segment from almost any part of the nephron and perfuse the single isolated tubule on the stage of a microscope (see Fig. 33-9D). The isolated perfused tubule technique offers two distinct advantages over the *in vivo* micropuncture and microperfusion techniques discussed above. First, one can study tubules from any segment of the nephron, not just superficial tubule segments. Second, the tubules can be isolated from nephron populations (juxtamedullary as well as superficial) located anywhere in the kidney. This consideration is important because of the heterogeneity that exists among nephrons. Thus, the isolated perfused tubule technique offers the ultimate in control over the environment of tubule cells.

In addition to the above four preparations, which permit one to study a defined tubule segment from a single nephron, several other preparations are available for studying cellular and subcellular events. This more narrowly focused approach is achieved at the expense of disrupting the normal tubule and vascular organization of the kidney.

Suspensions of Tubules or Single Cells

Suspensions of tubules or single cells have enough cell mass to permit the determination of cellular metabolism under a variety of experimental conditions. Although this approach can also be used to study solute transport, a disadvantage is that, because the cells have lost their normal polarity, it is impossible to assign function to either the apical or basolateral membranes.

Tubule Cells in Culture

A preparation of tubule cells in culture offers the advantage of preserving the sidedness of the apical and basolateral membranes. On the other hand, one must be aware that cells in culture—whether primary cultures or continuous cell lines—may acquire a phenotype different from that of tubule cells *in vivo*.

Membrane Vesicles

A membrane vesicle preparation is an extension of the single-cell suspension technique but takes the isolation a step further. When one disrupts tubule cells, the fragments of their plasma membranes spontaneously take the form of membrane vesicles—small, irregularly shaped volumes that are completely surrounded by a piece of cell membrane, complete with its lipids and proteins. It is possible to purify membrane vesicles into fractions that consist mainly of luminal (“brush-border”) cell membranes or basolateral cell membranes. These vesicles maintain many of the transport functions of tubule cells *in vivo* and can be examined in ways that allow one to study specific transport systems in vesicles derived primarily from the apical versus basolateral membrane (see Fig. 5-12). Two important caveats regarding this method should be recognized. First, vesicles may exhibit large variations in their passive leakiness via pathways that are not normally present in tubule cells *in vivo*. Second, many of the normal cytoplasmic constituents are absent from the vesicle preparation, so that signal-transduction mechanisms may not function normally.

This subchapter focuses on clearance measurements, which compare the rate at which the glomeruli filter a substance (water or a solute) with the rate at which the kidneys excrete it into the urine. By

measuring the difference between the amounts filtered and excreted for a particular substance, we can estimate the net amount reabsorbed or secreted by the renal tubules and can thus gain insight into the three basic functions of the kidney: glomerular **filtration**, tubule **reabsorption**, and tubule **secretion**. Although widely used, clearance methods have the inherent limitation that they measure *overall* nephron function. This function is “overall” in two different senses. First, clearance sums many individual transport operations occurring sequentially along a nephron. Second, clearance sums the output of all 2 million nephrons in parallel. Hence, clearance cannot provide information on precise sites and mechanisms of transport. Such information can, however, come from studies of individual nephrons, tubule cells, or cell membranes. One can also apply the clearance concept to other problems, such as clearance of bile by the liver (see p. 963) or clearance of hormones from the blood (see p. 1021).

The clearance of a solute is the virtual volume of plasma that would be totally cleared of a solute in a given time

All solutes excreted into the urine ultimately come from the blood plasma perfusing the kidneys. Thus, the rate at which the kidney excretes a solute into the urine equals the rate at which the solute disappears from the plasma, provided the kidney does not produce, consume, or store the solute. Imagine that, in 1 minute, 700 mL of plasma flow through the kidneys. This plasma contains $0.7 \text{ L} \times 142 \text{ mM}$ or $\sim 100 \text{ mmol}$ of Na^+ . Of this Na^+ , the kidneys remove and excrete into the urine only a tiny amount, $\sim 0.14 \text{ mmol}$. In principle, these 0.14 mmol of Na^+ could have come from only 1 mL of plasma, had all Na^+ ions been removed (i.e., cleared) from this volume. The **clearance** of a solute is defined as the virtual volume of blood plasma (per unit time) needed to supply the amount of solute that appears in the urine. Thus, in our example, Na^+ clearance was 1 mL/min , even though 700 mL of plasma flowed through the kidneys.

Renal clearance methods are based on the principle of mass balance and the special anatomy of the kidney (Fig. 33-7). For any solute (X) that the kidney does not synthesize, degrade, or accumulate, the only route of entry to the kidney is the renal artery, and the only two routes of exit are the renal vein and the ureter. Because the input of X equals the output of X,

$$\overbrace{\left(\frac{P_{X,a}}{\text{mmole/mL}} \cdot \frac{RPF_a}{\text{mL/min}} \right)}^{\text{Arterial input of X}} = \overbrace{\left(\frac{P_{X,v}}{\text{mmole/mL}} \cdot \frac{RPF_v}{\text{mL/min}} \right)}^{\text{Venous output of X}} + \overbrace{\left(\frac{U_X}{\text{mmole/mL}} \cdot \frac{\dot{V}}{\text{mL/min}} \right)}^{\text{Urine output of X}}$$

(33-1)

$P_{X,a}$ and $P_{X,v}$ are plasma concentrations of X in the renal artery and renal vein, respectively. RPF_a and RPF_v are rates of **renal plasma flow (RPF)** in the renal artery and vein, respectively. U_X is the concentration of X in urine. \dot{V} is urine flow (the overdot represents the time derivative of volume). The product $U_X \cdot \dot{V}$ is the **urinary excretion rate**, the amount of X excreted in urine per unit time.

FIGURE 33-7 Solute mass balance in the kidney.

In developing the concept of renal clearance, we transform [Equation 33-1](#) in two ways, both based on the assumption that the kidneys clear all X from an incoming volume of arterial plasma. First, we replace RPF_a with the inflow of the virtual volume—the clearance of X (C_X)—that provides just that amount of X that appears in the urine. Second, we assign the virtual venous output a value of zero. Thus, [Equation 33-1](#) becomes

$$\overbrace{P_{X,a} \cdot C_X}^{\text{Virtual arterial input}} = \overbrace{\dot{0}}^{\text{Virtual venous output}} + \overbrace{(U_X \cdot \dot{V})}^{\text{Actual urine output}} \quad (33-2)$$

Solving for clearance yields

$$C_X = \frac{U_X \cdot \dot{V}}{P_X} \quad (33-3)$$

This is the classic **clearance equation** that describes the virtual volume of plasma that would be *totally cleared* of a solute in a given time ([Table 33-2](#), section A). **N33-6** We need to know only three parameters to compute the clearance of a solute X:

1. The concentration of X in the urine (U_X)
2. The volume of urine formed in a given time (\dot{V})
3. The concentration of X in systemic blood plasma (P_X), which is the same as $P_{X,a}$ in [Equation 33-1](#)

TABLE 33-2
Renal Clearance

A. Clearance of any substance X	$C_X = \frac{U_X \cdot \dot{V}}{P_X} = \frac{(\text{mg or mol/mL}) \cdot (\text{mL/min})}{\text{mg or mol/mL}} = \frac{\text{mL}}{\text{min}}$ <p>C_X may vary between zero, for a substance that does not appear in the urine (e.g., glucose), and ~700 mL/min (i.e., total RPF) for a substance (e.g., PAH) that is totally removed from the blood in a single pass through the kidney.</p>
B. Clearance of PAH approximates RPF (at low plasma PAH concentration)	$C_{\text{PAH}} = \text{RPF} = \frac{U_{\text{PAH}} \cdot \dot{V}}{P_{\text{PAH}}}$
C. Clearance of inulin (In) equals GFR	$C_{\text{In}} = \text{GFR} = \frac{U_{\text{In}} \cdot \dot{V}}{P_{\text{In}}}$

N33-6

Symbols of the Clearance Equation

Contributed by Erich Windhager, Gerhard Giebisch, Emile Boulpaep, Walter Boron

In Equation 33-3, we present the clearance equation* as

$$C_X = \frac{U_X \cdot \dot{V}}{P_X}$$

(NE 33-1)

Here C is the clearance, X is the solute, U_X is the concentration of X in the urine, \dot{V} is the flow of urine (volume per unit time), and P_X is the concentration of X in the plasma. Most clinical texts replace the symbol \dot{V} simply with V. We use \dot{V} to distinguish an absolute *volume* of urine from the rate of urine *production*.

This use of symbols is very different from elsewhere in the text and, indeed, from elsewhere in the discipline of physiology. A cellular physiologist might write the same equation in the form

$$C_X = \frac{[X]_{\text{Urine}} \cdot \dot{V}}{[X]_{\text{Plasma}}} \tag{NE 33-2}$$

Indeed, an advantage of writing the clearance equation in its totally unofficial form (Equation NE 33-2) is that it avoids confusing P_X with the standard symbol for the permeability to X.

*The following mnemonic is attributed to John M. Russell: Imagine that you are in Brussels on a sunny day, gazing at the famous fountain that features the statue of a little boy urinating into a pool of water. The sunlight (which contains ultraviolet or “UV” rays) is obviously above the stream of urine (“pee”) ... yielding “UV over P.”

Together, the three basic functions of the kidney—glomerular filtration, tubule reabsorption, and tubule secretion—determine the renal clearance of a solute. In the special case in which the kidneys completely clear X from plasma during a *single passage* through the kidneys ($P_{X,v} = 0$ in Equation 33-1), the renal clearance of X equals RPF_a in Equation 33-1. Because **para-aminohippurate (PAH)** is just such a special solute, its clearance is a good estimate of RPF_a , which we simplify to RPF (see Table 33-2, section B). We discuss RPF on pages 749–750.

For all solutes that *do not* behave like PAH, the renal venous plasma still contains some X. Thus, the virtual volume cleared of X in a given time is less than the total RPF. For most solutes, then, clearance describes a virtual volume of plasma that would be *totally cleared* of a solute, whereas in reality a much larger volume of plasma is *partially cleared* of the solute.

We can use a clearance approach to estimate another important renal parameter: **glomerular filtration rate (GFR)**, which is the volume of fluid filtered into Bowman's capsule per unit time. Imagine a solute X that fulfills two criteria. First, X is freely filtered (i.e., concentration of X in Bowman's space is the same as that in blood plasma). Second, the tubules do not absorb, secrete, synthesize, degrade, or accumulate X. Thus, the amount of X that appears in the urine per unit time ($U_X \cdot \dot{V}$) is the same as the amount of X that the glomerulus filters per unit time ($P_X \cdot GFR$):

$$\begin{array}{ccc} \text{Input to} & & \text{Output into} \\ \text{Bowman's space} & & \text{urine} \\ \hline P_X \cdot GFR & = & U_X \cdot \dot{V} \\ \text{(33-4)} & & \end{array}$$

The input to Bowman's space is also known as the **filtered solute load** and is generally given in mmol/min (or mg/min). Rearranging Equation 33-4, we have

$$GFR = \frac{U_X \cdot \dot{V}}{P_X} \quad \text{(33-5)}$$

Equation 33-5 is in exactly the same form as the classic clearance equation (see Equation 33-3). In other words, GFR is C_X if X has the required properties. As discussed on pages 739–741, **inulin** is just such a solute (see Table 33-2, section C).

A solute's urinary excretion is the algebraic sum of its filtered load, reabsorption by tubules, and secretion by tubules

The homeostasis of body fluids critically depends on the ability of the kidneys to determine the amount of a given solute that they excrete into the urine. Renal excretion rate (E_X) depends on three factors (Fig. 33-

8):

1. The rate of filtration of X (F_x), known as the **filtered load** ($F_x = \text{GFR} \cdot P_x$)
2. The rate of reabsorption of X (R_x) by the tubules
3. The rate of secretion of X (S_x) by the tubules

FIGURE 33-8 Factors contributing to the net urinary excretion of a substance.

This interrelationship is expressed quantitatively by

$$\begin{array}{cccc} \text{Amount} & \text{Amount} & \text{Amount} & \text{Amount} \\ \text{excreted} & \text{filtered} & \text{reabsorbed} & \text{secreted} \\ \text{per unit} & \text{per unit} & \text{per unit} & \text{per unit} \\ \text{time} & \text{time} & \text{time} & \text{time} \\ \hline \widehat{E}_x & = & \widehat{F}_x & - \widehat{R}_x + \widehat{S}_x \end{array}$$

(33-6)

For some substances (e.g., inulin), no reabsorption or secretion occurs. For most substances, *either* reabsorption *or* secretion determines the amount present in the final urine. However, for some substances, *both* reabsorption *and* secretion determine excretion.

If a solute is only reabsorbed, *but not secreted*, we can rearrange Equation 33-6 to obtain the rate of **reabsorption**:

$$\begin{array}{ccc} \text{Reabsorption rate} & \text{Filtered load} & \text{Excretion rate} \\ \text{(mg/min)} & \text{(mg/min)} & \text{(mg/min)} \\ \hline \widehat{R}_x & = \widehat{GFR} \cdot P_x - \widehat{U}_x \cdot \dot{V} \end{array}$$

(33-7)

Conversely, if a solute is only secreted, *but not reabsorbed*, the rate of **secretion** is

$$\begin{array}{ccc} \text{Secretion rate} & \text{Excretion rate} & \text{Filtered rate} \\ \text{(mg/min)} & \text{(mg/min)} & \text{(mg/min)} \\ \hline \widehat{S}_x & = \widehat{U}_x \cdot \dot{V} - \widehat{GFR} \cdot P_x \end{array}$$

(33-8)

In applying Equations 33-7 and 33-8, we must keep in mind two important limitations. First, to estimate the rate at which a substance appears in the filtrate—the filtered load—from the product $\widehat{GFR} \cdot P_x$, we assume that P_x is the *freely filterable* concentration of X. Indeed, many substances (particularly univalent electrolytes, urea, glucose, and amino acids) are freely filterable. However, if the solute (e.g., Ca^{2+} , phosphate, Mg^{2+} , and PAH) binds to protein, then it will not be freely filterable. For such solutes it is necessary to measure plasma binding and correct for the nonfilterable fraction of the solute. Second, for us to apply the mass balance equation (see Equation 33-6), the kidney must not synthesize, degrade, or accumulate the solute. An example of a solute that is synthesized by the kidney is ammonium. Examples of solutes degraded by the kidney include glutamine and glutamate (which are deaminated to yield ammonium) as well as several other amino acids and monocarboxylic and dicarboxylic acids.

When the kidney both *reabsorbs* and *secretes* a substance, clearance data are inadequate to describe renal handling. For example, if the proximal tubule completely reabsorbed a solute that a later segment then secreted, clearance data alone would imply that only filtration and some reabsorption occurred. We would have no reason to implicate secretion. Complex combinations of reabsorption and secretion occur with K^+ , uric acid, and urea.

Another useful parameter for gauging how the kidney handles a freely filtered solute is the **fractional excretion (FE)**, which is the ratio of the amount excreted in the urine ($\widehat{U}_x \cdot \dot{V}$) to the filtered load ($P_x \cdot \widehat{GFR}$):

$$FE_X = \frac{U_X \cdot \dot{V}}{P_X \cdot GFR}$$

(33-9)

According to [Equation 33-3](#), however, the term $(U_X \cdot \dot{V} / P_X)$ is simply the clearance of X (C_X):

$$FE_X = \frac{C_X}{GFR}$$

(33-10)

As discussed on [pages 739–741](#), one estimates GFR by measuring the clearance of inulin (C_{In}). Thus, the FE of a freely filterable solute is the same as the **clearance ratio**

$$FE_X = \frac{C_X}{C_{In}}$$

(33-11)

Microscopic techniques make it possible to measure single-nephron rates of filtration, absorption, and secretion

Because clearance methods treat the kidney as a “black box,” reflecting the activity of many single nephrons and nephron segments, it is very difficult to determine which nephron segments are responsible for which transport processes. It is also impossible to determine which nephrons are responsible for overall urinary excretion. To learn how single nephrons function, and to understand how individual nephron segments contribute to overall nephron function, physiologists developed a series of invasive techniques for studying renal cells in the research laboratory ([Fig. 33-9](#)). 🍷N33-5

A FREE-FLOW MICROPUNCTURE

A pipette for collection of fluid is inserted into a superficially located tubule in the kidney; in this case, the proximal tubule.

B STOPPED-FLOW MICROPERFUSION

A droplet of oil is pipetted into the tubule through one barrel of a double-barreled pipette, and split...

Later, a second pipette with a single barrel samples the fluid that the tubule has modified.

C CONTINUOUS MICROPERFUSION

The tubule undergoes continuous perfusion through a pipette, as does the adjacent capillary.

A downstream pipette continuously collects the fluid.

D ISOLATED PERFUSED TUBULE

One may isolate a tubule from any segment of any nephron.

The lumen of the tubule, as well as its basolateral surface, are continuously perfused.

This pipette collects the fluid.

FIGURE 33-9 Methods for studying renal function in the research laboratory.

To apply the concept of clearance to a single nephron site, one uses the free-flow micropuncture approach (see Fig. 33-9A) and measures the concentration of the solute in the tubule fluid at that site (TF_x), volume flow at that site (i.e., the collection rate), and plasma concentration (P_x). By analogy with the *macroscopic* clearance equation, we can write a clearance equation for a single nephron:

$$C_x = \frac{TF_x \times \text{Volume collection rate}}{P_x} \quad (33-12)$$

Compared with Equation 33-3, here TF_x replaces U_x and “Volume collection rate” replaces \dot{V} . We can use this basic equation to compute the amount of fluid that a single nephron filters, as well as the amounts of fluid and solutes that a single tubule segment handles.

Single-Nephron GFR

If X in [Equation 33-12](#) is a marker for GFR (e.g., inulin, or In), one can calculate **single-nephron GFR (SNGFR)** using an equation that is similar to that in [Table 33-2](#), section C, to calculate total GFR:

$$\text{SNGFR} = \frac{\text{TF}_{\text{In}} \times \text{Volume collection rate}}{\text{P}_{\text{In}}}$$

(33-13)

Using the numeric values for rat kidney shown in [Figure 33-10](#), we can use [Equation 33-13](#) to compute the SNGFR:

$$\text{SNGFR} = \frac{(3 \text{ mg/mL}) \times (10 \text{ nL/min})}{(1 \text{ mg/mL})} = 30 \text{ nL/min}$$

(33-14)

FIGURE 33-10 Measurement of SNGFR. Data are for the rat.

Handling of Water by Tubule Segments in a Single Nephron

We also can use the same information that we used to compute SNGFR to calculate the rate of water reabsorption between the glomerulus and the micropuncture site. The fraction of filtered water remaining at the micropuncture site is

$$\frac{\text{Fraction of filtered water remaining}}{\text{water remaining}} = \frac{\text{Volume collection rate}}{\text{SNGFR}}$$

(33-15)

Substituting the expression for SNGFR (see [Equation 33-13](#)) into [Equation 33-15](#) yields

$$\begin{aligned} \frac{\text{Fraction of filtered water remaining}}{\text{water remaining}} &= \frac{\text{Volume collection rate}}{(\text{TF}_{\text{In}} \times \text{Volume collection rate}) / P_{\text{In}}} \\ &= \frac{P_{\text{In}}}{\text{TF}_{\text{In}}} \end{aligned}$$

(33-16)

Thus, to know the *fraction* of filtered water remaining at the collection site, we do not need to know the collection rate, only the concentrations of inulin in blood plasma and at the collection site. In the example of [Figure 33-10](#), in which the tubule reabsorbed two thirds of the fluid, the fraction of filtered water remaining at the sampling site is (1 mg/mL)/(3 mg/mL) or ~0.33.

The **fraction of filtered water reabsorbed** is 1 minus the fraction of filtered water remaining:

$$\text{Fraction of filtered water reabsorbed} = 1 - \frac{P_{\text{In}}}{\text{TF}_{\text{In}}}$$

(33-17)

In our example, the fraction of filtered water reabsorbed is 1 – 0.33 or ~0.67.

Handling of Solutes by Tubule Segments in a Single Nephron

We can use the same concepts of single-nephron clearance to quantitate the reabsorption or secretion of any *solute* along the tubule. The first step is to estimate the fraction of the filtered solute remaining at the puncture site. This parameter—the **fractional solute delivery**—is the ratio of the amount of solute appearing at the micropuncture site to the amount of solute filtered at the glomerulus (i.e., **single-nephron filtered load**):

$$\text{Fractional solute delivery} = \frac{\text{Rate of solute delivery to micropuncture site}}{\text{Single-nephron filtered load}}$$

(33-18)

The numerator is the product of volume collection rate and tubule solute concentration (TF_{X}), and the denominator is the product of SNGFR and the plasma solute concentration (P_{X}):

$$\text{Fractional solute delivery} = \frac{\text{Volume collection rate} \times \text{TF}_X}{\text{SNGFR} \times P_X} \quad (33-19)$$

In [Equations 33-15](#) and [33-16](#), we saw that the ratio (volume collection rate/SNGFR) is $(P_{\text{In}}/\text{TF}_{\text{In}})$. Making this substitution in [Equation 33-19](#), we obtain an alternative expression for fractional solute excretion:

$$\text{Fractional solute delivery} = \frac{\text{TF}_X/P_X}{\text{TF}_{\text{In}}/P_{\text{In}}} \quad (33-20)$$

The advantage of [Equation 33-20](#) over [Equation 33-19](#) is that no measurements of collection rates are required.

[Equation 33-20](#) is important for understanding the transport of a solute along the nephron. If $(\text{TF}_X/P_X)/(\text{TF}_{\text{In}}/P_{\text{In}})$ is >1 , **secretion** has occurred. Merely observing that the solute *concentration* in tubule fluid increases along the length of the nephron does not necessarily mean that the tubule secreted the solute; the concentration would also increase if water were reabsorbed. We can conclude that secretion has occurred only if the solute concentration in tubule fluid, relative to its concentration in filtrate, exceeds the concentration ratio of inulin. If $(\text{TF}_X/P_X)/(\text{TF}_{\text{In}}/P_{\text{In}})$ is <1 , **reabsorption** has occurred.

Rather than referring to the fraction of the solute excreted (i.e., remaining) up to the point of the micropuncture site, we can also refer to the **fractional solute reabsorption** at the puncture site. By analogy to [Equation 33-17](#) for water, this parameter for a solute is merely 1 minus the fractional solute excretion:

$$\text{Fractional solute reabsorption} = 1 - \frac{\text{TF}_X/P_X}{\text{TF}_{\text{In}}/P_{\text{In}}} \quad (33-21)$$

Thus, applying the principles of clearance and mass balance to a single nephron, we can calculate SNGFR as well as the fractional reabsorption of water and solutes at the micropuncture site.

The Ureters and Bladder

As discussed in [Chapters 44](#) and [45](#), the epithelium of the gastrointestinal (GI) system continues to modify the contents of the GI tract up until the point where the contents finally exit the body. The situation is very different in the mammalian urinary system. By the time the fluid leaves the most distal portion of the collecting duct, the fluid has the composition of final urine. Thus, the renal pelvis, ureters, bladder, and urethra do not substantially modify the urine volume or composition.

The ureters propel urine from the renal pelvis to the bladder by peristaltic waves conducted along a syncytium of smooth-muscle cells

The **ureters** serve as conduits for the passage of urine from the renal pelvis into the urinary bladder (see [Fig. 33-1A](#)). Located in the retroperitoneum, each ureter loops over the top of the common iliac artery and vein on the same side of the body and courses through the pelvis. The ureters enter the lower posterior portion of the bladder (**ureterovesical junction**), pass obliquely through its muscular wall, and open into the bladder lumen 1 to 2 cm above, and lateral to, the orifice of the urethra ([Fig. 33-11A](#)). The two ureteral orifices, connected by a ridge of tissue, and the urethral orifice form the corners of a triangle (**bladder trigone**). A flap-like valve of mucous membrane covers each ureteral orifice. This anatomical valve, in conjunction with the physiological valve-like effect created by the ureter's oblique pathway through the bladder wall, prevents reflux of urine back into the ureters during contraction of the bladder.

A URETERS AND BLADDER

B SMOOTH-MUSCLE ACTION POTENTIAL

FIGURE 33-11 **A**, Anatomy of the ureters and bladder. **B**, Ureteral smooth-muscle cells generally have a resting membrane potential of about -60 mV, mainly determined by a high K^+ membrane permeability. Na^+ channels speed the upstroke of the action potential, although Ca^{2+} channels are mainly responsible for the action potential.

The lumen of each ureter is lined by **transitional epithelium**, which is above a submucosal layer of connective tissue, as well as an inner longitudinal and an outer circular layer of smooth muscle. Ureteral **smooth muscle** functions as a syncytium and is thus an example of unitary smooth muscle (see pp. 243–244). Gap junctions (see pp. 158–159) conduct electrical activity from cell to cell at a velocity of 2 to 6 cm/s. Chemical or mechanical stimuli (e.g., stretch) or a suprathreshold membrane depolarization may trigger an **action potential** (see Fig. 33-11B) of the plateau type (see p. 244).

Contraction of ureteral smooth muscle is similar to that of other smooth muscle (see pp. 247–248), in which Ca^{2+} -calmodulin activates myosin light-chain kinase (MLCK). cAMP-dependent protein kinase (protein kinase A, or PKA) can phosphorylate MLCK, thereby lowering the affinity of MLCK for Ca^{2+} -calmodulin and impairing phosphorylation of myosin light chains. This mechanism may, at least in part, account for the relaxing effect of cAMP on smooth muscle.

Ureteral **peristaltic waves** originate from electrical **pacemakers** in the proximal portion of the renal pelvis. These waves propel urine along the ureters and into the bladder in a series of spurts at frequencies of 2 to 6 per minute. The intraureteral hydrostatic pressure is 0 to 5 cm H_2O at baseline but increases to 20 to 80 cm H_2O during peristaltic waves. Blockade of ureteral outflow to the bladder, as by a kidney stone, causes the ureter to dilate and increases the baseline hydrostatic pressure to 70 to 80 cm H_2O over a period of 1 to 3 hours. This pressure is transmitted in retrograde fashion to the nephrons, creating a stopped-flow condition in which glomerular filtration nearly comes to a halt. **Hydronephrosis**, dilation of the pelvis and calyces of the kidney, can evolve over hours to days. Patients complain of severe pain (renal colic) resulting from distention of involved structures. If not cleared, the obstruction can cause marked renal dysfunction and even acute renal failure. With persistent obstruction, the pressure inside the ureter declines to a level that is only slightly higher than the normal baseline. Even though the patient

produces no urine (anuria), glomerular filtration continues, albeit at a markedly reduced rate, a condition reflecting a balance between filtration and fluid reabsorption by the tubules.

Although ureteral peristalsis can occur without innervation, the autonomic nervous system can modulate peristalsis. As in other syncytial smooth muscle, autonomic control of the ureters occurs by diffuse transmitter release from multiple varicosities formed as the postganglionic axon courses over the smooth-muscle cell. *Sympathetic* input (via aortic, hypogastric, and ovarian or spermatic plexuses) modulates ureteral contractility as norepinephrine acts by excitatory α -adrenergic receptors and inhibitory β -adrenergic receptors. *Parasympathetic* input enhances ureteral contractility via acetylcholine, either by directly stimulating muscarinic cholinergic receptors (see p. 341) or by causing postganglionic sympathetic fibers to release norepinephrine, which then can stimulate α adrenoceptors. Some autonomic fibers innervating the ureters are afferent **pain fibers**. In fact, the pain of renal colic associated with violent peristaltic contractions proximal to an obstruction is one of the most severe encountered in clinical practice.

Sympathetic, parasympathetic, and somatic fibers innervate the urinary bladder and its sphincters

The urinary bladder consists of a main portion (body) that collects urine and a funnel-shaped extension (neck) that connects with the urethra (see Fig. 33-11A). A transitional epithelium lines the bladder lumen. Three poorly defined layers of smooth muscle make up the bulk of the bladder wall, the so-called **detrusor muscle**. At the lower tip of the trigone, the bladder lumen opens into the posterior urethra (i.e., distal part of bladder neck), which extends over 2 to 3 cm. The wall of the posterior urethra contains *smooth-muscle* fibers of the detrusor muscle interspersed with elastic tissue, together forming the **internal sphincter** (Table 33-3). Immediately adjacent is the **external sphincter**, made up of voluntary, mainly slow-twitch *striated-muscle* fibers.

TABLE 33-3
Urethral Sphincters

	INTERNAL SPHINCTER	EXTERNAL SPHINCTER
Type of muscle	Smooth	Skeletal
Nerve reaching the structure	Hypogastric	Pudendal
Nature of innervation	Autonomic	Somatic

In humans, bladder smooth muscle appears to lack gap junctions, which would indicate the absence of electrotonic coupling between cells. Thus, bladder smooth muscle is probably “multiunit” (see p. 243), with a 1 : 1 ratio between nerve endings and smooth-muscle cells. Contraction of bladder smooth muscle is typical of that of other smooth-muscle cells.

The bladder and sphincters receive sympathetic and parasympathetic (autonomic) as well as somatic (voluntary) innervation (Fig. 33-12). The **sympathetic innervation** to the bladder and internal sphincter arises from neurons in the intermediolateral cell column of the tenth thoracic to the second lumbar spinal cord segment (see pp. 335–339). The preganglionic fibers then pass via lumbar splanchnic nerves to the superior hypogastric plexus, where they give rise to the left and right hypogastric nerves. These nerves lead to the inferior hypogastric/pelvic plexus, where preganglionic sympathetic fibers synapse with postganglionic fibers. The postganglionic fibers continue to the bladder wall via the distal portion of the hypogastric nerve. This distal portion also contains the preganglionic *parasympathetic* axons discussed

in the next paragraph.

FIGURE 33-12 Autonomic and somatic innervation of the bladder.

The **parasympathetic innervation** of the bladder originates from the intermediolateral cell column in segments S2 through S4 of the sacral spinal cord (see p. 338). The *parasympathetic* fibers approaching the bladder via the pelvic splanchnic nerve are still preganglionic. They synapse with postganglionic neurons in the body and neck of the urinary bladder.

The **somatic innervation** originates from motor neurons arising from segments S2 to S4. Via the pudendal nerve, these motor neurons innervate and control the voluntary skeletal muscle of the external sphincter (see Fig. 33-12).

Bladder filling activates stretch receptors, initiating the micturition reflex, a spinal reflex under control of higher central nervous system centers

Bladder **tone** is defined by the relationship between bladder volume and internal (intravesical) pressure. One can measure the volume-pressure relationship by first inserting a catheter through the urethra and emptying the bladder, and then recording the pressure while filling the bladder with 50-mL increments of water. The record of the relationship between volume and pressure is a **cystometrogram** (Fig. 33-13, blue curve). Increasing bladder volume from 0 to ~50 mL produces a moderately steep increase in pressure. Additional volume increases up to ~300 mL produce almost no pressure increase; this high compliance reflects relaxation of bladder smooth muscle. At volumes >400 mL, additional increases in volume produce steep increments in passive pressure. Bladder tone, up to the point of triggering the micturition reflex, is independent of extrinsic bladder innervation.
